PREFACE

Welcome to the third edition of the *Wiley Encyclopedia of Packaging Technology*. For over two decades, this has been the most authoritative packaging encyclopedia around the world, providing useful and comprehensive information to serve the packaging community. In this new edition, we have done our best to continue the tradition.

Since the last edition of this encyclopedia published 12 years ago, what have been the major changes in packaging technologies? To answer this question, it is useful to understand that the packaging industry is largely driven by the needs of the consumers, the society, and the manufacturers. The consumers need higher quality products that are more convenient to meet their ever-changing lifestyle. The society needs products that are safer to respond to events such as September 11 and outbreaks of food pathogens, as well as products that are more environmentally friendly to meet the demands of the public and the activists. The manufacturers need better and more cost-effective packaging technologies to satisfy the market and make profits.

During the past decade, several new or improved packaging technologies have emerged to satisfy the needs of the market, specifically those relating to active packaging, sustainable packaging, and intelligent packaging. Active packaging involves advanced technologies that actively change the internal conditions of the package to extend product shelf life; for example, oxygen-scavenging films are an active packaging technology that is used to absorb oxygen inside the package and extend the shelf life of the product. Sustainable packaging involves technologies that are environmentally friendly, socially acceptable, and economically viable; for example, a sustainable package may be made of biobased materials that are biodegradable and inexpensive but yet possessing properties required for the application. Intelligent packaging involves the use of smart package devices (such as RFID tags, time-temperature indicators, and biosensors) to track product, sense the environment inside or outside the package, monitor product quality, and improve efficiency.

In this third edition, new articles are added to provide the reader with a basic understanding of active packaging, sustainable packaging, and intelligent packaging. Other new articles include important packaging topics such as nanotechnology, smart blending technology, packaging for space missions, military packaging, biobased materials, high-voltage leak detection technique, analytical methods for food packaging, application of predictive microbiology, and patent law primer for the packaging industry.

Although the packaging industry will adopt new technologies slowly, its operations continue to rely heavily on traditional technologies. In this edition, a balance is struck to allocate spaces for new and traditional technologies.

The scope of packaging is broad. It encompasses technical activities such as machinery design, graphic design, package development, package manufacture, shelf-life testing, distribution, and marketing. It deals with various types of packages, including metal cans, glass containers, paper cartons, plastic containers, and pouches. It involves the participation of packaging scientists and engineers, packaging material suppliers, packaging converters, manufacturers, retailers, and regulatory agencies. This encyclopedia endeavors to cover all relevant and contemporary aspects of packaging, although inevitably some aspects may be omitted or deemphasized. The A to Z format and the cross-index permit the readers to find everything in the encyclopedia easily.

This third edition is blessed by the dedication and contributions of the authors, the editorial advisory board, and the experts from the packaging industry. The editors of previous editions deserve credit for building a strong foundation for the encyclopedia. As the editor of this new edition, I am grateful to the assistance and hard work of the editorial staff from Wiley, particularly Arza Seidel, Mary Mann, Mickey Bickford, and Kris Parrish, along with the staff at MPS. The encyclopedia is also blessed by the support of the readers who make it the most recognized packaging encyclopedia ever published.

Finally, acknowledgments would not be complete without thanking my wife, Aileen, who as a research enthusiast, has acted as sounding board and support during countless hours of working.

It is my fervent hope that this new edition will continue to serve as a useful reference for the seasoned professionals, novices, students, and casual readers.

Kit L. Yam

ACRYLIC PLASTICS

J. T. Sullivan
Rohm and Haas Company
Updated by Staff

Acrylic plastics is defined as a family of synthetic or man-made plastic materials containing one or more derivatives of acrylic acid. The most commonly used derivative is poly(methyl methacrylate). Polymers based on acrylic monomers are useful in packaging as a basis for printing inks and adhesives and as modifiers for rigid PVC products.

ACRYLIC-BASED INKS

Paste Inks

Acrylic solution resins are used in lithographic inks as dispersing or modifying letdown vehicles (see Inks; Printing). A typical resin (60% in oil) offers excellent dot formation, high color fidelity, exceptional print definition, nonskinning, and good press-open time. Set times are fast (~60–90 s), and a minimal level of starch spray (75% of normal) is effective. Coatings on cartons, fabrication stocks, and paper are glossy and exhibit good dry resistance.

Solvent Inks

Because of their resistance to heat and discoloration, good adhesion, toughness, and rub resistance, acrylics are widely used in flexographic inks on paper, paperboard, metals, and a variety of plastics (1). These inks also give block resistance, resistance to grease, alcohol, and water, and good heat-sealing performance (see Sealing, heat). With some grades, adding nitrocellulose improves heat sealability, heat resistance, and compatibility with laminating adhesives. This family of methacrylate polymers (methyl to isobutyl) has broad latitude in formulating and performance. Solid grades afford low odor, resist sintering, and dissolve rapidly in alcohol–ester mixtures or in esters alone (gravure inks). Solution grades (40–50% solids) are available, as well as nonaqueous dispersions (40% solids) in solvents such as VMP naphtha, which exhibit fast solvent release and promote superior leveling and hiding. They are excellent vehicles for fluorescent inks.

Water-Based Inks

The development of waterborne resins has been a major achievement. Their outstanding performance allows them to replace solvent systems in flexographic and gravure inks and overprint varnishes on corrugated and kraft stocks, cartons, and labels. Approximately 50% of all the flexographic inks used are based on water as their primary solvent. Typical inks are water-based with acrylic emulsion resins as the main binder (1). Press inks are very fluid and of low viscosity. Inks contain a variety of additives for the elimination of foaming dipersion of pigments, rheological modifiers, slip agents, and so on. The paramount advantage of aqueous systems is a substantial decrease in environmental pollution by volatile organics. Aqueous acrylic colloidal dispersions (30% solids) and a series of analogous ammonium salts (46–49% solids) are effective dispersants for carbon blacks, titanium dioxide, and organic pigments. Derived inks give crisp, glossy impressions at high pigment loading, good coverage and hiding, and water resistance. The relatively flat pH–viscosity relationship assures formulation stability on presses despite minor loss of volatiles. Adjusting the alcohol–water ratio controls drying rate, and quick-drying inks can be made for high-speed printing. The resins are compatible with styrene–acrylic or maleic dispersants and acrylic or styrene–acrylic letdown vehicles. Blends of self-curing polymer emulsions are excellent overprint varnishes for labels and exhibit a good balance of gloss, holdout, slip, and wet-rub resistance.

Some aqueous acrylic solutions (37% solids) combine the functions of pigment dispersant and letdown resin and serve as ready-to-use vehicles for inks on porous substrates like kraft and corrugated stocks and cartons. They afford excellent color development, excellent heat-aging resistance in formulations, and fast drying. The flat pH–viscosity relationship gives the same benefit as the dispersants.

ACRYLIC ADHESIVES

Pressure-Sensitive Adhesives

Solution copolymers of alkyl acrylates and minor amounts of acrylic acid, acrylonitrile, or acrylamide adhere well to paper, plastics, metals, and glass and have gained wide use in pressure-sensitive tapes (2). Environmental regulations, however, have raised objections to pollution by solvent vapors and are requiring costly recovery systems. This opportunity has encouraged the development of waterborne substitutes, such as emulsion polymers, which eliminate these difficulties, offer excellent adhesion, show resistance to wet delamination, aging, and yellowing, and, like the solvent inks, need no tackifier. In packaging applications, the emulsion polymers provide high tack, a good balance of peel adhesion and shear resistance, excellent cling to hard-to-bond substrates, and clearance for food packaging applications under FDA Regulations 21 CFR 175.105, 21 CFR 176.170, and 21 CFR 176.180. Their low viscosity makes formulation easy, and the properties of the adhesives can be adjusted by adding surfactants, acrylic thickeners, and defoamers. The main advantages of pressure-sensitive adhesives compared to other tapes is convenience of use. There are no storage problems, and mixing or activation is not necessary. No waiting is involved. Often the bond is reversible. Disadvantages are that the adhesive strengths are low, they are unsuitable for rough surfaces, and they are expensive in terms of cost per bond area (3).

Resins are available that are designed specifically for use on polypropylene carton tapes (4). They are ready-to-use noncorrosive liquids applicable to the corona-treated side of oriented polypropylene film using knife-to-roll, Mayer rod, or reverse-roll coaters (see Coating equipment; Film, oriented polypropylene; Surface modification). A release coating is unnecessary because the adhesive does not stick to the untreated side and parts cleanly from the roll. The tapes are used to seal paperboard cartons with high-speed taping machines or handheld dispensers. Adhesion to the cartons is instantaneous and enduring. The colorless tape is well-suited for label protection. The material adheres well to other plastics and metals.

An acrylate–vinyl acetate copolymer-based tape is generally used in high-quality tapes for their better technical properties. They are paler in color, exhibit much better aging, and, if crosslinked after coating, can give a very good shear strength (3).

Hot-Melt Adhesives

The most recent development in pressure-sensitive tape manufacture is the the hot-melt coating process. These adhesives offer obvious advantages over solvent or water-borne materials if equivalent performance is obtainable. Acrylic prototypes gave better color and oxidative stability than rubber-based products, but exhibit poor adhesion quality. New improved grades are providing an impressive array of adhesive properties and superior cohesive strength at elevated temperatures in addition to stability and low color. The action of the adhesives involves a thermally reversible crosslinking mechanism that gives ready flow at 350°F (177°C), rapid increase in viscosity on cooling, and a stiff crosslinked rubber at ambient temperature. The resins give durable peel adhesion, good shear resistance, resistance to cold flow, and excellent photostability in accelerated weathering. On commercial machinery these resins have displayed excellent coatability on polyester film at high line speeds (see Film, oriented polyester). These adhesives form bonds without supplementary processing and are considered environmentally friendly. A drawback is the possibility of damage to a substrate that cannot withstand application temperatures (3). There is a wide variety of possible applications for these materials, including packaging tapes.

PVC MODIFIERS

Acrylics have played a major role in the emergence of clear rigid PVC films and bottles (5, 6). Acrylic processing aids provide smooth processing behavior in vinyl compounds when passed through calenders, extruders, blow-molding machinery, and thermoforming equipment (see Additives, plastics). One member of this group is a lubricant-processing aid that prevents sticking to hot metal surfaces and permits reduction in the level of other lubricants, thereby improving clarity. Other benefits of acrylics are low tendency to plateout and a homogenizing effect on melts to give sparkling clarity and improved mechanical properties. The usual level in vinyl compounds for packaging is about 1.5–2.5 phr.

In a second group are the impact modifiers, which are graft polymers of methyl methacrylate–styrene–butadiene used in the production of clear films and bottles. The principal function of impact modifiers is to increase toughness at ambient and low temperature. Levels of 10–15 phr, depending on modifier efficiency, are normal.

Many acrylics are cleared for use in food-contact products under FDA Regulations 21 CFR 178.3790 and 21 CFR 175.210 (7). These regulations stipulate limits in the permissible level of modifiers relative to their composition. Processors should seek advice from suppliers on the makeup of formulations. Many modifiers are fine powders that may produce airborne dust if handled carelessly. Above 0.03 oz/ft^3 (0.03 mg/cm^3), dust is a potential explosion hazard and its accumulation on hot surfaces is a fire hazard. The recommended exposure limit to dust over an 8-h period is 2 mg/m^3. Eliminate ignition sources, ground equipment electrically, and provide local exhaust ventilation where dusting may occur (8). Workers may wear suitable MSHA-NIOSH respiratory devices as protection against dust.

ACTIVE PACKAGING

ANDREW SCULLY
CSIRO Materials Science and
Engineering, Melbourne,
Victoria 3169, Australia

This is a revised and updated version of the article written by Michael Rooney

Packaging is described as active when it performs some desired role other than to provide an inert barrier between the product and the outside environment, although numerous other definitions also exist (1). Therefore, active packaging differs from conventional passive packaging in that one or more forms of interaction are planned, usually to offset a deficiency in an otherwise suitable package. The active component may be part of the packaging material or may be an insert or attachment to the inside of the pack. Active packaging is largely an innovation dating from the 1980s, although there are examples that have been in use for over a century. The tinplate can, for instance, provides a sacrificial layer of tin that protects the food from accumulation of catalytically active iron salts. Antioxidant release from waxed-paper packs for breakfast cereals has been used, as has been the impregnation of cheese wraps with sorbic acid.

It was in 1987 that the term "active packaging" was introduced by Labuza (2). Prior to that time, terms such as "smart," "freshness preservative," and "functional" were used to describe active-packaging materials. Sachets of iron powder have been described as "deoxidizers," "free oxygen absorbers," and "oxygen scavengers" (see Oxygen scavengers). Active packaging can enable the properties of the package to more adequately meet the requirements of the product. Therefore, the forms and applications of active packaging are diverse, addressing specific situations in the protection and presentation of foods and other products.

PROBLEMS ADDRESSED BY ACTIVE PACKAGING

Active packaging can be used to minimize the deterioration of the packaged product, which can occur through biological or physicochemical reaction mechanisms.

Biological deterioration may result from insect attack as occurs, for instance, in foods, furs, fabrics, and museum specimens. Elevated temperatures and humidities enhance the rate of activity at various stages in the life cycles of insects. Chemical fumigation is possible in some cases but is becoming more tightly controlled with foods such as grains and dried fruits. Accordingly, modified-atmosphere packaging (MAP) is now commonly used in many markets, including Europe and North America. Since low levels of oxygen and/or high carbon dioxide levels are required to suppress growth, packaging systems or adjuncts that assist in achieving such atmospheres can contribute to quality maintenance. Such adjuncts are oxygen scavengers, desiccants, and carbon dioxide emitters.

The other generically common cause of biological deterioration is microbial growth. This is usually enhanced by the same variables, but there is also danger from anaerobic pathogenic bacteria, such as clostridia, that grow at very low oxygen levels or in the absence of oxygen. Hence, the removal of oxygen is not necessarily a solution to all microbial growth problems. Antimicrobial treatments such as the release of carbon dioxide, ethanol, other preservatives, or fungicides can play a role in reducing microbial growth. Similarly, desiccants can assist in providing the "hurdle" of reduced water activity, especially in foods. Where liquid water is formed by condensation on the packages of fresh produce, the use of humidity buffers or condensation control films can be useful. Where tissue fluids from fish or white and red meats is unsightly, the use of drip absorbent pads is commonplace.

Biological deterioration of fresh produce also occurs naturally as part of the process of senescence. Reduction in the rate of senescence can be achieved in many cases by reduction of the respiration rate by reducing equilibrium oxygen concentrations to $\sim 2\%$. Ethylene synthesis that accelerates ripening and senescence can be suppressed by elevated carbon dioxide concentrations. Existing plastic packaging films seldom allow beneficial equilibrium-modified atmospheres to be developed, so some form of active packaging is needed. Transpiration of water by produce leads to condensation when temperatures fluctuate slightly. Furthermore, ethylene release by one or more damaged or ripe fruit can cause rapid ripening of others. This is akin to the "one rotten apple in the barrel" situation. Ethylene removal is therefore a highly desirable property of produce packaging.

Chemical deterioration vectors act on the widest range of packaged products. These include especially foods and beverages (lipid and nutrient loss, off-flavor generation), but also pharmaceuticals. The protection offered by active packaging is, in many cases, essential to achieving a satisfactory shelf life for pharmacologically active compounds, many of which can lose potency through hydrolysis and, therefore, require the use of a desiccant. With the intense search for new drug candidates, attention is now being directed to compounds that are subject to oxidation, in which case protection from oxygen becomes essential to maintaining efficacy. Similarly, active packaging can be useful for optimizing the shelf life of *in vitro* diagnostic preparations, which often include chemically and biochemically active compounds that may be subject to hydrolytic or oxidative degradation. The active protection in this case can either be incorporated within the package or be designed into the device itself. Some diagnostic formulas are enzyme-based, with the enzymes in the dry form or a fully hydrated form. The moisture content of dry enzyme preparations must be controlled at an appropriate low level, with sufficient residual moisture to ensure that the protein does not become denatured, thereby inhibiting its activity. Conversely, the moisture content of hydrated enzyme preparations must be maintained at a level that prevents the localized dilution or leaching of formula components caused by moisture evaporation and recondensation as a result of temperature fluctuations during storage and distribution. In this case, active moisture regulation within the package can be useful for maintaining functionality over the required shelf life.

Industrial chemicals such as amines, and particularly some printing inks, are oxidized on storage. Microelectronic components, some metals, and a variety of unrelated items can be subject to attack by oxygen. Often the rate of loss can be reduced adequately by inert-gas flushing and barrier packaging. However, these treatments are not always effective, convenient, or economical, particularly when oxygen levels below 0.5% are desired (3). Nitrogen flushed packs of dry foods often have residual oxygen levels of 0.5–2%. Chemical forms of in-pack oxygen scavenging have been introduced both to reduce these residual levels further and to deoxygenate air headspaces without the use of inert-gas flushing or evacuation.

Fried snacks are particularly susceptible to oxidation, depending on their moisture content. Although sliced, processed meats are packaged commercially under vacuum, improved presentation using MAP can be achieved when an oxygen scavenger is present. The pink nitrosomyoglobin is damaged by even low quantities of oxygen in the package. The flavor of alcoholic beverages such as beer and white wines is particularly sensitive to oxygen, so the relatively high oxygen permeability of poly(ethylene terephthalate) (PET) bottles makes them unsuitable for packaging most wines and beers. The presence of oxygen in glass bottles is usually offset by addition of sulfur dioxide to the beverage. However, oxidative loss of this antioxidant still limits the shelf life of beer and white wines and limits their packaging options. A similar sulfur dioxide loss occurs in dried apricots. In these cases the presence of an oxygen scavenger that does not react with this acidic gas is required. Porous adsorbents in current oxygen scavengers may also remove some of the sulfur dioxide.

The flavor of some foods changes on storage because of effects other than oxidation. Tainting is a recurrent problem. Moldy taints can result from long voyages in shipping containers. Methods of odor interception without the use of expensive barrier packaging are needed for the transportation of low-valued primary products. Besides interception of external taints, there is also a need for removal of food breakdown products that can be formed during storage. These include amines or thiols formed rapidly in fish or rancid odors in oil-containing foods. Such compounds can be present in trace amounts that are significant organoleptically but may not constitute a health hazard. The bitter principle in some orange juices, limonin, is formed on standing, and a method for its removal from juice has been reported (4).

Two physical properties of a product that can potentially be affected by active packaging are heating and cooling. Thus the microwave heating of packaged multicomponent entrees offers a challenge for uniform heating in spite of varying layer thicknesses and water contents (see Microwave pasteurization and sterilization). Canned drinks, such as sake and coffee, supplied via vending machines in Japan are frequently consumed warm. Other drinks may need to be cooled, and so dispensing from the one machine may necessitate building the temperature-changing capacity into the can itself.

GOALS OF ACTIVE PACKAGING

Active packaging is chosen to enhance the ability of conventional packaging to help deliver the product to the user in a desired state. The decision to use some form of active packaging will often be based on one or more of the following considerations (see also Shelf life).

1. *Extension of Shelf Life*. This extension may exceed the presently accepted limits as with sea shipment of some fresh produce.
2. *Less Expensive Packaging Materials*. Packaging of limited-shelf-life products may require enhancement of only one property for a fixed period. This can include bakery products, metal components shipped by sea, or chilled meats.
3. *Simpler Processing*. Introduction of additional microbiological “hurdles” can allow MAP to be achieved without use of expensive equipment.
4. *Reduction or Removal of Preservatives from Food Formulations*. This is done to meet consumer demands for “fresher” foods containing fewer additives by transferring preservatives from the food to the packaging.
5. *Difficult-to-Handle Products*. Oxygen can be removed from tightly packaged products such as cheeses that are subject to mold growth.
6. *Allowing Particular Types of Packages to be Used*. This could include (a) retortable plastic packages for products with multiyear shelf lives or (b) PET wine bottles.
7. *Presentation*. Heating by microwave susceptors and other adjuncts has allowed packaging innovation for convenience foods.

Other goals are developing as the potential is being realized. Indicators of time–temperature and temperature abuse are presently available. The composition of the package headspace can potentially indicate chemical, physiological, or microbiological state or the potency of the packaged product.

FORMS OF ACTIVE PACKAGING

The active components in packaging can exist either as part of an otherwise unmodified package or as an elaborate adjunct or design modification. The major form in use at present is the insertion of sachets of various scavengers or emitters. These have been followed more recently by plastics blends or compounds and, to a lesser extent, by composite packages of various forms.

Sachets and Other Inserts

Desiccants. Silica gel has been supplied for protection of packaged goods from water for many years. A range of sachets and porous canisters as well as saddles are manufactured in sizes from grams to kilograms by companies such as Multisorb Technologies, Inc. (Buffalo, NY) and Süd-Chemie. Silica gel has a capacity when dried for taking up 40% of its own weight of water vapor. An alternative is lime (calcium oxide), which takes up 28%. Both are used largely in the shipment of goods through humid atmospheres to protect against corrosion (steel, aluminum computers), caking (pharmaceuticals), or mold growth (foods). In Japan these are used with some snacks such as rice crackers to give a high level of crunchiness, as well as a sticky, dehydrating sensation on the tongue. Many variants in form have facilitated new uses for these well-known materials. Sachets are marked

"Do not eat" and are often between the primary and secondary package. Less severe desiccants can be also used for condensation control in the wholesale distribution of produce, particularly where the carton liner bag is heat-sealed to generate a modified atmosphere. A few products such as tomatoes are packed with large microporous sachets of salts, like sodium chloride, which absorb excess water at the high relative humidities experienced in such closed packages. The relative humidity can be lowered from ~95% to 80%. This was a first-generation approach to humidity buffering.

Oxygen Scavengers. Oxygen scavenging sachets were introduced in Japan in 1969 initially containing sodium dithionite and lime. This followed early work by Tallgren in Finland in 1938 using iron and other metals (5). Mitsubishi Gas Chemical Co. introduced Ageless® sachets in 1977 containing reduced iron powder, salt, and trace ingredients. This technology has developed with a wide variety of formulations being provided by Mitsubishi and other companies in Japan. Multisorb Technologies, Inc. manufactures the FreshPax™ series of iron-based oxygen absorbers, which are also marketed in the United Kingdom, and Standa Industrie of Caen manufactures a range of sachets under the name ATCO in France. It was estimated that around 12 billion such sachets were manufactured in Japan in 2001, and it is predicted that sales for 2007 will be on the order of 14.4 billion in Japan, 4.5 billion in the United States, and 5.7 billion in Europe (6). The global value of this market is predicted to grow from $588 million in 2005 to around $924 million in 2010 (7).

The oxygen scavenging materials can also be bonded to the inside of the package, resulting in even less chance of accidental ingestion or incorporation into food preparations. Mitsubishi Gas Chemical Co. introduced a hot-melt adhesive system for sachets, and Multisorb Technologies, Inc. market an adhesive label (FreshMax®), which is sufficiently thin that it can be applied with conventional labeling machinery (see Figure 1). The contents of oxygen-scavenging sachets differ, depending on the relative humidity of the product, usually food. Some are designed to operate at refrigerator or even freezer temperatures. Characteristics of some commonly used sachets are shown in Table 1. The form of triggering is one of the key aspects of oxygen scavengers of any type. It is preferable that the scavenging composition can be activated when required, because premature reaction with atmospheric air leads to loss of scavenging capacity and potential failure in the sealed package.

Figure 1. FreshMax® oxygen-absorbing label attached to the inside of processed meat package. (Courtesy of Multisorb Technologies, Inc.)

Combination sachets are also available from Mitsubishi Gas Chemical Co. and EMCO Packaging Systems (UK). Some of these release carbon dioxide while taking up oxygen. These are normally based on ascorbic acid and sodium bicarbonate. Ageless® E sachets contain lime as well as iron to absorb CO_2 and oxygen and are used in roasted-coffee packs.

Ethanol and Sulfur Dioxide Emitters. Low concentrations of ethanol, 1–2% in bakery products, have been shown to suppress the growth of a range of common molds. Higher levels are necessary to suppress bacteria and yeasts, and the effectiveness is dependent on the water activity of the product. Freund Corp. (Japan) has developed two ethanol-emitting sachets which release ethanol vapor in response to the absorption of water vapor from the food headspace. Antimold-mild® (also known as Ethicap) sachets contain food-grade ethanol (55%) adsorbed in silica powder (35%). The sachets consist of films of varying permeabilities to provide some control of the rate of ethanol release. Sachets are available from Freund in sizes of 0.6–6G containing 0.33–3.3 g of ethanol. The size of the sachet required can be calculated from knowledge of the water activity and weight of the product and the shelf life desired.

Food packages containing ethanol-releasing sachets should have an ethanol vapor permeability of $<2\,\text{g/m}^2$ per day at 30°C (Freund Corp.). Packaging films used with ethanol generators can be as simple as oriented polypropylene/polypropylene, but polyethylenes are too permeable for use. Ethicap has been investigated with pita bread, apple turnovers, strawberry layer cakes, and madeira and cherry cream cake. It is used widely in Japan with semimoist or dry fish products.

The second type of ethanol emitting sachet marketed by Freund Corp., under the name Negamold®, is a combined oxygen scavenger and ethanol emitter. This type of sachet is not widely used. Ethanol-emitting sachets are manufactured by other companies in Japan, including Ohe Chemicals Inc. (Oytech L). Pira International Ltd. estimated that the total global market (predominantly in Japan) in 2005 for these types of sachets was $37 million, and it forecasts growth to $65 million by 2010 (8).

Sulfur-dioxide-releasing pads are available for use in the transportation of cartons of table grapes. Grapes are readily separated from their stalks by the action of fungi in the moist atmosphere of polyethylene-lined cartons. Microporous pads containing sodium metalbisulfite (~7 g) placed on top of the fruit release sulfur dioxide as water vapor is absorbed. If the uptake of water vapor is too rapid, as is often the case, the rapid premature hydrolysis results in excessive levels of sulfur dioxide, resulting

Table 1. Properties of Some Oxygen Scavenging Sachets[a]

further in bleaching of the grapes, commencing at the bottom of the berries. Such pads are largely manufactured in Chile by companies such as Productions Quimicos & Alimenticos Osku SA, of Santiago (e.g., OSKU-VID® Grape Guard), and are widely distributed internationally.

Ethylene Absorbers. Ethylene-absorbing sachets, sometimes made of steel mesh, are available and follow from the variety of porous slabs and blankets developed for ethylene removal in cool stores and shipping containers. Several minerals are used to contain potassium permanganate in the form of purple beads or in other shapes. Typical inert substrates include perlite, alumina, silica gel, and vermiculite containing 4–6% potassium permanganate. The manner in which these might be used should be checked because potassium permanganate is toxic. There are many manufacturers such as Ethylene Control, Inc. of Salinas, CA and Purafil Co. of Chalamblee, GA. The efficiency of such absorbers will depend on the product, the surface area of the substrate, and possibly any water condensation.

Ethylene-absorbing sachets based on other principles for destruction of the ethylene, such as the use of carbon activated with a palladium catalyst, have also been reported (8). Nonspecific absorbents have also been marketed in sachet form in Japan for removal of gases such as ethylene, carbon dioxide, and unwanted odors from food packs. A product based on activated carbon is marketed by Mitsubishi Gas Chemical Co. (Ageless® C-P, which includes slaked lime). The capacity of such absorbents for ethylene at physiological concentrations (e.g., <1 ppm, 95% RH) and at the typically low temeprartures used for storage needs to be defined.

Plastic-Based Active Packaging Materials

Moisture Control. Moisture in packages may be in the form of liquid (condensate or drip/weep) or as the vapor. Desiccants remove both forms of water, although they are designed to remove the vapor. The simple form of liquid moisture sorption has been provided by drip-absorbent sheets consisting of two layers of nonwoven polyolefin, divided by heat seals into pouches containing polyacrylate superabsorbent polymers. These sheets are used under chicken or turkey pieces and sometimes under red meats to absorb drip during display. Other uses are to absorb drip from seafood, especially when air-freighted to avoid corrosion of airframes caused by spilling. These sheets are widely available from companies such as Maxwell Chase Inc. (Douglasville, USA) (Fresh-R-Pax™).

Although superabsorbent polymers can absorb up to 500 times their own weight of water, they do not function as such rapid absorbents for water vapor. Condensation can be prevented by use of multilayer plastic sheets containing a humectant or moisture absorbent material between the layers, such as those developed by Showa Denko K.K. (Japan) (9) and CSIRO (Australia) (10). At least one water vapor absorbent sheet has been produced for domestic use, known as Pichit. This consisted of an envelope of polyvinyl alcohol film sandwiching a glycol and carbohydrate in a strong water vapor absorber (see Figure 2). It is manufactured by Shoko Co. Ltd. (a subsidiary of Showa Denko K.K) and sold as a perforated role and as packs of single sheets for wrapping food portions in domestic refrigerators. Süd Chemie produce a desiccant polymer (2AP®) for use in a wide range of package formats including tubes and caps, and have patented approaches for producing such materials by inclusion of microchannels and humectants or desiccants.

Oxygen Scavenging. Oxygen scavenger films have been a goal of packaging industry researchers since the work of the American Can Co. in 1976 with the palladium-catalyzed reaction of oxygen with hydrogen. That package,

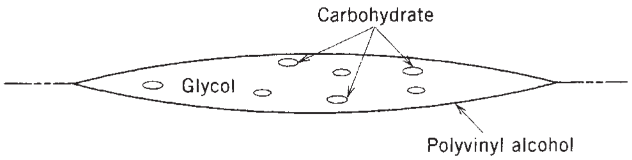

Figure 2. Pichit bilayer sheet for absorbing water from food portions. (Courtesy of Showa Denko K. K.)

marketed by American Can Co. as Maraflex, was not widely used commercially because of its complexity and its requirement for flushing with a nitrogen/hydrogen mixture. Oxygen-scavenging films or other plastic materials offer the opportunity to prevent oxygen ingress to the package by permeation as well as removing that originally present inside the package. They also offer the potential for package fabrication, filling, and sealing without the need for insertion or attachment of a sachet. Despite the substantial international R&D effort over the last two decades (11), only a few oxygen-scavenging film technologies have been commercialized, such as Sealed Air's light-activated Cryovac® OS System, which is based on the transition metal-catalyzed oxidation of rubber-like unsaturated polymeric components.

Oxygen-scavenging closure products are marketed by a number of companies, including Silgan White Cap (Stamford, Connecticut) (Plasti-Twist®), Grace Darex® Packaging Technologies (a business unit of W. R. Grace Company), and Bericap (O2S®). The Grace Darex® compositions, exemplified by Daraform® 6490, include up to 7% sodium sulfite and 4% sodium ascorbate in a polyolefin base (12), and they have been used by Heineken and Anheuser-Busch beer produced under license in the United Kingdom. More recently, Grace Darex® launched Celox™, a closure liner that is claimed by the manufacturer to provide a substantially faster scavenging rate. Toyo Seikan Kaisha Ltd. (Yokohama, Japan) has taken a different approach using a reduced iron base for reaction with oxygen. The crown closure consists of three layers with the middle, reactive layer separated from the beer by a microporous polymer layer. The scavenging reaction involves water vapor from the beer, especially during pasteurization, and premature reaction is presented by keeping the composition dry prior to use. The closure sealant designs can be compared by reference to Figure 3, which represents the Grace approach (top) and the Toyo Seikan Kaisha approach (bottom).

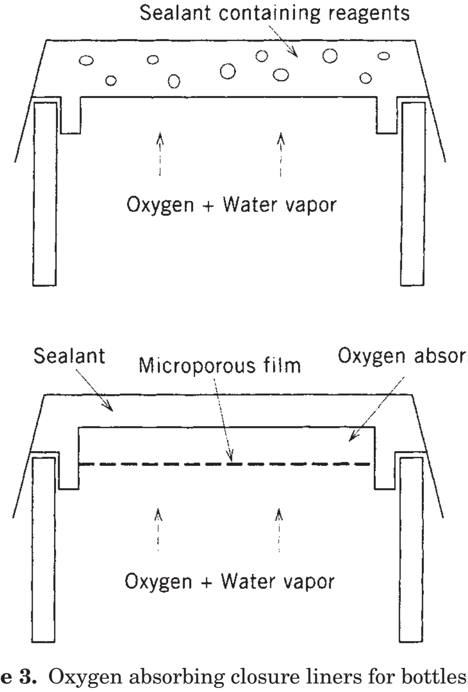

Figure 3. Oxygen absorbing closure liners for bottles. Top: W. R. Grace type. Bottom: Toyo Seikan Kaisha Ltd. type.

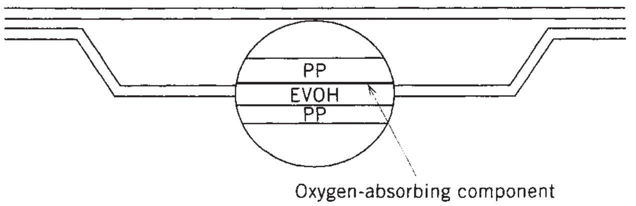

Figure 4. Oxygen-absorbing thermoformed multilayer tray for semiaseptic rice (PP, polypropylene; EVOH, ethylene vinyl alcohol copolymer). (Courtesy of Toyo Seikan Kaisha Ltd.)

The first thermoformable oxygen-scavenging sheet (Oxyguard™) was commercialized in 1994 by Toyo Seikan Kaisha Ltd. for use in retortable plastics trays. The oxygen scavenging layer is between the EVOH (ethylene vinyl alcohol) oxygen-barrier layer and the inner, permeable polypropylene layer. Figure 4 shows this structure diagramatically. The scavenging process involves moisture-activated reaction of oxygen with iron particles embeded in the polypropylene layer. Similar thermoformable oxygen-scavenging polymeric materials are also produced by Ciba Speciality Chemicals (SHELFPLUS® O2).

Active Oxygen Barriers. More recently, oxygen-scavenging has been used to improve the barrier performance of PET containers. The Oxbar™ technology involves the transition-metal-catalyzed oxidation of polymeric materials such as MXD6 Nylon, and it was originally developed by CMB Technologies plc UK for making PET bottles oxygen-impermeable while scavenging oxygen from the packaged beverage. This technology is now the basis of PET bottles manufactured by Constar International Inc. (Philadelphia, Penn.), as well as by other packaging companies, such as Amcor Ltd. (Melbourne, Australia), under license. Other approaches based on the use of transition-metal-catalyzed oxidation to produce PET bottles having enhanced oxygen-barrier properties include those of BP Amoco (Amosorb®), Valspar (ValOR™), and Toyo Seikan Kaisha Ltd. (Oxyblock, also referred to as SIRIUS101). M&G has developed a technology involving incorporation of iron particles into the PET, and it produces actively enhanced oxygen barrier PET bottles (ActiTUF®).

Antimicrobial Films. Antimicrobial agents, fungicides, and natural antagonists are applied to harvested produce in the form of aqueous dips or as waxes or other edible coatings. Their roles and their U.S. regulatory status have been tabulated (13). Besides produce, foods with cut surfaces are subject to largely superficial microbial attack and some cheeses are packaged with wrappings or separating films (sliced cheese) containing sorbic acid. Although many foods are subject to rapid attack at the cut surfaces, potentially useful antimicrobial packaging films are still largely a subject of research (14–16).

Sinanen Zeomic Co. Ltd. in Japan produces a synthetic zeolite, Zeomic, which has silver ions bonded into the

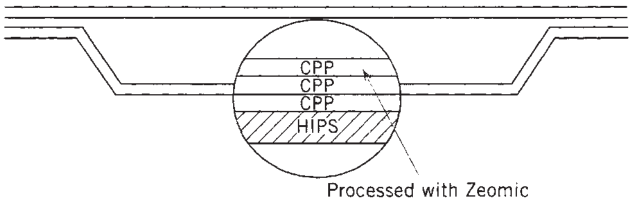

Figure 5. Antimicrobial thermoformed tray containing Zeomic silver zeolite heat-seal layer. (CPP, cast polypropylene; HIPS; high-impact polystyrene). (Courtesy of Sinanen Zeomic Co. Ltd.)

surface layers of the pores. The zeolite is dispersed in, for instance, a polypropylene or polyethylene 3- to 6-μm-thick layer and protrudes into the package from this layer as indicated in Figure 5. Other layers provide package strength and permeation barrier as required. Liquid in the food is meant to have access to the zeolite, and it appears that the mode of action is uptake of silver ion that dissolves in the aqueous phase (17). The zeolite has been found to be highly effective against several vegetative bacteria, especially dispersed in water, saline solution, or oolong tea. The effect of amino acids in food proteins is the subject of research (18). Zeomic is approved as a Food Contact Substance by the U.S. FDA and can be used in any type of food packaging resin product. The Zeomic product is distributed outside Japan and in parts of Southeast Asia by AgION Technologies Ltd. (Wakefield, MA).

Odor Absorption. Since odors can be sensed at very low levels, there is the opportunity to use packaging materials to reduce the concentrations of these components in otherwise acceptable foods (see Aroma barrier testing). The inclusion of molecular sieves and other agents capable of adsorbing odorous volatile compounds has been explored. Packaging technologies capable of removing specific classes of odorous compounds through chemical reaction have also been investigated with several patents in this area relating to elimination of aldehydes having been granted to Dupont and Cellresin Technologies LLC. A different approach has been patented by Minato Sangyo Co. Ltd., based on ascorbic acid and an iron salt dispersed in the plastic, and is aimed at removing amine or sulfur compounds from fish in domestic refrigerators.

Thermal Control. Microwavable packages containing foods with differing reheating requirements can be made to crisp or brown some components by use of susceptors and reduce the heating of other components by use of foil shields. Susceptors normally consist of a vacuum-deposited layer of aluminum, typically with a light transmission of 50–60%, or a 12-μm-thick film of biaxially oriented PET. The film is laminated to paper or paperboard by means of an adhesive. In a microwave field, susceptors have reached a temperature of 316°C in the absence of food, or 223°C in pizza packs (19). These temperatures have caused regulatory authorities to investigate the stability of all components of susceptor films, particularly the adhesives. The microwave field strength can be intensified by specific distributions of foil patches in the dome lids of microwaveable packs.

Beverage cans can be made either "self-heating" or "self-cooling" by means of chemical reactions in compartments separated from the beverage (20). Sake is heated by the exothermic reaction of lime with water in aluminum cans. This process is potentially valuable in the vending machine market. Cooling is achieved by the endothermic dissolution of ammonium nitrate and ammonium chloride with water. Both of these thermal effects are brought about by shaking and thus are unsuitable for use with carbonated beverages.

RESEARCH AND DEVELOPMENT

Active packaging materials have been evolving through a series of innovations dating from the late 1980s, with many hundreds of primary patent applications having been filed for both chemical principles and package designs relating to oxygen scavenging alone. Despite considerable industry interest, so far very few of these innovations have led to commercial products. There is a substantial amount of innovation in progress, especially in the area of active plastic-based packaging incorporating in-polymer chemistry. Methods of activating chemical systems that are stable during thermal processing are particularly interesting. The benefits of using active packaging need to be established clearly, and performance claims for these technologies need to be supported by unambiguous, independent research results demonstrating their effectiveness.

SUMMARY

The emergence of active packaging has required reappraisal of the normal requirement that the package should not interact with the packaged product. For example, the introduction of a new EU Regulation (1934/2004) repealing the earlier relevant EU Directives for food contact materials (89/109/EEC and 80/590/EEC) attempts to reconcile the EU's philosophy that food contact materials should not give rise to chemical reactions that alter the initial composition or organoleptic properties of the food, while recognizing the potential benefits of active packaging technologies to enhance the preservation of packaged food. The introduction of this new EU Regulation paves the way for more rapid uptake of these new packaging materials (21). Active packaging introduced so far represents substantial fine-tuning in the matching of packaging properties to the requirements of the product. Accordingly, it will be seen increasingly in niche markets and in wider applications in which specific problems are inhibiting the marketing of the product. Indeed, the specific examples being introduced are too numerous to describe here, and the reader is referred to the Bibliography and the Further Reading sections.

ADHESIVE APPLICATORS

Adhesive applicating equipment used in packaging applications is available in a vast array of configurations to provide a specific means of sealing containers. The type of adhesive equipment chosen is determined by several factors: the class of adhesive (cold waterborne or hot-melt), the adhesive applicating unit and pump style that is most compatible with the adhesive properties, and production line demands. The variables in the packaging operation are matched with the available adhesives and equipment to achieve the desired results.

PACKAGING ADHESIVES

Adhesives used in packaging applications today are primarily cold waterborne or hot-melt adhesives (see the Adhesives article).

Cold waterborne adhesives can be broadly categorized into natural or synthetic. Natural adhesives are derived from protein (animal and casein) and vegetable (starch and flour) sources. Synthetic-based adhesives (primarily resin emulsions) have been gradually replacing natural adhesives in recent years. The liquid "white glue" is generally composed of protective poly(vinyl alcohol) or 2-hydroxyethyl cellulose colloids and compounded with plasticizers, fillers, solvents, or other additives. Also, new copolymers have been developed and used to upgrade performance of cold emulsion adhesives in dispensing characteristics, set time, and stability.

Cold adhesives have good penetration into paper fiber and are energy efficient, especially when no special speed of set is required. Hot-melt adhesives are thermoplastic polymer-based compounds that are solid at room temperature, liquefy when heated, and return to solid form after cooling. They are blended from many synthetic materials to provide specific bonding characteristics. Most hot melts consist of a base polymer resin for strength, a viscosity

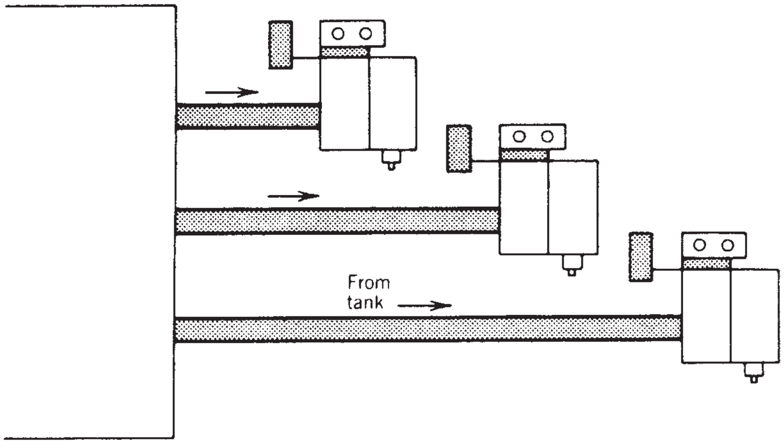

Figure 1. Noncirculating gun installation (parallel) system.

control agent such as paraffin, tackifying resins for greater adhesion, and numerous plasticizers, stabilizers, antioxidants, fillers, dyes, and/or pigments.

Hot melts are 100% solid; they contain no water or solvent carrier. This offers several advantages: rapid bond formation and short set time because heat dissipates faster than water evaporates, shortened compression time, and convenient form for handling and long-term storage. Being a thermoplastic material, hot melts have limited heat resistance and can lose their cohesiveness at elevated temperatures.

ADHESIVE APPLICATING EQUIPMENT CLASSIFICATION

Both cold waterborne and hot-melt adhesive application systems are generally classified as noncirculating or circulating. Noncirculating systems are the most common (see Figure 1). They are identified easily because each gun in the system is supplied by its own hose. The noncirculating system is often referred to as a "dead-end system" because the hose dead ends at the gun. An offshoot of the noncirculating system is the internally circulating hot-melt system (see Figure 2). Circulation occurs between the pump and manifold, but from the manifold to the gun it is the same as a dead-end system.

Circulating systems are used to some extent in applications that require a standby period, as in a random case sealing operation, when some setup time is needed. A circulating system is identified by the series installation of the hoses and guns (see Figure 3). In the typical circulating installation, many automatic extrusion guns are connected in series with the hot-melt hose. Molten material is siphoned out of the applicator tank and pumped into the outlet hose to the first gun in the series. The material then flows from the first gun to the second gun and continues on until it passes through a circulation valve and back into the applicator's tank. The circulation valve permits adjustment of the flow of material.

COLD-GLUE SYSTEMS

Most cold-glue systems consist of applicator heads to apply adhesive either in bead, spray, or droplet patterns; fluid hoses to carry the adhesive to the applicator head from the tank; a pressure tank of lightweight stainless steel that can include a filter, quick-disconnect couplings for air and glue, a pressure relief valve and an air pressure gauge; and a timing device to control the adhesive deposition.

The applicator heads are controlled by either an automatic pneumatic valve or a manually operated hand valve. The bead, ribbon, or spray patterns can be dispensed using multiple-gun configuration systems with resin or dextrin cold adhesives. Cold-adhesive droplet guns dispense cold mastic and plastisols, and they come in a wide variety of configurations for spacing requirements. In bead and ribbon cold glue extrusion, the tips either make contact or close contact with the substrate. Spray valves emit a mistlike pattern without touching the substrate's surface.

HOT-MELT SYSTEMS

Hot-melt application equipment performs three essential functions: melting the adhesive, pumping the fluid to the point of application, and dispensing the adhesive to the substrate in a desired pattern.

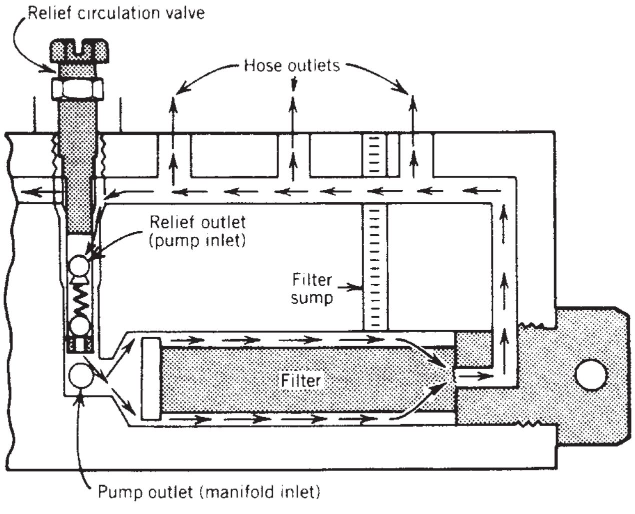

Figure 2. Internally circulating system.

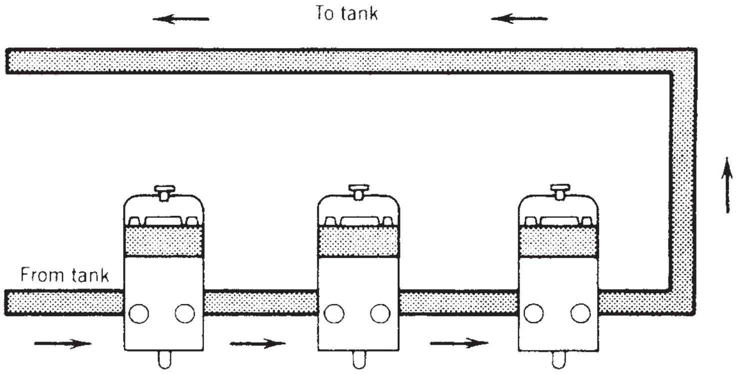

Figure 3. Circulating gun installation (series) system.

Melting Devices. Tank melters are the most commonly used melting unit in packaging applications. Best described as a simple open heated pot with a lid for loading adhesive, a significant feature of tank melters is their ability to accept almost any adhesive form. The tank melter is considered the most versatile device for accepting hot melts with varying physical properties of adhesion and cohesion.

In tank melters, the tank size is determined by melt rate. Once melt rate objectives or specifications are determined, the tank size is fixed. Larger tanks have greater melt rates than smaller tanks. Holding capacities range from 8 lb (3.9 kg) in the smaller units to more than several hundred pounds (>90 kg) in the larger premelting units (see Figure 4).

The tanks are made of highly thermal conductive material, such as aluminum, and they are heated by either a cast-in heating element or a strip or cartridge-type heater. The side walls are usually tapered to provide good heat transfer and to reduce temperature drop.

Adhesive melts first along the wall of the tank as a thin film. Internal circulation currents from the pumping action assist in transferring heat throughout the adhesive held in the tank. Even when the hot melt is entirely liquid, there will be temperature differences within the adhesive. Under operating conditions, adhesive flows along tank surfaces and absorbs heat at a faster rate than it would if allowed to remain in a static condition. Even though adhesive in the center of the tank is cooler, it must flow toward the outer edges and pick up heat as it flows into the pumping mechanism.

Grid melters are designed with dimensional patterns resembling vertical cones, egg crates, honeycomb shapes, and slotted passages arranged in a series of rows. Such an arrangement creates a larger surface area for heat transfer. The grid melter is mounted above a heated reservoir and pump inlet (see Figure 5).

The grid melting process is exactly the same as the tank melting process; however, the film of adhesive flows along with surfaces and flows through ports in the bottom of the grid. In this way, the solid adhesive will rest above the grid and force the molten liquid through the grid. The grid is designed for deliberate drainage of liquid adhesive to maintain a thin film adjacent to the heated surfaces. This thin film provides for a greater temperature difference than normally found in a tank, and a much larger heat flow is attainable. The grid melter also achieves a much greater melt rate for a given size or area of melter. It can heat higher performance adhesives because it provides relatively uniform temperature within the melter

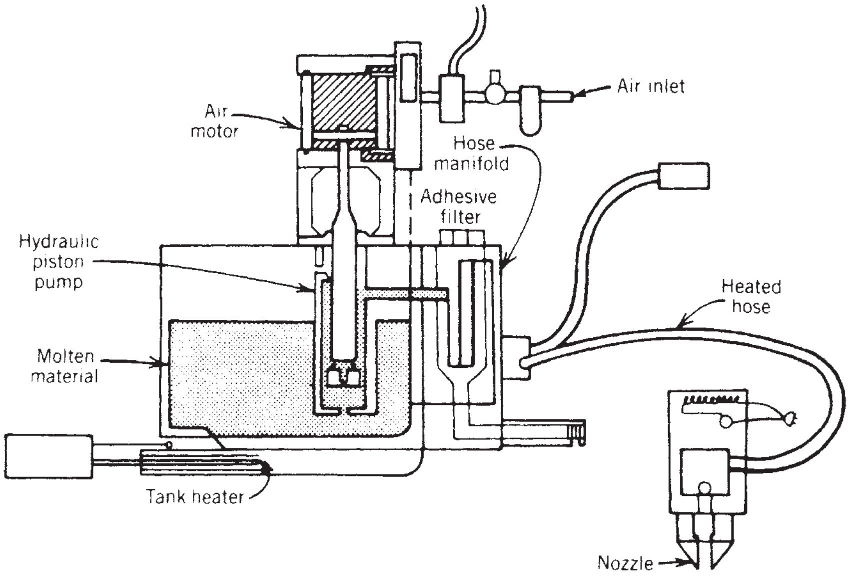

Figure 4. Tank-type hot melt unit.

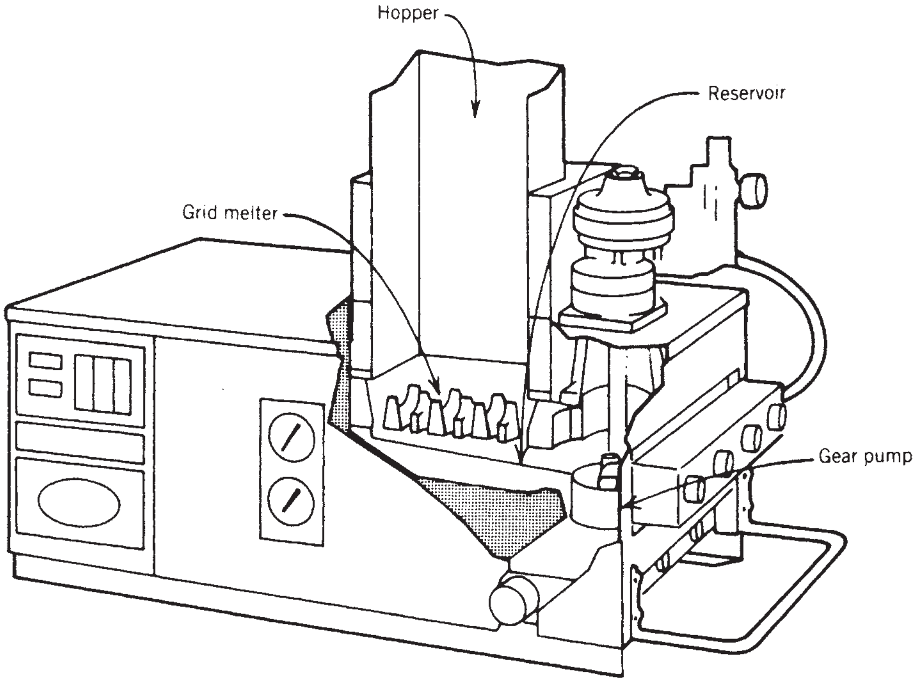

Figure 5. Grid melter hot melt unit.

itself, which also minimizes degradation. These features are achieved with some sacrifice of versatility because the adhesives must normally be furnished as pellets or other more restricted geometries.

Between each row of patterned shapes are passageways that open into a reservoir beneath the melter. The passageways ensure a constant and unobstructed flow of molten material to the reservoir below.

The reservoir has a cast-in heating system similar to that of most tank applicators. The temperature control can be separate from the grid melter. The floor of the reservoir is sloped so that molten material is gravity-fed toward the pump inlet.

Grid melters are available with optional hopper configurations. The major difference, other than capacity, is the ability to keep the material "cool" or "warm" before it reaches the grid. The cool hopper merely supplies adhesive and the material becomes molten at the grid. The molten time of the material is shortened before actual application. The cool hopper works well with hot melts of relatively high softening and melting points.

Warm hoppers are insulated and attached to the grid so that heat is radiated from the hopper through the hopper casting. Materials that are better formulated to melt in a zone-heating process, such as hot melts with medium to low melting points, and pressure-sensitive materials work well with the warm hopper design.

The tank capacities of both tank and grid melting devices can be extended with premelt tanks. They may be equipped with their own pumping devices or act on a demand signal from a level sensor in the applicator tank; however, all perform like tank units to keep hot melt materials molten at controlled temperatures. One of the newer premelting devices is in the bulk melter unit (see Figure 6).

Bulk melting systems are designed to dispense hot-melt adhesives and other highly viscous thermoplastic materials in applications requiring a high volume or rapid delivery of material. Units can be used as direct applicators or as premelters as part of a central feed system.

The material is pumped directly from the drum or pail in which it is shipped. This provides ease of handling and lower material costs of bulk containers. In premelting

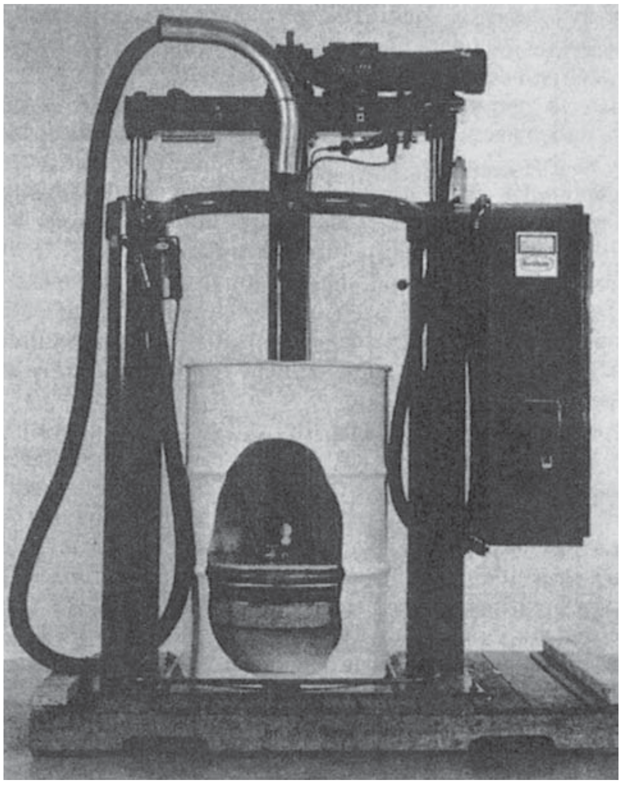

Figure 6. Cutaway of drum showing bulk melter system.

applications, the bulk melter system preheats the material before it is pumped into heated reservoirs. The material is then pumped from the reservoirs to the application head on demand.

The electrically heated platen is supported by vertical pneumatic or hydraulic elevating posts. The platen melts the hot melt material on demand directly from the container and forces it into the pump inlet.

The platen can be a solid one-piece casting, or in the larger units, several grid or fin sections. It is important that the platen size match the inside diameter (ID) of the drum or pail. The platen is protected by one or more seals to help prevent leakage.

Pressurized melters, or screw extruders, are among the earliest designs used in hot-melt applicators. Imitating injection-molding machinery (see the Injection molding article), early screw-extruder and ram-extrusion handgun systems had limited success because they were designed only for continuous extrusion. The closed-system and screw-extrusion design allows for melting and pumping of high-viscosity, highly degradable materials.

Extruder equipment is now adapted to intermittent applications; it consists of a hopper feeder, a high-torque dc-drive system, a heated barrel enclosing a continuous flight screw, and a manifold area (see the Extrusion; Extrusion coating article). Heating and drive control systems can be controlled independently by a microprocessor. Temperatures and pressure are monitored by digital readouts. Adapted for high-temperature, high-viscosity, or degradation-sensitive adhesives, the new technological advances in extruder equipment give greater potential for adhesive applications such as drum-lid gasketing, automotive-interior parts, and self-adhering elastic to diapers (see Figure 7).

Pumping Devices and Transfer Methods. Once the hot-melt material is molten, it must be transferred from the tank or reservoir to the dispensing unit. Pumping mechanisms are of either piston or gear design.

Piston pumps are air driven to deliver a uniform pressure throughout the downstroke of the plunger. Double-acting piston pumps maintain a more consistent hydraulic pressure with their ability to siphon and feed simultaneously. Piston pumps do not provide complete pulsation-free output, but they are well suited for fixed-line speed applications.

Gear pumps are available in several configurations: spur-gear, gerotor, and two-stage gear pump.

Spur-gear pumps have two counterrotating shafts that provide a constant suction and feeding by the meshing action of the gear teeth (see Figure 8). They are becoming more common because of their versatility in handling a variety of high viscosity materials and their efficient performance in high speed packaging.

Gerotor gear pumps have a different arrangement of gears and larger cavities for the transfer of materials. The meshing action, which occurs on rotation, creates a series of expanding and contracting chambers (see Figure 9). This makes the gerotor pump an excellent pumping device for high-viscosity hot-melt materials and sealants.

The latest patented two-stage gear pump introduces an inert gas in a metered amount into the hot melt. When the adhesive is dispensed and exposes the fluid to atmospheric pressure, the gas comes out in solution, which foams the adhesive much like a carbonated beverage (see Figure 10).

All types of gear pumps provide constant pressure because of the continuous rotating elements. They can be driven by air motor, constant speed electric motors, variable-speed drives, or by a direct power takeoff from the parent machine. PTO and SCR drives allow the pump to be keyed to the speed of the parent machine. As the line speed varies, the amount of adhesive extruded onto each segment of substrate remains constant.

Variations and modifications to the pumping devices incorporate improvements to their transfer efficiency and performance. Multiple-pump arrangements are also offered in hot-melt systems to meet specific application requirements.

The transfer action of the pumping device moves the hot-melt material into the manifold area. There, the adhesive is filtered and distributed to the hose or hoses. In the manifold, there is a factory-set, unadjustable relief valve, which protects the system from overpressurization. The adhesive then passes through a filter to remove contaminants and is directed through the circulation valve. The circulation valve controls the hydraulic pressure in the system. The material circulates to the hose outlets and out the hose to the dispensing devices.

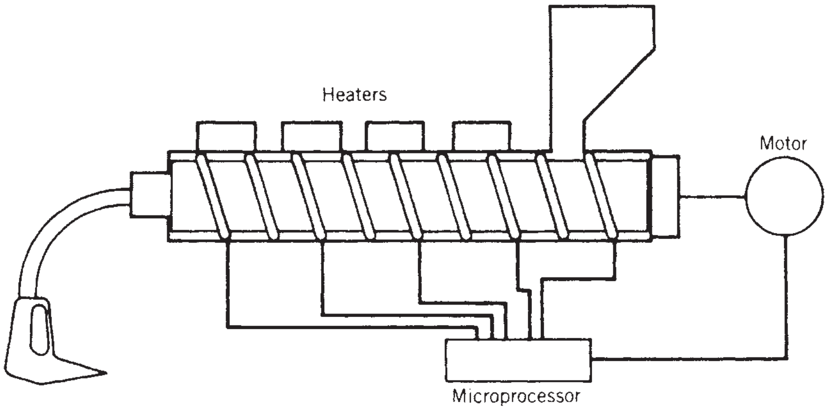

Figure 7. Screw extruder.

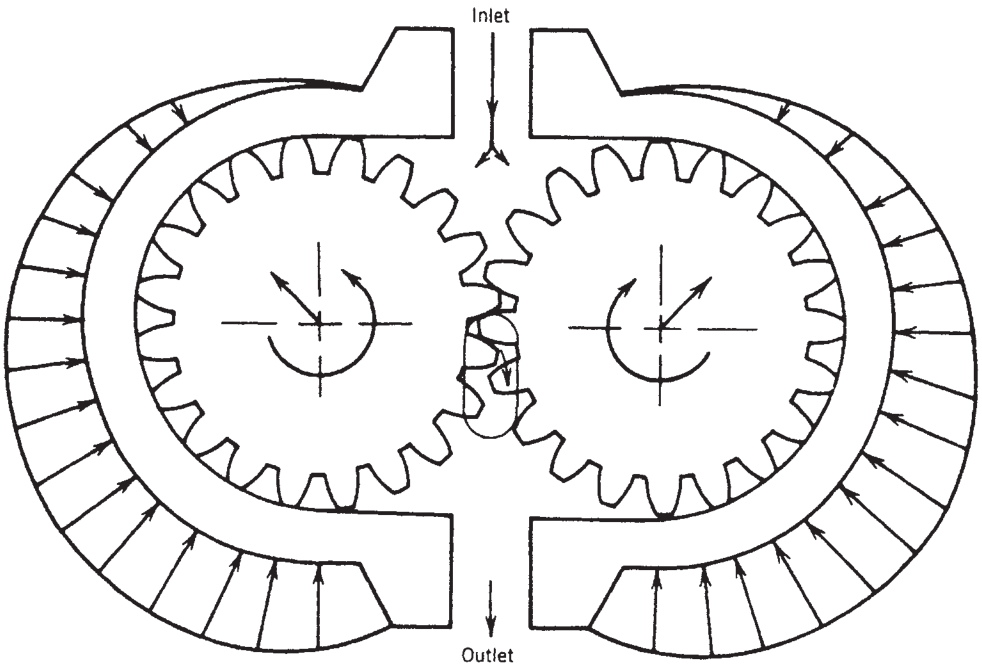

Figure 8. Spur gear pump.

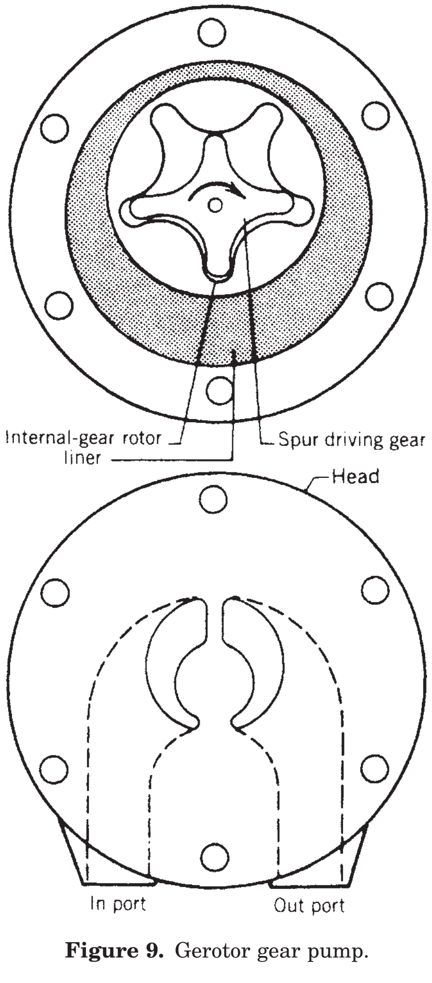

Figure 9. Gerotor gear pump.

For hot-melt systems that require a fluid link between the melting-pump station and the point of application, hot-melt hoses provide a pipeline for transferring the adhesive. Some methods of dispensing (e.g., wheel-type applicators) do not use hoses and will be discussed later.

To withstand operating hydraulic pressures up to 1600 psi (lb/in.^{2}) (11.3 MPa), hot-melt hoses are constructed of aircraft-quality materials. They are flexible, electrically heated, and insulated, and they come in various lengths to accommodate particular installation requirements.

Hot-melt hoses are generally constructed of a Teflon innertube that is surrounded by a stainless steel wire braid for pressure resistance (see Figure 11). Noncirculating hoses maintain temperature with a heating element spirally wrapped around the wire braid throughout the length of the hose. Circulating hoses sometimes use only the wire braid to maintain heat. Wrapped layers of materials such as polyester felt, fiberglass, and vinyl tape provide insulation. For abrasion resistance, the entire hose is covered with a nylon braid.

The hose temperature can be independently controlled and is monitored inside the hose by a sensing bulb, thermistor, or resistance temperature detector.

Dispensing Devices. There are several methods of depositing adhesive onto a substrate once the material is in a molten state. The applicating devices can be categorized as follows:

1. Extrusion guns or heads (automatic and manual).
2. Web-extrusion guns.
3. Wheel and roll dispensers.

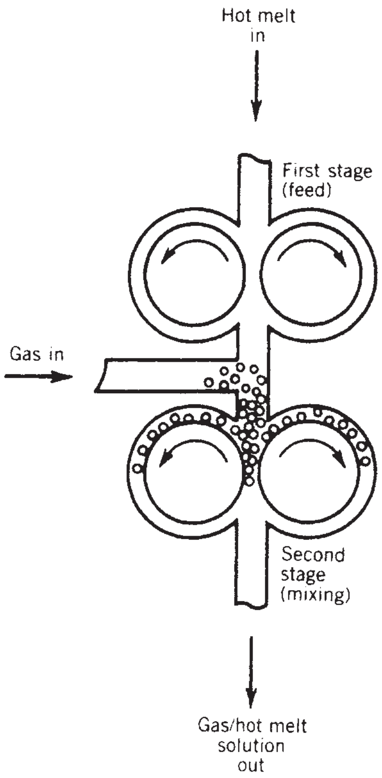

Figure 10. Foaming process of two-stage gear pump.

Extrusion guns are used on most packaging lines. This extrusion method entails applying beads of hot melt from and nozzle. The gun is usually fed from the melting unit through the hose or directly from the unit itself.

Most high-speed applications use automatic guns that are triggered by timing devices or controllers on line with the parent machinery to place the adhesive on a moving substrate.

Automatic guns are actuated by pressure that forces a piston or plunger upward, lifting the attached ball or needle off the matched seat. Molten adhesive can then pass through the nozzle as long as the ball or needle is lifted off its seat by the applied pressure. The entire assembly can be enclosed in a cartridge insert or extrusion module (see Figure 12). Either style, when fitted into or on the gun body, allows for multiple extrusion points from one gun head. Modular automatic guns with up to 48 extrusion modules are possible (see Figure 13).

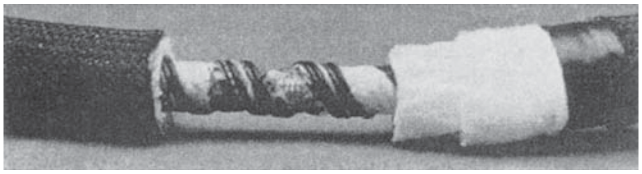

Figure 11. Cutaway of hot-melt hose.

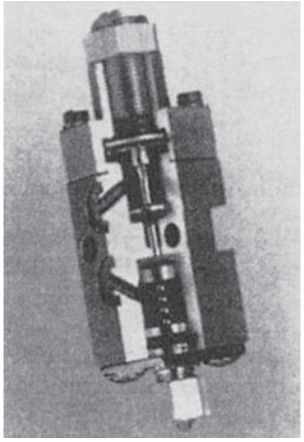

Figure 12. Cutaway of extrusion module.

The pressure to actuate automatic guns is either electropneumatic by means of a solenoid or electromagnetic with a solenoid coil electrically signaled.

Gun temperatures can be controlled thermostatically with cartridge heaters to a maximum of 450°F (230°C). A maximum operating speed of 3500 cycles per minute (58.3 Hz) is possible.

Handgun extrusion is based on the same principles but with manual rather than automatic triggering. A mechanical linkage operated by the gun trigger pulls the packing cartridge ball from its seated position to allow the adhesive to flow through the nozzle.

The extrusion nozzle used on the head or gun is the final control of the adhesive deposited and is used to regulate the bead size. It is designed for varying flow rates that are determined by the nozzle's orifice diameter and length. Classified as low-pressure–large-orifice or high-pressure–small-orifice nozzles, they provide different types of beads. Low-pressure–large-orifice nozzles are specified for continuous bead applications with the large orifice helping to limit nozzle clogging.

High-pressure–small-orifice nozzles are better adapted to applications that require clean cutoff and rapid gun cycling. Drooling and spitting must be controlled for applications such as stitching.

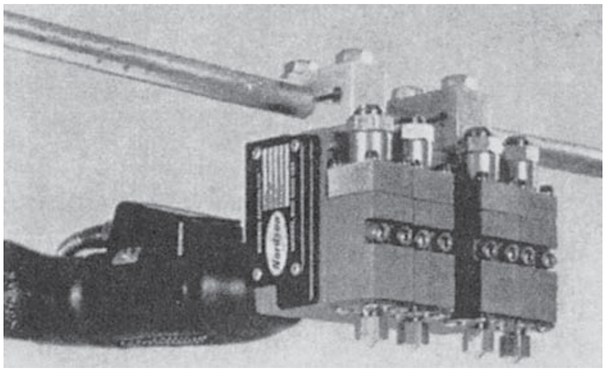

Figure 13. Automatic gun with four modules.

Patterns can be varied even more by selection of multiple-orifice designs, right-angle nozzles for differences in positioning, and spray nozzles for a coated coverage.

Heated in-line filters can be installed between the hose and gun to provide final filtering before adhesive deposition. Independent temperature control helps keep the temperature constant. However, more options are available to provide optimum control by combining a heat exchanger and filter integrally with the gun (see Figure 14). These specialized guns can precisely elevate the temperature of the adhesive material and can hold adhesive temperature within ±2°F (±1.1°C) of the set point. This allows the rest of the system to be run at lower temperatures, which thereby minimizes degradation of the material. The filter assembly incorporated into the service block catches contaminants not trapped by the hot-melt system filter.

Efforts to prevent nozzle clogging and drool have resulted in a zero-cavity gun that replaces the traditional ball-and-set seat assembly with a tapered needle and precision-matched nozzle seat. In traditional guns, the ball-and-seat assembly interrupts adhesive flow some distance from the nozzle, allowing the adhesive left in the nozzle to drool from the tip and char to lodge in the nozzle orifice. With the zero-cavity gun, no separate nozzle is needed. A microadjust feature adjusts the needle for precise flow control. When the needle closes into the nozzle seat, any char is dislodged. In addition, with no nozzle cavity area the cutoff is clean and precise.

Web-extrusion guns have adapted extrusion dispensing technology to deposit a film of hot melt on a moving substrate. Better known as *slot nozzles* or *coating heads*, they are well suited to continuous or intermittent applications. Mounted on an extrusion gun, a heated or non-heated slot nozzle extrudes an adhesive film of varying widths, patterns, and thickness. Pattern blades can be cut to desired patterns. Film thickness is adjustable by using different thickness blades, by stacking of blades in the slot nozzle, or by varying the adhesive supply pressure (see Figure 15).

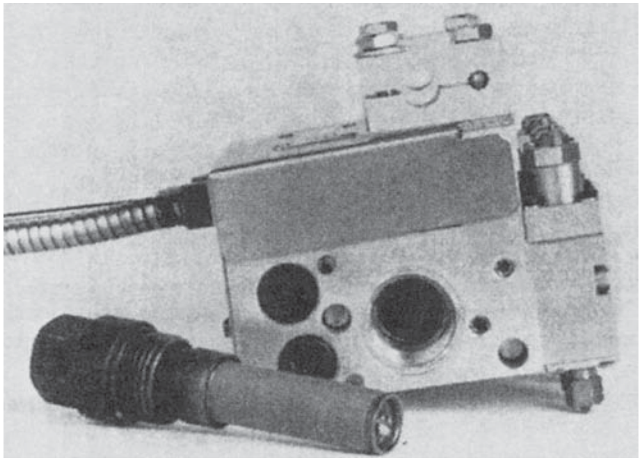

Figure 14. Heat exchanger gun.

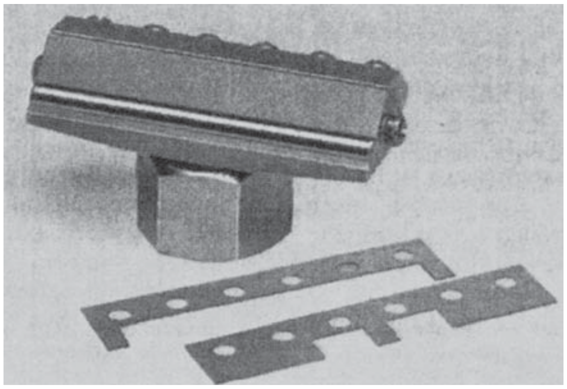

Figure 15. Two-inch slot nozzle with pattern blades.

Web extrusion is well suited to coating applications such as labeling, tape/label, envelopes, business forms, and web lamination as in nonwovens.

For temperature-sensitive adhesives in continuous web extrusion, the slot nozzle is used with a heat-exchanger device to minimize temperature exposure of the material.

Wheel and roll dispensers are the predecessors of present coating extrusion. Wheels or rolls are mounted in a reservoir of molten adhesive. The wheels or rolls are finely machined and may be etched, drilled, or engraved with desired patterns for specific pattern transfer. As the wheel rotates in the reservoir, it picks up the hot melt and transfers it to the moving substrate by direct contact (see Figure 16). The reservoir may be the primary melting unit or fed by an outside melting device.

Roll coaters involve a series of unwinding and rewinding units for paper coating, converting, and laminating, plus wide-web applications for tape and label applications.

Timing and Controlling Devices. Automatic applications require installation of one or more devices to control the placement of adhesives on the moving substrate. Such devices normally include a sensor or trigger to detect the presence of the substrate in the gluing station, and a timer or pattern control to measure the predetermined intervals between beads of adhesive or the substrate and to activate extrusion guns at the proper moments (see Figure 17).

The sensor may be operated mechanically (as with a limit switch activated by the substrate or a cam on the packaging machine) or optically (as with photo eyes or proximity switches).

Timers or pattern controls may be used at constant line speeds to time delay extrusion intervals or produce stitched beads. When the line speed varies, pattern controls equipped with line speed encoder or tachometer must be used to compensate for changes in line speed so that bead lengths remain the same. Such devices are highly reliable but are more complex and correspondingly more expensive than duration controls. They can usually control bead placement accurately at line speeds up to 1000 ft/min (5.1 m/s).

Some pattern controls can also be equipped with devices that electronically vary air pressure to the hot-melt

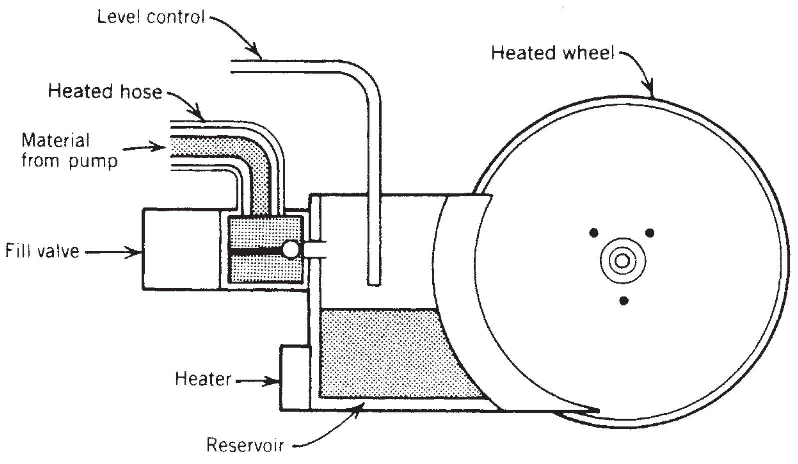

Figure 16. Wheel-type applicator.

applicator to control adhesive output, which maintains constant bead volume as well as placement at varying line speeds. Other accessories can be obtained to count the number of packages that have been glued, check for missing beads, and allow the same device to control guns or different lines. Advanced controls are often modular in construction, user oriented, and include self-diagnostic features.

System Selection. Choosing the correct system to produce the results desired on the packaging line is not difficult once the variables are identified. Some primary variables to consider in specifying equipment for a hot-melt system include rate of consumption, rate of deposition, adhesive registration, and control. Trained factory representatives for adhesive applicating equipment can identify and recommend the best system to fit those variables.

The melting device selected must be capable of handling the pounds-per-hour demand of the packaging operation. The unit must also have sufficient holding capacity to prevent the need for frequent refilling of the adhesive tank or hopper.

Adhesive consumption is affected by line speed, bead size, and pattern. The adhesive consumption rate and maximum instantaneous delivery rate of the pump must be matched to the application requirements (see below).

The pattern to be deposited will determine the dispensing device. Also, the pattern size and registration of the adhesive deposit must be matched with the cycling capabilities of that device.

The system must fit neatly into the entire operation with spacing considerations for mounting unit, gun, and hoses; location to point of application; and accessibility for maintenance.

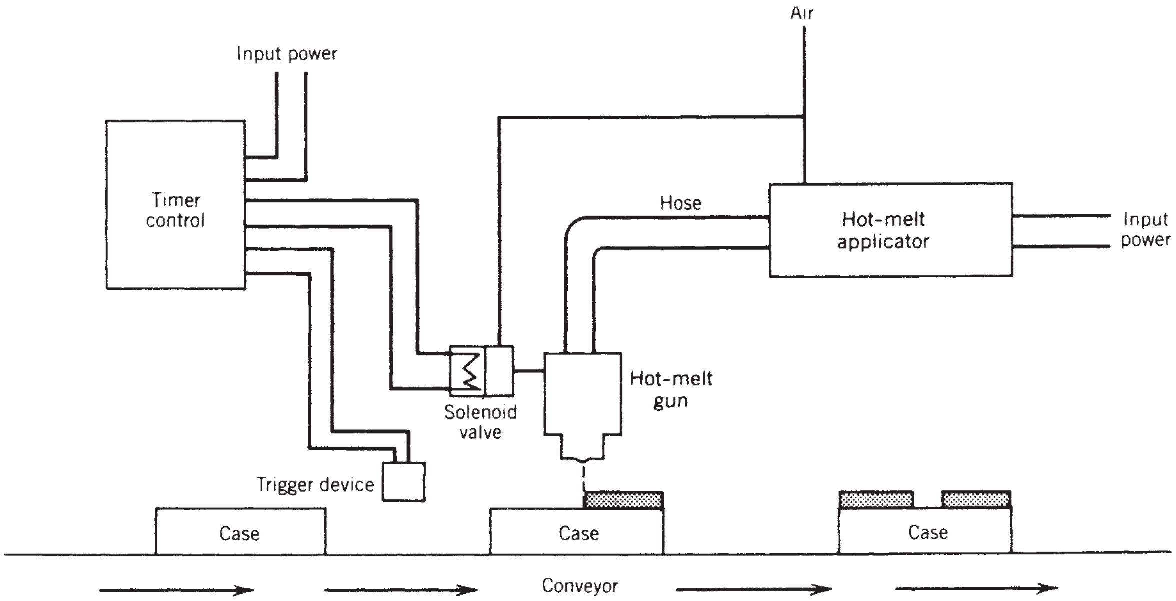

Figure 17. Timer application process. The timer control sequence is activated when the trigger device senses the leading edge of the case. The timing sequence controls preset adjustable delay and duration gun actuations.

CALCULATING MAXIMUM INSTANTANEOUS DELIVERY RATE

The acronym MIDR (maximum instantaneous delivery rate) is used interchangeably with IPDR (instantaneous pump delivery rate). MIDR is the amount of adhesive that a pump would need to supply if its associated guns were fired continuously for a specified period of time. Useful units for measuring MIDR are pounds per hour (lb/h) and grams per minute (g/min).

To calculate the MIDR for a specific application, follow the steps in the example below. Refer to Figure 18 for a visual description of the physical parameters used in the calculation.

Given

1. Four beads per flap, top and bottom sealing, for a total of 16 beads per case.
2. Case length of 16 in. (41 cm).
3. Production rate of 20 cases per min at 100% machine efficiency.
4. Bead length of 4 in. (10 cm), 1 in. (2.5 cm) from case end, with a 6-in. (15-cm) gap between beads.
5. Eight-in. (20-cm) gaps between cases.
6. Adhesive "mileage" of 700 lineal ft · lbf (949 J).

"Mileage" is a function of bead size and the specific gravity of the adhesive. The 700 lineal ft · lbf used above is based on a 3/32-in. (2.4 mm) half-round bead (standard-size packaging bead) and melt density of 0.82 g/cm^3 (melt density of standard packaging adhesive). Adhesives of this type yield approximately 30 in.^{3}/lb (1 cm^3/g).

Calculation

1. Determine the total bead length in in./h (cm/h) and convert to ft/h (m/h).

$$(20\ \text{cases/min}) \times (4\ \text{in./bead}) \times (16\ \text{beads/case})$$

$$\times (60\ \text{min/h}) = 76{,}800\ \text{in./h}\ (195{,}000\ \text{cm/h})$$

$$(76{,}800\ \text{in./h}) \times (1\ \text{ft}/12\ \text{in.}) = 6400\ \text{ft/h}\ (1950\ \text{m/h})$$

2. Determine the adhesive consumption rate at 100% machine efficiency using total bead length per hour and adhesive mileage:

$$(6400\ \text{ft/h}) \times (1\ \text{lb}/700\ \text{ft})(1\ \text{g}/1.54\ \text{m})$$
$$= 9.14\ \text{lb/h}\ (4.15\ \text{kg/h})$$

3. Determine duty cycle using length of bead during machine cycle and machine cycle (length between case leading edges).

$$\frac{\text{8-in. bead length}}{\text{24-in. cycle length}} = 0.333$$

4. Determine the MIDR using the inverse of the duty cycle and the adhesive consumption rate from step 2.

$$\frac{1}{0.333} \times (9.14\ \text{lb/h}) = 27.42\ \text{lb/h}\ (207\ \text{g/min})\ \text{MIDR}$$

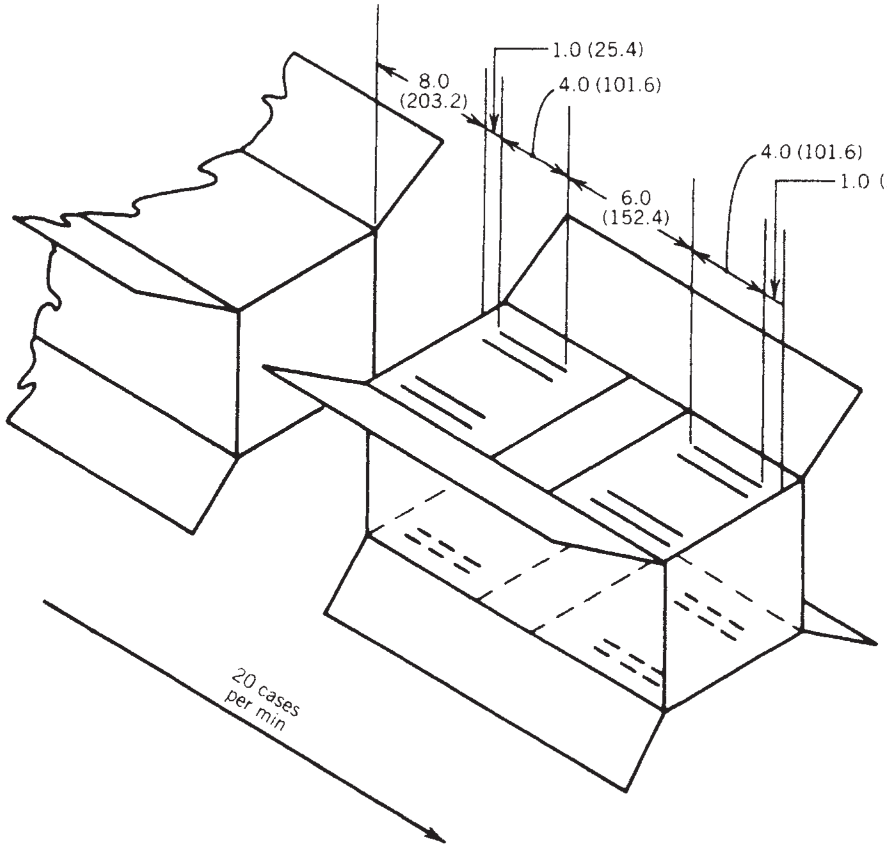

Figure 18. Calculating the MIDR for a specific application. Dimensions are given in inches (millimeters in parentheses).

This example demonstrates the difference between the delivery rate and the adhesive consumption rate. When the guns are firing, the pump is delivering adhesive at a rate of 27.42 lb/h. This is the MIDR. Speed reducers are rated and selected according to the MIDR they can provide. This figure should not be confused with the consumption rate, because the consumption rate is an *average* measure of consumption that includes the time when adhesive demand is zero.

Several equations may prove helpful in some applications:

Bead Length, Line Speed, and Duration

$$\frac{5 \times \text{bead length(in.)(cm)}}{\text{line speed(ft/min)(cm/s)}} = \text{duration(s)}$$

$$\frac{\text{line speed(ft/min)(cm/s)} \times \text{duration(s)}}{5} = \text{bead length(in.)(cm)}$$

$$\frac{\text{bead length(in.)(cm)} \times 5}{\text{duration(s)}} = \text{line speed(ft/min)(cm/s)}$$

INTRODUCTION

The packaging industry represents a significant market for adhesives materials. Some applications include coatings, which act as adhesive layers for bonding to other forms of packaging, such as labels or tapes, or are used in the actual assembly of a carton, or to prepare a laminate.

Adhesives make up more than 80% of the adhesive and sealants market. In 2002, the global market was about 16.7 million tons and was expected to rise about 3–4% per year. In the United States, the market was estimated to be 8.89 million tons in 2004; as a comparison, the market in 1999 was 6.89 million tons (1).

The principal uses of adhesves include: the forming and sealing of corrugated cases and folding cartons; the forming and sealing of bags; the winding of tubes for cores, composite cans, and fiber drums; the labeling of bottles, jars, drums, and cases; the lamination of paper to paper, paperboard, and foil; and the lamination of plastic films for flexible packaging. The markets for packaging materials are diverse, mainly concerned with food, beverage, medical, and heavy-duty industrial applications, each of which can bring stringent performance requirements and impose harsh environments under which the adhesive layer is expected to function.

There is a strong movement to replace solvents and solvent-based adhesives in both the United States and Europe, in order to minimize volatile organic emissions. This has led to a growth in water-based and hot-melt adhesives at the expense of solvented types. Also, there has been a strong interest in recyclable adhesives based on requirements for recycled paper content in the United States and Europe. There is a desire to develop single material packaging to facilitate recycling and minimize sorting. A problem is that adhesive residues left in board can produce difficulties in the subsequent handling of the regenerated material. Under consideration is the use of bioadhesives to assist in the material breakdown (2).

There are many types of packaging adhesives, frequently for the same end-use applications, with the choice dictated by cost, productivity factors, the particular substrates involved, special end-use requirements, and environmental considerations (see also Adhesives, extrudable). To help clarify this complex picture involving many different chemical types, it is useful to classify packaging adhesives into three physical forms: water-based solutions and dispersions, solvent-based systems, and solvent-free 100% solids and hot melts.

WATER-BASED SYSTEMS

This is the oldest—and still, by far, the largest-volume—class of adhesive used in packaging. These adhesives share the general advantages of ease and safety of handling, energy efficiency, low cost, and high strength. Water-based adhesives can be further divided into two categories, natural and synthetic.

Natural Water-Based Adhesives

The earliest packaging adhesives were based on naturally derived materials—indeed, almost all were until the 1940s—and they still constitute a large segment of the market. However, they have seen their gradual replacement in many applications. Starch and dextrin have been replaced by synthetic poly(vinyl acetate) emulsions. However, starch-based adhesives are still being investigated (3).

Starch. The largest class of natural adhesives is based on starch; in the United States, this means corn starch. Some potato starch is used in Europe primarily because of economics, since they are heavily subsidized. Adhesives are produced from raw flour or starch, but more frequently the starch molecule is broken down into smaller chain segments by acid hydrolysis. Depending on the conditions of that reaction, the resulting material can be a fluidity or thin-boiling starch or a dextrin. These can then be further compounded with alkaline tackifiers such as borate salts, sodium silicate, or sodium hydroxide, with added plasticizers or fillers.

A principal use of starch adhesives is in the manufacture of corrugated board for shipping cases. The standard process involves suspending ungelatinized cornstarch in a thin carrier-starch cook as a vehicle. When the bond line is subjected to heat and pressure, the cornstarch gelatinizes almost instantly, forming a bond between the flutes and the linerboard at very high rates of production. Additives are usually used to improve adhesion, lower gel temperature, increase water resistance, and further increase speed of bond formation.

Other important uses of modified starches and dextrins are in the sealing of cases and cartons, winding of spiral or convolute tubes, seaming and forming of bags, and adhering the seams on can labels. Glass bottles are frequently labeled with a special class of alkaline-treated starch adhesive called a “jelly gum.” These have the special tacky, cohesive consistency required on some moderate-speed bottle labeling equipment. Specially modified starches based on genetically bred high-amylose strains are also used as primary ingredients in the remoistening adhesive on gummed tape used for box sealing.

There are many strong points to recommend starch-based adhesives. They are regarded as very easy to handle, clean-machining, easy to clean up, and, above all, inexpensive. Starch has excellent adhesion to paper; and, being nonthermoplastic, it has outstanding heat resistance. Starch also has a green, environmentally friendly image, being “natural” and based on a renewable resource. The negatives are the relatively slow rate of bond formation, the limited adhesion to coatings and plastics, and poor water resistance.

Protein. Another class of natural adhesives is based on animal or plant protein. Proteins are highly susceptible to changes in their structure through changes in pH, the process of denaturation, and breakdown in molecular weight to effect solubilization.

Soybeans. Soybeans are important sources of both proteins and trigylceride oils. Proteins for adhesives are obtained from harvested soybeans by extracting and pressing out the oils and then heating. Soy in combination with blood or casein seems to exhibit the most water resistance. Protein-based adhesives are of interest to the medical industry; however, blood contamination is an issue (1). Considerable work is being done in this area. Stable adhesives from urea-denatured soy flour have been reported (4).

Animal Glue. This is one of the earliest types of adhesive. It is derived from collagen extracted from animal skin and bone by alkaline hydrolysis. When used as a heated colloidal suspension in water, animal glues have an unusual level of hot tack and long, gummy tack range. However, because of fluctuating availability and cost, along with the development of improved synthetics, there are only two significant uses of animal glue in packaging: (*1*) as a preferred ingredient in the remoistening adhesive on reinforced gummed tape use for box sealing and (*2*) as the standard adhesive used in forming rigid setup boxes.

Casein. This is produced by the acidification of skimmed cow’s milk. The precipitated curds thus produced form the basis of casein adhesives. There is a lack of suppliers of casein in the United States. The main sources for casein are Australia, New Zealand, and Poland, but it is also produced in Argentina and the Scandinavian countries.

There are two packaging applications where casein is used in large volume. One is in adhesives for labeling glass bottles, particularly on newer high-speed labelers where they outperform starch-based adhesives. They are especially favored for beer bottles, where casein provides the resistance to cold-water immersion required by brewers, together with removability in alkaline wash when the bottles are returned. The second use is as an ingredient in adhesives used to laminate aluminum foil to paper. Combined with synthetic elastomers such as polychloroprene or styrene-butadiene lattices, casein provides a unique balance of adhesion and heat resistance (5).

Natural Rubber Latex. This is extracted from the rubber tree, *Hevea brasiliensis*, and is available in several variations of concentration and stabilization. One major use in packaging is as a principal ingredient in adhesives for laminating polyethylene film to paper, as in the construction of multiwall bags. Natural rubber latex also finds use in a variety of self-seal applications, since it is the only adhesive system that will form bonds only to itself with pressure. This property is used in self-seal candy wraps (where it is called *cold-seal*) and in press-to-seal cases, as well as on envelopes.

Synthetic Water-Based Adhesives

Synthetic water-based adhesives are the most broadly used class of adhesives in general packaging. Almost all are resin emulsions, specifically poly(vinyl acetate) emulsion, which is a stable suspension of poly(vinyl acetate) particles in water. These systems usually contain water-soluble protective colloids such as poly(vinyl alcohol) or 2-hydroxyethyl cellulose ether and may be further compounded by the addition of plasticizers, fillers, solvents, defoamers, and preservatives.

These emulsions are supplied in liquid form (the ubiquitous “white glue”) in a range of consistencies from thin milky fluids to thick, nonflowing pastes. They are used in a broad range of packaging applications, to form, seal, or label cases, cartons, tubes, bags, and bottles. In most of these uses they have replaced natural adhesives because of their greater versatility. They can be compounded to have a broad range of adhesion not only to paper and glass but also to most plastics and metals. They can be rendered very water-insensitive for immersion resistance, or very water-sensitive to promote ease of cleanup and good machining. They are the fastest-setting class of water-based adhesives, facilitating increased production speeds. They are low in odor, taste, color, and toxicity and have excellent long-term aging stability. They are tough, with an excellent balance of heat and cold resistance. The equipment used to apply them is relatively simple and inexpensive to purchase and to operate. Finally, they are economical and reasonably stable in cost.

The utility of these emulsion systems has broadened in recent years with the greater use of copolymers of vinyl acetate. Copolymerizing vinyl acetate with ethylene or acrylic esters in particular has greatly improved the adhesion capabilities of these emulsions, particularly where adhesion to plastics or high-gloss coatings is required. For example, crosslinking acrylic–vinyl acetate copolymer emulsions have replaced polyurethane solution systems for laminating plastic films for snack packages. The largest areas of use for vinyl emulsions, however, are in case and carton sealing, forming the manufacturers joint on cases and cartons, and the spiral winding of composite cans.

All acrylic emulsion pressure-sensitive adhesives have to a significant degree replaced acrylic or rubber solution products in the manufacture of pressure-sensitive labels. The development of water-based acrylics eliminates a source of solvent vapors. The development of pressure-sensitive adhesives compared to other tapes is convenience of use. There are no storage problems, and no mixing or activation is necessary. No waiting is involved. Often the bond is reversible. Disadvantages are that adhesive strength is low and they are not suitable for rough surfaces.

Polyurethane dispersions have found acceptance in medium-performance flexible packaging applications laminating plastic films together where some chemical resistance is required.

The use of other synthetic water-based systems is quite minor and specialized. Some synthetic rubber dispersions are used in film adhesives and, in conjunction with casein, for the lamination of aluminum foil to paper. There is some use of tackified rubber dispersions as pressure-sensitive masses on tapes and labels replacing solvent-based rubber–resin systems.

Sodium silicate was once widely used in many paper packaging applications, ranging from corrugating to case sealing, but today the primary use of silicate adhesives is in tube winding, especially in the convolute winding of large drums or cores where it produces a high degree of stiffness.

SOLIDS/HOT-MELT ADHESIVES

Hot melts are the fastest-growing important class of adhesives in packaging. Most of their volume goes into high-speed large-volume case and carton sealing. Hot melts can be defined as 100% solids adhesives based on thermoplastic polymers, which are applied heated in the molten state and set to form a bond on cooling and solidification. Their chief attraction is the extremely rapid rate of bond formation, which can translate into high production rates on a packaging line.

The backbone of any hot melt is a thermoplastic polymer. Although almost any thermoplastic can be used, and most have been, the most widely used material by far is the copolymer of ethylene and vinyl acetate (EVA). These copolymers have an excellent balance of molten stability, adhesion, and toughness over a broad temperature range, as well as compatibility with many modifiers. The EVA polymers are further compounded with waxes and tackifying resins to convert them into useful adhesives. The function of the wax is to lower viscosity and control set speed. Paraffin, microcrystalline, and synthetic waxes are used, depending on the required speed, flexibility, and heat resistance. The tackifying resins also function to control viscosity, as well as wetting and adhesion. These are usually low-molecular-weight polymers based on aliphatic or aromatic hydrocarbons, rosins, rosin esters, terpenes, styrene or phenol derivatives, or any of these in combination. The formulations always include stabilizers and antioxidants to prevent premature viscosity change and char or gel formation that could lead to equipment stoppage.

Two variations on traditional EVA hot melts have recently become commercially significant. First, the recent availability of very low-molecular-weight EVA copolymers has made possible EVA hot melt that can be run at much lower temperatures, 250°F (121°C), rather than the traditional 350°F (177°C). This allows for much safer running conditions as well as energy savings. Second, an analog of EVA, ethylene-butyl acrylate, has been introduced as the backbone polymer in some packaging hot melts (6), providing advantages in both adhesion and in heat and cold resistance. Decrease in the application temperature has lessened safety concerns associated with this type of adhesive (1).

Another class of hot melts used in packaging is based on lower-molecular-weight polyethylene, compounded with natural or synthetic polyterpene tackifiers. These lack the broader adhesion capabilities of the EVA-based hot melts as well as their broader temperature resistance capabilities. However, they are economical and are adequate for many paper bonding constructions, and they find application in case sealing and bag seaming and sealing.

A third type of hot melt is based on amorphous-poly α-olefin (APAO) polymers. Originally these were based on amorphous polypropylene, which was widely available as the byproduct of the polymerization of isotactic polypropylene plastics. As a byproduct, it was inexpensive, but it suffered from low strength and was limited to applications such as lamination of paper to paper to produce water-resistant wrapping material on two-ply reinforced shipping tape. Improvements in polypropylene polymerization catalysts have almost eliminated this byproduct, but several producers noted the market and began producing on-purpose APAO polymers, albeit at somewhat higher costs.

Another recent class of hot melt is based on thermoplastic elastomers: block copolymers of styrene and butadiene or isoprene. These find primary application in hot-melt pressure-sensitive adhesives for tapes and labels replacing solvent-borne rubber systems. More recently, their broad adhesion and low temperature and impact resistance are finding use such as (a) the attachment of polyethylene-base cups to polyester soft-drink bottles (7) and (b) the sealing of film laminated frozen-food cartons. Pressure-sensitive adhesives from high-molecular-weight block copolymers having a high diblock copolymer are suitable for PVC film labels and decals (8).

Even more specialized applications use hot melts based on polyamides or polyesters when specific chemical- or heat-resistance requirements have to be met, but their high cost and relatively poor molten stability have precluded their widespread use to date.

The most recent and highest-performance hot-melt technology is moisture curing polyurethane hot melts, but these have been limited to higher-requirement product assembly applications and have found few uses in packaging.

All hot melts share the same basic advantages, based on their mechanism of bond formation by simple cooling and solidification. They are the fastest-setting class of adhesive—indeed, preset before both substrates can be wet is the most frequent cause of poor bonds with hot melts. Because of the wide range of polymers and modifiers used, they can be formulated to adhere to almost any surface. With no solvent or vehicle to remove, they are generally safe and environmentally preferred. They are excellent at gap filling, since a relatively large mass of material can “freeze” in place, thus joining poorly mated surfaces with wide dimensional tolerances.

However, all hot melts share the same weakness, which is the rapid falloff in strength at elevated temperatures. They also have a tendency to damage substrates that cannot withstand their application temperature (1). Properly formulated hot melts can be suitable for almost all packaging applications, but they are not appropriate for very hot-fill or bake-and-serve applications.

SOLVENT-BASED ADHESIVES

Solvent-based adhesives, which are by far the smallest, and most rapidly declining, of the three classes of adhesive used in packaging, find use in specialized applications where water-based or hot-melt systems do not meet the technical requirements.

Rubber–resin solutions are still used as pressure-sensitive adhesives for labels and tapes. However, factors of cost, safety, productivity, and, above all, compliance with clean-air laws have led to a strong movement toward water-based or soilds/hot-melt alternatives. Such alternatives are available to meet most requirements and most knowledgeable observers predict an almost total disappearance of rubber–resin solvent-based pressure sensitives for packaging tapes and labels in the near future.

Solvented polyurethane adhesives are widely used in flexible packaging for the lamination of plastic films. These multilayer film constructions find application in bags, pouches, wraps for snack foods, meat and cheese packs, and boil-in-bag food pouches. They have the ideal properties of adhesion, toughness, flexibility, clarity, and resistance to heat required in this area. However, here, too, alternative systems are being introduced to eliminate the costs, hazards, and regulatory problems associated with solvent-based systems. Crosslinking waterborne acrylic polymers have gained acceptance in the large snack food laminating market for constructions such as potato chip bags. Polyurethane dispersions and (100% solids) “warm melt” systems are starting to find use in some of the more demanding food packaging applications.

Solvent-based ethylene–vinyl acetate systems found use in some heat-seal constructions, such as the thermal strip on form–fill–seal pouches, or on lidding stock for plastic food containers such as creamers or jelly packs.

ADHESIVES, EXTRUDABLE

Stephen R. Tanny
DuPont Polymers,
Wilmington, Delaware

In its broadest definition, extrudable adhesives are polymeric resins that can be processed by standard extrusion processes and are useful for bonding together various substrates. In practice, extrudable adhesives are commonly polyolefin materials useful in processes such as blown and cast film, blow molding, and extrusion coating.

OVERVIEW

The variety of polymeric materials available to both the industrial user and the consumer and are useful as adhesives include several materials almost equal to the number of polymer types themselves (see also Adhesives). Adhesives are developed from such polymers as polyvinyl acetate, polyvinyl alcohol, polyamides, polyesters, and many others. Adhesives can be applied as solvent solutions, aqueous dispersions, pastes, spray coatings, tapes, and thermally activated films. One special subset of adhesives, called *extrudable adhesives*, are different in that, in their application, they are applied in an extrusion process, in which they are melted, conveyed, and inserted between the substrates that are to be bonded together. Although there are many adhesive application methods that require the melting of a polymeric adhesive, extrudable adhesives are distinguished from other adhesive types used in processes such as powder coating, flame spraying, and the thermal lamination of adhesive films and webs. As a second distinction, extrudable adhesives are also distinguished from hot-melt adhesives that generally require a resin viscosity unsuitable for traditional extrusion processes. Thus, extrudable adhesives are those materials specifically designed to function in processes such as coextrusion blown and cast film, monolayer and coextrusion coating and lamination, coextrusion cast sheet, coextrusion blow molding, and coextrusion tubing.

TYPES OF EXTRUDABLE ADHESIVE

Extrudable adhesives are most often polyolefin-based compositions. The most common use of these polyolefin extrudable adhesives is as a specific layer in a multilayer coextrusion. Coextrusion is a technique that allows the creation of a plastic composite, in a single operation, which combines the benefits of a number of different materials. The plastic composite may be, for example, a packaging film that combines the properties of an oxygen-barrier resin with a heat-sealable layer on one side and an abuse-resistant layer on the other side. The purpose of the extrudable adhesive is to bond the diverse plastic materials in the construction that would not, under ordinary circumstances, bond with each other. The polyolefin adhesive is designed to bond with similar polyolefins by a diffusion process. That is, during the extrusion process, the molten extrudable adhesive resin comes in contact with the molten polyolefin. Their molecules diffuse together creating a strong bond between the materials (1). The polyolefin extrudable adhesive is designed to bond with other polymeric materials, such as oxygen-barrier resins like polyamides and ethylene vinyl alcohol, through a chemical reaction between a functional group on the adhesive and a functional group on the barrier resin. Often, the functional group on the extrudable adhesive can be chosen for bonding to specific materials of interest.

Many types of extrudable adhesive exist. Polyethylene can be considered to be an extrudable adhesive. Commonly, polyethylene is used in extrusion lamination of paper to aluminum foil. The polyethylene is extruded at very high temperatures. The melt is oxidized by contact with air creating polar functionality on the surface of the melt. This process provides chemical bonding to the aluminum oxide on the surface of the foil (2). The low viscosity of the melt and its polar nature allows for good wetting on the paper and for encapsulation of the individual fibers. Co-polymers of ethylene and vinyl acetate also are useful extrudable adhesives and capable of bonding polyethylene to polyvinyl chloride. However, the most sophisticated extrudable adhesives are polyolefins with either acid or anhydride functionality. Acids and anhydrides are particularly reactive and can create strong bonds to several different materials in extrusion processes. Examples of acid-modified polyolefins are the copolymers of ethylene with acrylic acid or methacrylic acid. Variations include the partially neutralized acid co-polymers with metal ions referred to as ionomers or terpolymers of ethylene, an acid and an acrylate such as methyl acrylate or isobutyl acrylate. Acid-containing extrudable adhesives are widely used to bond with aluminum foil (3, 4). Examples of anhydride modified polyolefins include terpolymers of ethylene, maleic anhydride, and acrylates such as ethyl acrylate or butyl acrylate and the anhydride grafted polyolefins.

The anhydride grafted polyolefins are created by combining the polyolefin with an anhydride, most commonly maleic anhydride. The anhydride is added to the polyolefin with a free-radical initiator in a solvent or the melt. This addition allows for the attachment of the highly reactive anhydride to polyolefins, such as high-density polyethylene, linear low-density polyethylene, polypropylene, ethylene vinyl acetate copolymers, or ethylene propylene rubbers. Although the polar functionality of the anhydride and the polyolefin backbone are the necessary ingredients for the extrudable adhesive to function, almost all commercially available extrudable adhesives are formulated with other polymers. Formulations of anhydride modified extrudable adhesives will generally contain two or three basic components. Two-component extrudable adhesives will contain the anhydride graft blended into a second, or matrix polyolefin (5). The purpose of the second polyolefin is to lower the overall cost of the adhesive and to control the viscosity, modulus, tensile, thermal, and other properties of the adhesive. The three-component formulation will contain the anhydride graft, the matrix polyolefin, and a modifier (6). The purpose of the modifier is to enhance the peel strength characteristics of the bonded composite. In most cases, the efficiency of the extrudable adhesive is judged by peeling the bonded composite apart in a “T” peel mode. The modifier affects the peel strength characteristics of the adhesive by dissipating the force at the interface where the composite is being peeled apart. The result of this process is the necessity for more work to peel apart the bonded composite (7). These extrudable adhesives also can have other additives, such as antioxidants, slip agents, or resin tackifiers.

Although the formulation of an extrudable adhesive is very important to its utility, many other factors also affect how well an extrudable adhesive will bond different materials together. How the extrudable adhesive is processed, its thickness, and whether the bonded composite is oriented, shaped, or exposed to aggressive environmental conditions can affect the performance of the adhesive (8, 9).

COMMERCIAL OFFERINGS

Many producers of extrudable adhesives around the world exist. Some of these producers will produce only a few types of extrudable adhesive. Others have a broader product line. Some manufacturers market their adhesives internationally; others only market regionally, to specific market areas, or for use in specific applications. Manufacturers of acid copolymers include Dow Chemical Company as Primacor and E. I. DuPont de Nemours as Nucrel. DuPont also manufactures acid terpolymers. Ethylene terpolymers of anhydride with acrylate are produced by Atochem under the name Lotader. DuPont manufactures extrudable adhesives based on anhydride graft technology under the name Bynel. Quantum Chemical Company also makes and sells extrudable adhesives under the name Plexar. Other manufacturers include Mitsui Petrochemical Company with Admer, Morton International with Tymor, Atochem with Orevac, and DSM with Yparex.

EXTRUDABLE ADHESIVE APPLICATIONS

Extrudable adhesives are used primarily in coextrusion processes (see Coextrusion). The major market area is food packaging. Examples include the coextrusion coating of an oxygen-barrier material, extrudable adhesive, and polyolefin onto paperboard to create high-barrier, nonscalping fruit juice cartons. Oxygen barriers, extrudable adhesives, and ionomers are coextruded by either cast-film or blown-film processes to produce packaging films for hot dogs, bacon, and other processed meats. A third example is the coextrusion blow molding of polyolefin, extrudable adhesive, and oxygen barrier to produce high-barrier ketchup bottles. Extrudable adhesives also are used in applications that do not involve the packaging of foods. Extrudable adhesives are used to bond high-density polyethylene to ethylene vinyl alcohol in a coextrusion blow-molding process to produce automotive gas tanks (see Blow molding). Extrudable adhesives also are used to bond cross-linked polyethylene to ethylene vinyl alcohol through a coextrusion crosshead tubing process to make radiant hot-water heating pipes.

The selection of the proper extrudable adhesive for any particular application may be a complex problem. The first consideration is always the materials that need to be bonded together. The adhesive must be able to bond with these materials. When bonding a polyolefin with an oxygen barrier, such as ethylene vinyl alcohol or polyamide, extrudable adhesives with anhydride functionality are usually the adhesive of choice. The type of anhydride modified polyolefin will depend on the polyolefin being co-extruded with the barrier. For example, if polyamide is being co-extruded with polyethylene, an anhydride-modified polyethylene or anhydride modified ethylene vinyl acetate will be the resin best able to perform in the application. If polypropylene is coextruded with polyamide, then an anhydride modified polypropylene will be chosen. Second, the adhesive must be processable in the equipment that the converter intends to use. This may mean choosing a resin with a relatively lower viscosity for coating applications and a relatively higher viscosity for blow-molding applications. If the bonded composite is going to see a specific environment, such as oil or grease, then it should be resistant to that product. If the composite will be exposed to either very high or very low temperatures, then the adhesive must be functional at those temperatures. Finally, some extrudable adhesive resins may have to have a specific regulatory compliance depending on the application for the bonded composite. Most manufacturers of these extrudable adhesives are prepared to help the converter select the best adhesive for their application.

AEROSOL CONTAINERS

MONTFORT JOHNSEN
Montfort A. Johnsen &
Associates, Ltd., Danville,
Illinois

The first aerosol cans were heavy steel “bombs,” consisting of two shells about 0.090 in. (2.3 mm) thick, brazed together at the lateral centerline. They were known at least since the early work of Eric A. Rotheim (Oslo, Norway,

1931) and gained fame during 1943–1945 as insecticides for U.S. troops fighting in such places as Guadalcanal and other South Pacific areas. After the war, these products were made available to the public, but acceptance was very poor, due to the high initial expense and the aspect of having to return the emptied unit for refilling. It was obvious that a lightweight, disposable can was needed.

In 1946–1947, Harry E. Peterson developed such a can in the laboratories of the Continental Can Corporation in Chicago. It consisted of a 2.68-in.-diameter solder side seamed can body, to which were seamed a pair of concave end sections. The top section, assembled to the body by the canmaker, carried a small valve, soldered at the centerline. The can was designed to be filled upside-down with highly refrigerated (-45°F or -43°C) aerosol concentrates and propellants, after which the end was double-seamed to the body. The final unit stood 4.8 in. tall and had a capacity of about 12.2 fluid oz (361 mL). In an almost concurrent but independent development, Earl Graham of Crown Cork & Seal Company developed a higher-strength modification of the "Crowntainer" beer can. This was a two-piece container. The base was double-seamed onto a drawn steel shell that contained a soldered valve. The early valves were manufactured by Bridgeport Brass Company, Continental Can Corporation, and many other firms. Most were outrageously costly and inefficient. Slightly later, pioneers such as Robert Alplanalp (Precision Valve Corp.) and Edward Green, Sr. (Newman-Green, Inc.) patented more efficient types.

A major innovation occurred about 1951, when Crown Cork & Seal Company engineers developed the "1-in." ("25.4-mm") hole, along with a corresponding valve cup. The cup could carry the valve components within the central pedestal (except for actuator and dip tube), and it could be crimped (swaged) onto the curl or bead that surrounded the "one-inch" ("1-in.") hole. This secondary plug-type closure rather quickly displaced the soldered valve units, the last of which were filled during October 1953. The Continental Can Company developed a can dome—called a "cone" in the United Kingdom—to provide the needed "1-in." hole, while at the same time enlarging their can somewhat and making it taller.

The budding aerosol industry had to make do with these two nominal 12-oz cans until 1953, when the 2.12-in.-diameter can size was developed as a nominal 6-oz container.

At the insistance of a fast-growing industry, the two can companies introduced some additional can heights. They were joined in 1955 by the American Can Company, who entered the market with their "Regency" line of 2.47-in.-diameter cans in four heights. The National Can Corporation followed soon afterward.

The impact extrusion technology for drawing aluminum beer and beverage cans was well developed by the 1950s. The Peerless Tube Company produced aerosol units as early as 1952 and perhaps even earlier. The American Can Company made a unique two-piece aluminum can (Mira-Spray and Mira-Flo) in just two 6-oz sizes. Other very early entrants were Victor Tube, White Metal, and Hunter-Douglas Corporation (see also Cans, aluminum; Cans, fabrication).

Glass aerosols were made, first by the Wheaton Glass Company (Mays Landing, NJ) about 1953 and then by Ball Brothers and several other firms. The valve was incorporated into a ferrule by Risdon Manufacturing Corporation, Emson Research, Inc., and Precision Valve Corporation, and the ferrule was sealed to the glass finish by means of clinching—a method then also used to seal metal caps on beer bottles.

During 1954, Wheaton developed a method for encasing their bottles in a heavy skin of PVC. The plastic envelope helped the bottle withstand minor falls to hard surfaces, but if breakage should occur, it contained the glass shards and kept them from flying outward and possibly injuring persons nearby. Later on, a bonded film was developed and made an unofficial industry standard on glass bottles of >1-oz (30-mL) capacity.

The packaging process also underwent dramatic changes. Several equipment suppliers are now specialized in the manufacture of aerosol filling and packaging equipment. As aerosol volume grew, higher speed lines were needed. Even double-indexing, two-lane-in-line equipment could not produce more than 125 cans/minute. Reengineering resulted in a production rate of 216 cans/minute. This rate was important to contract fillers because it related directly to competitivety and profitability. Today, very complex rotary machines are available with rated capacities of 480 cans/minute.

In recent history, the aerosol industry has had to contend with many obstacles: the ban on the popular CFC propellants, the global warming potential of various propellants, and, in 2007, legislation that curtails the use of volatile organic chemicals (see Propellants, aerosol).

CAN-MAKING TECHNOLOGY

Tinplate

The three-piece tinplate can still command about 82% of the U.S. aerosol market. This translates to 3.65×109 cans in 2006.

Tinplate, in a number of thicknesses of steel and tin, is routinely delivered to the can-making plant in the form of large rolls typically 39.4 in. (1 m) wide and 48 in. (1.22 m) in diameter. A roll may weigh 15,000 lb (6800 kg) and contain about 4.5 mi (7.25 km) of tinplate, depending on the thickness. After sending the roll through a straightener, a slitter cuts it into sheets best suited for making can bodies with a minimum of waste. At the same time, a scroll cutter produces strips from which dome and base section circles can be cut—again with a minimum of waste (see also Cans, steel).

The body sheets are first lined with epoxy–phenolics or other materials, baked in huge ovens, and then lithographed. At this point the individual can bodies are cut apart. A bare metal fringe is allocated for the area to be welded. The WIMA or other type of bodymaker acts to roll up the can body and tackweld it every inch or two to hold it in place with just the right lapover. After this the welding process produces either a "standard" or "full" (tin-free) weld line. Weld nuggets ($\sim 31\,\text{in.}^{-1}$) form the basic structure. While still extremely hot, the overlap thickness is reduced by heavy compression to only ~1.4 times the average plate thickness. The cylindrical can body is then flanged top and bottom for a "standard" or straight-wall can, or is both necked-in and flanged for the "necked-in" containers. The latter have several advantages and are increasingly popular.

Meanwhile, can domes and bases are being formed in multistage presses. They either are used directly or are "sleeved" into long paper tubes for later fabrication. Quite often, one large plant will make sleeve packs of can ends, for shipment to satellite locations where the assembly process is undertaken. The same is true for can bodies, which can be easily shipped in the flat to other facilities.

The final can is assembled using double seamers that typically operate at about 350 cans/minute. As a rule, the finished cans are then tested using a large wheel-like device that pumps a significant air pressure into each one and then checks for pressure leakage, if any. Such cans are automatically shunted aside and scrapped. Finally, the cans are tiered onto pallets of about 40-in. × 44-in. size, strapped, plastic shrink-wrapped, and warehoused for delivery to fillers.

A recent innovation in tinplate can manufacturing is simply known as shaping. It was developed in the 1970s. The process consists of placing a cylindrical can in a metal mold and then pressurizing it with about 1160 psig (80 bars) of nitrogen (or purified compressed air) to create a can with the shape of the mold. This process remained dormant for 20 years, to some extent because the process was expensive. The method has been improved upon and is now commercialized. Today a relatively large number of aerosol cans are shaped, especially those made of aluminum. One reason for shaping relates to the increasing duplication of U.S. product labels by firms in foreign countries. The use of shaped cans has corrected the problem for now since forgien can-makers do not have the technology. As an example, the WD-40 Company has collected 380 cans of foreign-made specialty lubricants, many of which have patterned their labels and product claims on WD-40 aerosols, They have now changed to shaped cans.

Another innovation dating back to the 1970s involves the development of a compartmentalized tinplate aerosol. The initial product consisted of a 52-mm × 149-mm aerosol can into which a fluted collapsible polyethylene bag was inserted before the base section was attached. The tubular chimney of the bag protruded through the nominal 1-in. can opening and then it was gently heated and flared around the can bead. The aeosol filler poured the concentrate into the bag, almost filling it but leaving a little space for the insertion of the valve. After the valve was crimped into place, isobutane was added through the bottom hole and into the space between the can and the bag. With the isobutane exerting a constant squeezing pressure in the bag of the concentrate, the product would be dispensed when the valve was actuated regardless of the can position. In this fashion the dispenser could extrude such products as honey, jellies, ointments, and so on. This process was expensive and languished until S. C. Johnson & Sons, Inc. developed a unique gelled shave cream concentrate that contained 2–3% of a weak propellent blend. When the mixture was dispensed into the hand and touched with the fingertips, the consumers had the pleasing experience of generating their own foam. The company patented their invention and marketed it under the "Edge" brand. By 2006, the compartmentalized shave creams captured over 62% of the market despite their higher price.

Aluminum

Aluminum cans, which constituted about a 18% of the U.S. market in 2006 (and growing), are made quite differently. Pure (99.70%) aluminum slugs or pucks are lubricated with zinc stearate in a tumbler and are then conveyed to an extruder, where they are formed into a "cup." The cup may be drawn and ironed (draw–ironed), in some advanced operations, to obtain a more uniform wall thickness and lighter structure. After trimming and vigorous cleaning, the lining and exterior decoration coatings are applied. The top is then formed in a number of stages (the number increasing with can diameter) and finally convoluted into either an outside or inside curl configuration. The outside curl is more common. Both have different advantages. Curl machining is sometimes done to smooth the curl surface of larger-diameter cans. Finally, they are strapped into typically 96-pack hexagon shapes and loaded onto 40-in. × 44-in. wood pallets. After strapping and shrink-wrapping, they are ready for delivery. Table 1 gives some details on aluminum aerosol cans.

Table 1. General Information on Aluminum Aerosol Cans

- Most common diameters: 22, 25,35, 38, 45,50, 55, 59, and 66 mm.
- Largest size is 66 × 235 mm. Overflow capacity is 709 mL. (Typical use: Saline rinsing solution—sterile.)
- The 22- and 35-mm cans require valves with 20-mm-diameter ferrules.
- Since aluminum cans are nonmagnetic, most production lines have "puckers" and "de-puckers." The pucks must be ordered for each can diameter.
- Aluminum cans of 45- to 66-mm diameters must use valve with "lathe-cut" rubber cup gaskets, generally Buna-N. (With over 10% DME, use butyl or cholorbutyl.)
- The 38 × 97 mm is (more or less) standard for laboratory samples. (Fills can be 2 oz.)
- Tare weights in a lot of aluminum cans are quite constant as compared to tinplate or steel.
- Aluminum can corrosion can create hydrogen, but very rarely. This overpressurizes the can.
- The passivity range for aluminum is about pH = 4.3 to 8.2 (25°C).

Other

Very small numbers of cans are made by other methods. The Sexton Can Company produces one-piece steel cans by an extrusion process. For larger diameters, they extrude a steel shell, and then double-seam a can bottom to it. The company is able to make very strong cans by this process, able to withstand pressures up to 650 psig (lb/in.^{2} gauge) (45 bars). They are used to pack such higher-pressure products as HCFC-22 refrigerant, which generates 302 psig at 130°F (21 bars at 54.4°C). A special permit from the U.S. DOT (Department of Transportation) is required for such high pressures. As part of the development process, Sexton learned how to produce these cans with a bottom indentation, able to open at about 425 psig (30 bars) and thus long before heating could cause bursting. The orifice lets the product come out with a fair degree of control; otherwise, the dispenser might eventually burst with the brissance and concussive effects of a grenade.

TINPLATE OPTIONS

The electrotinplated steel sheet stock from the tin mill is available in a modest variety of plate thicknesses and tin coating weights. The steel for aerosol cans will typically be ~0.007–0.015 in. (0.18–0.38 mm) thick, according to intended use. The thinnest plate is used for bodies of small (45 to 52-mm)-diameter cans. The bodies of larger cans (57–76 mm in diameter) will typically be made from 75 to 85-lb ETP, which is a can-making term for stock of ~0.0083–0.0094 in. (0.21–0.24 mm) thick. Tops and bottoms require still heavier plate, to prevent premature buckling (eversion) and subsequent unwrapping of the top or bottom double seam, leading to a burst event. End sections of the smaller cans typically use 112-lb ETP, or plate that is 0.0123 in. (0.31 mm) thick. The largest-diameter aerosol can is a nominal 3.00-in. (76-mm) size and requires 135-lb ETP, or 0.015-in. (0.38-mm)-thick plate. Valve cups are almost always made of 95-lb ETP [e.g., 0.0105-in. (0.266-mm) plate].

Since aluminum is notably softer and more deformable than steel, these cans are extruded to have thicker metal. The thickness must be increased as diameters are made larger. The thinnest part of a typical 52-mm-diameter aluminum aerosol can will be about 25% up on the body wall, measuring about 0.017 in. (0.43 mm). The base of the largest aluminum can (66 mm) may easily get to 0.080 in. (2.0 mm). Aluminum valve cups average 0.016 in. (0.41 mm) thick.

In the past, tinplate could be ordered with very heavy tin coatings: up to 1.35 lb of total tin weight per basis box area of 31,360 in.^{2} on each side. This is equivalent to a tin coating of 15.1 g/m^2 on each side. But today, with economic considerations forcing lower inventories, plus improvements in the tinplating process, it is rare to see tinplate of greater than 0.50 lb—that is, 5.6 g/m^2 per side. Some tinplates are made with the so-called “kiss of tin” (0.05-lb ETP) having a nominal coating weight of only 0.56 g/m^2 per side. The thickness then averages only 0.00000303 in. (0.077 μm) per side. The dark gray color of the steel and $FeSn_2$ alloy layer can be easily seen through this ultrathin coating.

With electrotinplating methods it has been possible to obtain differentially coated tinplates; that is, plate having coatings of different thickness on each side. For example, D50/25-lb ETP (more accurately noted as D0.50/0.25-lb ETP) will carry 0.25 lb of tin on one face and 0.125 lb of tin on the other (5.6 + 2.8 g/m^2). This type of plate is generally used with the heavier tin-coated area turned toward the aerosol product, to provide corrosion protection.

Linings

Over half of all tinplate aerosol cans and virtually 100% of all aluminum cans have organic linings. Single linings are the most common, but double linings and (for a few tinplate can bodies) even triple linings can be ordered. A variety of lining materials are used. The most common are the epoxyphenolics, used for about 70% of tinplate cans and around 78% of aluminum cans. Other options include the vinyl organosols, polyamideimide (PAM), and now the polyimideimide (PIM). The PAM and PIM coatings are relatively costly and often more difficult to apply, especially on tinplate. They are extremely resistant to permeation. Finally, there are the pigmented epoxyphenolics and the vinyls. The latter do not adhere well to metal substrates, and are used as a second or top coating, when extra performance is needed. They are unaffected by water, but quickly dissolved by methylene chloride, oxygenated solvents, and certain other solvents.

Corrosion inhibitors should be considered whenever aqueous solutions or dispersions are packed in tinplate. Typical inhibitors include sodium nitrite, sodium benzoate, and various amines.

Can decorations are a very valuable sales tool. They must always be the correct color and not affected by body contouring, consumer use or product spillages. The lining is often critical as a means of assuring product purity and dispenser shelf life. Table 2 gives data on the surface coatings (or linings) process for aluminum aerosol cans.

Size

The can-making industry has strived for uniform dimensions of cans, both from different plants of a given supplier and between suppliers. This acts to save fillers from making time-consuming adjustments to crimping and gassing machines when moving from one lot of cans to the next. The CSMA (Aerosol Division) Commercial Standards Committee has now developed about 13 key dimensions and their tolerances for tinplate cans—both standard and necked-in—and about 10 more for aluminum cans (see Figures 1 and 2).

The smallest tinplate can is 112 × 214 (45 × 72 mm) size, holding 101 mL. Aluminum aerosol cans are known in sizes down to 13 × 26 mm and posibly smaller. The 13-mm size is used for such products as metered dose inhalants (MDIs), breath fresheners, and pepper sprays (which attach to key chains). These tiny aerosols require a 13-mm ferrule-type aerosol valve.

The terminolgy used to designate tinplate can sizes is never used for aluminum aerosol cans, which are always described in the metric system. For tinplate, the

Table 2. Surface Coatings (or Linings) for Aluminum Aerosol Cans

Exterior coatings are applied by offset printing.

The Base Coat	• Selected for adherence to the metal, absence of crazing, radia fracturing, and blistering during the oven-curing process. • Appearance aspects: ○ High-opacity white or colored enamel. ○ Clear or clear-tinted lacquer. ○ Pearlized lacquer. ○ Metallic lacquer. • Selected for a relatively low curing temperature.
The Decorative Coat	• May be applied, up to 7 or 8 colors, in a single operation. • Special effects include: ○ Half tones. ○ Color gradation. • Transparent lacquers, often showing brushed metal.
The Exterior Coat	• Hard, protective varnish, usually glossy but sometimes matte.

Interior linings are applied by three-stage spraying of the “cup,” before die-forming the can dome and curl.

- Epon-phenolic are the most common.
- Organosols (as “Microflex”) are preferred for mousse.
- P.A.M. (polyimideamides) are very resistant.

long-established practice of describing cans in English measurements is now more or less unique to North America, but it is well understood in Western Europe. For instance, 112 signifies 1 and 12/16 in. in diameter, while 214 indicates 2 and 14/16 in. for the height from the base of the bottom double seam to the top of the top double seam. For tinplate (or steel) cans not having a top double seam, the height measurement is the total height to the top of the can curl.

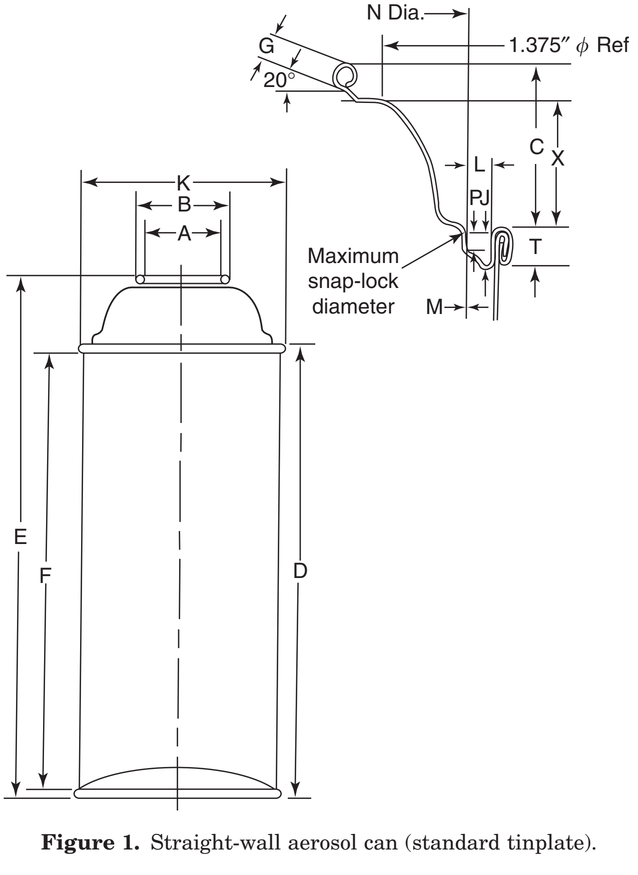

Figure 1. Straight-wall aerosol can (standard tinplate).

Well-known examples of can dimensions are *A*, which is 1.000 ± 0.004 in. (25.4 ± 0.1 mm) for all can sizes and metals, and *B*, which is 1.232 ± 0.010 in. (31.3 ± 0.25 mm) for tinplate cans of all sizes. These particular dimensions are quite critical because the valve cup must fit rather perfectly into the “1-in.” can opening to avoid jamming or scraping and to allow a good hermetic seal when crimped. The outer wall diameter of the valve cup is ~0.992 ± 0.003 in. (25.2 ± 0.08 mm), and this leaves a contingency clearance of only 0.001 in. (0.025 mm) between the largest cup and the smallest hole. This is important not only for fit, but to anticipate traces of out-of-round, metal dimpling and other factors. The *B* dimension is important in making the top rim and shirt of the standard valve cup fit snugly to the can bead, increasing the statistical probability of a good seal. See the article “Pressure containers” for more information.

Seams

The tinplate can has three seams, which can occasionally become matters of concern. Aside from aesthetics, if can leakage occurs, it will often be at the side seam and will more rarely be at the top or bottom double seams. The side seam is also a favored site for can corrosion, due to exposed iron and the relatively poor coverage of side-seam enamel stripes, if applied. The dimensions of the top and bottom double seams are about the same, for a given can diameter. Small-diameter side seamed cans (35, 38, and most importantly 45 mm) have smaller-size double seams than the larger cans. In fact, the 35- and 38-mm

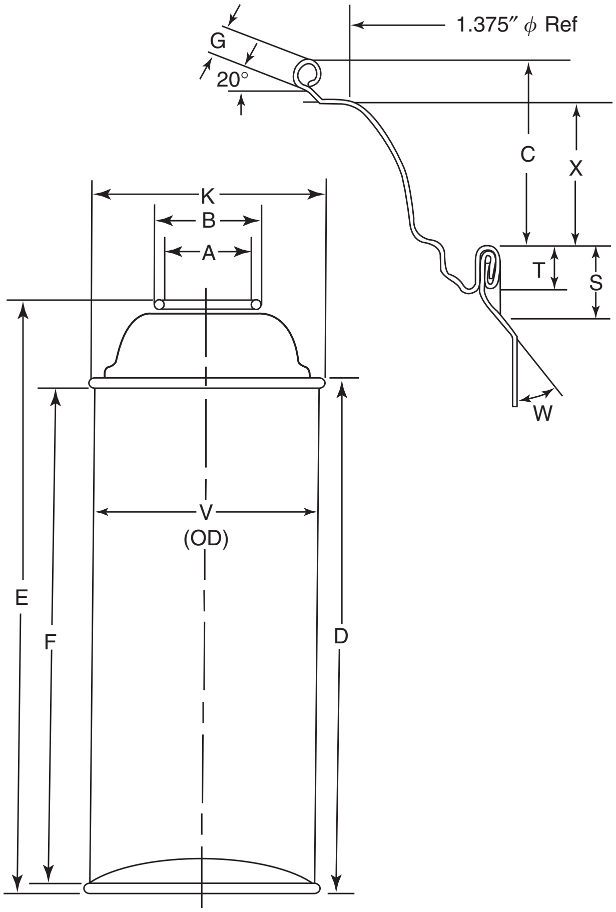

Figure 2. Necked-in aerosol can (tinplate).

cans actually have no top double seam; the metal (side seam and all) is smoothly formed into the "inch–inch" curl. Figure 3 can be used to illustrate the general shape and important elements of a typical side seam. In general, these seams are about 0.125 in. (3.2 mm) high, from sealing wall radius to end hook radius, if the can is 52 mm or larger in diameter.

Description

The United States and Canada use a "sales description" method for indicating can overall dimensions that is based on the English (inch) measurement system. England is changing over to the metric system to conform to the ISO descriptions used in the rest of Europe and generally throughout the rest of the world. Australia and Canada have taken steps in the same direction.

The U.S. "can description" system can be best described by illustrations. The 202 can is one with a body diameter of $2\frac{2}{16}$ in., or 2.125 in. The ISO diameter (actually the inside diameter of the body) would be 52 mm.The U.S. can height is dimension *D* (see Figure 1 or 2), measured as total body height over the two seams. A 612 can would then have a body height of $6\frac{4}{16}$ in., or 6.250 mm. The system extends to such descriptions as 211×1208 and 207.5×605. Seeds of change are being sown in the United States by the United Nations and other international groups, but the system is deeply ingrained and is likely to persist.

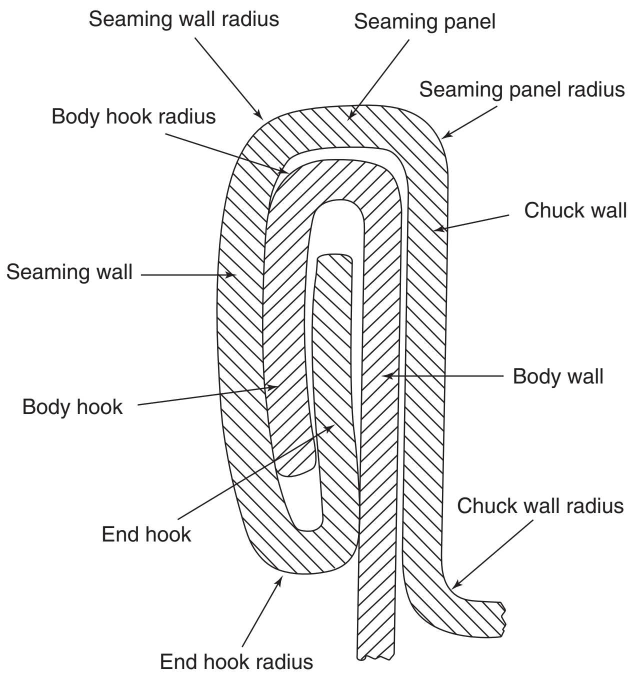

Figure 3. Anatomy of a double seam.

CAN-MAKING TRENDS

The three-piece aerosol can is highly serviceable and is produced by the daily use of heavy equipment valued in the multi-billion-dollar range. There are no massive changes predicted during the next decade. The aerosol dispenser has been accused of having about the same cylindrical shape it had over 40 years ago. Minor improvements—such as necking-in, welding side seams, plastic labeling (to cover the side seam scar), and the "ecogorge" indentation on some aluminum cans, for the attachment of full-diameter caps—have been relatively unnoticed by consumers. To them the aerosol is a cylindrical package, although sometimes with a variously convoluted top portion.

The cylindrical image is an architectural necessity for a pressure-resistant dispenser (see also Pressure containers). Even though glass aerosols had somewhat wider limits, the underlying shape limitations have been a factor in having nearly all the perfume and cologne business transfer to nonpressurized glass pump sprayers and other containers. However, some advances have been offered recently, in the metal can area.

In the United Kingdom the Wantage Research Center of CarnaudMetalBox, plc (a firm now being purchased by Crown Cork & Seal Co.) engineers have developed a process by which a finished (plain or lithographed) three-piece tinplate can is placed momentarily in a heavy steel mold cell and expanded against the contoured sidewalls of the cavity by pressurization with some 1200 psig (83 bars) of filtered dry air. The volume increase is limited to about 12–18%, depending on relative can length. The emerging cans

Table 3. DC Containers: Steel Aerosol Cans

- The sole U.S. supplier is DC Containers, Batavia, IL.
- They currently produce two sizes: 211 × 604 and 211 × 713. DC Containers will make 52-mm cans in 2008. All cans are "DOT-2Q." List prices are about \$0.26 to \$0.29. Cans are "two-piece," with rounded domes and bottoms necked in double seams.
- Using Corus Research technology (from Europe, but perfected in Japan), all inside and outside surfaces of tin-free steel are laminated with:
  - Chrome/chrome oxide (Cr/CrO_x) optimized for PET.
  - Adhesive.
  - Main layer of PET. ''Protact''
  - Top layer of PET. ''Protact''
- The total thickness, on each side, is about 0.020 in. (0.5 mm). WACO testing shows 0-mA conductance—inside to outside. All cans are automatically pressure-tested to 120 psig.
- The main PET layer can be colorized, but printing is done on an eight-color offset machine on the top layer, then baked. The top layer also provides gloss and abrasion resistance.
- For comparison, the lining of tinplate and aluminum cans is typically 0.0004 in. (0.01 mm or 10 μm), or 2% as thick.
- WACO readings on aluminum cans are typically 2–20 mA, while those on lined tinplate cans are typically 300–800 mA.
- Pure dimethyl ether (DME) greatly softens PET, but solution of up to 38% DME (as in some 55% VOC hair sprays) are said to have no effect.

are necked-in and may have pleated, quilted, crestlike, ergonomic finger depressions or other debossings in the body wall. In general, these are never more than ~0.15 in. (3.8 mm) deep. Round-the-can lateral depressions must not be too sharply defined, or the can will increase in height when pressure-tested during later can-making checks or in filler hot tanking. The fact that this is presently an extra cost operation has thus far prevented marketer acceptance, but one is mindful that such innovations as welded seams and necked-in profiles were well-engineered decades before marketers paid them much attention.

The trend toward aluminum cans has been quite noticable. During 2006, the production of these cans grew at about 18%/year, which is much more than the more proseic 2–3% increase/year for the total aerosol market. This is thought to relate to the greater aesthetics of aluminum, more than anything else. Marketers who use tinplate cans are responding by increasing the trend toward necked-in types and by permanently covering at least the unsightly valve cup, and ideally the entire can dome with a spray cap or foam spout. In Europe and Japan, starch and fabric finish products are offered with "pistol-grip handles" that are integral with a full-diameter, nonremovable spray cap. The accoutrement not only provides aesthetics but also reduces hand and finger fatigue.

During 2006, the firm of DS Containers, Inc. began production of two large sizes of 65-mm steel cans using the "Protact" process of double PET lamination developed by Corus RD&T unit, Hoogevans Division of British Steel and refined by the Japanese can-maker, Daiwa Can Company. The plate is delivered in huge rolls of chrome/chrome oxide-coated steel, optimized for adhesion of PET and to which the main layer of PET is attached with a special adhesive, followed by a top layer for gloss, printability, internal lubrication, and scratch resistance. These laminates, the same for both sides of the steel plate, are about 80 times thicker that the typical 9 μm (0.0004-in.) thickness of roller-coated or sprayed-on can linings, so they offer outstanding protection for the metal substrate. A few solvents, such as dimethyl ether (DME), are claimed to soften PET plastics, and DS Containers state that the hydroalcoholic hair sprays containing a much as 37% of DME propellant can be packaged with no adverse effects.

DC Containers has produced containers for at least 50 domestic and international marketers to date. They plan to install can-making equipment to produce various sizes of the popular 52-mm-diameter aerosols during 2008. With their nicely rounded tops and unobtrusive botton double seams, these cans have an appearance almost identical to that of the 66-mm aluminum aerosol cans. There is no information of their ability to be shaped, but this probably will not occur until a few years in the future. Table 3 gives some general data on these cans.

Aerosol formulations weave their effects into the fortunes of the steel and aluminum can-makers. Because of environmental considerations centering on the issue of clean ambient air, along with the reduction of emissions that directly or indirectly produce air pollutants, the U.S. aerosol industry has been obliged to reformulate most of their products toward those that have reduced amounts of volatile organic compounds (VOCs). The state governments of California and New York have been very active in limiting the VOC content of aerosols and other products. As a result, many hair sprays and other products now incorporate significant amounts of water; otherwise they use new propellants, such as (non-VOC) HFC-152a (1,1-difluoroethane). Quite often, these new formulations favor aluminum cans, from both a corrosion resistance and a smaller package standpoint. In some other countries the percentage of aluminum cans is in the area of 40–60% of the total, and it is possible that the United States and Canada may slowly approach this high ground, as time goes by.

AIR CONVEYING

Timothy Aidlin
Aidlin Automation,
Sarasota, Florida

The fast changes within both lightweight packaging and plastics technology during the 1980s brought forth the development of a new technology: the air conveyor. Because of the backpressure created on chain conveyors, the new lightweight packages and bottles were getting crushed and marred—but with the advent of the air conveyor, those problems were no longer of great concern. The air conveyor is faster, easier, cleaner, and safer than its predecessors, the belt, cable, and chain conveyors. For these reasons, the air conveyor has quickly become the conveying method of choice.

AIR CONVEYING

How does it work? All air conveyors share several basic operating principles that are as follows:

- Use of air as the transport medium.
- Containers are moved using a high volume of low-pressure air to transport the product along the conveyor path.

The major differences among the leading air conveyor manufacturers are the following:

- Where the air is directed against the product, container, or bottle
- How the airflow is created (design of motors and fans for maximum efficiency)
- Where the airflow is created: one large blower vs multiple small blowers
- Construction details and "user-friendly" features of the air conveyor

See Figures 1–3 for air conveying operations.

How does the air conveyor solve the problems found with the chain conveyor, and why is it the better method of conveying? It eliminates crushing. The air conveyor moves the packages by a directed flow of air against the containers. The flow of air can be controlled throughout the air conveying system. In this way, crushing of packages is eliminated as follows:

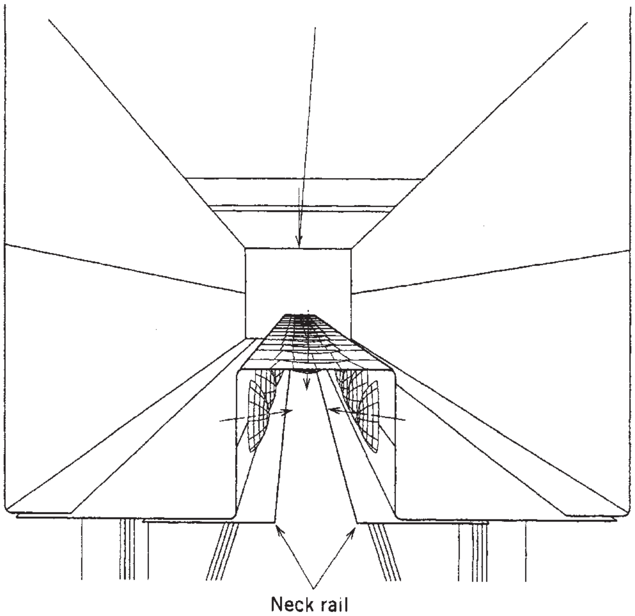

Figure 1. Airflow inside plenum.

- By reducing the backpressure force against the first product in a long line of products in a backfeed condition.
- By controlling the velocity of the product through the use of manual or automatic baffles, one can reduce the impact force of a product arriving from upstream and reduce damage.
- By introducing lift holes in combination with louvers, the product can hover while using the conveyor for accumulation on the flat-top air conveyor—no marking of crushing is evident from the friction caused by the belt or chain.

In beverage applications, the bottles cannot fall, which is detailed as follows:

- The bottles cannot fall when the bottle is transported hanging by the neck support ring.
- Eliminating bottles falling down on the conveyor and getting caught in the starwheels or timing screws.

As a result, users of air conveyors derive the following benefits:

- *Gapless filling*. At the higher production speeds, even small inefficiencies are costly and unacceptable. Air conveyors will virtually eliminate the possibility of a missed cap or container by assuring that a sufficient supply is provided to the infeed of the filler, rinser, capper, or packaging equipment. In the event of a "hiccup" of the upstream equipment, bottles, caps, or other products from upstream will be conveyed quickly, which allows the line to recover.

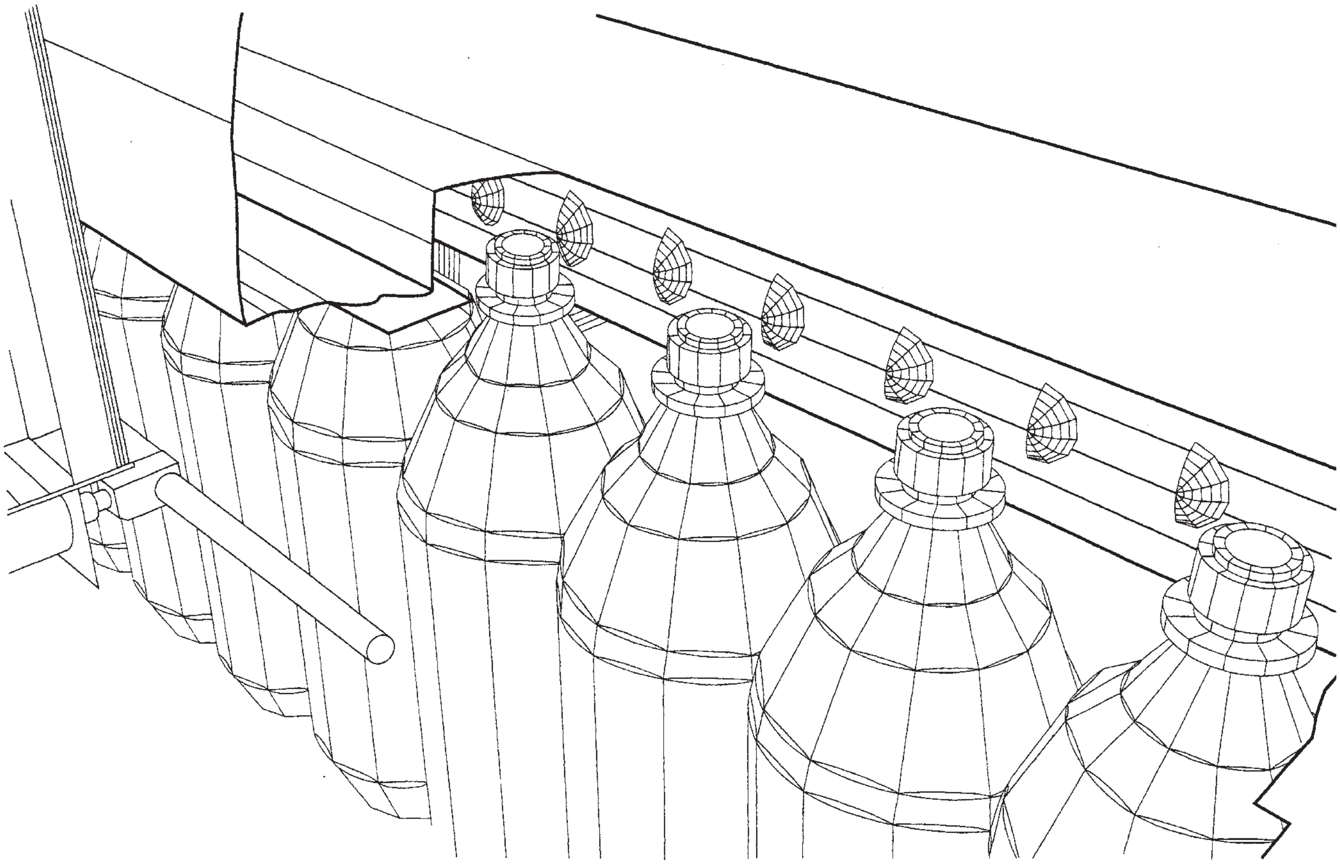

Figure 2. Plenum, cutaway view.

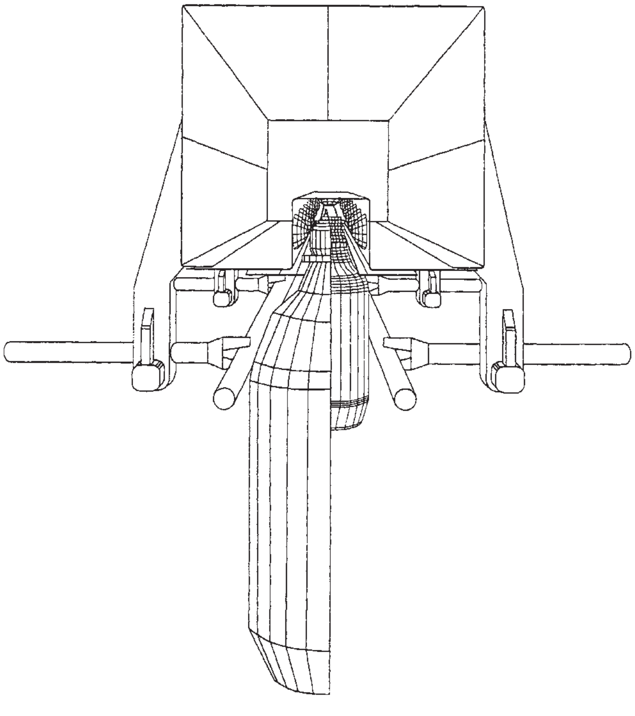

Figure 3. Single-lane air conveyor, adjustable bottle guide.

- *Shorter surge areas*. Faster conveying speeds allows for quicker recovery from the upstream supply of a product to the rinsers, fillers, cappers, or packaging equipment. As a result, users of air conveyors will be able to greatly reduce the lengths of a conveyor to accommodate surges.
- *Reduction in buffer areas* (*BIDI tables*). For the same reasons as described above, bidirectional accumulating tables can be eliminated. There still may be the need for accumulation as, for example, where the labelers need to be changed over. For beverage applications we recommend side lengths of air conveyor where the bottles can be diverted for additional accumulations as the most effective means of accumulating and preventing bottles from falling over.

The net result of these advantages is less overall length of conveyor in the plant. This length reduction also results in both lower cost for the conveyor installation and freeing up of valuable plant space at floor level.

CHARACTERISTICS OF A PROPERLY DESIGNED AIR CONVEYOR

Construction Materials. We recommend and use stainless steel construction for the conveyor; this material will result in lowered maintenance costs and in easier washdown. Most importantly, the use of stainless steel guiderails on neckring a air conveyor avoids the need to replace guiderail wear strips.

Airflow. In cap conveying applications on flat-top air conveyors, center louvers are the most efficient. On heavier parts, the addition of lift holes combined with louvers aids the product flow, especially where accumulation is required. The three methods used most commonly are neck blow, shoulder blow, and sidewall blow in neckring air conveyor applications. In these applications, we feel that neck blow is the preferred method, because most bottles have the same neck dimensions as compared with body diameter dimensions. Using the neck dimension as the criterion, adjustment for different sized containers is reduced.

Flat-Top Air Conveyor Applications. The food industry found a solution in a flat-top air conveyor and, in turn, is a major user of it. Because of the flat-top air conveyor's ability to convey with virtually no damage to the product, the manufacturers of candy, for instance, turned away from conventional tabletop conveyors and turned toward air conveyors. Because of the flat-top air conveyor's ability to lift as well as convey, the air conveyor can be used to accumulate products, eliminating the damage caused by friction from a belt or chain. These features make the air conveyor the product transportation vehicle of choice.

The beverage industry has changed significantly with the growth of the 16- and 20-oz bottles. Use of 28- and 38-mm plastic beverage caps has grown as well. The beverage industry was now looking for a versatile method of conveying them while maintaining orientation to the capper. Their solution was to use an air conveyor coupled with a cap feeder/orientor. In general, the bottlers were now able to convey their caps quickly, efficiently, and 100% oriented to their cappers at speeds to 1800 Hz from remote locations, such as warehouses and production facilities.

BEVERAGE INDUSTRY APPLICATIONS

Faster Filling Speeds. Filling line speeds have and will continue to increase. Our company is now involved with projects where the required line speeds are as follows:

- 2-L container: 800/min
- 20-oz bottle: 1100/min
- 16-oz bottle: 1200/min

Our company's Airtrans Air Conveyor installations have been to provide better control of the containers out of the depalletizers that are running at higher speeds.

One-Piece and Single-Serving Bottles. Because of their higher center of gravity and thin-walled, lighter design, most one-piece bottles are inherently less stable than the base-cupped bottle. Also, in recent years, an increase has occurred in market share for the 16-oz and now the newly introduced 20-oz PET bottles. These containers are less stable on filling lines than the 2-L bottle, and they fall over more easily than the glass bottles they replaced. The higher filling line speeds of the smaller bottles (up to 800 bottles per minute) continually aggravate the problem of the bottles falling over and jamming on the conveyors. The neckring air conveyor virtually eliminates these problems by conveying quickly, cleanly, and with little to no jamming or tipping. Because the bottles are suspended by the neckring, the possibility of tipping is eliminated. Also, because the bottles are conveyed with air, there is much less back pressure exerted on the new, thin-walled bottles, significantly reducing damage. (see also Carbonated beverage packaging)

Marketability. A major trend has been the expansion of blow-molding plant outputs, in terms of both total output and numbers of packaging lines. This growth 6L in output has resulted in an increased need to eliminate cable or chain conveyors and in an increased implementation of air conveyors. Bottlers are splitting the output of their blow molding machined into several streams to downstream packaging equipment and combining the output of multiple blow molders into their packaging equipment. However, as shown in the applications of flat-top air conveyors, the applications of air conveying are not limited to blow molding applications by any means.

Problems of Conventional Tabletop Conveyors Needing Solution. The following problems of cable and chain conveyors are commonly known by the industry:

- Greater nonproductive costs of mechanical conveyors because of higher maintenance of high-speed chain conveyors—mechanical conveyors have moving parts that are subject to wear and mechanical failure.
- The following spare parts are required:
  - Chain
  - Wear strips
  - Gears
  - Sprockets
  - Bearings
- Expense for disposable lubricants and wear parts
- Unsanitary—grease and constant soap on bottles and product
- Higher unplanned downtime of tabletop conveyors—these mechanical components will fail unexpectedly
- Greater crushing of lightweight plastic bottles and delicate packages
- Bottles fall over
- Bottles jam on tabletop conveyors

BENEFITS OF AIR CONVEYORS AND ELIMINATION OF POPULAR MYTHS

Expense. An air conveyor system can actually be more cost-effective than chain, belt, or cable conveyor for the same application. Although initial costs of an air conveying system may be more, the reduced maintenance, amount of spare parts, and downtime make air conveying an overall less expensive method of transport. Basic capital expenditures of the conveyor are only part of the complete cost picture. The true and total cost of the conveying system also includes the following:

- *Spare parts*. The air conveyor needs and uses less. Few moving parts exist on an air conveyor so the initial capital for spare parts and yearly additional parts' costs are less than for mechanical conveyors.
- Maintenance labor costs are less than for mechanical conveyors. Because few moving parts are present, it is less likely to break down and need repair breakdown and need of repair.
- Air conveyors can be more readily located overhead. These savings in floorspace costs may be applied as cost saving.

Flexibility. Air conveyors offer significantly more flexibility than chain conveyors for the following:

- *Revisions to floorplan*. Both flat-top and neckring air conveyor systems are furnished in sections that bolt to each other in a continuous path. The modules typically are combinations of straight sections, horizontal curves, vertical curves, and gates for merging and diverging. Any of these modules can be reconfigured in a different combination and can be added or deleted. Our company reconfigured a system that had been shipped four years previously, and by adding additional sections to the original system as well as by adding other new sections, we provided a totally different conveyor system layout. Few of the old sections were wasted; rather they were reused elsewhere in the new conveyor line. The entire system was reconfigured with less than one week of installation and dismantling.
- *Multiple sizes of containers*. The flat-top air conveyor can generally carry 5 lb/ft^2. Also, our flat-top air conveyor can be designed to accommodate many differently sized products. Whether it be through a dual-lane, multi-lane, or single-lane flat-top air conveyor, from unwrapped candy to boxes to caps, a virtually endless variety of products can be transported using this system.
- *Multiple sizes of beverage containers*. Multiple sizes of containers are accommodated using several different techniques. Different heights of containers are accommodated by adjusting the height of the air conveyor through hand wheel adjustment or automatically. The air conveyor transports bottles hanging by the neck support ring. The Aidlin Airtrans has hinged end sections on the infeed and discharge ends of the air conveyor. Similarly, the height would be adjusted when discharging bottles to the infeed screw of the filler. Infeed and exit plenums are hinged to allow adjustment of bottle height in the air conveyor. Also, bottle heights from the same supplier can have height variations for which the conveyor may need to be adjusted. Fixed height neck rails obviously do not have the necessary adjustability for this condition. Different neck diameters are accommodated by Aidlin's Dual-Lane Airtrans. The Dual-Lane Neck Ring Air Conveyors is a double-lane neck rail. One lane is set up for 16-oz bottles, whereas the other is set for 2-L containers; similarly, one lane could be set for 28-mm neck finishes and the other lane set up for 38-mm neck finishes (as on 3-L containers). A single air plenum is switched over to supply either set of neck rails as required.

Interfacing with Other Equipment. One significant advantage of both flat-top and neckring air conveyors is their ability to interface easily with other packaging equipment (see also, Blow holding; Labels and labeling machinery; Palletizing).

Mechanical interfacing.

- The flat-top air conveyor can transport from and to most equipment: from the orienting orientors to the cappers, liners, or decorators; or to a wrapper, cartoner, or case packer. When needed, the air conveyor can be fit to virtually any line. The transport process is described as follows:
- *Blow molders*. Bottles are received either through a bottle collector conveyor (as on the Cincinnati, Magplas, and Nissei) or directly from the output neck rails (as on the Sidel and Krupp).
- *Palletizers*. An escapement is mounted to the discharge of the air conveyor to stabilize the bottle and match the container's speed to be the same as the infeed conveyor to the palletizer.
- *Depalletizers*. Containers are received off the outfeed conveyor directly to the split neck rails of the air conveyor. The bottles are accelerated and conveyed away from the palletizer at a faster line rate than the depalletization. In this way, no possibility exists of bottles falling down.
- *Labelers*. Containers can be placed directly into the infeed starwheel or timing screw of the labeler.
- *Fillers*. Bottles are placed directly into the infeed timing screw of the filler. By assuring a proper backpressure and constant supply of bottles, maximum filling speed is achieved.

Maintenance. The total maintenance factor of the air conveyor is significantly less than that for mechanical conveyors. For example, the normal maintenance in the Airtrans system consists of replacing, in less than one minute, the 5-μm fan filters as needed. In our flat-top air conveyor, both the top guiderail and the Lexan covers are hinged for easy cleaning.

Less Contamination to Products. Based on R&D done at Aidlin Automation in Bradenton, FL, the air transporting the bottles or products is filtered, in our case, to 5 μm. The net result is that bottles or products, such as food or caps, remain cleaner than in the typical plant where the neck, cap, or product is open to unfiltered ambient air.

Conclusion. As one clearly can see, air conveying provides the alternative to chain, cable, or belt conveyors. Air conveying provides clean, consistent, and predictable performance. The new generation of conveying technology is here and in great demand. To be profitable in this quickly changing industry, one must keep up to date with new technology—and that is the air conveyor.

AMPULS AND VIALS, GLASS

Ampuls and aluminum-seal vials are glass containers used primarily for packaging medication intended for injection. Ampuls are essentially single-dosage containers that are filled and hermetically sealed by flame-sealing the open end. Vials, which contain single or multiple doses, are hermetically sealed by means of a rubber closure held in place with a crimped aluminum ring.

An ampul is opened by breaking it at its smallest diameter, called the *constriction*. A controlled breaking characteristic is introduced by reproducibly scoring the glass in the constriction, or by placing a band of ceramic paint in the constriction. The ceramic paint has a thermal expansion that differs from the glass, thus, forming stress in the glass surface after being fired. This stress allows the glass to break in a controlled fashion at the band location when force is applied. Medication is then withdrawn by means of a syringe.

Medication can be withdrawn from a vial by inserting the cannula of a syringe through the rubber closure. Because the rubber reseals after cannula withdrawal, multiple doses can be withdrawn from a vial.

Both ampuls and vials are fabricated from glass tubing produced under exacting conditions. The glass used for these containers must protect the contained product from contamination before use and, in the case of light-sensitive products, from degradation caused by excessive exposure to light. In addition, the glass must not introduce contamination by interacting with the product.

GLASSES

The most important property of a glass used to contain a parenteral (injectable) drug is chemical durability; that is, the glass must be essentially inert with respect to the product, and contribute negligible amounts of its constituents to the product through long-term contact before use. The family of glasses that best meets chemical durability requirements is the borosilicates. These glasses also require higher temperatures for forming into shapes than other glass types.

When glass-product interactions are far less critical, the soda-lime family of glasses can be used to fabricate vials. These glasses can be formed at lower temperatures than borosilicates but do not nearly have their chemical durability. Typical compositions are shown in Table 1. Borosilicate and soda-lime glasses contain elements that facilitate refining, but borosilicates generally do not contain arsenic or antimony.

Both borosilicate and soda-lime glasses can be given a dark amber color by adding small amounts of coloring agents, which include iron, titanium, and manganese. The amber borosilicate and soda-lime glasses then can be used to package products that are light-sensitive.

The interior surface of containers formed from soda-lime glass is often subjected to a treatment that enhances chemical durability without affecting the desirable lower melting and forming temperatures typical of soda-lime glass. For very critical applications, borosilicate ampuls and vials can be treated to improve their already excellent chemical durability.

For pharmaceutical packaging applications (see Pharmaceutical packaging), the various types of glass have been codified into groups according to their chemical durabilities, as specified by the *United States Pharmacopeia* (USP) (1). The glasses are classified by the amount of titratable alkali extracted into water from a crushed and sized glass sample during steam autoclaving at 250°F (121 °C). Thus, borosilicate glasses are typical of a USP Type I glass, and most soda-lime glasses are typical of a USP Type III glass. Some soda-lime glasses exist that are less chemically durable than Type III glass, and these glasses are classified as USP Type NP.

USP Type III (soda-lime) containers that have had their interior surface treated to improve durability can be classified as USP Type II if they meet the test requirements. The test in these cases is performed on the treated container instead of a crushed sample and uses a similar steam autoclave cycle.

The pharmacopeiae of other nations also have classified glass into groups according to their chemical durability.

Table 1. Compositions of Soda-Lime and Borosilicate Glasses, wt%

Constituent	Soda-lime	Borosilicate
SiO_2	68–72	70–80
B_2O_3	0–2	10–13
Al_2O_3	2–3	2–7
CaO	5	0–1
MgO	4	
Na_2O	15–16	4–6
K_2O	1	0–3
Typical forming temperatures	1796–1895°F (980–1035 °C)	2066–2264°F (1130–1240 °C)

These classifications are generally similar to those specified by USP.

FORMING PROCESSES

Ampuls and vials are formed from glass tubing. The glass tubing is formed by processing in a glass furnace and by a tube-forming operation. The glass furnace operation consists of bulk batch preparation, continuous batch melting, and refining (see Glass-container manufacturing). The tube forming is done to exact specifications in either a Danner process or a downdraw process. The Danner process involves continuous streaming of molten glass onto an angled rotating sleeve that has an internal port for inflation air. The inflation air controls the tubing outside diameter (OD). The downdraw process is an extrusion process through an annular area. The inner core has an inflation air hole. The inflation air serves the same purpose as in the Danner process. In either process the tubing wall weight is controlled by adjusting the rate of glass withdrawal and supply. Typical ampul and vial tubing dimensions and tolerances are shown in Figures 1 and 2.

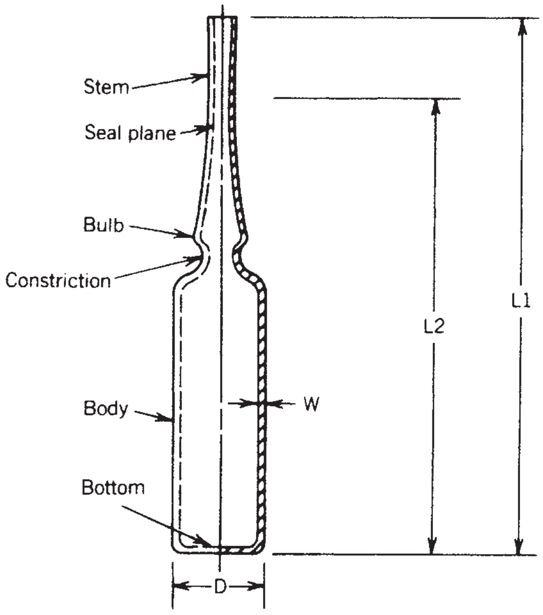

Figure 1. Standard long-stem ampul.

Capacity, mL	Diameter (D) mm	Width (W), mm	Length (L1), mm ± 0.50 mm	Length (L2), mm
1	10.40–10.70	0.56–0.64	67	51
2	11.62–12.00	0.56–0.64	75	59
5	16.10–16.70	0.61–0.69	88	73
10	18.75–19.40	0.66–0.74	107	91
20	22.25–22.95	0.75–0.85	135	120

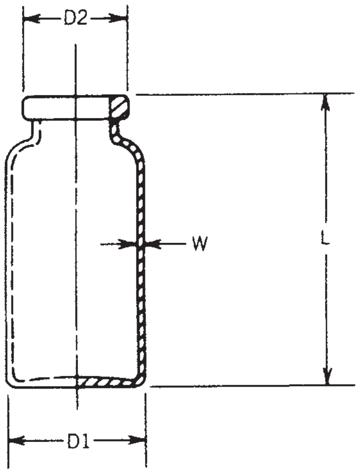

Figure 2. Standard tubular serum vial.

Capacity, mL	Diameter (D1), mm	Width (W), mm	Length (L), mm ± 0.50 mm	Diameter (D2), mm
1	13.50–14.00	0.94–1.06	27	12.95–13.35
2	14.50–15.00	0.94–1.06	32	12.95–13.35
3	16.50–17.00	1.04–1.16	37	12.95–13.35
5	20.50–21.00	1.04–1.16	38	12.95–13.35
10	23.50–24.00	1.13–1.27	50	19.70–20.20
15	26.25–27.00	1.13–1.27	57	19.70–20.20

The tubing is formed in a continuous-line process. Various devices are used to support the tubing during pulling. A device, normally consisting of pulling wheels on belts and a cutting mechanism, is situated downstream to pull and cut the tubing. The tubing is cut to prescribed lengths and used in vertical- or horizontal-type machines for converting the tubing into vials or ampuls.

Many machines are rotary and either index or operate with a continuous action. The tubing is placed in the machines and is handled in a set of chucks. Heat is applied in the space between the chucks, and forming of the ampul or vial occurs throughout the machine rotation cycle.

Ampuls are formed on continuous-motion rotary machines. One sequence is shown in Figure 3. The process consists of sequentially heating and pulling (elongating the glass) to form the constriction, bulb, and stem contours of the ampul. The ampul contours are controlled primarily by proper temperature patterns in the tubing and by pulling rate of the tubing. Mechanical tooling of the glass can be used to assist in constriction contour forming. The forming process accurately controls the seal plane diameter, which controls ampul closing after filling. After the basic ampul is formed on the machine, the ampul blank is separated from the tubing and is transferred to a horizontal afterforming machine. On the afterforming machine the ampul is trimmed to length, glazed, and treated if necessary. Also, the ampul constriction can be either color banded with a ceramic-base paint or scored to control opening properties. The ceramic paint and scoring cause stress concentrations in the constriction, which assist in obtaining desirable opening force and fracture characteristics. Identification bands are applied

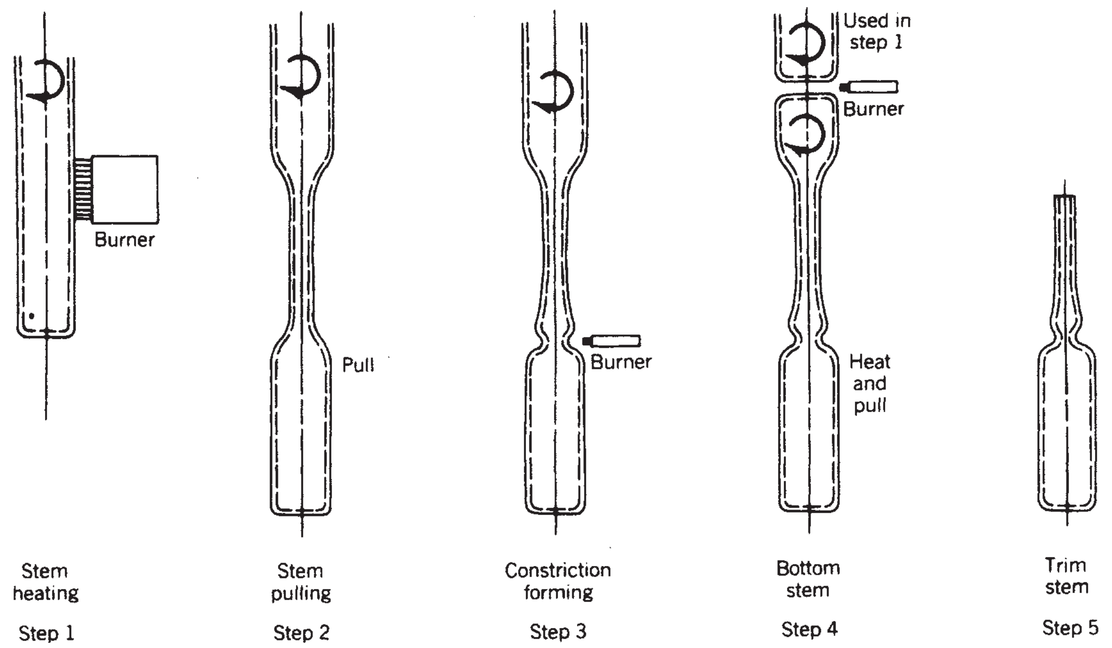

Figure 3. Ampul contour-forming sequence.

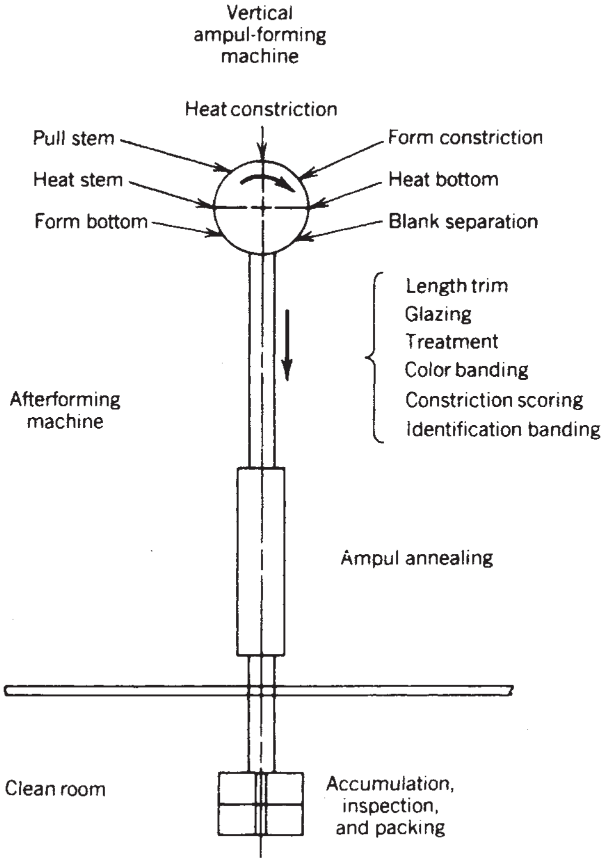

Figure 4. Tube converting for ampul manufacture.

and the ampul is annealed to relieve the strains caused by the thermal forming of the ampul. The completed ampuls are then transferred into a packing area where the ampuls are accumulated, inspected manually or automatically, and packed into clean trays for distribution (see Figure 4).

Vial forming is done on vertical machines that either index or have a continuous motion. A vertical forming sequence (see Figure 5) consists of a parting (separation operation), wherein a narrow band of glass is heated to a soft condition and the vial blank and the tubing are pulled apart. After parting, the finish-forming operations occur. The finish forming consists of heating and mechanically tooling the glass in sequential steps. Normally, multiple heating and tooling operations are necessary to form the closely held tolerances of aluminum-seal finishes. The tooling is done with an inner plug to control the contour and diameter of the finish bore and with outer contoured round dies that control the contour and diameter of the finish outer surface. The vial bottom contours are formed in the lower chucks whereas finish forming occurs for another vial in the upper chucks. After tooling, the vial length is set by a mechanical positioner. The process then continually repeats itself until the whole tubing length is consumed. After fabrication, the vial blank is transferred to a horizontal afterforming machine. The operations that are normally performed on an afterformer are dimensional gauging, vial treatment, and annealing. The vials are then transferred to a packing area where they are accumulated, inspected manually or automatically for cosmetic conditions, and packed in clean containers (see Figure 6).

ANALYTICAL METHODS FOR FOOD PACKAGING AND SHELF LIFE STUDIES

CRISTINA NERIN
Aragon Institute of Engineering Research (I3A), CPS;
University of Zaragoza, Dept. Analytical Chemistry, Zaragoza, Spain

INTRODUCTION

According to the Encyclopedia of Packaging Technology, shelf life is the time after production and packaging that a product remains acceptable under defined environmental conditions. To establish this period of time is nowadays required for every food product, not only for commercial reasons but also for safety reasons, as all foods deteriorate with time. The main causes for these deteriorative processes are as follows:

1. Oxidation processes during which the color fades and may give way to a brownish appearance, rancid tastes, and odors and the food becomes unacceptable.
2. Microbiological, which is the consequence of the micro-organisms growth, either molds, bacteria or yeasts, some of them pathogens and dangerous for human beings. Often together with the micro-organisms, new compounds appear that are responsible for the bad odors or off flavors.
3. Water losses, which is the consequence of the aging that affect the texture, hardness, appearance, and the taste.

However, although the causes of the limitation of the shelf life were known, the analysis of the macroscopic effects usually is not enough to establish the limits, and more and more other parameters are required to establish the end of the shelf life.

Besides, the evaluation of the deadline cannot be subjective, just as a global measurement, and analytical procedures are needed to standardize the parameters used for establishing the deadline limits.

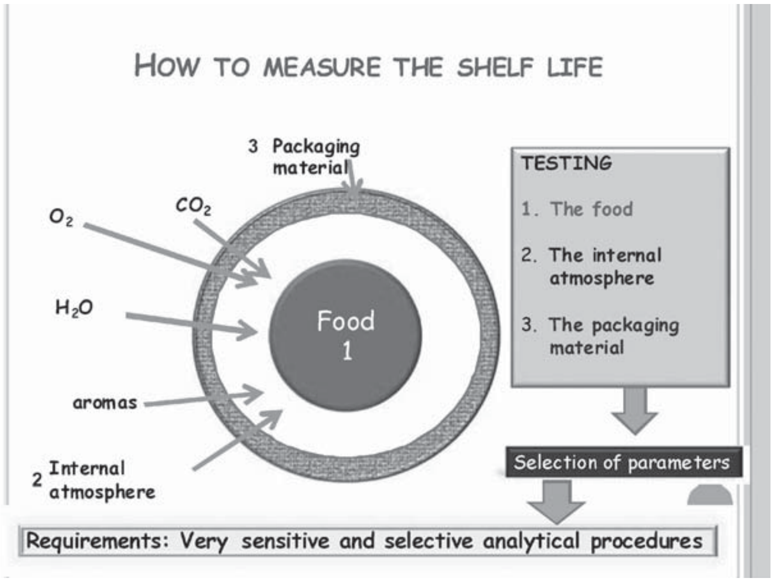
The 21st century is characterized by globalization. In the food area, this means to have the food packaged, because in these conditions, the transport, storage, logistic, and distribution chain can reach distant markets, and a global commercialization can take place. Foodstuffs themselves cannot stand for long time, and new technologies such as vacuum packaging and modified atmosphere packaging, combined with the use of high barrier materials and active packaging, can extend the shelf life of the food inside the package. Emerging technologies like intelligent packaging are then proposed to show that the packaged food is still good and safe.

But the challenge is how to measure the shelf life of food. When developing the packaging material or the packaging system, there are different materials, parameters, and variables to modify and to measure. Figure 1 shows a scheme in which the material, the food, and the internal atmosphere play an important role in the shelf-life definition and testing. Interactions between them as well as absolute measurements have to be carried out to study the shelf life. According to this process and depending on the type of samples that we have, different parameters and different analytical methods will be used. This chapter deals with the main analytical methods, which can be useful for shelf-life evaluation, taking into account that the main purpose in this task is to have an objective and independent series of methods. Avoiding the subjective and personal skills is the main way to measure the key parameters. There is not an exhaustive list of analytical methods, and only those considered as the most appropriate or most common in this type of studies are referred to.

As Figure 1 shows, the food, internal atmosphere, and packaging material should be tested to establish the shelf life. The food qualities have to remain constant and be as good as possible and the most similar to the fresh food or just-made food. These qualities involve color, taste, hardness, texture, volatile compounds, odor, water content, chemical contaminants, absence of microbiological contamination, and freshness, among others.

The internal atmosphere means the analysis of gases such as oxygen, carbon dioxide, and other permanent gases and vapors, such as water, volatile compounds transferred by the packaging material, or those released by the food.

Finally, the packaging material, which involves the testing of the permeability properties, the analysis of likely contaminants as potential migrants, the migration tests to ensure that the material is safe for being in



HOW TO MEASURE THE SHELF LIFE

TESTING

Selection of parameters

Requirements: Very sensitive and selective analytical procedures

Figure 1. Scheme of the food packaging to measure the shelf life.

contact with the food, and the sorption properties of the material to guarantee that the material does not affect the quality of food, by scalping aromas or by trapping the compounds responsible for the color, flavor, or other food attributes.

In all cases, the first key point is the selection of the parameters to be measured in a quantitative manner for the shelf-life studies, and the second point is the selection of the analytical technique and the procedure to measure the changes, if any, in the whole system.

THE ANALYTICAL PROCESS

Figure 2 shows a scheme of the analytical process. Three main steps can be distinguished: the “sampling,” the “sample treatment,” and the “final analysis.” A short comment of the main procedures involved in each step will be described below.

THE SAMPLING STEP

Usually, this is the first step, as the sample has to be taken for analysis. Some critical requirements should be followed to be sure that the final analysis represents a real diagnostic of the sample. The three points mentioned in the Figure 2 have to be decided by the analyst, and such a decision should be based on scientific parameters. The first step, the sample size, seems to be obvious, as if low concentrations are expected for the analytes, higher amount of sample should be taken. However, the sample size will condition the second step of the analytical procedure, which is the sample treatment, and it will affect the handling, time, and price of the analysis. However, if the sample size is small the representativeness of the sample is in danger. Then, to decide about this parameter, it is recommended to think about the detection limit of the final analytical technique in which the variable under study will be measured as well as the expected concentration of the analyte after the test. Sometimes, only differences between the concentration before and after the shelf-life studies are going to be measured instead of absolute values. In this case, the sensitivity is higher, as the absolute value measured is higher than the difference itself. When absolute values have to be measured, for example, the concentration of an analyte formed during the shelf life study, the expected value can be extremely low, and thus higher amount of sample is needed.

Representativeness

This point is critical and affects any kind of analysis. It is close-related with the homogeneity of the sample. With food samples, the lack of homogeneity can let us take discriminant portions of food for the analysis, and obviously in this case the diagnostic is wrong. To avoid this problem, a previous homogenization is recommended. Sample size is also conditioned here, as with small sample size there is a high risk of discrimination, which ruins the analysis. All parts of the food should be taken and mixed together to reproduce the real situation as much as possible. Interactions between the different components in the food sample is also very important, what requires that all the components were represented in the sample taken for analysis.

Homogeneity

The problem of homogeneity is more common in food analysis, where the samples can be macroscopically homogeneous but nonhomogeneous at microscopic level. Different devices are nowadays available to homogenize the samples. Mills, blenders, mixers, and similar machines

are common in any laboratory. Liquid and solid portions are mixed together if they are present in the food sample. Then, an homogeneous sample is produced, usually smashed and fluid enough to be sure that any portion of it has the same composition.

SAMPLE TREATMENT

The sample treatment involves the sample dry, the extraction and the clean-up steps. To dry the sample is not always required before the analysis, although the values should be always referred to the dry sample for comparison. Sometimes, an aqueous extraction is going to be applied to the sample, and then there is no point to remove the water. Anyway, it is important to measure the water content in a different aliquot from that used for the sample analysis.

However, the extraction and the clean up steps are usually the bottleneck of the analytical process (1). It is in fact the area in which more analytical development has taken place in the last decade, and there are several reasons for that. Let us go to explain more in detail the newest extraction techniques that can be applied for shelf-life studies.

It is true that the shelf-life studies require sensitive analytical methods for measuring low concentrations of compounds that are formed either during the shelf life of a foodstuff or disappear as long as the time goes on. Alternatively, the packaging has to be measured, and then low concentrations of compounds are also analyzed either in the packaging material or in the atmosphere inside the packaging. In any case, the analytes have to be isolated from the matrix, the interferences have to be removed as efficiently as possible, and simultaneously the concentration of the analyte in the final solution that will be analyzed has to be as high as possible. This way, the detection and quantification limits will be surpassed, and no limitations concerning the sensitivity will be present.

The classic extraction procedures involve the *liquid–liquid extraction*, in which the liquid sample to be extracted is shaken with a small volume of a nonmiscible liquid-extracting phase, nonsoluble with the sample, in which the analytes will be efficiently dissolved and then extracted from the matrix. It is obvious that for an aqueous matrix, the extracting agent will be an organic, and vice versa. To gain sensitivity using this extraction procedure, the volume of extracting agent can be reduced as much as possible, but in any case, handling low volumes of liquids and putting them in intimate contact with a much higher volume of the liquid sample is difficult, and the risk of losing efficiency in the process is high. Another disadvantage of this classic extraction is the use of high volumes of organic solvents, which are toxic, dangerous, and not environmental friendly.

Also included in the classic extraction panorama are the *solid–liquid extraction* techniques or better known as "leakage," which are usually from a solid matrix that can be either a foodstuff or a packaging material. Among them, Soxhlet extraction is the most common. Its high efficiency is based on the fact that it is a continuous extraction in which new solvent is continuously put in contact with the sample while maintaining the total volume of solvent. As the partition constant is reached each time, the efficiency can be high without increasing the total volume of solvent but increasing the total mass of the analyte extracted. Although it is a good and well-recognized method, it takes time, usually from 6 to 20 h, and it requires a high amount of solvent.

An improvement of the classic extraction is the accelerated solvent extraction (ASE), which consists of carrying out the extraction at high temperature and high pressure. The increase of temperature increases the extraction coefficient and then the extraction efficiency, but when increasing the temperature, the solvents used as extracting agents are evaporated and they would be in vapor phase. To avoid the evaporation and maintain the solvent in liquid phase, a high pressure is applied, and thus the extraction is accelerated both in time and in efficiency.

When the analytes are dissolved in a liquid solvent either in aqueous solution or organic solvent, the solid-phase extraction (SPE) is the most common technique to isolate and concentrate the analytes and to remove the interferences from the matrix. SPE is also useful in the cleanup step, which is usually applied to the sample after any extraction to remove the interferences. The solid phase usually is inside a cartridge, ready to use, and commercially available, and the nature of this solid phase can vary from the current stationary phases based on polymeric sorbents to modified silica such as C18, pure adsorbents such as alumina or active charcoal to ionic exchange, which are both cationic and anionic phases. Its versatility and ease of use make SPE one of the most common techniques in any analytical procedure in which the isolation of analytes or concentration steps and cleanup are required.

But without a doubt, the trends in extraction systems drive us to the microextraction techniques in which a few drops of solvent, if any, are employed as extracting agents while maintaining the efficiency and having short periods of extraction.

For these reasons, new microextraction techniques have been developed to avoid the mentioned problems. The most important ones will be described in this chapter.

Solid-Phase Microextraction (SPME)

SPME was proposed for the first time by Arthur and Pawliszyn in early 1990s (2), and it has been used more and more widely in sample preparation. SPME is based on the partitioning of analytes between a coated fiber and a sample. The coated fiber consists of a small fused silica rod covered with a thin layer of a sorbing material, which acts as stationary phase. When exposed to the vapor phase above a solution (head space sampling) or by direct immersion in the solution, this fiber enters a mass-transfer process driven by the second law of thermodynamics, according to which the chemical potential of each compound should be equal throughout the system. The chemical species will cross the interface until their concentrations are such that their corresponding partial molar free energies are the same in all parts of the system formed by the fiber and the sample. After the coated fiber is exposed to the sample for a given period, it is inserted into the injection port of a chromatograph to release the analyte. In gas chromatography (GC), it is carried out by thermal desorption, whereas in high-performance liquid chromatography (HPLC) it is accomplished by dissolution and injection with the elution solvent (3, 4). In both approaches, all the substances eventually reach the analytical instrument detector to produce a trace in which there is no large solvent peak. Although a small amount of analyte is transferred, it is sufficient to produce a significant analytical signal in modern detectors. The SPME uses a capillary fiber on which the stationary phase is coated or chemically bonded; therefore, it is a solventless technique. Usually, only the analytes and related molecules are trapped on the fiber, and for this reason most of the interferences remain in the matrix and do not affect the final analysis (5). This technique is useful in both modes, headspace, and total immersion, and its high sensitivity, based on the high concentration rates that the analytes have on the capillary fiber are without a doubt their main advantages. There is no limitation for either of the nature of samples, as both packaging materials and foodstuffs can be analyzed (6–16).

Liquid Microextraction Techniques

Using liquid phases for extraction from liquid matrices, several microextraction techniques have been recently developed and applied to food packaging and shelf-life studies. Among them we can point out the single drop microextraction (SDME), the liquid–liquid–phase microextraction (LLPME), and the hollow fiber liquid phase microextraction (HFLPME).

SDME. SDME was first introduced by Liu and Dasgupta (17), but it is felt that the works by Jeannot and Cantwell (18, 19), who studied its kinetics and mass transfer model, and by He and Lee (20), who gave the technique for much of today's aspect, provided the basics needed to consider it as an independent technique. Many applications have been introduced since then (21) and are summarized in many devoted reviews (22–25). It consists of the partition of the analytes between two nonmiscible solvents, but in this case only one drop of the extracting solvent hanging from the tip of a syringe is used. Once the extraction is finished, the drop is withdrawn into the syringe and directly injected into the gas chromatograph for the final analysis. It can be considered as solventless technique as well, as the amount of solvent is negligible. Also, most of the matrix interferences are avoided in both exposure modes, as only the compounds soluble in the drop of solvent, either in headspace mode or in total immersion in the sample solution are extracted. There is no doubt that this technique is useful in many applications and allows the analysis at high sensitivity level. The drawback of this technique is the fall of the single drop during the sampling, which requires the procedure to start again with a new sample, as the presence of the lost drop of solvent in the same vial affect the extraction greatly. In such a case, the analytes are simultaneously extracted in both drops, although only one is analyzed, which is why a new sampling in a different vial is required.

Liquid–Liquid Microextraction. Several approaches have been recently proposed to increase the extraction efficiency using only a few drops of organic solvent. Among them, those that employ a few microliters of solvent directly added to the aqueous liquid sample are useful when using liquid samples, and no particulate matter or slurries are involved. The supernatant solvent is recovered after the extraction and analyzed. For quantitative purposes, the use of an internal standard is compulsory to guarantee the quanitative results, as the handling of such a low volumes of solvents is always difficult.

HFLPME. Another improvement of the SDME that eliminates its main disadvantage is the use of polymeric membranes as support of the small volumes of solvent. Few microlitres can be swallowed inside the pores of a semipermeable polypropylene capillary tube, and then this hollow capillary can be used for extraction, which allows high concentration factors (26, 27). When organic compounds in aqueous solution have to be analyzed, HFLPME is the appropriate technique for sampling and extraction, using for instance, an organic solvent as extracting agent inside the hollow fiber, being the sample outside (see Figure 3). This technique has been recently automatized and proposed for migration studies from packaging materials (27).

Several studies have been carried out in the last 3 years dealing with different approaches of this technique, and there are several options in which up to three liquid phases can be involved to extract and concentrate ionic analytes from complex matrices (28–30).

TOTAL DISSOLUTION

When the analyte to be measured cannot be directly extracted, the total dissolution of the sample is required. This problem often happens when dealing with plastic samples, in which the analytes are inside the matrix or even linked to it. For example, if the shelf life of a new

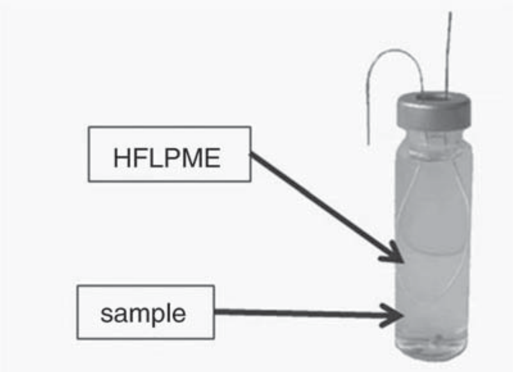

Figure 3. Scheme of the HFLPME extraction from a liquid sample.

active packaging material is under study, then the remaining active agents in the material should be analyzed. If it is a plastic material, then it may be difficult to apply an efficient extraction, as the recoveries are commonly low.

Thus, the total dissolution is preferred. The solvent and conditions used for the total extraction, have to be optimized. If a synthetic polymer is dissolved, the polymer itself has to be removed from the solution, as the compounds of interest are the small molecules, no the large polymeric chains. The addition of methanol, or in general a solvent in which the polymer is insoluble, is usually enough to precipitate the polymer, and another filtration removes the polymer from the solution (31). Obviously, the compounds of interest have to be soluble in the solvents used in the precipitation step and they have to be free from the polymer, which means that no chemical bonds exist between the polymer and the compounds of interest. Large volumes of organic solvents are obtained, and additional concentration and cleanup steps are usually required to cope with the final analysis. Anyway, only a few times the total dissolution is required in shelf-life studies but often is necessary for the packaging analysis.

Final Analysis

The final analysis means the identification and quantification of the compounds of interest. The analytical technique to be used depends on several variables as follows:

- The chemical structure and properties of the analytes
- The concentration level in which the analytes are expected to be in the sample
- The information required

For volatile compounds, the most appropriate technique is GC. Depending on the information required, different detectors can be used, such as follows: (a) flame ionization detector (FID), which is ideal for organic compounds with carbon atoms, as the response is based on the carbon atoms number; (b) the electron capture detector (ECD), which is very sensitive for electronegative atoms such as halogens and oxygen; (c) the nitrogen-phosphorous detector (NPD) with a high sensitivity for the compounds that contain these atoms; and (d) the thermal conductivity detector (TCD), which is only sensitive for those compounds that have a thermal conductivity very different from that of the carrier used as background or reference, usually the hydrogen. That means that this detector is mainly used for permanent gases, such as nitrogen, carbon dioxide, and so on. and it is no sensitive for other compounds. None of the mentioned detectors can be used for identification purposes if the nature of the analyte is unknown, as only using the standards, what means the pure compounds analyzed exactly in the same conditions as the sample, the compounds could be identified. For identification purposes, the mass spectrometry (MS) coupled to GC is the right technique. The molecule is broken by electronic impact that produces positive ions, which are the characteristic mass fragments of each molecule that constitue the mass spectrum. Then, this mass spectrum of each compound is obtained and compared with the mass spectra contained in the MS library. The software of this hyphenated technique (GC-MS) give as the list of compounds with the most similar spectra and is the analyst who decides which one can be present in the sample, according to the matching parameters provided by the software.

Two different systems for MS detectors can be chose: the quadruple and the ion trap. For quantitative purposes, it is generally recommended the quadrupole, whereas for qualitative objectives the ion trap is more appropriate, as it pemits to have the MS^n fragmentation. This means that once the molecule is fragmented and the characteristic masses are known, the analyst can select some of these characteristic masses and apply a new fragmentation. This operation can be repeated several times. Even the isomers or quiral compounds, which are very similar between them, have differences in some of the fragmentation profile; these differences can be used for unequivocal identification. Recent advances on the MS detectors have launched in the market new instruments with novel systems that increase the sensitivity of the MS detectors. Combinations of MS-MS, triple quadrupole (TQ) or time of flight (TOF) techniques are now available. These analytical tools allow the identification of unknowns and permit as well the quantitation of the compounds at low level of concentration. The selection of the right technique depends on the sample, the analyte, and the information required from the sample.

There are also several options for injecting the compounds into the GC. The head space (HS) technique is useful for the analysis of volatile compounds. It consists of injecting the vapor in equilibrium with the sample at a fixed temperature. The sample is thermostatized, and only a fraction of the vapor in equilibrium is taken for the analysis. This technique can be used in either manual or automatic modes, but the reproducibility is much higher in the latter. As only vapor is introduced into the GC, most of the interferences from the matrix remain in the sample, either in liquid or solid state, and the sample treatment is considerably simplified. For this reason, this technique is applied to a wide series of samples and volatile analytes. The scarce handling and time consuming required make it appropriate for the analysis of volatile compounds.

An improvement of this technique is the dynamic HS, also called purge and trap (P&T), which is coupled to the GC. The advantage is that in the dynamic system, the analytes are continuously purged from the sample using an inert gas and trapped on a solid adsorbent, which is thermally desorbed to introduce the analytes directly into the GC. This technique is the most sensitive for volatile compounds, as the total mass of the analytes present in the sample is introduced into the analytical system and arrives at the detector (31, 32). To have an idea of the high sensitivity of P&T-GC-MS, we can compare the real mass of analytes at the detector in this case with that of liquid injection in GC-MS. For example, 10 mL of sample containing 1 ng/mL of a volatile analyte are analyzed by both direct injection into GC-MS and HS-GC-MS. If 1 μL is injected in the former case, 1 pg arrives at the detector. However, in P&T-GC-MS, the total mass of the same volatile compound contained in the 10 mL of sample arrives at the detector, which is 10 ng of analyte. This amount is 10,000 times higher in the detector. To have the equivalent mass at the detector in both cases, the concentration of the analyte in the sample should be 0.1 pg/mL, that is 0.1 ppt. However, the main drawback of this technique is also its high sensitivity, as it is very difficult to have a blank sample, and often interfering compounds appear and overlap the peaks of interest. Another problem is the calibration plot for quantitative purposes, because in this system the equilibrium is not reached, as the volatile compounds that would be in equilibrium in the vapor phase are continuously removed from the vapor and trapped on the solid trap. Then, the calibration plot should be prepared exactly in the same conditions as those used for the sample.

Another interesting approach for injecting the volatile or semivolatile compounds into the GC column, apart from the injection of liquid solutions, is the SPME injection. Nowadays, there are commercially available automatic injectors for SPME, HS, P&T, and of course for liquid injections into the GC.

The analysis of non/volatile compounds is usually carried out by liquid chromatography (LC), in which the compounds present in the sample are separated. Several detectors can be used; the most common ones are ultraviolet-visible spectrometry (UV-VIS), molecular fluorescence spectrometry (Fl), refraction index (RI), and MS. UV-VIS is the most general and common one coupled to HPLC, whereas Fl is more selective as only fluorescent compounds can be detected. RI is usually applied to analyze sugars, wheras MS can be applied to any compound with a molecular mass higher than 50 units of mass and able to be ionized in the ionization step of the LC-MS.

As in GC, the separation takes place in the chromatographic column where the stationary phase exerts an interaction with the compounds. Depending on the nature of this stationary phase, either partition, ionic exchange, or size exclusion can be the main process between the compounds (the analytes) and the column. The analyst has to take an important decision and choose the right LC column, according to the analyte and the sample. Also other conditions such as the size of the column and the mobile phase in each analytical procedure have to be optimized in each case. Recent developments to increase the resolution in LC launched in the market new instruments in which a higher pressure, more narrow LC columns, and lower particle size in the LC columns occurs. This is the case of the new systems of ultrahigh performance, such as ultrahigh performance liquid chromatography (UPLC), which increase the resolution and considerably reduce the time of analysis compared with the normal HPLC. The UPLC-UV analysis is not in real time but it can last only a few minutes to have the whole chromatogram with more than 20 compounds (33).

When using MS as detector, one of the main decisions to take is the ionization step. This is a critical step in which the analytes are transformed into ions, either positive or negative ions, which can be driven to the MS detector in which they are separated according to their mass and then counted (abundance). The ionization step in LC is commonly a soft ionization that mainly produces the molecular ion. The interface between the ionization step and the MS analyzer has been the most difficult part of the development of this hyphenated technique of LC-MS. This is because the ionization step is applied to the liquid sample injected into the LC and the nonvolatile solvent, usually water, methanol-water, or acetonitrile, which has to be removed efficiently to get the high vaccum required for MS, to avoid the saturation of the MS detector, and to remove the interferences associated to the solvents. Two different ionization devices and techniques are the most common in current LC-MS, and they are the Electrospray (EI) and the atmospheric pressure chemical ionization (ApCI), although more and more the EI is gaining importance, as most problems are solved using the EI.

During the last 10 years, new approaches dealing with LC-MS have been launched to the market to increase the sensitivity and reproducibility, and to widen the type of analytes that can be analyzed. Also, the instrumental equipments are nowadays more friendly for the users and easier to handle.

Also, the advanced MS techniques such as the TOF supply new tools for the identification of unknowns, using the exact mass values. Without a doubt the identification of unknown compounds is the most challenging area, and new and more sophisticated techniques are required for this purpose. Artifacts formed during the analysis, degradation compounds caused by the interaction between the components in the packaging materials or in the food, or degradation compounds coming from the additives used in the food or from the packaging materials in contact with the food, which include the presence of compounds non intentionally added, pose new analytical problems and make the analyst face a real challenge in food packaging and shelf-life studies. To help with the identification, MS-MS can be used. As was mentioned above, this consists of identifying the characteristic ion (MS) and then applying the fragmentation to this ion to break this fragment. The breakage of each fragment is specific and is of great help to identify the compounds. Triple quadrupole instruments in which the first fragments (parent ions) obtained in the first quadrupole goes through the second quadrupole in which a gas, usually argon, enters and crash into the fragments, causing the second fragmentation (daughters) of each ion, which are analyzed in the third quadrupole. These systems are also available in LC-MS and are useful for identification purposes, although the sensitivity using the triple quadrupole is lower than that obtained when using only the first quadrupole.

Recently double-dimension chromatography has been developed. This is a new hyphenated technique in which two different chromatographic separations using two columns of different polarity and different size each, connected in series, are applied to the same sample. Usually, the first column is of normal size, for example 30 m in GC, and the second one is short, about 1.5 m. The final detection can be FID or even better the MS or its different MS options. This double dimension can be also used in liquid chromatography. In this case, the use of for example a size exclusion column as the first one to eliminate the polymers, proteins, or in general the macromolecular

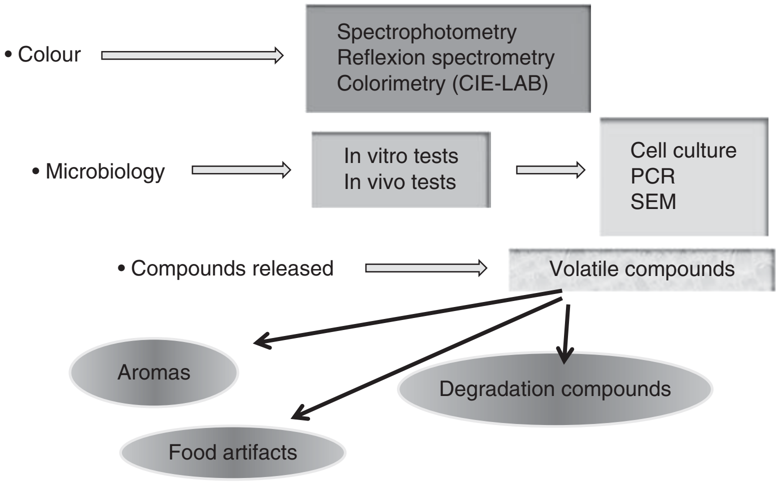

Figure 4. Testing the food.

compounds, and a reverse phase (C18 or similar) as second dimension can be a good alternative for analyzing in one single run the compounds of interest without the interferences from the matrix (34).

A different approach from chromatography is electrophoresis, where the compounds are separated based on the application of an electric field. Then, the ionic compounds move through the liquid solvent according to their mass and their charge. Although gel electrophoresis is old and novery sensitive, the new capillary electrophoresis (CE) has been shown as a good technique for ionic organic molecules, such as drugs, proteins, amino acids, and so on, as these compounds can be easily transformed into ionic ones just controlling the pH. This technique can be also used in shelf-life studies, but its frequency is not as high as the chromatographic techniques. The new hyphenated technique CE-MS can be one alternative in future studies.

OTHER ANALYTICAL PROCEDURES

Figures 4, 5, and 6 summarize the most common techniques for shelf-life studies. Besides the analytical techniques mentioned above, the optical techniques, such as UV-Vis spectrophotometry or infrarred spectrometry (IR) are useful. The former is used to measure the color and color changes (VIS) occurred in the food or in the packaging materials either in absorption or in reflexion modes. The latter (IR) is used to identify the packaging materials or organic components. The most recent advances in near infrared (NIR) allow also to quantify some components in not complex samples, mainly in packaging materials more than in food.

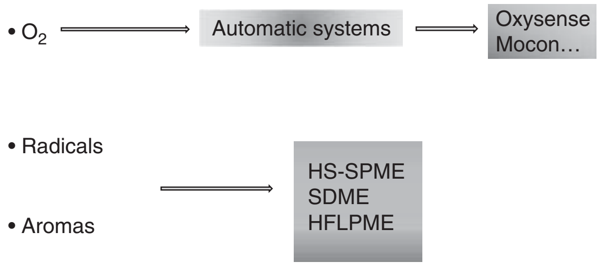

Figure 5. Testing the internal atmosphere.

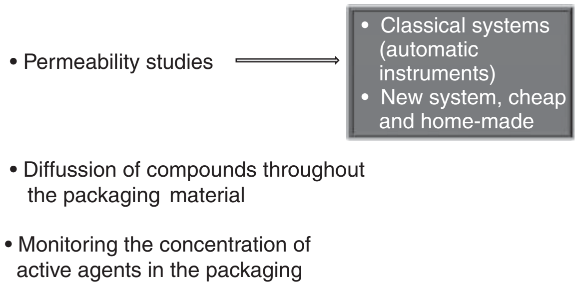

Figure 6. Testing the packaging.

Also, the combination of different techniques provide an useful an important information in the shelf-life studies (35) and can be observed as a powerful tool for having as much information as possible about the state of the packaging material, the food inside the packaging, and the internal atmosphere between them.

ANTI-COUNTERFEITING PACKAGING

STEVE WERBLOW
Steve Werblow Communications
Ashland, OR

Counterfeiting is a huge business, threatening not only sales revenue, but also the health and safety of consumers who may end up with adulterated food or medicine, unsafe engine parts, or other dangerous fake goods. Liability for those counterfeit products, as well as the negative publicity that can befall a company whose brand has been compromised by piracy, can have devastating impacts on business.

In the United States, the Brand Protection Alliance asserts that counterfeiting and piracy cost the U.S. economy \$200 to \$250 billion per year. The Organization for Economic Co-Operation and Development in Europe calculated that international trade alone in counterfeit goods represented an additional \$200 billion in 2005; the International Chamber of Commerce (ICC) estimates the total counterfeit economy at more than three times that amount. In fact, in the middle of the first decade of the new millenium, ICC figured the counterfeiting industry represented about 10% of world trade, equivalent to the 12th largest economy in the world.

Counterfeit products range from cheap bootleg videos to phony bottles of wine sold for thousands of dollars to fake aircraft parts.

Fortunately, label and packaging technology can help deter or thwart counterfeiters. Printing techniques, materials such as substrates and inks, and high-tech sensors can all play a role in protecting brand integrity.

OVERT AND COVERT

The first decision to make in an effort to protect a brand from counterfeiting is to determine whether the effort should be visible or invisible to the counterfeiter.

A highly visible, or overt, tactic can warn off potential counterfeiters, much as a flashing alarm light does in an expensive car. An adept thief could break into the vehicle and disable the alarm, but is more likely to consider saving the time and hassle by moving on to an unprotected vehicle.

Overt measures can also communicate to consumers. It may put them on guard against counterfeit products. It may reinforce a sales message that says, in essence, “this product is so desirable, people want to counterfeit it.” And it may also reassure customers that the product they are buying is well protected.

By contrast, covert measures tend to be secret and unobtrusive, generally revealed only through close observation or with special readers or detectors. The theory behind covert tactics is often that if counterfeiters do not know what the authentication features are, they are less likely to fake them.

Many anti-counterfeiting efforts rely on a combination of overt and covert methods. It’s like protecting your home with a good lock, a loud dog, and a burglar alarm.

TACTICS AND MATERIALS

The U.S. \$20 bill introduced in 1998 illustrates the use of a variety of anti-counterfeiting features, all of which may be employed in the manufacture of labels and packaging. Rare paper, embedded fibers and strips, watermarks, sophisticated printing, special inks—each feature makes the bill difficult to reproduce and easy to authenticate.

Special Paper

The U.S. currency anti-counterfeiting effort begins with cotton/linen paper manufactured specifically for the U.S. Bureau of Engraving and Printing for the production of currency. A swipe with an iodine pen is an easy authentication measure: Unlike wood-based paper, which contain starches that turn black in the presence of iodine, the linen/cotton blend will not show a dark line where the pen left its mark.

In addition to its unique composition, the banknote paper includes embedded red and blue fibers, so average paper stocks cannot be substituted for the real thing.

Papers with embedded fibers or planchettes—inclusions that look like confetti or tiny dots—are widely available as label stocks. Even the use of expensive or unusual substrates, such as textured stock or parchment, may serve as a mild deterrent to counterfeiters.

Watermarks

Watermarks are a classic anti-counterfeiting feature found in the U.S. notes as well as currency and other important documents around the world. A watermark is created during the manufacture of the paper: While the paper is still wet, it is pressed with a cylinder roll bearing an image in relief. The raised areas on the roll compress fibers in the paper, making the paper thinner in those areas. Thinner paper transmits more light, allowing the watermark to “appear” when light is shined through the note.

Embossing

Embossing a document, label, or package—creating a raised figure or pattern on the surface using a die, heat, or varnish—can be used to deter counterfeiters. Embossing and texture are increasingly important as scanners and printers improve. Though new imaging technologies are better than ever at reproducing color and print quality, they cannot reproduce the texture of an embossed surface.

Reactive Inks

Inks formulated to react to stimuli by changing color challenge counterfeiters and can be relatively easy for consumers to recognize. The $20 bill features an optically variable ink (OVI) that appears to shift from green to black as light hits it from different angles. Thermochromatic inks, which change color in response to changes in temperature, can be activated when a shopper puts her thumb on a label. Other inks may fluoresce in the presence of ultraviolet (UV) light or change colors when exposed to specific chemicals.

Inks with highly specific spectral signatures can be authenticated with photospectrometers, even when they appear no different from counterfeiters’ inks to the naked eye. Inks provide a good illustration of the difference between overt and covert technology. Thermochromatic inks are overt—the authenticating feature can easily be seen by the public. Measuring the photospectral signature of an ink requires a specialized reader and the knowledge that the feature is included in the package, making it a covert technology.

Taggants

Inks may also be impregnated with taggants, microscopic markers that can be detected with various decoders. For instance, a microscope can reveal cell-sized particles that feature a company’s logo. A hand-held reader wand can detect specific reflection, refraction or electromagnetic properties of taggants in ink. One Australian wine producer even blended DNA from a grape vine into its label ink as a very unique taggant.

Printing Techniques

High-quality printing is a classic anti-counterfeiting measure. Microprinting, or the creation of extremely tiny characters such as the words “United States of America” around Andrew Jackson’s portrait on the U.S. $20 bill, cannot be readily achieved by most small printers or replicated on inkjets in a home counterfeiting operation. Similarly, printing elaborate scrollwork and other ultrafine geometric patterns—called guilloche printing—can challenge counterfeiters. Some anti-counterfeiting companies offer sophisticated guilloche patterns that reveal a signal word, such as “VOID,” if a protected document is photocopied. Digital “watermarks” can be embedded in graphics and detected by scanners.

Holograms

A technology that got its start in the 1940s, holograms have long been used to authenticate valuable items such as credit cards, electronic parts, software, and even clothing.

There are two types of holograms. Surface-relief, or rainbow transmission, holograms are the familiar rainbow-colored images that are common in packaging because of their low cost and minimal thickness. Surface-relief holograms are embossed onto thermoplastic film backed with aluminum. Lippmann holograms—created by capturing wave interference patterns on special photographic materials—offer the illusion of greater depth and clarity, are more difficult to produce, and can include multiple frames, microprinting, and extremely fine details that can aid in authentication.

Holograms are interesting and attractive enough to capture the eye of consumers, which offers some overt brand protection, but the relative ease of counterfeiting surface-relief holograms themselves mean that the most effective security features on a good hologram are more covert.

A variant on holograms, latent image technology, uses a polarizer to reveal a very sharp, difficult-to-counterfeit image.

Electronic Tags

Integrated circuit (IC) and radio-frequency identification (RFID) technologies are catapulting anti-counterfeiting efforts to a new level. Tiny printed circuits can be affixed to labels and packages to carry significant amounts of information. Active RFID chips draw power from built-in batteries to send a signal many meters; as battery technology becomes increasingly miniaturized and inexpensive, active RFID will find many new uses in packaging. Passive RFID chips do not require a power source—a radio query from an electronic reader provides enough energy to allow the chip to report its data—so they can be extremely small, thin and inexpensive. Users may write new information to IC tags, adding flexibility.

TAMPER EVIDENT FEATURES

Rather than try to reproduce a package, some counterfeiters use a brand's genuine packaging and refill it or adulterate the ingredients. Any tampering with a package represents a significant threat to both the brand and the consumer, so anti-tampering features can be extremely important elements of a brand protection campaign.

From the days of sealing wax, signet rings and signatures across the folds of an envelope, tamper-evident features have been employed. In many ways, the principles remain the same as they have been for centuries.

Induction Sealing

The familiar foil seals under the lids of products from pain reliever to peanut butter utilize a technology called induction sealing. A laminate consisting of a foil and polymer on a paper backing is placed across the top of a plastic or glass container. Passing the container and lidding material under an electrical induction coil causes the foil layer to heat up in response to the electromagnetic energy supplied by the coil. The foil is released from the backing, and the polymer (heated by the aluminum) fuses with the lip of the container. The result is a tight seal. Any attempt to access the contents of the container is immediately apparent in the form of a torn or missing seal. Many induction seals are designed to leave a residue on the lip of the container, showing that the laminate has been removed.

Tamper-Evident Films

Many polymer materials are employed as heat-sealed wraps or capsules over lids to provide evidence of tampering. The materials are typically quite durable, but are prone to ragged tearing or shattering when someone applies force to them or attempts to slip them off of the package. Many tamper-evident films also include holograms or other anti-counterfeiting features to establish authenticity and to ensure that they are not replaced with a simpler shrink film after the package has been opened.

Tamper-Evident Labels

Some pressure-sensitive labels include a layer that remains firmly adhered to the product, leaving behind adhesive residue or displaying a message such as "void" if the label has been removed. Other labels are constructed with perforations or built-in weak points to prevent their intact removal. (This is often seen with price tags, which are difficult to remove intact and move to a more expensive product. The same benefits apply when preventing the movement of wine or pharmaceutical labels to unauthorized packages.)

RFID Chips

Radio-frequency identification (RFID) chips are playing an increasing role in tamper protection. Active RFID chips, which include a power supply, can sound a radio-frequency distress call, including specific product or package information, if they have been tampered with. Passive RFID chips, which respond to electronic queries from readers, may provide evidence of tampering when they are deployed on destructible labels—tampering destroys the antenna, so the chip's non-performance can serve as a warning that tampering has taken place.

ANTI-FOG COATING

Craig D. Boyd
Sun Chemical

One of the main purposes of a package is to facilitate consumers to repeatedly purchase the product that it contains. Inks and coatings are continually expected to have a higher contribution to the overall performance and/or aesthetics of the package. There is possibly no coating that offers a more significant effect on the consumers' acceptance of a package than the anti-fog coating.

CONDENSATION PROBLEMS DEFINED

Whenever a sealed high-humidity environment is placed through a temperature gradient, moisture condensation will occur. This condensation will materialize as small beads of water droplets forming on the inside of the package. The droplets will begin to vaporize and then form a fog on the inside of the package and transform a clear package into an opaque one and thus conceal the contents from the consumer. Most manufactures want the consumer to see their product. This is normally achieved either by packaging the product in a clear film or by printing a pictorial of the product on the outside of the package. Therefore, it is obvious that when a manufacturer packages a product in a clear package, they expect that it will remain clear. The produce manufacturer wants the consumers to see the multicolor mixture of the green lettuce, orange carrots, red cabbage, and radishes.

CONVENIENT, HEALTHY EATING

In order to attract more consumers, produce manufactures are marketing the convenience of prewashed produce. These packages are an attractive way of quickly preparing a healthy meal. Today, there are literally dozens of different salad and vegetable blends sold in the produce department in the grocery store. These packages are sealed in a plastic bag and the produce contains a relatively large amount of moisture.

REFRIGERATION UNIT TYPES

There are two different classification of refrigeration units used in the produce section of the grocery store. They are either vertical or horizontal. Because cold air is denser than warm air, the horizontal refrigeration units allow for the entire package to maintain a consistent temperature and therefore will not produce a great amount of condensation. The main drawback of the horizontal unit is that it conceals the packages from consumers as they navigate through the produce section. Because of this, the horizontal unit is not used very often any more. The vertical unit, when positioned properly in the store, can allow consumers to see products from virtually across the produce section of the store. The largest problem with the vertical unit is that it allows the refrigerated package to be in direct contact with the warm ambient air in the store. This configuration is a perfect design to allow the outside of the package, the side facing the consumer, to be exposed to a rather drastic temperature gradient. Thus vertical units create a perfect environment for the generation of a great amount of moisture condensation. In the vertical refrigeration unit, only the most outside package will experience condensation. Therefore, the greater the popularity of the product, the less time any one package will set on the outside of the unit. Ironically, the less popular the product, the more the package will require an anti-fog coating.

PRODUCE PACKAGE TYPES

Produce packages fall into two different categories. First is the “pillow” pouch. These pouches are made from soft, subtle films that will contain loose packaged produce. This is the most popular package for produce. Lettuce and cole slaw blends as well as baby carrots and small pieces of vegetables such as broccoli flowerets are usually packaged in the pillow pouch. These pouches have very little rigidity and thus the package will contain many wrinkles to allow for the water droplets to collect. The second type of produce packages are vertical stand-up packages. These vertical packages are made from very rigid films and will not allow any wrinkles to form. These packages usually contain more rigid produce like romaine lettuce or celery stalks. In order to work properly, these packages will utilize different types of anti-fog coatings. The rigid packages will be printed with an anti-fog that will cause the condensation to bead up and then gravity will draw the water beads to the bottom the pouch where they will do no harm. The pillow pouch will use an anti-fog that will allow the water vapor to easily wet out the wrapper. This way the moisture will not gather and will not create any fogging. This type of anti-fog is required for the pillow pouch because the wrinkles will cause the water beads to gather and will eventually cause fogging. The coatings for rigid pouches are designed to produce a dried coating that will have a very low surface energy, while the coatings for the pillow pouches are designed to have a very high surface energy.

NOT JUST PRODUCE PACKAGING

Anti-fog coatings are used not only in produce packaging, but often also in raw and prepared meat and poultry packaging. For example, meat may be packaged in rigid trays using modified atmosphere packaging (MAP), where the trays are flushed with an optimum composition of O_2/N_2 and then sealed with a shrink film. These packages allow a greatly increased shelf life when compared to the old-fashioned meat wrappers. However, these packages can easily experience condensation and will often need an anti-fog coating on the inside of the shrink film. Preprepared meats have become very popular at grocery stores. Rotisserie chickens are available at most grocery stores. These chickens are placed in an opaque rigid tray and then covered with a clear rigid bubble. The inside of the clear bubble will often contain an anti-fog coating.

NOT ALL REFRIGERATED PACKAGES REQUIRE ANTI-FOG COATINGS

Any package where the film is in direct contact with the product does not require an anti-fog coating no matter how much moisture the package contains. When the film is in direct contact with the product, no matter how the structure of the refrigeration unit, there is no area of air space that will allow the formation of condensation. For example, an unwashed head of lettuce with a film that is tightly wrapped around the lettuce will never experience condensation and therefore will not require the use of an anti-fog coating. Another example of a package that will not contain an anti-fog coatings are meat wrappers that are in direct contact with the meat. For example, the old-fashioned styrofoam meat trays that are tightly wrapped with a flexible film do not require an anti-fog coating.

ANTI-FOG COATING APPLICATIONS AND FORMULATIONS

Since anti-fog coatings are designed to deter condensation formation on the inside of the package, these coatings are always applied to the inside of the wrapper. Therefore, all anti-fogs at a minimum have two things in common. They must be FDA compliant for direct food contact and must be designed to print and adhere to the untreated side of the film. Since the inks are applied to outside of the film, the treated side is always on the outside of the package. These coatings are normally applied with at a very low coating weight, resulting in a very thin film of <1μm. Anti-fog coatings are tested for smudge resistance, block resistance, and offset (transferring to the back side of the film) resistance.

Some anti-fog coatings will affect packaging seal bond strengths, while other will not. The coatings that do interfere with seal bonds must be patterned out of the heat seal areas. Anti-fog coatings can be difficult to reach correct register because they are absolutely clear. Therefore, the coatings that do not interfere with heat seal bonds are more popular. The problem with these coatings is that they are much more prone to offsetting, so achieving the correct film weight is essential with either coating. Excessive coating applications can greatly interfere with heat seals, while a lack of coating will not allow the coating to reach its anti-fog potential.

Anti-fog coatings for flexible films are normally applied using the flexographic process; coatings for rigid dome lids for the precooked poultry are normally spray applied.

CONCLUSION AND REVIEW

Some flexible substrates are manufactured with anti-fog agents added to them. These films will only provide marginal anti-fog properties because the active agents are diffused throughout the entire thickness of the film, while the coatings are concentrated on the surface. Therefore, the use of anti-fog coatings are typically required for high-performance applications.

There is far more to anti-fog coatings than immediately meets the eye. Whether a package receives an anti-fog coating is always the decision of the manufacturer. This decision is based on the type of the product, the type of refrigeration unit, and the turnaround time of the product. The requirements for the correct type of anti-fog are mostly dependent on the type of product and package. The purpose of anti-fog coating is to allow the clear film to remain clear so that the consumer can easily see the colorful and wholesome product that the package contains. The main use of anti-fog coatings is a matter of manufacturers wanting to increase market share and product differentiation.

ANTIMICROBIAL PACKAGING

INTRODUCTION

In the past, the functions of packaging had been limited to the roles of containment, protection of its content from environmental effects, consumer convenience, and communication of the product information. While the conventional functions of packaging was considered as passive, the new paradigm of packaging—called *active packaging*—has been emerged. The active packaging may be defined as a packaging system in which the product, the packaging, and the environment interact in a positive way to extend shelf-life or to achieve some characteristics that cannot be obtained otherwise (1). Antimicrobial packaging is a form of active packaging that can control the growth of microorganisms on the surfaces of foods and packaging materials and eventually reduce cell counts in the products.

Antimicrobial function of packaging materials can be achieved by providing unfavorable environmental conditions to microorganisms by eliminating growth requirements, rendering direct contact of microorganisms to the immobilized antimicrobials on the packaging material surface, or transferring antimicrobial agents originally incorporated into the packaging materials. With the above actions, antimicrobial packaging extends the shelf life of food and secure consumer safety by controlling spoilage and pathogenic microorganisms in foods.

According to the Flexible Packaging Association (2), the market size of flexible packaging in the United States in 2007 is about $23,500 million, garnering 18% $130,000 million packaging market. The largest market for flexible packaging is food industry (retail and institutional) accounting for over 57% of shipment. Active role of food packaging has been empathized for sustainable development of food packaging industry. Antimicrobial packaging would make the food packaging industry possible to achieve an innovative development with the aid of regulatory requirements such as food product liability and HACCP. Therefore, research and development trends of antimicrobial packaging systems may progress to achieving more effective antimicrobial activity with broader spectrum, utilizing natural extracts and creating new applications.

A BRIEF HISTORY OF ANTIMICROBIAL PACKAGING

Early Works on Antimicrobial Packaging

As an early stage application of antimicrobial packaging, shelf-life extension of perishable product had been achieved by applying modified atmosphere packaging (MAP) technologies that provided adverse environments of microbial growth. MAP eliminates oxygen level and elevates the concentration of carbon dioxide to inhibit the growth of aerobic microorganisms.

The antimicrobial polymeric materials were first introduced to protect biomedical devices from microbial contamination in Japan (1). A considerable progress in antimicrobial packaging technology has been made in 1990s, and various antimicrobial products was developed and commercialized in household goods, textiles, surgical implants, biomedical devices, and food packaging materials. The progress could be attributed to the development of inherently antimicrobial polymers and also to the development of antimicrobial agent that was incorporated into polymer matrix. For example, chitosan-based polymers and copolymerized acrylic with protonated amine co-monomer have been developed as antimicrobial packaging materials (3). Preservatives with antimicrobial activity play an important role in preventing microbial contamination. Many of these agents such as silver substituted zeolite, potassium sorbates, sodium benzoate, propionic acid, and acetic acid have been successfully incorporated directly into packaging materials to control the microbial contamination (4, 5).

Current Works on Antimicrobial Packaging

The use of chemical preservatives as antimicrobial agents caused public concerns on the potential risks of chemical preservatives that might migrate into food products. These agents are categorized as food additives and controlled by legislation.

Although the chemical preservatives in packaging materials had been carefully regulated by domestic authorities, the increased consumer demand for preservative free foods has rendered the development of antimicrobial packaging with natural antimicrobial agents. The natural antimicrobials and GRAS antimicrobials may include bacteriocins, enzymes, plant extracts, and natural essential oils (5, 6). They hold a great potential and represent excellent activities for controlling microbial contamination. With the effort of finding safe antimicrobial agents, considerable studies have been exerted on developing antimicrobial biopolymer matrix as a carrier for natural antimicrobial agents (6).

ANTIMICROBIAL PACKAGING SYSTEM

Antimicrobial packaging is a system that is designed to control the growth of microorganisms by extending the microbial lag phase and by reducing the growth rate, thereby extending the shelf life of perishable products and enhance the safety of packaged products (4). Antimicrobial packaging can be constructed using antimicrobial packaging materials and/or antimicrobial agents.

Antimicrobial packaging systems can be classified into three types according to the mode of antimicrobial agent's action: absorption, release, and immobilization (5). The first type is the packaging materials containing antimicrobial agents that eliminate oxygen and moisture in the packaging system by absorption. This type of packaging controls the growth of microorganisms by providing unfavorable conditions to cell growth. The second is the packaging materials containing antimicrobial agents that migrate to the surface of food materials. The antimicrobial action is achieved by the release of the antimicrobial agents from the packaging material. The third type is those containing antimicrobial agents without migration. This type of packaging needs direct contacts between packaging materials and food product since the antimicrobial agents in the packaging material does not release into foods.

The antimicrobial agents may be coated, incorporated, immobilized, or surface modified onto the packaging materials according to the characteristics of the antimicrobials and to the antimicrobial mechanisms how the agents are working (6). Thermal polymer processing methods such as extrusion and injection molding are used for heat-stable antimicrobial agents like silver substituted zeolites. Meanwhile, solvent compounding methods may be a more suitable method to combine the antimicrobial agents and the packaging materials for heat-sensitive antimicrobials such as enzymes and volatile compounds (7).

Antimicrobial Packaging Containing Oxygen Absorbing Agent

Modified atmosphere packaging (MAP) with the absence of oxygen along with elevated concentration of carbon dioxide has been used for controlling the aerobic microorganisms that are responsible for food spoilage. Generally, oxygen concentrations of 0.1% v/v or less in package headspace are required to inhibit the growth of aerobes (1). However, MAP does not guarantee this anaerobic condition in the packaging system throughout the shelf life since the flexible packaging materials show considerable gas permeabilities. Introduction of oxygen absorbing agent in the packaging system rendered active control of oxygen level in the package headspace suitable for antimicrobial purpose by removing oxygen molecules.

In general, oxygen scavenging technologies are constructed by the oxidation of oxygen absorbing agents: iron powder, ascorbic acid, photosensitive dyes, enzymes (e.g., glucose oxidase and alcohol oxidase), unsaturated fatty acids (e.g., oleic acid or linoleic acid), and immobilized yeast on a solid substrate (8). Iron-based material is known to the most effective oxygen scavenging system among the above substances. It has been reported that 1 g of iron will react with 300 ml of oxygen (8). The oxygen-absorbing antimicrobial packaging has been successfully commercialized in bakery, pasta, and meat products by applying the agents enclosed in sachets or incorporated in polymer matrix. Recently, diversified matrices for oxygen absorbents are available in film, tray, label, and closure liner as well as sachet (8). In spite of the strong antimicrobial activity of the oxygen scavenging system against aerobic microorganisms, this system does not possess the effective activity against anaerobic microorganisms.

Antimicrobial Packaging Containing Antimicrobial Agent that Migrate into Food

The packaging materials may act as a carrier for antimicrobial agents to perform their active role to control microorganisms. Some of the antimicrobial agents may be coated or directly incorporated into the packaging materials and subsequently migrate to the food system. The antimicrobial action is achieved by release of the antimicrobial agents from the packaging material. The released antimicrobial agents control the growth of microorganisms by altering cell membrane properties or by inhibiting essential metabolic pathways of the microorganisms (4–6).

Most spoilage incidents occur primarily at food surface by the contamination of aerobic microorganisms. The concentration of the antimicrobial agents above their minimal inhibitory concentration (MIC) is required to impart antimicrobial function. Without the antimicrobial packaging concept, the excess amount of preservatives such as benzoates and sorbates should be included in foods to control the spoilage microorganisms. Thus, releasing antimicrobial additives to the food surface conveniently increases the additives concentration in the food surface above the MIC while maintains the preservative concentration inside the food at sufficiently low level (4). Considering that the use of preservatives for shelf-life extension has been strictly controlled by food safety authorities, antimicrobial packaging is advantageous in reducing potential risks of consuming excess amount of food preservatives.

An additional advantage of antimicrobial packaging is the sustainable antimicrobial activity. The antimicrobial agents initially included in food ingredients might be inactivated by interacting with other food components. For example, bacteriocins and enzymatic antimicrobial agent applied in the foods or onto the food surface may interact with proteolytic enzymes in food and may cause the loss of antimicrobial activities. On the contrary, incorporation of the above substances in packaging films did not cause the loss of antimicrobial activity, controlled the release of the antimicrobial agents, and maintained antimicrobial activity for fairly long periods.

Nonvolatile Migration. The incorporated antimicrobials are migrated to the food surface in either solute or gas states. The migrating solutes are nonvolatile materials such as organic acids and their salts, enzymes, bacteriocins, fungicides and some of natural extracts, while the gases are volatiles such as alcohols, small phenolics, aldehydes, and others (4–6, 8). They moved from the film matrix to the food surface and diffused or dissolved into the food. Diffusion is a primary mechanism of nonvolatile solute transfer in the film matrix, in which relates to the release rate. The migration kinetics of nonvolatile solute followed the Fick's second law of diffusion, where diffusion coefficient depends on the type of film materials, microstructural voids in film matrix, and environmental temperature (9, 10). The migration of the antimicrobial agents in the film to the food surface requires directly contact. The contact between the film matrix and the food surface throughout the shelf life should be assured for their migration and, consequently, their antimicrobial action. For this, the food should be a continuous matrix without any factors that interfere with the diffusional migration. This food matrix could be a liquid solution, a semisolid paste, or a smooth solid matrix without significant pores, holes, or heterogeneous particles. The antimicrobial agents in the food surface will move into the center of the food by diffusion or dissolution. The solubility and diffusion coefficients of the agent in the food are very important factors that govern the rate of agent removal in the food surface. The antimicrobial concentration in the food surface could be maintained above the MIC for their effectiveness in controlling the microbial growth when the agent transfer in the food and films are balanced (5).

Volatile Migration. The migrating antimicrobials could be gaseous compounds released from a gas emitting material. The gaseous antimicrobials can be migrated into the food surface and its packaging headspace or into the air gap between the package and the solid food (4).

The migrating volatile gases include SO_2, ethanol, essential oils, and a component of natural herb and spice extracts. The advantage of using volatile antimicrobial agents is that the packaging film does not need to contact directly to the food surface. Therefore, food matrix in this system could be highly porous foods, powdered foods, particulate foods, or shredded and irregularly shaped foods. Sometimes, however, the use of volatile antimicrobial is limited by the incompatibility of the agent with the packaging materials, or by the loss of volatile antimicrobials during incorporation into packaging by extrusion or coating (5).

The volatile antimicrobial agent initially incorporated in the packaging film or sachet material is transferred to the film surface and subsequently evaporated to the packaging headspace. The vaporized agent in the headspace is then absorbed to the food surface. Eventually, the agent concentration in the food surface is equilibrated with the volatilized antimicrobials in the headspace (4). For the antimicrobial efficacy of the agent, the agent concentration in the food surface should be maintained above the MIC of target microorganisms. The concentration of migrated agent in the food surface is determined by the release rate of the volatile agent from the packaging material and by the absorption rate of headspace volatile agents into the food. The release rate of the agent from the packaging material to the headspace depends on the volatility of the agent which represents the partitioning behavior between packaging material and headspace. The absorption rate of the agent into food depends on the solubility of the agent into the food ingredient. Therefore, the composition of the food is a very important factor of the agent's solubility to the food materials. In general, the volatile agents are more soluble in lipid foods than in hydrophilic food materials.

The desired antimicrobial concentration of a food surface can be attained by controlling the release rate of antimicrobial agent from the packaging material surface. When we use an appropriately selected film layer that has a specific permeability of the volatile substance, the antimicrobial's release rate could be controlled efficiently. The microencapsulation of the volatile substance with appropriate wall materials may control the release of antimicrobials. This encapsulation method can also provide a solution against the loss of volatile antimicrobials during packaging material fabrication processes.

Antimicrobial Packaging without Antimicrobial Agent Migration

Antimicrobial packaging can also use agents that are not migrated into the food. The nonmigrating antimicrobial packaging system can be achieved using inherently bioactive polymers or developing novel packaging materials where the antimicrobials are attached to the nonactive films by either covalent bond or ionic immobilizations (4). In this antimicrobial packaging system, many antimicrobials are enzymes or chemicals that are directly and indirectly participated in the microbial inactivation function. They participate in the biological reactions that lead to the microbial inactivation or produce biologically active radicals, ions, and reactive singlet oxygen that may induce antimicrobial effects.

Since the biologically active compounds are not mobile, the incorporation of the antimicrobials in the matrix during film fabrication processes is not considered necessary. Although the incorporated antimicrobials uniformly distributed in the film matrix, their activity is limited to the film surface only. Therefore, imparting a biologically active ingredient to the film surface would be sufficient to exhibit the antimicrobial efficacy of the nonmigrating antimicrobial packaging film. Therefore, assigning an antimicrobial activity without migration of antimicrobials can be performed by immobilizing nonmigrating antimicrobials on the polymer film surface, by coating a very thin layer of active matrix on to the packaging film, or by attaching antimicrobial compounds covalently on the film surface with the aid of multifunctional ligands (11).

The active materials in the film surface may catalyze antimicrobial action or provide sufficient energies to form ions and radicals on the food surface which are capable to control microbial growth. Therefore, this type of antimicrobial film is particularly effective for the packaging with liquid food and is advantageous for regulatory compliances. Since antimicrobial agents do not migrate into the food system, the antimicrobial agents that are not permitted as food ingredient and food additives may be used for this purpose as food contact substances.

Inherently Antimicrobial Packaging Materials. Some polymers are inherently antimicrobial, and they have been utilized in many fields currently such as biomedical instruments, filters, membranes, and packaging materials. Cationic polymers such as chitosan, poly L-lysine, lysozyme, and numerous synthetic polymers that have quaternary ammonium, phosphonium, and biguanide compounds have exhibited to be effective antimicrobial polymers.

It has been well known that chitosan (a natural polysaccharide), and its derivatives have an antimicrobial effect due to the presence of a positively charged ammonium group. Besides the natural antimicrobial polymers, antimicrobial synthetic polymers have been produced by polymerizing biologically active monomers. The widely used biologically active materials for synthetic polymers are the cationic compounds including quaternary ammonium compounds (QACs), biguanide groups, quaternary pyridinium compounds, phosphonium compounds, sulfonium compounds, and 2-(4′-thiazolyl) benzimidazol (TBZ) (Table 1). The functional groups are linked to reactive groups of monomers and, in turn, have been polymerized to form synthetic antimicrobial polymers (Figure 1). Therefore, most synthetic antimicrobial polymers can be understood as polymerized biocides, and the polymer backbone has the multiplied activity of the antimicrobial functions of attached biocides. Many of these polymers are amphiphilic and positively charged.

The antimicrobial action of polycationic compound has been considered as the disruption of cytoplasmic membrane of bacterial cell (13). Polycationic antimicrobial polymers are absorbed onto the negatively charged bacterial cell surface at physiological pH by electrostatic interaction. The absorbed polycations are bound to cytoplasmic membrane, and disrupt it. The consequent leakage of potassium ions and other cytoplasmic constituents lead to cell death. In particular, the mode of antimicrobial action of QACs is the damage of cytoplasmic membrane of bacteria through surfactant-like interaction resulting in the loss of permeability properties of the membrane (14). This means that the functional groups of the antimicrobial polymer must diffuse through the microbial cell wall, be water soluble, and have no interaction with the microbial cell wall. For this, spacer molecules that link the biologically active agents to the polymer backbone are required to allow the agent to have sufficient freedom of motion when the polymer backbone does not act as the spacer (11).

Physical modification of polymers often produces biologically active packaging films. Ultraviolet or electron beam irradiation on polyamide films increases positively charged amine concentration on the film's surface, resulting in enhanced cell adhesion potential. However, this type of film has limited microcidal effect, and microbial adsorption on the film surface diminishes antimicrobial activity. Incorporation of antimicrobial agents into this film matrix may overcome these drawbacks successfully (7).

Immobilized Antimicrobial Agents in the Packaging Film Matrix. The immobilized antimicrobial agents are not removed from polymer surfaces. Various immobilization techniques have been developed to overcome the contact problems of antimicrobial residues to food surfaces.

The antimicrobial materials used for immobilization include the hydrolysis product of a quaternary amine-containing organosilicon salt, hexachlorophene, acriflavine, antibiotics such as streptomycins and gentamycins, and antimicrobial enzymes including lactoferrin, sulfhydril oxidase, and bile-salt- stimulated lipase. The changes

Table 1. A List of Synthetic Antimicrobial Polymers with Their Active Compounds (12)

Active Compound	Biologically Active Polymer
Quaternary ammonium compounds (QACs)	Poly[{dimethylalkyl-3-(and -4-)vinylbenzyl}alkylammonium chlorides]
	Polyionenes (in-chain QAC of *p*-xylene spacer, in-chain QAC of hexamethylene spacer)
	Hydroxyterechelic polybutadienes carrying covalently-bonded QAC
	Polysiloxanes with pendant primary alcohol groups
Biguanide group	Poly(hexamethylene biguanide hydrochloride)s
	Polymer of methacrylate containing biguanide units
Quaternary pyridinium salt	4-[2,29-Bis(ethoxycarbonyl)ethyl]-1-alkylpyridinium bromide
	Poly[iminoethyleneimino-2-[(1-butyl)pyridine-4-ylmethyl]malonyliminoethyleneiminoadipoyl bromide]
Phosponium salt	Poly{trialkyl-3-[(and-4-)vinylbenzyl]phosphonium chloride}
	Poly([ethylenebis(diphenylphosphonio)]ethylene dibromide)
	Poly{[4-(2-tributylphosphonioethyl)styrene chloride]-co-4-(2-chloroethyl)styreme}
	Poly{[4-(3-tributylphosphoniopropyl)styrene chloride]-co-4-(3-chloropropyl)styreme}
Sulfonium salt	Poly[*p*-vinylbenzyltetramethlenesulfonium tetrafluoroborate]
2-(4′-Thiazolyl) benzimidazol (TBZ)	Poly[*N*-Acryloyl-2-(4′-thiazolyl)benzimidazol]
	Poly[2,4,4′-trichloro-2′-acryloyloxydiphenyl ether]

in conformation and denaturation of proteins and peptides may result in reduced antimicrobial activities of antimicrobial enzymes. The active site should be protected during the film formation.

INGREDIENT OF ANTIMICROBIAL PACKAGING

Film Matrix

The antimicrobial packaging system is comprised of film matrix and antimicrobial agents. In considering the biologically active role of the antimicrobial agent in the film, the relationships between the film matrix and the antimicrobial agent would be critical, since thermal degradation of the antimicrobial agent during film fabrication and its chemical compatibility with the film material may limit the antimicrobial activity. Synthetic polymeric packaging materials are produced by thermal processing method such as extrusion. Thermally stable antimicrobial agents should be incorporated. In general, synthetic flexible films consist of many layers of different films. Low-density polyethylene (LDPE) has been used for the film layer that is in direct contact with the food. Therefore, LDPE has been most widely used packaging materials among the synthetic polymers for antimicrobial agent carriers. For further modification of the contact film layer, poly(ethylene-co-methacrylic acid) (PEMA) has also been explored as a film matrix (15).

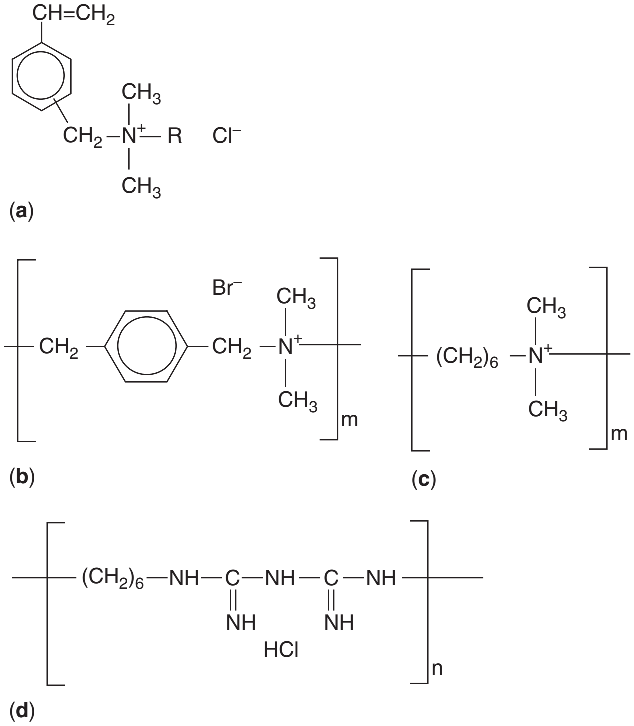

Figure 1. Monomers with antimicrobial activities. (**a**) Dimethylalkyl-3-(and -4-)vinylbenzyl ammonium chlorides, (**b** and **c**) polyionenes, and (**d**) poly(hexamethylene biguinide hydrochloride) (12).

Thermally unstable antimicrobial agents cannot be used with extruded synthetic polymer films, but they can be applied to the biopolymeric film matrix instead. In general, biopolymer films are formed by removing the solvent from the film solution in the cast plate. Therefore, they do not require high temperature for polymer melting. Examples of biopolymers are hydrocolloids including polysaccharide and protein, lipid, and the composite of hydrocolloid and lipid. For antimicrobial purposes, the use of biopolymeric films such as chitosan, soy protein, whey protein, corn zein, methyl cellulose (MC), and hydroxypropyl methyl cellulose (HPMC) films with various antimicrobial agents have been reported (16).

Antimicrobial Agent

The widely used method to inhibit the growth of undesirable microorganisms is the use of chemical agents exhibiting antimicrobial activity. These chemicals may be either synthetic compounds intentionally added to foods or naturally occurring, biologically derived substances. The selection of an antimicrobial agent depends primarily on its activity against the target microorganisms, compatibility with the packaging material, and the heat stability during the thermal process (4–6).

Currently, synthesized chemical preservatives have been widely employed to control the number of microorganisms in the packaged food, but increasing consumer awareness of potential health risk associated with the synthetic agent requires a substituent that is available in the nature. The natural antimicrobial agents such as bacteriocins and spice extract have long been used as constituents of foods and showed negligible toxicity. Therefore, natural antimicrobial agents are on the way of replacing the synthetic antimicrobial agents as food preservatives for direct deposition and also as ingredients of packaging materials for migration into food.

Organic Acid. Sorbic acid, benzoic acid, propionic acid, and their salts have been widely used for preventing microbial deterioration of food. They are on the food additive list in many countries and have been used under the control of regulation for their potential health risk. High polarity of organic acids causes them to be incompatible with the apolar LDPE. Acid anhydrides were thought to be more compatible than free acids and their salts because of their lower polarity. Organic acid antimicrobials could be incorporated into the biopolymeric film for their compatibility.

Inorganic Metallic Ion.

Silver Ion. Silver ions in the microbial cell inhibit metabolic enzymes and have strong antimicrobial activity. Silver ions are generally incorporated into polymer films in the form of silver substituted zeolite, an ionic bonded metallic compound in which the sodium ions present has been substituted with the silver ions. Silver-substituted zeolite is thermo-stable and can be applied to the thermal process of synthetic polymers like polyethylene, polypropylene, and nylon as well as biopolymeric films (11, 17, 18). Silver ions are released from the silver-substituted zeolite incorporated in the film matrix to the food materials for antimicrobial action (18).

Titanium Ion. Titanium dioxide (TiO_2) is nontoxic and has been approved by the U.S. Food and Drug Administration for the use in foods and food contact materials (19). Ultraviolet energy shifts the energy level of TiO_2 to the excited state. On its way back to ground state, TiO_2 releases absorbed energy to the food material (20). The released energy may form very reactive radicals and singlet oxygen which have antimicrobial function. In this system titanium ion is not a migrating agent but trapped in the film structure (20). Currently there is considerable interest in the self-disinfecting property of TiO_2 to satisfy hygienic design requirements in food processing equipment surfaces (21, 22).

Natural Compounds. The naturally occurring antimicrobials are enzymes, peptides, oils, and other materials that have been present self-defense functions against microbial contamination. Typical examples are bacteriocins in lactic acid bacteria, lysozymes in egg white, flavonoids in plant extracts, and essential oils.

Bacteriocins. Bacteriocins are small bacterial peptides that show strong antimicrobial activity against closely related bacteria. Antimicrobial effectiveness of bacteriocins in food is related to specific antimicrobial activity of the bacteriocin, amount of the bacteriocin used, number of microorganisms, process conditions, interaction with food components, and pH and temperature of the product (23).

Nisin is a polypeptide produced by *Lactococcus lactis* spp. It has been approved as a food additive with GRAS status in over 50 countries worldwide. It has a relatively broad spectrum of antimicrobial activity against various lactic acid bacteria and other Gram-positive bacteria (24). It is particularly effective against heat-resistant bacterial spores of *Clostridium botulinum* (25). It is not effective against gram-negative bacteria because it cannot penetrate outer lipid membrane of cell to the cytoplasm (24). Use of nisin in conjunction with ethylenediamine tetraacetic acid (EDTA) may increase the antimicrobial effectiveness against Gram-negative bacteria (26). Nisin has been incorporated into biopolymer films such as soy protein, corn zein, chitosan, and methylcellulose films for antimicrobial edible coating applications (27, 28). The thermal processing in film production may reduce antimicrobial activity of nisin (28).

Lysozyme. Lysozyme, also known as muramidase or *N*-acetylmuramichydrolase, is a relatively small enzyme from hen egg white. Lysozyme is effective against spoilage and pathogenic microorganisms by disintegrating the cell wall structure. Antimicrobial activity of lysozyme is attributed to the function that catalyzes the hydrolysis of the β-1, 4 glycosidic bond between *N*-acetylmuramic acid and 2-cetyl-amino-2-deoxy-D-glucose residues in the bacterial cell wall (29, 30). Lysozyme demonstrates a strong antibacterial potential against Gram-positive bacteria such as *Listeria monocytogenes* (30). Lysozyme has been applied to biopolymer films such as chitosan, whey protein, fish gelatin, corn zein, and sodium alginate films in either purified or unpurified forms alone and in combination with EDTA and other bacteriocins (31, 32). Antimicrobial activity of immobilized lysozyme in polyvinyl alcohol film also has been reported against various spoilage and pathogenic bacteria (33).

Plant Extracts. Antimicrobial activity of phytochemicals in the extracts of spices and herbs has been demonstrated by many researchers (5, 6, 31). In many cases, the concentration of biologically active component in spices and herbs and their essential oils are too low to be effectively used for packaging applications due to their limited sensory acceptance at high concentration level (23). They may be used in junction with other biologically active agents and contribute to total hurdle technology system for microbial control. Many phytochemical compounds in essential oils and extracts responsible for antimicrobial activity are phenolic compounds.

1. *Essential Oils.* Plant extracts of coffee, green tea, spices, and herbs (i.e., cinnamon, cloves, mustard seed, oregano, rosemary, thyme and vanillin) have been evidenced for their antimicrobial activity against a wide spectrum of microorganisms (5, 34). The antimicrobial activities of the spices are

associated with phenolic compounds in their essential oil fraction. The antimicrobial essential oil components of cinnamon and cloves are eugenol and cinnamaldehyde, respectively. Terpenes such as carvacrol, *p*-cymene, and thymol are the major volatile components of oregano and thyme (23). Many essential oils are volatile and can be applied to volatile migration when they are incorporated into the packaging film (31).

2. *Allyl Isothiocyanate (AIT).* Allyl isothiocyanate is a naturally occurring nonphenolic volatile compound responsible for the flavor of horseradish, wasabi, and mustard. Volatilized AIT has an effective antimicrobial activity against variety of pathogens when used at low concentration. AIT causes metabolite leakage by affecting cell membranes (35). Antimicrobial activity of AIT-incorporated gelatin film, nylon 6,6 film, and PVDC/PVC copolymer film has been reported against spoilage and pathogenic microorganisms (36).

COMMERCIAL APPLICATIONS

Commercialized Antimicrobial Packaging

Even though many research works have been conducted all over the world, there are only a few commercialized products of antimicrobial food packaging materials. This is because of strict hygienic regulation on food packaging, high price, and limited consumer perception and acceptance on their effectiveness. The area of food preparation and utensil products has less strict regulation in applying the antimicrobial materials into real practices and has seen a higher number of commercial products—for example, kitchen board and gloves. Table 2 lists some examples of commercial products available in market. The list is not exclusive and covers only those observed in the writers' eye for the last 20 years. Some products available in a country or area may not be allowed for sale in other countries because of the difference in food safety regulation.

In a practical sense, ethanol emitter and plant extracts have acquired wider acceptance, depending on people's attitude and corresponding country's legislation. Some ethanol emitters combine the oxygen-scavenging capacity to inhibit aerobic spoilage organisms. Ag-containing ceramic materials have been applied in plastic films and containers where people generally recognize silver as hygiene-improving and antitoxic material. SO_2 generator may be used in postharvest handling and storage of agricultural products, where agricultural safety practices are applied. A ClO_2-generating plastic tube, Knick'n'clean®, which is activated by bending to mix two fluids in it, is marketed for the use in refrigerators for a limited time period of about 30 days. A ClO_2-emitting film (MicroGarde™) claimed to produce antimicrobial microatmosphere for 10 days keeping freshness of foods and breaking down ethylene gas. Until 2008, ready-to-eat food applications of this system await FDA clearance in the United States. Triclosan is not approved as a food additive and is incorporated into a plastic master batch, which is converted into food-contact household equipments such as cutting board and hand gloves.

Edible coating being a component of food may be applied for antimicrobial function when it contains safe

Table 2. Some Commercialized Antimicrobial Packaging or Food-Contact Materials in Food Storage, Packaging, and Preparation

Active Compound or Releasing Compound	Matrix or Form	Application	Trade Name and/or Producer
Ag-substituted zeolite or zirconium	PVC, LLDPE, PE, rubber	Wrap, film, kitchen board, kitchen glove	Agion® (Agion Technologies, USA), Zeomic™ (Sinanen Zeomic Co., Japan), Cleanaid™ (Gyunghyang Industrial Co., Korea)
Chlorine dioxide	Polyolefin	Film, compartmented stick for refrigerator	MicroGarde™ (BarrierSafe Solutions International Inc., USA), Knick'n'clean® (Helrik Bobke, Germany)
Ethanol	Silicon dioxide	Sachet	Ethicap™ (Freund Corp., Japan), Ageless™ type SE (Mitsubishi Gas Chemical., Japan)
Sulfur dioxide	Laminated plastic sheet with $Na_2S_2O_5$	Sheet or pad for postharvest storage of grape fruits	Uvasy™ (Grapetek, South Africa)
Triclosan	Polymer, rubber, etc.	Food preparation equipment and supplies, kitchen sponge and gloves	Microban® (Microban International Ltd., USA), Ultra-Fresh® (Thomson Research Associates, Canada)
Wasabi (Japanese horseradish) extract	Encapsulation in cyclodextrin	Coated PET film, tablet	Wasapower™ (Sekisui Plastics Co., Japan)

bioactive compounds, organic acids, or edible essential oils of plant or spice origins. Because the coating may be understood as a food component, there would be no barrier of application in the regulations if all active/inactive ingredients are food grade. The potential edible coating matrices include chitosan, hydroxy propyl methyl cellulose, and alginate gels (29).

Effectiveness of Antimicrobial Food Packaging

Many studies showed potential benefits of antimicrobial packaging for fresh fruits and vegetables, milk, beverages, cheese, ham, meat and fish (37, 38). Packaging materials with nisin, chitosan, or acids typically resulted in marginal microbial count reduction of 1.5–2.5 log10 compared to control (37). The reduction or suppression of microbial growth by the antimicrobial packaging is varied too much to conclude that any specific system or condition is universally optimal or better than others. It is generally accepted that the results in microbial media or buffer solutions cannot be directly applied to the real food applications. Conducting test with real food sample is needed for practical or commercial application.

The effectiveness of microbial inhibition by antimicrobial packaging is generally improved when combined with other preservation hurdles such as modified atmosphere, low pH, high-pressure treatment, and low temperature (38–40). Analysis of microbial spoilage kinetics with antimicrobial packaging showed that the microbial growth was suppressed more with lower storage temperature (41). The microbial inhibition of antimicrobial packaging at the low temperature could be represented by low cell concentration, extended lag time, and reduced growth rate.

When the temperature dependence of microbial lag time was analyzed by square root kinetic model [equation (1)], antimicrobial packaging showed higher temperature dependence (increased b value) with increase of hypothetical minimum growth temperature (increased $T_{\min}$) (41):

$$\sqrt{\frac{1}{t_{\text{lag}}}} = b \cdot (T - T_{\min}) \tag{1}$$

where T is the temperature (in °C), b is slope parameter representing temperature effect, and $T_{\min}$ is respective theoretical minimum temperatures for growth estimated by extrapolation of the regression line to the temperature axis (Figure 2).

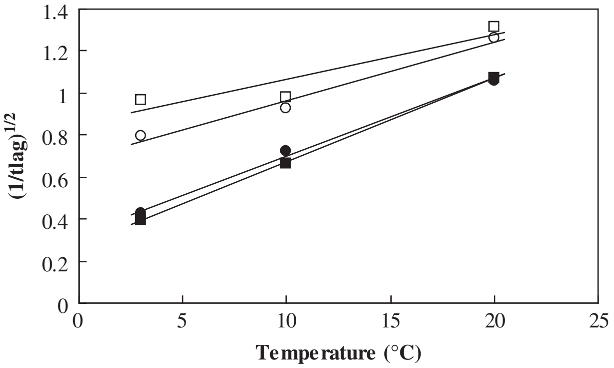

Figure 2. Effect of antimicrobial packaging (incorporated with chitosan and nisin) on temperature dependence of microbial lag time. (□) Yeasts of orange juice in plain package; (■) yeasts of orange juice in the antimicrobial package; (○) aerobic bacteria of milk in plain package; (●) aerobic bacteria of milk in the antimicrobial package. (From data of Ref. (41)).

The effectiveness of antimicrobial packaging may vary with food type, release kinetics of antimicrobial agents, and environmental factors. Many antimicrobial packaging systems that show effective activity with microbial culture media may not work with real foods. Some food components such as fatty acids, amino acids, sulfates, and/or enzymes may diminish the activity of the antimicrobial packaging films (11, 42). Food–package interaction may change the mechanism and effectiveness of microbial inhibition of the antimicrobial packaging system (29). There are possibilities that the incorporation of antimicrobials into the plastic material may change its mechanical, barrier, and optical properties. Sensory properties of food may also be affected by food–package interaction. For example, film with plant extract such wasabi essential oil may alter flavor of the contained food. The antimicrobial packaging may have to be designed, selected, and customized for each food type (43). The packaging system has to be selected after consideration on the primarily concerned target microorganism, spoilage organisms, its activity spectrum, microbial inhibition mode, food properties, release of active agent, and storage conditions.

Regulations

Antimicrobial packaging to be marketed in the United States is subject to the food additive approval process if its components are reasonably expected to migrate to foods for effective microbial inhibition (4). There are two processes of food contact substance approval in FDA: food contact notification process and food additive petition process. Packaging material that has no intended technical effect on the food may be approved by the former process, in which a manufacturer should notify the FDA to market a new product at least 120 days before its introduction and can sell it unless the FDA objects to the notification. However, the material that exerts antimicrobial effect on the food through migration or controlled release needs to be processed through the food additive petition process. Food contact substance notification is specific only to the manufacturer named in the notification, and it does not apply generically to the product category. Due to complicated and strict regulation on approval of antimicrobial food packaging materials, their applications in food packaging is very limited in the United States. Chlorine-dioxide-releasing material seems to reach the commercial stage (42). Some silver incorporated materials are approved for food-contact purpose (6).

Until 2004, plastic packaging regulations in the EU did not allow any specific provisions for antimicrobial packaging and, thus, required that any potential antimicrobial component in the antimicrobial food packaging should be covered by "positive lists," which would have specific migration limit (44). The plastic packaging material should also have met overall migration limit, typically 60 mg per kg food. In 2004, active and intelligent packaging including antimicrobial food packaging has been allowed in the EC Framework Regulation 1935/2004. Further detailed requirements and specification on adopting antimicrobial packaging will soon come out, to include positive lists of authorized substances and/or materials and articles.

General food packaging regulations in Japan made allowances for active packaging emitting ethanol and wasabi extract volatiles to preserve the bakery products and prepared foods. Australia and New Zealand legislation permits silicon dioxide sachets containing ethanol and flavors specifically (45), which may act to inhibit microbial growth.

APPLICATIONS OF PREDICTIVE MICROBIOLOGY TO FOOD PACKAGING

SHIOWSHUH SHEEN
Eastern Regional Research
Center, Microbial Food Safety
Research Unit, Agricultural
Research Service, U.S.
Department of Agriculture,
Wyndmoor, Pennsylvania

INTRODUCTION

This section is to introduce the currently available predictive microbiology models, such as microbial growth, inactivation, survival, and others, to food applications including packaging. Because packaging may be the last step in food-processing operations, it may inherit the consequences of microbial transfer, growth, inactivation, and survival cascaded down during the food manufacturing. Packaging also functions as a protection barrier to environmental changes and potential abuses, which may cause food spoilage. In general, food-processing operations should have eliminated or reduced the harmful microbial counts to a safety level before the final packaging step, which provides a means to control the food qualities, including foodborne hazards. The microbiological shelf life can be estimated or predicted using mathematical models, if available and properly selected.

Microbial safety is one of the major quality control attributes for packaged food. Pathogen contamination in consumer food products happens every year. The development of effective methods to reduce and eliminate the potential microbial food hazards is the primary goal of food scientists, producers, and government at different levels. Several food pathogens have potentials to cause public foodborne hazards including *Listeria monocytogenes*, *Escherichia coli* O157:H7, *Salmonella spp*. and so on. The Centers for Disease Control and Prevention (CDC) estimated that about 2500 cases of listeriosis occurr each year, which results in 500 deaths in the United States. A survey in eight categories of ready-to-eat foods, collected over 14–23 months, from retail markets in Maryland and northern California FoodNet sites showed that 1.82% samples were positive with *L. monocytogenes* contamination (1). The *E. coli* O157:H7 outbreaks in spinaches and ground beef stress the needs of effective means to monitor and to ensure food safety, even more. The most recent *Salmonella* outbreaks in peanut butter indicated that microbial cross-contamination could occur during food production. Pathogenic public health hazard is always on the top of safety list for food producers and inspection agencies. Predictive microbiology is a useful tool to describe, predict, and assess the potential hazard in processed and packaged consumer food products.

The Food and Drug Administration (FDA) and the United States of Department of Agriculture (USDA) have established food-safety regulations that govern the manufacture and distribution of domestic and imported foods to ensure the safety of food supply chain. These regulations are often difficult to locate and/or complicated to comply even for food companies that have resources to employ food safety experts and to interpret the regulations. To promote food safety and reduce the financial burden, especially for small companies, the Predictive Microbiology and Bioinformatics for Food Safety and Security research group of USDA/Agricultural Research Service (ARS)/Eastern Regional Research Center (ERRC) has implemented a 3-year project to create the Predictive Microbiology Information Portal (PMIP) available on the Internet to help food producers and safety researchers better access food-safety information, regulations, and tools at no cost to the end users. The PMIP provides a wide range of food-safety-related information such as regulations, microbiological models, and microbiological data. The portal has been available to the public since September 2007, and it can be accessed at http://portal.arserrc.gov/. The portal was designed to make food regulations and tens of thousands of microbiological data accessible to the public.

The PMIP has been accessed million times from tens of thousands unique Internet Protocol (IP) addresses worldwide since its launch. The microbial modeling component in the portal, the USDA Pathogen Modeling Program

(PMP), was developed and is maintained and regularly improved by the USDA/ARS/ERRC staff. The PMP is a user-friendly software that contain a set of mathematical models, which predict the behavior of major human pathogens in foods under selected environmental conditions commonly used in the food industry. The PMP is used throughout the world to assist food companies comply with food-safety regulations and to reduce the human illness risk through better food process and product designs. The PMP was downloaded about 5000 times annually and is routinely used by 30% of the food industry. The number of downloads of the PMP has increased 40% to an estimated 7000 times/yr since the PMIP launch, which indicates the portal is reaching out a wider customer base including the food packaging and shelf-life applications.

PREDICTIVE MICROBIOLOGY AND FOOD PACKAGING

The predictive microbiology (microbial predictive models) include growth, inactivation, surface transfer (or cross contamination), and survival models, which play important roles in the microbial food safety while tied in the food packaging design to reduce the microbial hazard. The transfer model may predict the pathogen transferred among process equipment or surfaces. The growth models show the potential growth of a specified pathogen under different conditions, e.g., temperature, pH, water activity, added preservative, and so on. The growth models may take into account of other environmental factors, which include modified atmosphere packaging (MAP) conditions, transportation, distribution, and consumer abuses if those factors are built in. Thermal or nonthermal process to reduce or eliminate microbial counts may be evaluated using the inactivation models. For the entire microbial safety assessment in a packaged product, a microbial transfer model can be applied to estimate the quantity of contamination, followed by the growth and/or inactivation models with designed process conditions to predict the potential pathogenic health hazards. With all information collected and available in the models, the users may select the parameters to match the packaging conditions and to predict the shelf life, for example, the fresh-cut packaged ready-to-eat vegetables. Other packaging-related models may apply to the model construction step, which describes the entire production processes to achieve the microbial shelf-life assessment.

Users also can utilize the models and database in the portal (PMIP) to reduce food-safety challenge studies for their new products. The PMP and Combase, which are accessible through PMIP, may provide the useful tools for microbial-safety-related shelf-life optimization and packaging design.

PREDICTIVE MICROBIOLOGY MODELS

For microbial growth, the sigmoid functions have been the most popular empirical models used to describe the microbial growth; one of such models is the modified Gompertz model, which is shown below (2):

$$\log x(t) = A + C\exp\{-\exp[-B(t-M)]\} \tag{1}$$

where $x(t)$ is the number of cells at time t; A is the asymptotic count as t decreases to zero; C is the difference in value of upper and lower asymptote; B is the relative growth rate at M; and M is the time at which the absolute growth rate is maximum or the inflexion point of the curve. Using the parameters in equation (1), the following terms can be derived to characterize the microbial growth:

$$\text{Lag time} = M - (1/B) + \frac{\log N(0) - A}{BC/2.718} \tag{2}$$

$$\text{Exponential growth time} = BC/2.718 \tag{3}$$

$$\text{Generation time} = \log(2)\cdot 2.718/BC = 0.8183/BC \tag{4}$$

The lag phase is the time for microbial to adjust to a new environment, followed by the exponential phase with a maximum growth rate until the available medium deprived or limited by other factors, then to the stationary phase. Baranyi and coworkers (3–5) introduced a mechanistic model, which includes the lag phase, the exponential growth phase, and the stationary phase. The explicit Baranyi model is expressed as the following:

$$y(t) = y_o + \mu_{\max}A(t) - \frac{1}{m}\ln\left(1 + \frac{\exp(m\mu_{\max}A(t)) - 1}{\exp(m(y_{\max} - y_o))}\right) \tag{5}$$

$$A(t) = t + \frac{1}{v}\ln\left(\frac{\exp(-vt) + q_o}{1 + q_o}\right) \tag{6}$$

where $y(t) = \ln x(t)$, $y_o = \ln(x_o)$, and v is the rate of increase of the limiting substrate, which is generally assumed equal to $\mu_{\max}$. Parameter m is an index of the curvature before the stationary phase. The q_o and x_o represent the initial concentration of limiting substrate and cell number, respectively. $\mu_{\max}$ is the maximum growth rate. Baranyi models are more complicated than the modified Gompertz models and may be applied to the dynamic process conditions, e.g., temperature changes with time.

Other predictive models may include inactivation (thermal and nonthermal), cooling survival, and growth under influence of other factors, added or environmental. The growth models are classified as the primary model. The growth and/or inactivation models with parameters that interact with other factors are considered as the secondary models. Recently, the surface transfer models were developed to describe the cross contamination of food pathogens during slicing of foods, e.g., ready-to-eat deli meats, smoked salmon, and so on.

The transfer models typically only consider the pathogens transferred from one step to another step. The microbial counts may be performed at each individual step or at the end of one series of steps. Because it is a continuous and in a relative short time period, no growth or inactivation factors were built in this kind of modeling. The important factors will be the processing parameters used in the process flow, and therefore, empirical models were considered. Typically, a microbial count as a function of several operation parameters was presented. The surface transfer models shown below were the recently developed by Sheen (6) for *L. monocytogenes* transfer during slicing in two cross-contamination routes.

I: Slicing blade to meat product,

$$Y = 0.461 \cdot Exp(0.255 \cdot n) \cdot Exp\left(\frac{-X}{0.0215 \cdot n\hat{}4.962}\right) \tag{7}$$

II: Meat to blade to meat product,

$$Y = 0.495 \cdot Exp(0.244 \cdot n) \cdot Exp\left[\frac{-X}{23.98 \cdot Exp(0.413 \cdot n)}\right] \tag{8}$$

where Y is the log colony forming unit (CFU) per slice; X is the slice number index; and n is the initial microbial count in log CFU.

The general microbial inactivation model developed following the first-order kinetic chemical reaction described the microbial death reasonably well. However, the microbial inactivation could become complicated because of the microbial itself, environment conditions, and treatment applied to kill the micro-organism, especially for food pathogens. Some important parameters may be temperature dependent. The D and Z values, which are typically used in the thermal process to evaluate the thermal lethality and also can be adopted to other inactivation study. To simulate the inactivation, some studies used the curve-fitting method simply fit the experimental data. A nonlinear approach using the power law function that best represented the inactivation is shown as:

$$\text{Log}\,(N/\text{No}) = -(t^p/D) \tag{9}$$

where p is the power. A concave or convex curve is represented by $p < 1$ or $p > 1$, respectively.

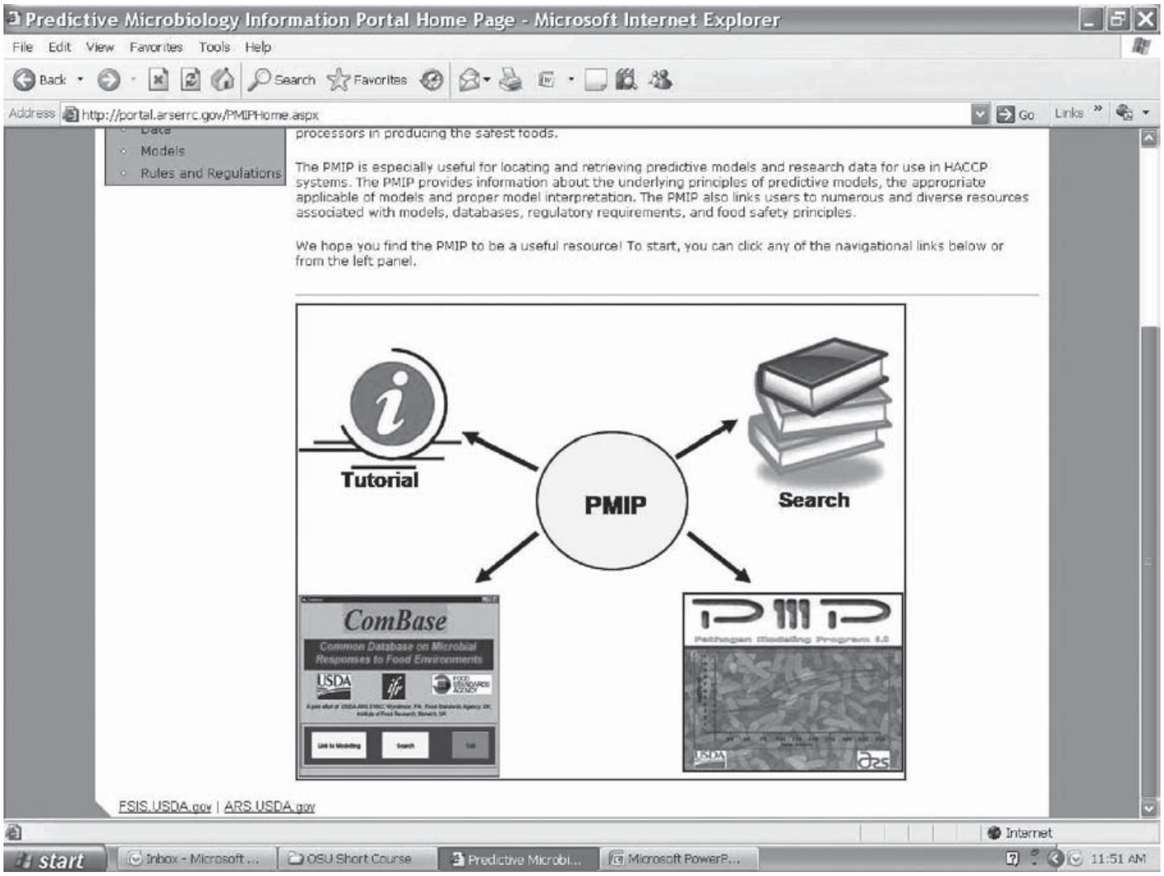
If shoulder or tailing appears in the inactivation curve, then the model will become even more complicated. Researchers have demonstrated that the asymmetric Gompertz function or the mirror image of Baranyi growth model may fit certain nonlinear survival or inactivation curves well.

PMIP AND PMP SAMPLE CASE DEMONSTRATIONS

The homepage of PMIP shown below serves as the gateway to access other components available to the users. It is highly beneficial for the users to navigate the website and become familiar with all options and available data. Two examples are demonstrated.

EXAMPLE 1: THERMAL INACTIVATION OF PATHOGENS IN FOODS

The inactivation on microbial growth due to thermal (temperature) effect can be estimated by using the PMP models,

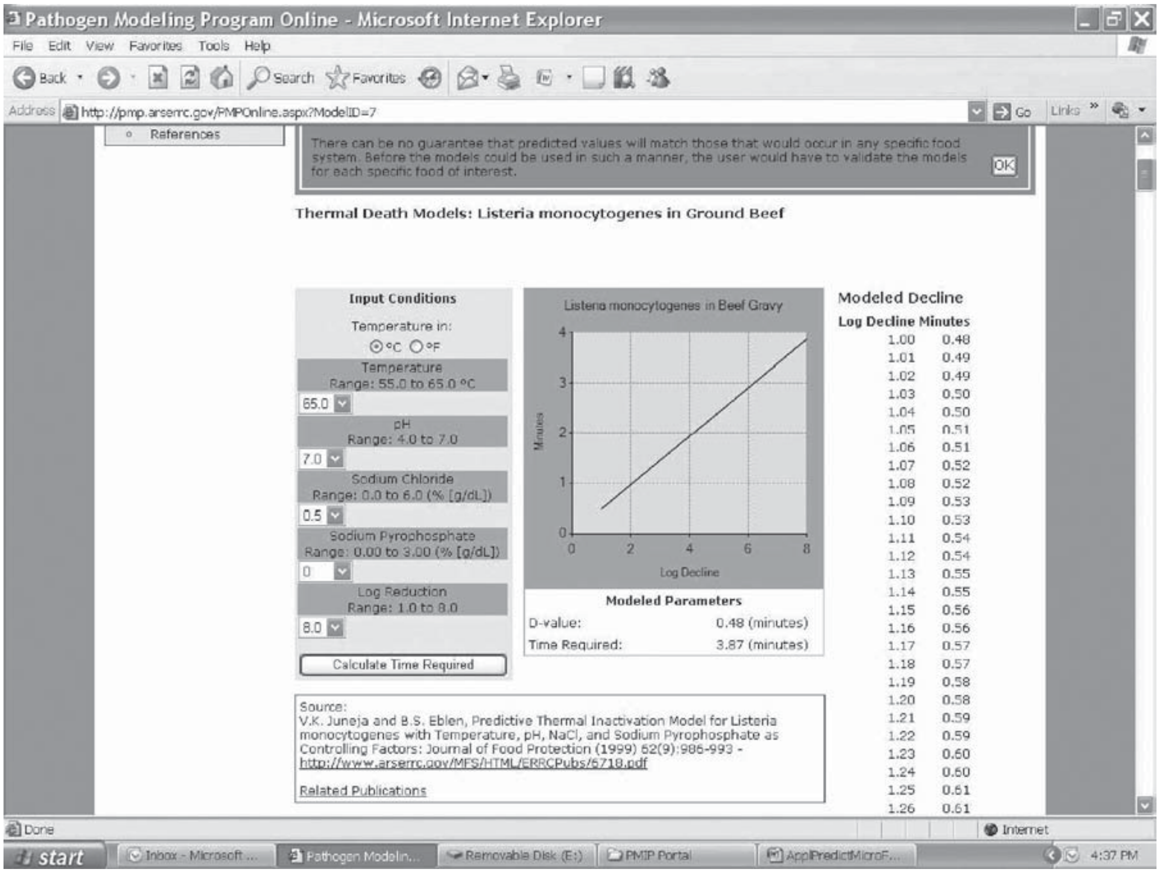


processors in producing the safest foods.

The PMIP is especially useful for locating and retrieving predictive models and research data for use in HACCP systems. The PMIP provides information about the underlying principles of predictive models, the appropriate applicable of models and proper model interpretation. The PMIP also links users to numerous and diverse resources associated with models, databases, regulatory requirements, and food safety principles.

We hope you find the PMIP to be a useful resource! To start, you can click any of the navigational links below or from the left panel.

FSIS.USDA.gov | ARS.USDA.gov



There can be no guarantee that predicted values will match those that would occur in any specific food system. Before the models could be used in such a manner, the user would have to validate the models for each specific food of interest.

which are available to certain food items. The user may select the heat inactivation (under the "Models≫Bacterium" headline, online option), then the "food pathogen" to select the microbe, which leads the user to key in other parameters, like pH, salt content, sodium pyrophosphate, and targeted log reduction. The temperature also needs to be specified for the time-required calculation. The following figure shows the heat inactivation of 8 log *L. monocytogenes* reduction in ground beef requires 3.87 min (D-value = 0.48 min at 65°C). If a lower temperature at 55°C is selected with other factors remained the same, the process time becomes 159.93 min (*D*-value = 19.94 min at 55°C). Therefore, to achieve the desired thermal inactivation, the PMP model may provide useful information to select the proper process with parameters fit to the product.

EXAMPLE II: SHELF LIFE STUDY AND PREDICTION

The PMP models can be used to predict the shelf life of packaged foods. The user may find the parameters to match or closely fit the conditions of a food item and make the reasonable shelf-life prediction. For example, to predict the shelf life of vacuum-packaged seafood salad with the targeted pathogen like *L. monocytogenes* <100 CFU/g, the user may apply the following steps: (a) bacteria≫model; (b) *L. monocytogenes*; (c) growth anaerobic (shrimp and imitation crab salad); (d) select temperature, pH, time duration, time interval, initial level of *L monocytogenes* and level of concern; and (e) calculate growth data. Results will appear on the screen as the following, which indicates the shelf life is about 10 days. For comparison, one may increase the temperature to 8°C and pH to 5.0, and the shelf life becomes 5 days.

The table also shows some useful information, us such as growth rate, generation time, lag phase duration, and so on. When the users apply a low level of *L. monocytogenes* (e.g., <0.1 log CFU), it is recommended that the worst-case situation used for food safety. This example is for demonstration only; the user should visit the regulatory component available on the same website and acquire the food regulations in different country and products. The *L monocytogenes* detection level in the United States is zero (negative) per 25 g and other countries may impose different tolerance levels.

Bourgogne, Dijon, France

The aroma of a food product is the whole of the volatile compounds that may be perceived by the olfactory system at extremely low levels, which implies that a reduced loss or sorption (adsorption and/or absorption) will be detected by the consumer (1). Losses of aroma compounds can be selective (affecting one or few components in a complex mixture) and result in changes of the aromatic profile. The food industry has long depended upon reliable, impermeable packaging materials such as glass and metal. Both suppliers and food manufacturers focus research efforts into lighter-weight, flexible and semirigid packages, which are typical qualities of plastics. While parameters such as functionality, recyclability, and cost are critical characteristics, the lack of complete impermeability and inertness in these polymer materials can have important effects. Due to their size (molecular weight $<400\,\mathrm{g}\cdot\mathrm{mol}^{-1}$) and nature (very little polar until apolar and hydrophobic), the aroma compounds will interact with packaging materials often consisting of lipophilic hydrocarbons (2). Aroma compounds are able to interact with the polymer matrix, leading to polymer structural changes (3). Plastic packages are made up of polymers that form a matrix of crystalline and amorphous regions (which contain submicroscopic voids). Aromas permeate through packaging by first being adsorbed onto the package's surfaces, diffusing through the voids (absorption), and, without a barrier material, desorbed to the package's exterior. A sorption–diffusion mechanism is thus applied (4, 5). The mass transfer phenomenon, commonly described by the sorption, the migration, and the permeation can be determined by three parameters: S, the solubility coefficient; D, the diffusion coefficient; and P, the permeability coefficient (6). When diffusion is Fickian and sorption follows Henry's low, the relationship $P = D \cdot S$ can be used. Literature and knowledge on mass transfer of aroma compounds are few and no standard procedure is recommended. Methods developed for aroma compounds permeability measurements are commonly approached by isostatic or quasi-isostatic methods and depend on the physical state (vapor or liquid) of the aroma compounds (6, 7).

The issue is how to obtain results of aroma permeability of packaging films in a reasonable time-frame. Depending on the static or dynamic conditions of permeation measurement, the detection systems and the environmental conditions (temperature, pressure, flows, physical state of the aromas, etc.), numerous apparatus have been designed, to different degrees of success, to obtain this information (4, 7):

Systems can be classified as a function of:

- the vapor or liquid state of the flavored medium in contact with the packaging film;
- the static, quasi-isostatic or dynamic methods;
- or the detection or analysis systems.

The aroma compound in contact with the film can be pure or dilute in a simple solution or in the food, in a vapor state, or in a liquid state at the inner surface of the film. When the flavored medium or pure aroma compound are static (no stirring, no sweeping), the technique is qualified as static and employs an accumulation process. These methods correspond to integral permeation processes (8). In dynamic (or quasi-isostatic) systems, the flavored medium and/or medium collected for analysis are stirred or swept, and the method deals with a differential permeation in which the instantaneous flow rate through the films is measured. When the two sides of the film are exposed to the same total pressure, but with different partial vapor pressures of the aroma, the technique is qualified as isobaric.

AROMA VAPOR PERMEABILITY MEASUREMENT

One primary concern when dealing with aroma barrier testing is generating an accurate test vapor of aroma. Accurate data require precise control of the test permeant concentration in the vapor phase. Since aromas are a complex mixture, the use of an aroma as a test permeant is typically difficult. Aroma generation is usually obtained by bubbling the carrier gas through pure liquid aroma and diluting the aroma saturated carrier gas with another flow of aroma-free carrier gas or with a second flow containing an other aroma compound.

The Isostatic and Isobaric Methods

The gravimetric method is probably the most simple but one of the less accurate. It requires us to work with pure aroma compounds and then at saturated concentration of aroma in the vapor phase in contact with the film. Only a partial vapor pressure differential of the flavor compound is applied between the two faces of the film; that is, the same total pressure is applied on both faces of the film. The method consists in storing pure aroma compound in a permeation cell, usually in glass or metal, sealed by the film to study which is fixed between two Teflon O-rings. The permeation cell is stored in a ventilated room where the air is permanently renewed to maintain the lower concentration of flavor in the outside environment of the cell. The cell is periodically weighted and the cumulative mass of aroma loss as a function of time is plotted. This method is also called the integral permeation method (8). Figure 1 gives an example of the permeation cell and the kinetic obtained. This method, even when coupled with a very sensitive microbalance or a DVS system (Dynamic Vapor Sorption, Surface Measurement Systems Ltd, UK), such as done by Zhou et al. (9), is one of the less accurate (except when coupled with gas chromatography analysis) and permits us to measure permeability to only one pure compound.

The sensory method is sometimes more accurate than the gravimetric ones, and it only needs selected and trained panelists and does not required any specific equipment. First, the concentration level (threshold) at which the panelist perceived the flavor has to be measured and quantified by sensory experiments (or has to be found in the literature). Second, permeation cells having two compartments, one containing the flavor solution or flavored food and the other empty, separated by the tested film were stored in standard conditions [Figure 2 (10)]. The panelists smelt at different times. When the flavor is detected in the empty compartment, permeability could be calculated. The results obtained by this method were comparable to those obtained by the analytical method which used gas chromatography quantification. The advantage of this method is also that it uses either (a) low flavor concentrations and aroma compound mixtures because the nose is very accurate and is able to detect several flavor compounds at concentrations lower than parts per billion or (b) real food products instead of pure aroma compounds. Indeed, the nose is very accurate and is able to detect simultaneously several flavor compounds at

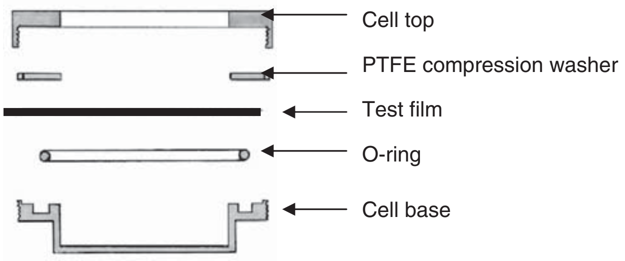

Figure 1. Permeation cell for gravimetric method and cumulative amount of aroma transferred through a film.

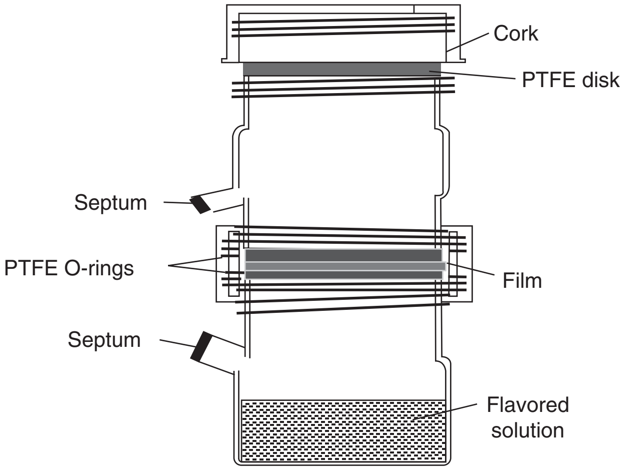

Figure 2. Permeation cell for measuring film permeability from sensory analysis. [From reference (10).]

concentrations lower than the ppb. Numerous studies demonstrate the performances (detection level and identification of aroma) of the panelists and concluded that the technical instrument's (electronic nose) capability for detecting the aroma differences was fairly comparable with the sensory human detector.

The Gas Chromatography method uses the same type of cell that is used for the sensory method. The cell is made either of glass or stainless steel, but the two chambers of the permeation cell are equipped with a sampling port having PTFE septa. The gas phase is periodically collected with a gas-tight syringe in both chambers and injected in gas chromatograph for analysis (11).

Quasi-isostatic and Isobaric Method

In this method, the cell consists of an upper and lower chamber separated by the test packaging film (Figure 3). Complete separation and closure of each chamber were accomplished with Viton or PTFE O-rings between which the film is placed. The cell is accurately maintained at the testing temperature. The pure aroma compound, or a dilute aroma solution or a real flavored product, was placed in a glass dish at the bottom of the lower cell as used by Rubino et al. (12). The RH conditions could also be controlled. A smaller dish filled with a saturated salt solution controlling the water activity was placed in the center of the aroma dish. Aroma vapor that diffused through the film was purged by a stream of carrier gas (nitrogen, helium, or argon) that flowed through the upper cell at a constant rate and that carried the permeated vapor to the gas chromatograph for measurement as displayed in Figure 3.

Isostatic with Dynamic (or Continuous) Flow and Isobaric Methods

The isostatic technique is very similar to that of quasi-isostatic and is the most used technique for measuring aroma vapor permeabilities. The material sample was also mounted in a two-chamber permeability cell, but both chambers of the permeation cell are continuously swept by the flow of gas: on one side the aroma-enriched carrier gas and on the other side the permeated low aroma concentration carrier gas (Figure 4a). As the permeant diffuses across the membrane, headspace samples are automatically collected and quantified using gas chromatography. This principle corresponds to the automatic apparatus sold for aroma permeability measurement, such as the Aromatran® (Mocon, Minneapolis, MN, USA) or the MAS2000® (Mas Technologies Inc., Zumbrota, MN, USA). Instead of FID-equipped gas chromatography analysis or detection, some authors used more specific detectors such as PDS or mass spectrometer coupled with the gas chromatograph, or UV–VIS spectrometer, FTIR or ATR–FTIR spectrometer directly coupled at the vent of the permeation cell (13).

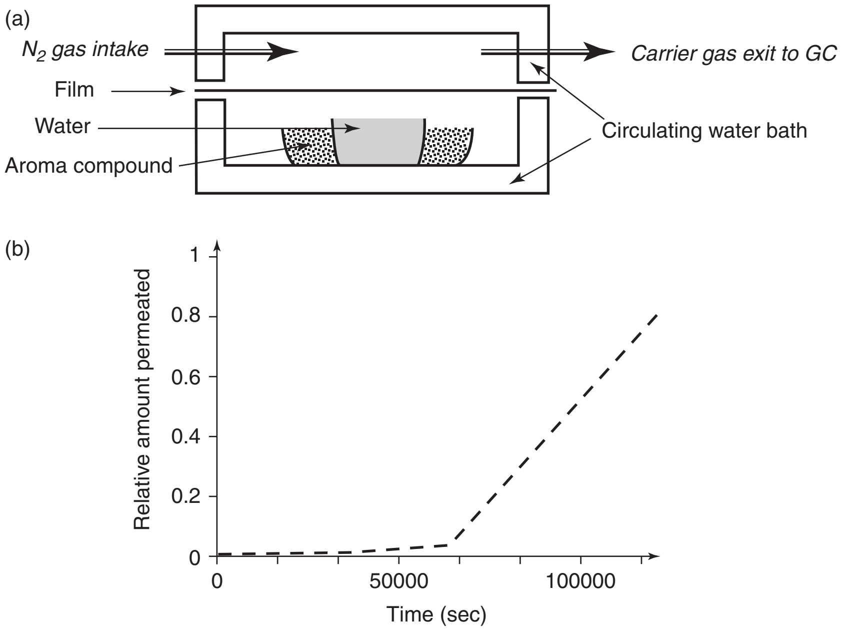

Figure 3. (a) Quasi-isostatic permeation cell (adapted from reference 12) and (b) an example of kinetic of 1-hexanol permeation through polypropylene film. [Adapted from Gavara et al. (6).]

In this method, permeant flow values as a function of time is recorded during the experiment. Initially the permeant flow is zero. After some time, permeant flow starts to increase during the transition state until it reaches a constant value. At this time, the system is in a stationary state and the experiment can be stopped. From the flow F_∞ at the stationary state, the permeability can be calculated according differential permeation equations (6, 8, 14). Figure 4b shows the data obtained for 1-hexanol through a polypropylene film (6).

To improve the sensitivity and accuracy of the isostatic method, a cold trap (liquid nitrogen) or adsorbent trap (tenax, active charcoal, etc.) can be placed at the vent of the cell to concentrate the permeated aroma compounds. After definite times, the trap is desorbed by heating and injected in a gas chromatograph as shown in Figure 5 (15–17). This is necessary for obtaining a suitable method allowing the permeability measurement of high-barrier polymer films at low permeant vapor pressures.

Static and Manometric Methods

Basically, the manometric methods measure the quantity of aroma vapor that has permeated through a test specimen in a given time, as a change in pressure and volume (18). The test specimen forms a barrier between two chambers in a permeation cell. A constant pressure of the aroma vapor is maintained in one chamber and a low pressure, usually vacuum, is initially established in the other chamber. A manometer is coupled to the low-pressure chamber and is used to measure the change in pressure and volume over a specified length of time. In order that the quantity of vapor measured be equal to that entering the polymer film, steady-state conditions must exist. This requires a period of time to lapse so that a constant concentration gradient is obtained across the film.

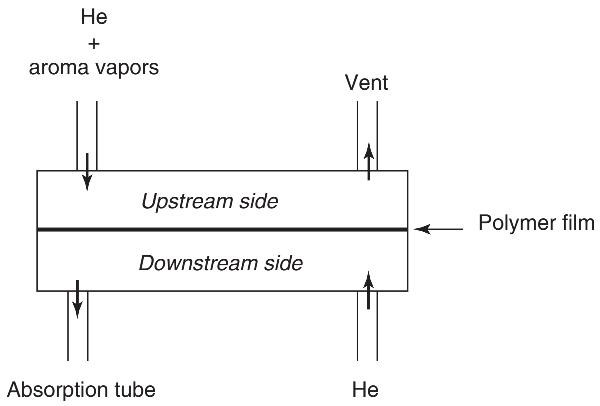

Figure 5. Improved device for the isostatic method using adsorbent trap to concentrate permeated compounds. [Adapted from reference (15).]

In the permeation device developed by Okuno et al. (19) and described in Figure 6, the permeability is determined in static conditions and for a pressure differential lower than 1 atm. This method allows us to strongly improve the sensitivity of the Lomax (18) manometric method previously described. First, the liquid (aroma compound or volatile organic compound) in the vessel was degassed as follows: After closing the valve V_1, the liquid in the liquid vessel was frozen at liquid nitrogen temperature (−196°C). Then the liquid vessel was evacuated by opening the valve V_1, and the frozen liquid was melted at ambient temperature. This procedure was repeated several times. The valves V_1, V_2, V_5, and V_6 were closed, followed by heating the liquid vessel at a certain temperature. The vapor pressure supplied to the membrane was controlled by the liquid temperature in the vessel. The permeation measurement started by opening the valve V_1.

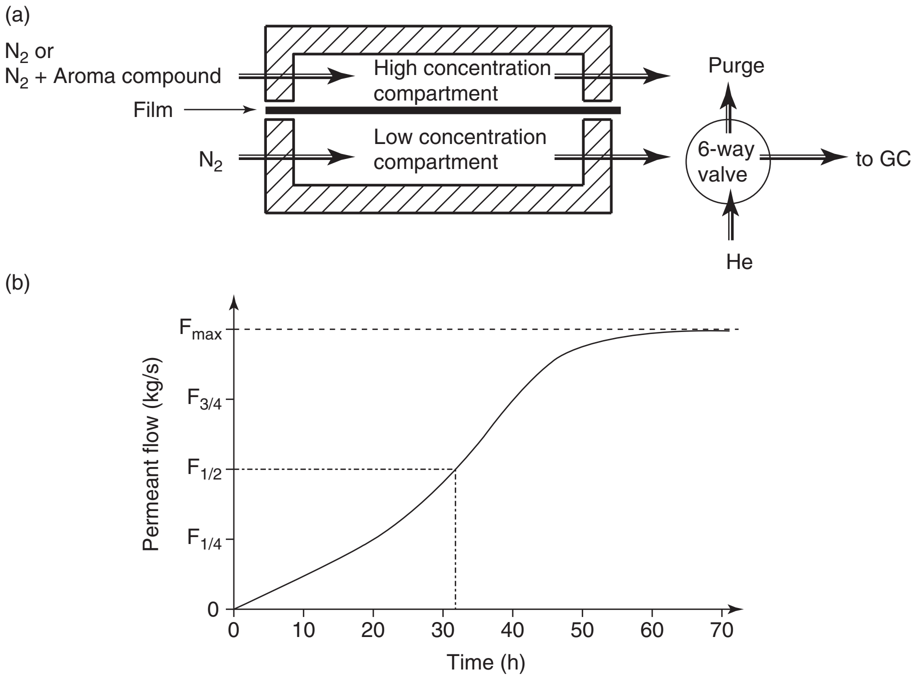

Figure 4. (a) Isostatic permeation device and (b) an example of typical kinetic of aroma permeation through polypropylene film.

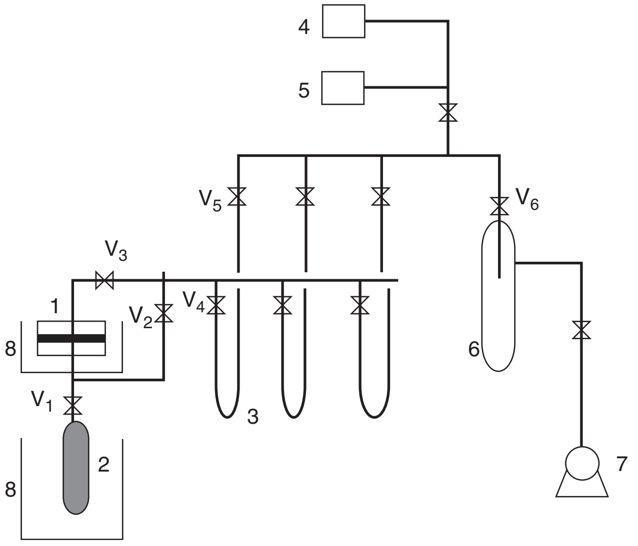

Figure 6. Permeation device for measuring permeability of organic vapors (1, permeation cell; 2, liquid vessel; 3, U-tube; 4, pressure gauge; 5, Pirani low-pressure gauge; 6, cold trap; 7, vacuum pump; 8, thermostat; V, valves). [Adapted from Okuno et al. (9).]

The vapor permeated through the membrane was collected in one the U-tube at liquid nitrogen temperature. The collected permeants were vaporized in the U-tube disconnected from the system by closing the valve V_4. The valve V_5 was opened and then the pressure of the permeated aroma vapor in a known volume is measured by the pressure gauge 5. During the above pressure measurement, another U-tube was used to collect the permeated vapors. The steady state of permeability of the vapor was determined by repeating this procedure. If several compounds and mixed and studied simultaneously, the composition of the permeate has to be analyzed by gas chromatography. The main limit of this method is that the permeability value is strongly dependent of the vapor pressure applied at the inner surface of the membrane, and of the efficiency of the cold trap, as shown in Figure 7 where the permeability of a PVC sheet to ethanol varies twice according the ethanol vapor pressure used.

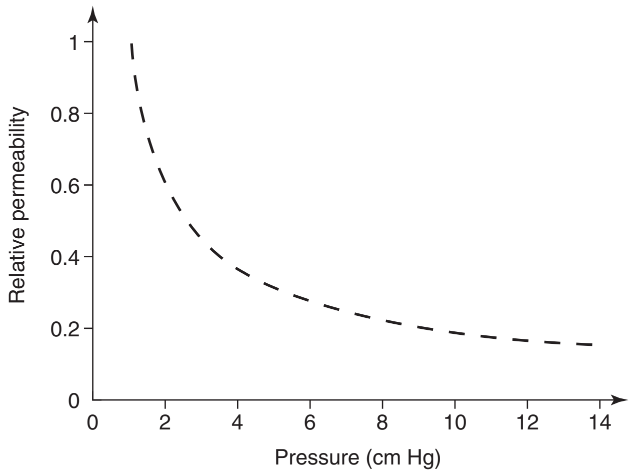

Figure 7. Effect of vapor pressure on permeability of ethanol vapor through a PVC membrane. [Adapted from reference (18).]

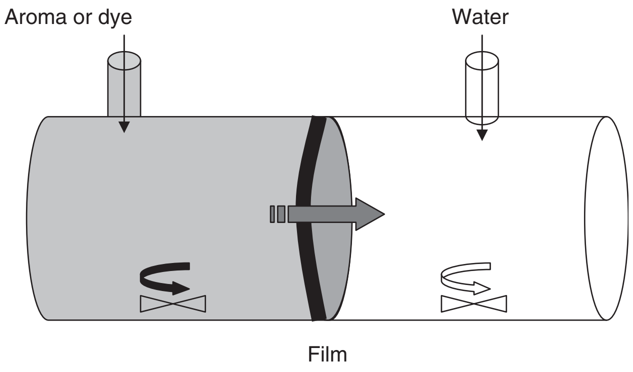

Figure 8. Experimental design for measuring permeability of aroma compounds (or dye compound) in packaging films.

AROMA LIQUID PERMEABILITY MEASUREMENT

Quasi-isostatic Isobaric Method

The permeability of packaging films in liquid medium is simply determined using a two-compartment glass diffusion cell (20). The two compartments were separated by the film and were continuously stirred with a magnetic stirrer to ensure homogeneity of the solutions on both sides of the film. The permeate concentration can be measured by gas chromatography analysis or, in the case of Figure 8, by fluorescence spectrometry.

This method was also adapted for measuring the permeability of a complete package, taking into account the sealing zone, and using a continuous measurement of the permeated aroma concentration by UV–VIS spectrophotometer such as done by Gotz and Weisser (21) and shown in Figure 9.

Static High-Pressure Method

Gotz and and Weisser (21) designed a permeation device for measuring permeation of packaging in liquid submitted

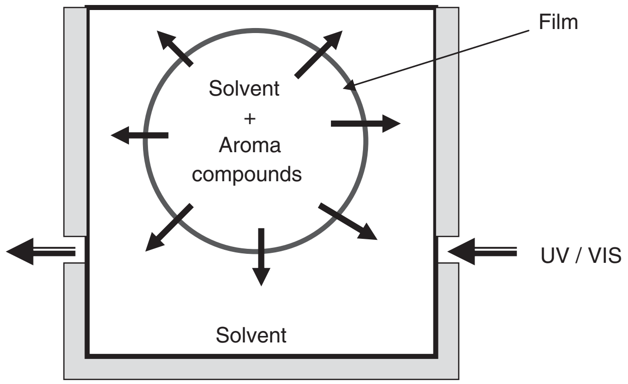

Figure 9. *In situ* permeability measurement of aroma in liquid medium. [From reference (21).]

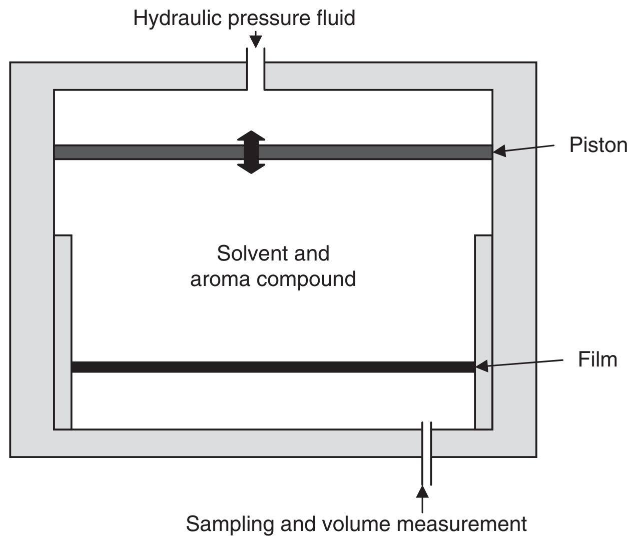

Figure 10. Experimental design of a liquid permeation cell under high pressure. [Adapted from Gotz and Weisser (21).]

to high pressure. A two-compartment permeation cell was integrated in a high-pressure autoclave (Figure 10). The bottom of a compartment of the cell is moving like a piston to apply high pressure on the liquid in contact with the film. The pressure p_0 of the hydraulic fluid (water/glycol) is applied by a piston to the lower region of the autoclave filled with water. Another piston separates the water from the aroma–solvent (water/ethanol) solution. After the pressure is built up, the cell is rinsed again in order to obtained the amount of aroma that permeated at $p_{\max} = p_0$ through the film. The end of the rinsing defines the beginning of the holding time. After the holding time, the cell is rinsed again with the solvent out of the reservoir. The amount permeated and then the liquid permeability is determined by GC analysis of the solvent after holding time.

Dynamic Isobaric Method

The rotating diffusion cell is designed hydrodynamically so that stationary diffusion layers of known thickness are created on each side of the film (Figure 11). The flux of aroma compound from the inner compartment across the film was measured by periodically sampling with a micro syringe from the solution in the outer compartment and analyzed by GC. The rotating diffusion cell method enables us to carry out a study on the mass transfer of solutes from a liquid phase to another liquid. The fundamental theory of the Levich model (22) provides the means of aroma compound transfer from the inner to the outer compartment by the overall permeability of aromas but also the aroma diffusivity within the film packaging and the interfacial resistances.

SORPTION METHODS

There are many works focused on the determination of aroma mass barrier which are based on sorption experiments. The retention or the release of substances is monitored during the experiment. This evolution can be followed by gravimetry (DVS, electrobalances, spring balances), by manometry, by GC or HPLC, and so on. Figure 12 (24) presents aroma compound sorption kinetics. The quantity of aroma compounds adsorbed by the film during transient state of the mass transfer was often obtained using a modified microatmosphere method. Dried films cut into small pieces were exposed to atmospheres saturated with pure or dilute aroma compound. This atmosphere was usually conditioned at 0% relative humidity and continuously swept with a carrier gas (helium) containing a known vapor concentration of aroma compounds. The atmosphere inside the flask containing the film was kept at a constant aroma concentration. The total amount of volatile compound sorbed at a given time until constant Q was determined after solvent extraction such as n-hexane (for which extraction yield is 97%) of a film sample

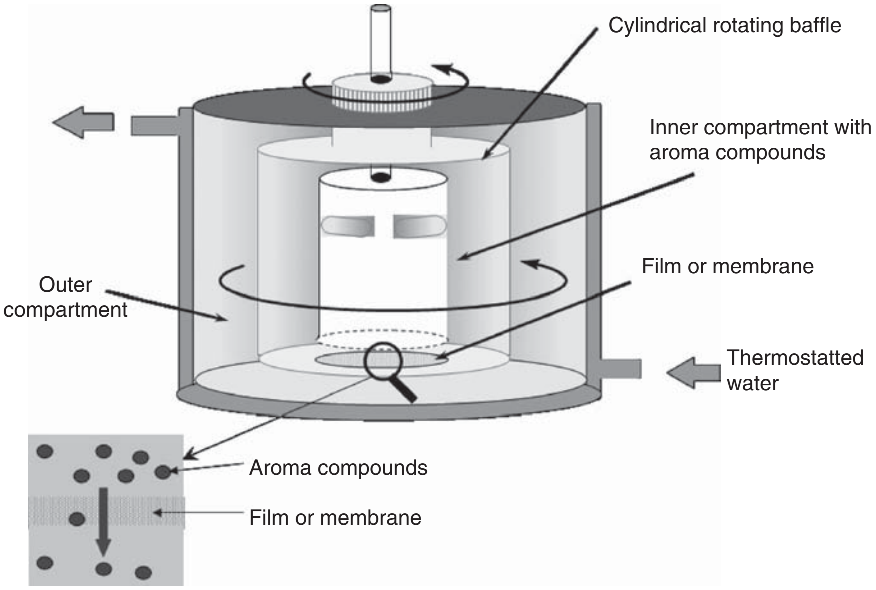

Figure 11. Rotating diffusion cell for measuring permeability of aroma compound between two liquid phases. [Adapted by Debeaufort from works of Rogacheva et al. (23).]

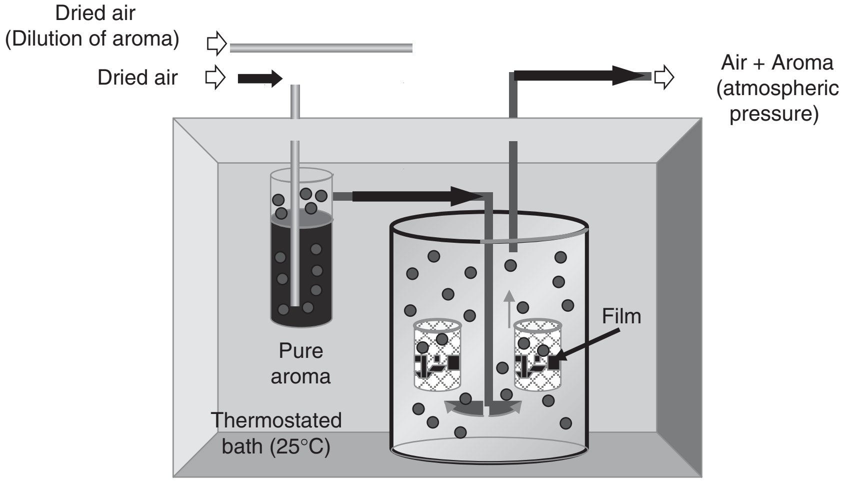

Figure 12. System to determine aroma compound sorption kinetics (micro-climate method).

and by injection of the resulting aroma solution in a gas–liquid chromatograph (GLC). The quantities of aroma compounds adsorbed in the films are expressed as $\mu g \cdot mL^{-1}$ of dry film. The aroma flux was defined as the ratio of the weight of permeated vapors (g) to the product of exposed area (m^2) and time (s). The flux was expressed as $g \cdot m^{-2} \cdot s^{-1}$. In practice, permeability P and solubility coefficients S are calculated from the following equations:

$$P = F/\Delta p \cdot e \quad \text{and} \quad S = Q/\Delta p$$

where F is the transfer rate ($\mu g \cdot m^{-2} \cdot s^{-1}$), Δp is the vapor partial pressure gradient, e is the film thickness (m), and Q is the quantity of volatile compound sorbed in the film ($\mu g \cdot mL^{-1}$).

The diffusion coefficient can be calculated from the half-time method of sorption experiment (Figure 13), designating the time $t_{1/2}$ at which the transfer rate is equal to half of the transfer rate at the steady state obtained by a differential permeation method (5, 8, 25) or from numerical solution of Fick equations. The diffusion coefficient (D) was calculated using the equations

$$D = \frac{e^2}{7.199 t_{1/2}}$$

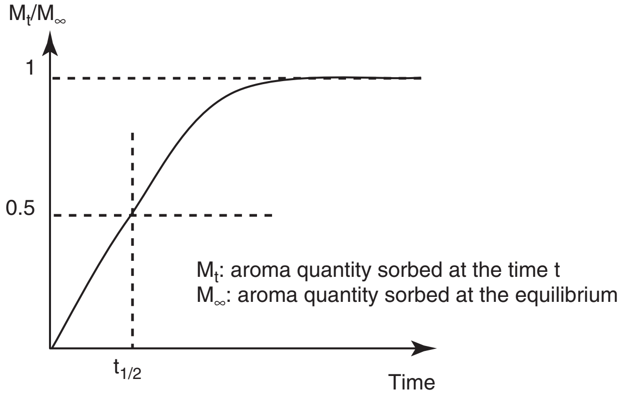

Figure 13. The half-time method of diffusivity determination from sorption kinetics.

and

$$\frac{M_\infty - M_t}{M_\infty - M_0} = \frac{8}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{(2n-1)^2}\exp\left[-\frac{(2n-1)^2\pi^2 Dt}{4e^2}\right]$$

where M_t is the aroma quantity sorbed at the time t, M_∞ is the aroma quantity sorbed at the equilibrium, and M_0 is the initial aroma quantity in the film sample.

The measurements methods of sorption are often used to search the affinity properties of the aroma compounds. These methods can also be used to determine diffusion and then the permeability from the sorption kinetics. But permeability can be only estimated from the sorption method when the Henry and Fick's laws are obeyed. This calculation applies only in the absence of strong interactions between the volatile compound and the polymer– that is for a constant diffusivity and a linear sorption isotherm.

BAG-IN-BOX, DRY PRODUCT

Gilles Doyon
Agriculture & Agri-Food
Canada, Ministry, Saint-
Hyacinthe, Quebec, Canada

When the bag-in-box concept is applied to dry products, it generally involves a bag inside a folding carton (see Cartons, Folding). In order to appreciate the impact of the bag-in-box (BIB) concept for dry products, one must understand the history of the folding carton. The turn of the century marked the first use of the folding carton as a package when National Biscuit Company introduced the "Uneeda Biscuit" (soda cracker). Instead of opting for the conventional bulk method of selling crackers, Nabisco decided to prepackage in smaller boxes, using a system that would prolong freshness. The paperboard carton shell with creased score line flaps had recently been developed, along with a method for bottom and top gluing on automatic machinery (see Cartoning machinery). Waxed paper (see Paper; Waxes) was to be added manually to the inside of the carton. So was born the "lined carton."

The evolutionary process eventually culminated in two basic methods of producing lined cartons. The first was a machine to automatically open a magazine-fed side-seamed carton and elevate it around vertically indexed mandrels where glue is applied to the bottom flaps and folded up against the end of the mandrel with great pressure. The result is a squarely formed open carton with a very flat bottom surface capable of being conveyed upright to a lining machine that plunges a precut waxed-paper sheet into it by a system of reciprocating vertical mandrels. The lining is overlapped at the edges and sealed together to form an inner barrier to outside environmental factors. It protrudes above the carton top score line by a sufficient amount of paper to be later folded and sealed at a top-closure machine. Straight-line multiple-head filling machines are used to fill premeasured product into the carton. Initial fill levels are often above the carton-top score line and contained within the upper portion of the lining, which eventually settles with vibration before top sealing takes place. This fact has relevance with respect to the bag-in-box concept.

The second method involves the use of a double-package maker (DPM), which combines the carton forming/gluing operation with a lining feed mechanism that wraps the lining paper around a solid mandrel prior to the carton feed station. In this instance the carton blank is flat and is side-seamed on the DPM. The lined carton is then discharged upright onto a conveyor leading to the filler and top closing machine.

These packaging lines are typically run at up to 80 packages per minute (in some special cases 120/min). They are considered to be very complex machines requiring skilled operating personnel and are usually restricted up to a single size.

Although the time reference is rather vague, it would appear that the bag-in-box concept began with the refinement of vertical form/fill/seal (VFFS) machinery in the 1950s (see Form/Fill/Seal, Vertical). Packaging machinery manufacturers and users saw an alternative to the DPM in the horizontal cartoner coupled with VFFS equipment. The idea of automatically end-loading a sealed bag of product into a carton offers the following important advantages compared to lined cartons: simplicity (i.e., fewer and less-complicated motions); flexibility (i.e., size changes more easily and quickly accomplished); higher speed (i.e., up to 200 packages per minute is theoretically possible with multiple VFFS machines in combination with a continuous-motion cartoner); lower packaged cost (i.e., higher speeds and lower-priced machinery); improved package integrity (i.e., bags are hermetically sealed using heat-seal jaws); reduced personnel (i.e., possible for one operator to run line); requires less floorspace (i.e., more compact integrated design); and wider choice of packaging materials (i.e., unsupported as well as supported films can be handled).

Although bags are sometimes inserted manually, the high-speed methodology (see Figure 1) employs multiple VFFS machines stationed at right angles to the cartoner infeed, dropping filled and sealed bags of product onto an inclined conveyor that carries them to a sweep-arm transfer device for placement into a continuously moving bucket conveyor. The VFFS machines are electrically synchronized with the cartoner, and the transfer device is mechanically driven by the bucket conveyor. When the bag reaches the carton-loading area, it is gradually pushed out of the bucket by cammed push rods through guides and into the open mouth of the box which is contained within chain flights traveling at the same speed adjacent to the bucket. A guide plate drops into the bucket from overhead to confine the bag during insertion into the box. Once the bag is in the box, the end flaps are glued and rail closed before entering compression belts for discharge to the case packer.

When difficulties occur in this system, it is usually at the insertion station, caused by misshaped or rounded bags with a girth larger than the carton opening. An attempt is made to condition the bag on the inclined conveyor by redistributing the product within the bag more evenly and, once in the bucket, by vibrating tampers to flatten it. However, if there is too much air entrapment in the bag, or a high product fill level, or an improperly shaped bag, these devices become futile. Increasing the carton size would be a simple solution, but the packager is often not free to do this. Marketing departments are generally reluctant to change the size of a carton that has been running satisfactorily on DPM equipment. The main problem is that the BIB manufacturer must allow more clearance of bag to box than is required on a close-fitting lining. The usual BIB bag-sizing rule of thumb is a

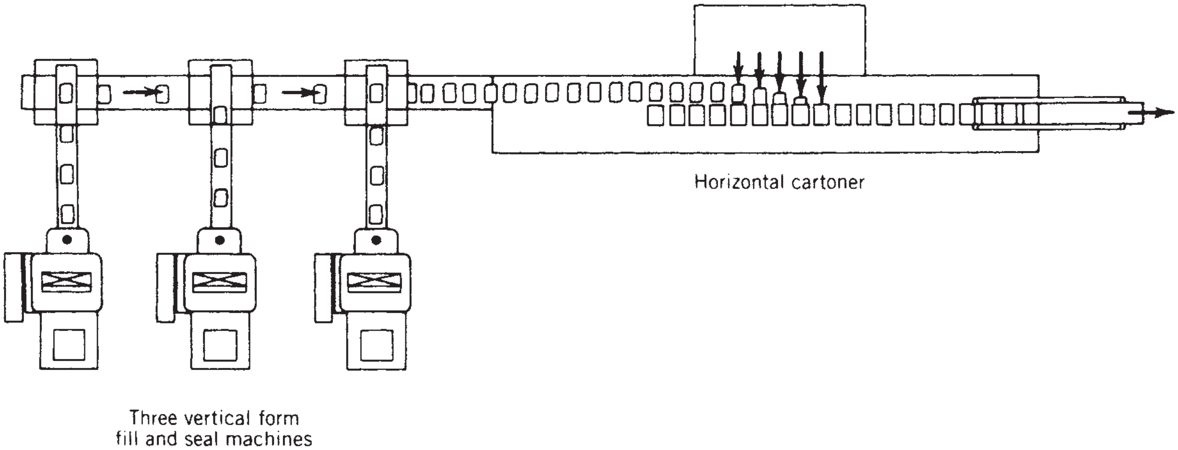

Figure 1. Bag-in-box packaging system with horizontal cartoner.

gusseted bag having a width $\frac{3}{6}$ in. (9.53 mm) less than the carton face panel and $\frac{1}{4}$ in. (6.4 mm) less than carton thickness. This can vary somewhat, but the bag must be small enough to transfer positively into the bucket and subsequently into the box without interference.

One manufacturer has attempted to deal with the problem by wrapping the carton blank around the bucket after the bag has been top-loaded into it (see Figure 2). In wraparound cartoning, flat blanks are used and glue is applied to the manufacturer's joint and side-seamed against the mandrel by rotating-compression bars. The mandrel/bucket is withdrawn, leaving the bag in the box ready for flap gluing and closing. This approach is more forgiving than end-loading, but is still susceptible to bag-sizing problems because additional clearance must be allowed to compensate for the gauge of the three-sided bucket walls. Speeds of ≤ 140 per minute are possible.

The vertical load concept has gone a long way toward overcoming bag insertion problems (see Figure 3). It relies on simple gravity and special bag-shaping techniques to drop the bag directly into the box from a film transport-belt-driven type of VFFS machine. The carton shell is formed from a flat blank and bottom glued on a rotary four-station mandrel carton former. The upright carton is conveyed to a starwheel-timed flighted chain indexing device to position it squarely under the VFFS rectangular forming tube. Two VFFS machines with electronically synchronized motor drives operate independently of the carton former. A prime line of empty cartons initiates the operation of each VFFS machine.

The bag-forming parts consist of a rectangular-forming shoulder and tube that has been manufactured to produce a bag with cross-sectional dimensions $\frac{1}{4}$ in. (6.4 mm) less than carton face panel and $\frac{1}{6}$ in. (3.2 mm) less than the side panel. This very close fit is made possible by a combination of several mechanisms. First a gusseting device creates a true flat-bottom bag using fingers that fold in the film from the sides as contoured cross-seal jaws close on the bag. The bottom of the rectangular forming tube is within $\frac{1}{4}$ in. (6.4 mm) of the seal jaws and acts as a mandrel around which the bag bottom is formed. The bag is thereby given a sharply defined rectangular shape, which is maintained as it is filled with product and lowered through a shape-retaining chamber. This chamber is vibrating so as to present a moving surface to the bag to reduce frictional

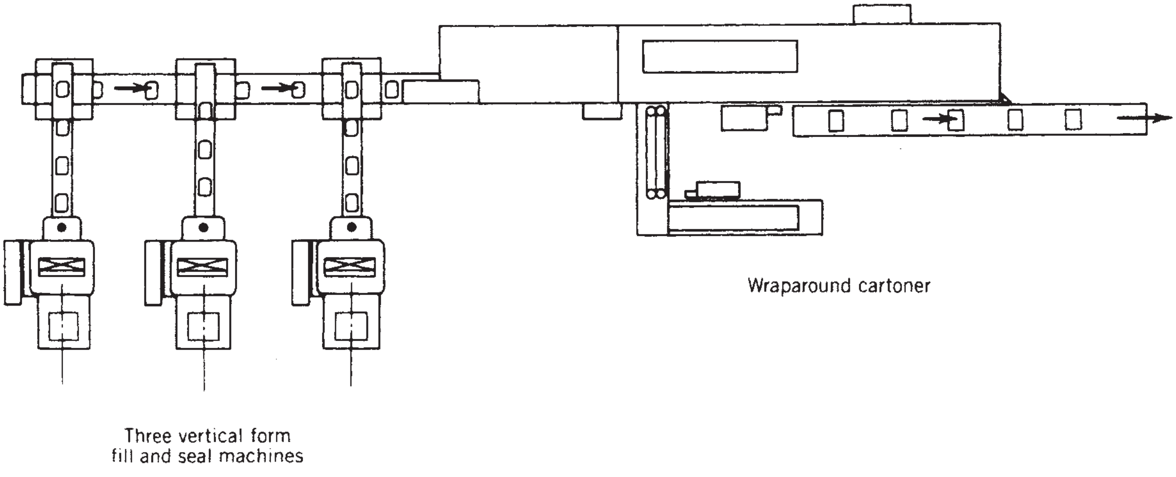

Figure 2. Bag-in-box packaging system with wraparound cartoner.

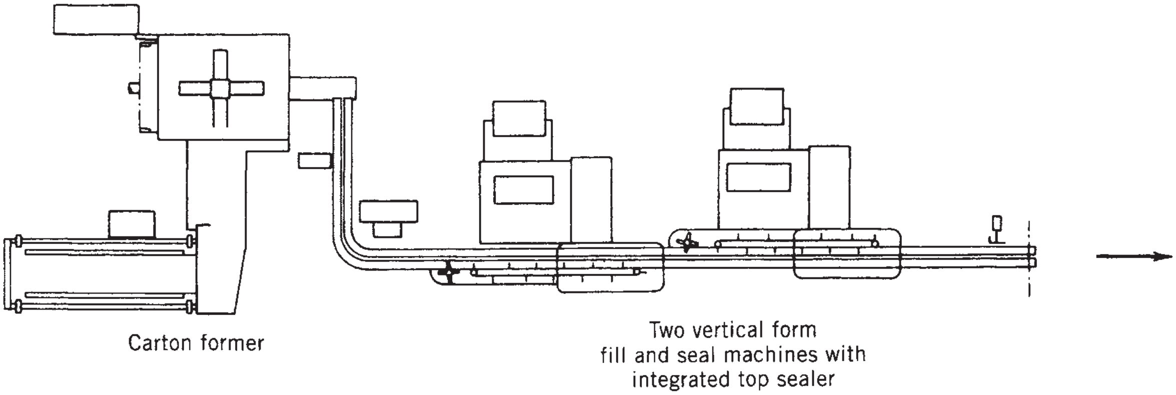

Figure 3. Bag-in-box packaging system with mandrel carton former.

contact and, more important, to settle the product before the top seal is made. Since the bag is confined and not allowed to round out, headspace between product and top seal is kept to a minimum, thereby reducing air entrapment to manageable levels. Flap spreaders ensure that there is unobstructed access into the box.

The shaped filled bag slips freely into the box, allowing the four corners of the bag to settle snugly into the bottom, making maximum use of available volume. The bag cutoff is determined by product fill level and, if necessary, can be made so that the top seal protrudes over the score line by several inches. (centimeters) when fully seated in the box, which is neatly pressed down at the next station. While the carton is contained in the flighted chain, it is indexed through a top sealer where hot-melt glue is applied to the flaps, which are railed over before passing under compression rollers. The top sealer is integrated mechanically and electrically with each VFFS machine, and because the operation is performed immediately after bag insertion, the carton never has a chance to bulge, which is eventually important for efficient case packing.

This packaging system is rated at up to 100 cartons per minute, and two lines can be mirror-imaged for higher speeds. A recent adaptation of the vertical-load system integrates a carton erector for side-seamed blanks with one VFFS and a top-and-bottom gluer into a single compact module rated at up to 50 boxes per minute.

Another BIB system close-couples a carton former (preglued or flat blanks) with a pocket conveyor that indexes the box to a series of bag insertion, filling, sealing, and carton top/bottom gluing stations. The bag is formed using vertical form/fill techniques utilizing a rectangular forming tube. A unique gripping mechanism engages the bottom seal of the bag and pulls it into the box from underneath. The bag top is left open to be filled with product at succeeding stations. This system offers the advantages of multiple-stage filling for optimum accuracy, checkweighing, and settling before the bag top is sealed. This is a very effective way of dealing with the problem of high fill levels. Outputs of 65–80 packages per minute are claimed for this type of machinery.

RELATED CONCEPTS

A field that has grown is institutional bulk packaging of large quantities of product in 10 to 20-lb (4.5 to 9.1-kg) sizes which usually require corrugated-box materials (see Boxes, Corrugated). The VFFS unit is an expanded machine capable of producing large deeply gusseted bags and is usually set up for vertical bag loading. Speeds are in the range of 15–30 cartons per minute. In a related process, not technically "bag-in-box," horizontal pouch (three-side-seal) machines are close-coupled to a cartoner to automatically insert one or multiple pouches into a carton at high speeds.

BAG-IN-BOX, LIQUID PRODUCT

Jim Arch
Scholle Corporation

Gilles Doyon
Marco Lagimonière
Agriculture & Agri-Food
Canada, Ministry, Saint-
Hyacinthe, Quebec, Canada

Bag-in-box is a form of commercial packaging for food and nonfood, liquid and semiliquid products consisting of three main components: (a) a flexible, collapsible, fully sealed bag made from one or more plies of synthetic films; (b) a closure and a tubular spout through which contents are filled and dispensed; and (c) a rigid outer box or container, usually holding one, but sometimes more than one, bag (see Figure 1).

The bag-in-box concept appeared in the United States in the late 1950s. As early as 1957 (1), the package was introduced into the dairy industry in the form of a disposable, single-ply bag for bulk milk. By 1962, it had gained acceptance as a replacement for the returnable 5-gal (19-L) can used in institutional bulk-milk dispensers (2). One of the first nonfood items to be offered in a bag-in-box package was corrosive sulfuric acid used to activate dry-charge batteries.

During this early period, bags were manufactured from tubular stock film by labor-intensive methods. Initially, the physical properties of monolayer films (chiefly low-density polyethylene homopolymers) limited the applications, and filling equipment was slow and often imprecise. This situation changed significantly with the introduction in the 1960s of ethylene–vinyl acetate (EVA) copolymer films that provided added sealability and resistance to stress and flex cracking. By 1965, faster, dual-head fillers became available featuring semiautomatic capping capabilities. Developments in automated box forming and closing kept pace. Also, by 1965, proprietary bag-manufacturing equipment capable of making bags from single-wound sheeting sealed on all four sides had been developed (see Sealing, heat). In the mid-1970s, filling machines that automatically loaded filled bags into boxes came on-line. This was followed by totally automatic filling equipment that accepted a continuous feed of bags in strips (3), separated, filled, and capped them, then placed them in outer boxes. Meanwhile, barrier films (4) (see Barrier polymers) with improved handling and storage characteristics were being developed. Multilayer films of polyethylene coextruded with polyvinylidene chloride or PVDC to provide an oxygen barrier had become commercially available as Saranex (Dow Chemical Co.) in the early 1970s (see Vinylidene chloride copolymers). The application of this barrier film permitted packaging of oxygen-sensitive wines and highly acidic foods such as pineapple and tomato products. Beginning in 1979, multiple-ply laminates (5) (see Multilayer flexible packaging) combining foil (aluminum) or metallized polyester substrates were introduced and were also in wide use by 1982 (see Film, polyester). Such laminations are thermally or adhesively bonded and in some instances by hot melt extruding the adhesive layer (see Adhesives; Extrusion coating). The most commonly used barrier film in the United States today is a three-ply laminate consisting of 2-mil (51-μm) EVA/48-gauge (325-μm) metallized polyester/2-mil (51-μm) EVA. The barrier properties of metallized polyester are directly proportional to the optical density (OD) of the metal deposit. Multilayer coextruded films combining the barrier properties of ethylene–vinyl alcohol copolymer (EVOH), the strength of nylon, and sealability of linear low-density polyethylene are being successfully used for some bag-in-box applications. It is the sensitivity to moisture by EVOH that is limiting the films' wider use (see Ethylene-vinyl alcohol; Nylon; Polyethylene, low density).

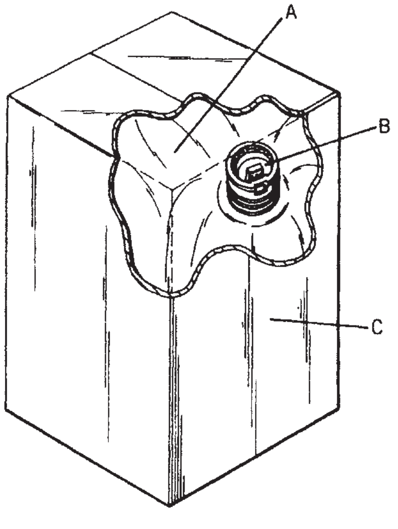

Figure 1. A bag-in-box package for liquid products consists of a bag (A), a closure and tubular spout (B), and a rigid outer container (C).

Fully automatic filling machines with as many as six heads (6) handling up to 40 two-liter ($\sim$2 qt) bags per minute are in operation. Films have been refined and specialized to meet tight packaging specifications for such procedures as hot fill at 200°F (93.3°C) temperatures. Bags are also presterilized by irradiation for filling with a growing number of aseptically processed products for ambient storage without preservatives (see Aseptic packaging). Outer boxes have become not only stronger, but more attractive and appealing as consumer sales units.

MANUFACTURING PROCESS

In general, large producers of bag-in-box packaging design, develop, and manufacture packages to specifications meeting customer requirements. Containers vary in capacity from small, consumer and institutional sizes 1 qt to 5 gal (or 2–20 L), to large, process and transportation packs of 52–312 gal (or 200–1200 L).

A corrugated board box for enclosing a flexible, collapsible bag with a closed spout is described (1997). The box may be used to deliver soft drink syrups, milk, water contained in plastic pouch (7). The next invention (8) relates to post-mix dispensers of the type using peristaltic pump located below a bag-in-box package of concentrate (1997). Novel use of oxygen-scavenging compositions in packaging material that comprise a gas and vapor barrier-forming layer or coating is introduced (1998) and disclosed (9). Applications could be for carton, bag-in-box, thermoformed trays or cups, over-wraps, shrink-wraps, closure liners, and cans. More recently (2000), an improved bag-in-box packaging system for storing, transporting, and dispensing liquid products such as chemicals, soft drink syrup, fruit juices, and food condiments is patented (10). It allows for more complete drainage of the liquids. An improved bag-in-box packaging has a shell surrounding the carton (11) that can be separated to form a stand for the carton (2004) is presented. It facilitates dispensing of the beverage from the bag by allowing glasses and cups to be placed on the table under the tap, eliminating the need to use two hands to fill the glass. A multipurpose four-sided sealed bag with a bag-in-box container system for viscous or powdery (particulate) products as vegetable oils, syrups, salad dressings, peanut butter, or soy sauce is described (12). The method of producing and using the bag are also included (2004). A bridge and adapter system for filling a bag-in-box packaging with liquids, solids, and semisolid products is claimed to provide a quick connection between the supply line and the dispensing part of the packaging (13). The bridge can be made of food grade stainless steel, plastic, or aluminum (2004). A collapsible flexible liner for a bag-in-box container system or flexible intermediate bulk container (FIBC) is detailed (14). The liner is designed to prevent unwanted collapsing of the liner during filling or draining (2005). It is also suitable for shipping various products including powder detergent. A new bag-in-box beverage container and dispenser is patented (15, 16), which incorporates (a) an outer shell preferably fabricated from corrugated paperboard material and (b) an inner liquid-containing bag fabricated from a suitable material (2006). A recessed handle is also provided. Finally, a bag-in-box for containing and dispensing liquids (e.g., beverages) is described (2006). The interior surface of the bottom of the box preferably slopes downwards toward the spout of the bag and/or has terraces, curves, corrugations, fan-like ridges, or beams to help feed the liquid toward the spout (17). The invention may also be used to advantage in other liquid dispensing applications.

Bag

The principal considerations in choosing a film laminate or coextruded for the bag construction are strength and flexibility, with low permeability and heat resistance added critical factors in an increasing number of applications. In the case of laminates, the bond between the layers of dissimilar materials must be maintained at a high level. Minimum requirements of over 1.1 lbf (500 gf) per inch (2.54 cm) (i.e., ~193 N/m) is not uncommon. Films, laminates, and coextruded have to be resistant and must also, of course, be compatible with the product from which they are in direct contact with.

Once the appropriate film compositions have been determined for a specific application, the typical manufacturing procedure is as follows: Referring to Figure 2, two or three pairs of rolls of single-wound sheeting (A) are unwound on a machine where the webs advance intermittently, holes are punched (B), and spouts are sealed (C) into one of the duplex or triplex film sheets at predetermined points depending on finished size, and the bags are formed by sealing the two films together along the sides (D) and then at the ends (E). Therefore, the bags for liquids are of a "flat" nature, not gusseted. Because precise time and temperature must be maintained to generate the seal between the thin films, the uneven thickness resulting from wrinkles or folds must be avoided because the resulting "darts" will not be fully sealed. A removable closure is applied to the spout (F), and after passing by the draw rolls (G) the bags are either cut apart as the final operation or are perforated (H) for subsequent machine separation at time of filling.

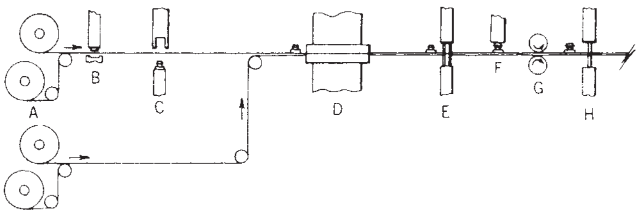

Figure 2. Typical bag-in-box manufacturing procedure.

Bag Size

The box size must be measured first, and then the exact sizing of the inner bag can be determined with respect to capacity or desired volume. The bag must occupy virtually all of the interior space of the box without unfilled corners or potentially damaging excess headspace resulting from an oversize box. The relationship between the effective surface area in contact with atmospheric air from the bag-in-box and the volume capacity is important, as well as, the residual air bubble inside. Referring to Table 1, one can demonstrate by doing some rapid calculations that a better shelf life for larger bag-in-box capacity is anticipated for similar bag structure. Furthermore, variability of the bubble diameter or its out-of-control specification per type of volume capacity is a good visual tool for quality control (QC) procedures and automatic filling machine adjustment.

Spout and closure

The spout is the filling port of the bag. Together with the closure, they are designed to mate with filling heads and must be able to withstand the mechanical shock of the closure being removed and replaced during the filling operation without damage to the spout or closure. Spouts are generally molded of polyethylene with a thin flexible flange to which the bag film is sealed. The spout has handling rings for holding the spout during the filling sequence, and the closure likewise has rings for the same purpose. Figure 3 shows the filling head in the fill position. The closure (A) has been removed and lifted up and away at an angle permitting the filling nozzle (B) to come downward and enter the spout (C) that is being held firmly in position. Because the design of bag-in-box packages provides for the contents always to be in contact with the spout, the spout-closure fit must be leakproof. When high oxygen-barrier property is essential, the spout and closure appear as the weakest area of the global bag + spout/closure structure, even though the valve is now of high barrier material. The oxygen ingress remains important unless the tightness or snugness of the spout/closure is ensured. This is a mechanical fit with tight

Table 1. Bag-in-Box (BIB) Capacity, Effective Surface Area, and Equivalence per Unit of Volume

Capacity (BIB)	2 L (2.10 qt)	3 L (3.15 qt)	4 L (4.20 qt)	10 L (10.5 qt)	20 L (21.0 qt)
Mean surface. cm^2 or [in.^{2}]	1376 [213]	1546 [240]	2140 [332]	3941 [611]	5838 [905]
Surface equivalent cm^2/L or [in.^{2}/qt]	688 [101]	515 [76]	535 [79]	394 [58]	292 [43]

Conversion units used in this paper are
0.001 in. = 1 mil = 25.4 μm (micrometer)
1 cm^2 = 0.155 square inch (in.^{2})
1 Liter (L) = 1.05 US quart (qt)
1 L = 0.26 US gallon (gal)
1 US gal = 3.79 L

specifications. Their behavior with respect to temperature changes is not to be forgotten. Some commercial products are available, but the list is not exhaustive: Presstap, Malpass, Vitop, Flextap, Viniplus, to name a few. The reader is recommended to peruse references 19 and 20 for complementary information. Also of importance is some application of nitrogen gas (N_2) or the liquid- form droplet to flush the headspace of residual air moments prior to final positioning of the valve or spout on the bag-in-box neck.

There are many designs for spouts and closures, depending on function. In packages destined for consumer use, the closure typically is a simple, one-piece, flexible valve that opens and closes as a lever is activated. Such a combination is shown in Figure 4. Two layers (A, B) of film are sealed to the spout sealing flange (C). Around the tubular wall (D) are one or more spout handling rings (E). The closure also has a handling ring (F) that facilitates its removal by the filler capping head. The closure is retained on the spout by a mating groove and head (G), and the liquid seal is achieved by a pluglike fit (H) between the two components. The one-piece closure is molded from a resilient material and becomes a dispensing valve by flexing the toggle (I), creating an opening to an orifice (J) and providing a path for the contents to exit.

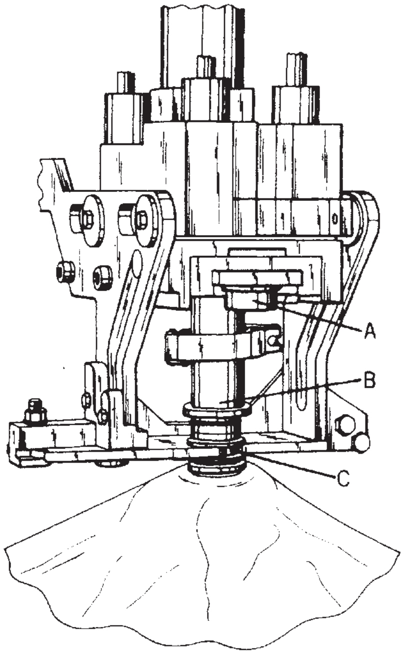

Figure 3. Filling head in fill position. The closure (A) has been removed to permit the filling nozzle (B) to come down and enter the spout (C).

For food-service use, such as in restaurants, the closure may have a dispensing tube attached or be compatible with a quick-connect-disconnect coupler leading to a pump. For other uses, just a cap may need to be removed prior to emptying of contents.

Box

In some dairy applications, the bags are transported in returnable plastic crates. Most typically a wide variety of materials in many forms may be used for the nonreturnable box of bag-in-box packages. For smaller sizes (1–6 gal, or 4–23 L), the outer box is usually made of corrugated board in a conventional cubic configuration. For larger sizes (30–54 gal, or 114–208 L), rigid plastic and metal containers, or even cylindrical drums, may be employed. The required strength must be designed into the box as dictated by the specific application.

Outer boxes may be manufactured with built-in handholds or locked-in-place handles, and some have special wax or plastic coatings for moisture protection. Most boxes are built with punch-out openings for easy access to the spout and closure.

FILLING

Filling bag-in-box packages may be a manual or semi- to fully automatic operation and is adaptable to a wide range

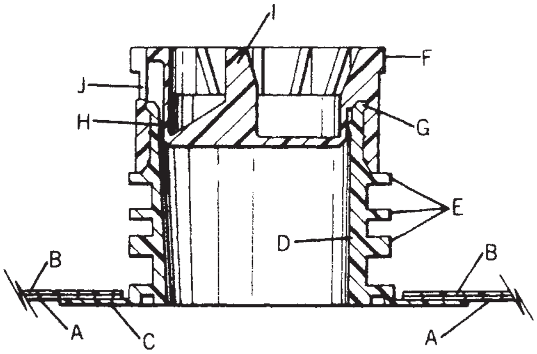

Figure 4. A flexible-valve closure. See text.

of standard industrial processing procedures, including cold, ambient, high-temperature, and aseptic filling. The basic design of a typical filling machine incorporates a flow meter, filling head or heads, an uncap–draw vacuum–fill–recap sequence, and filled bag discharge (see Filling machinery, still liquid). Bags may be manually loaded into the film head or automatically fed in strip form into more sophisticated models. Advanced filling equipment can also be provided with such devices as a cooling tunnel where hot-filled bags are agitated and cooled by jets of chilled water; a specialized valve to allow passage of liquids with large particulates; steam sterilizing and sterile air chambers for aseptic filling; or other modifications as determined by application.

Five-gallon (or 19-L) bags can be filled at speeds that range from four units per minute (1200 gal/h or 76 L/min) to 20 units per minute (6000 gal/h or 380 L/min). Low-speed filling is done on single-head, worker-attended fillers, whereas high-speed is done on filling on multihead equipment, comparing favorably with line speeds of conventional rigid-container operations. Complete systems including box formers, conveyors, automatic bag loading, and top sealers are available to support the automated large-capacity fillers.

SHIPPING AND STORAGE

Bag-in-box packaging offers significant weight- and space-saving economies. Before filling, components are shipped flat; after filling, the basic cubic shape of most bag-in-box outer boxes occupies less space and tare weight than cylindrical metal containers of comparable volume. Limitations include (a) restrictions on palletizing and stacking height, where content weight may exceed outer box ratings, especially those constructed of corrugated board, (b) vulnerability of uncoated boxes to humidity and moisture, (c) possibility of flex cracking of the bag structure is plausible, mainly if we have metallized polyester from the effect of internal handling, (d) short as well as long transportation, and (e) age in distribution (national and international levels). Damages by surrounding materials, leaking units, and vibrations as well as shocks (frequency and intensity) must not be forgotten nor neglected.

DISPENSING

Dispensing may be accomplished in one of three basic ways: uncapping and discharging contents; attaching one or more packages to a pumping system; or activating a small volume, user-demand closure often referred to as a dispensing valve.

In single-bag packages, the spout closure is contained within the outer box for protection and withdrawn prior to use through a perforated keyhold opening in the box. During dispensing, the bag collapses from atmospheric pressure as contents are expelled without the need for air to be admitted. When completely empty, bag-in-box package components, except those outer boxes or containers specifically designed for reuse, are fully disposable. Corrugated board and polyethylene are easily incinerated, and metallized and foil inner bags compact readily to go to landfills.

APPLICATIONS

With advancements constantly being made in bag film capabilities, along with filling and dispensing techniques, practically every commercial product is either being considered for or is now available in bag-in-box packages. Major users include the dairy industry with fluid milk, cream, and soft ice cream mixes. Also of interest are fruit juices and concentrates, edible oil, sauce, and jams, from 5- to 1000-L (1.3- to 260-gal) capacity. Clients are increasing for restaurants, institutions, and fast food markets (21, 22). The wine industry since the 1970s in Australia and South Africa have expended their success of the bag-in-box material and packing technologies worldwide (23); and, finally, most important transportation abuse and shelf-life extension are under close scrutiny (19, 24). From 3–4 L (3.2 qt to 1 gal), soon some 2-L (2.1 qt) containers will be available for retail; also, institutional size (10–20 L, or 2.6l–5.2 gal) and long preservation storage size (1200 L, or 312 gal), respectively, will be available. Purees and ketchup have modest applications too. Some soft drinks are also prepared from fountain syrup pumped from a bag-in-box arrangement (18), which eliminates the need for recycling and accounting for metal transfer containers.

BAGMAKING MACHINERY

Heavy-duty bags, i.e., shipping sacks, of multiwall paper or single-wall mono- or coextruded plastic are used to package such dry and free-flowing products as cement, plastic resin, chemicals, fertilizer, garden and lawn-care products, and pet foods. These bags typically range in capacity from 25 to 100 lb (11.3–45.4 kg), although large plastic bulk shipping bags may hold as much as a metric ton (see Bags, paper; Bags, heavy-duty plastic; Intermediate bulk containers).

Although there are dozens of variations in heavy-duty bag constructions, there are only two basic styles: the open-mouth bag and the valve bag. The former is open at one end and requires a field-closing operation after filling. Valve bags are made with both ends closed, and filling is accomplished through an opening called a valve. After filling, the valve is held shut by the pressure of the bag's contents.

MULTIWALL-BAG MACHINERY

Traditionally, multiwall bags are manufactured in two operations on separate equipment lines. Formation of tubes takes place on the *tuber*. Closing of one or both ends of the tubes to make the bags is done on the *bottomer*. Multiwall bags have two to six plies to paper. Typical constructions are three and four plies. Polyethylene (PE) film is often used as an inbetween or innermost ply to provide a moisture barrier.

Tube Forming. The tuber (Figure 1) starts with multiple giant rolls of kraft paper of a width that will finish into the specific bag width. At the cross-pasting station, spots of adhesive are applied between the plies to hold them together. The material is then formed into a tube that is pasted together along the seam. The tube may be formed with or without gussets. During seam-pasting, the edges of the various plies form a shingle pattern. When they are brought together to form a seam, these edges interweave so that each ply glues to itself. This provides optimal seam strength.

Flush-cut tubes are cut to the appropriate sections by a rotating upper and lower knife assembly. With stepped-end tubes, perforating knives are used to cut stepping patterns on both ends of the tube. The tube sections are

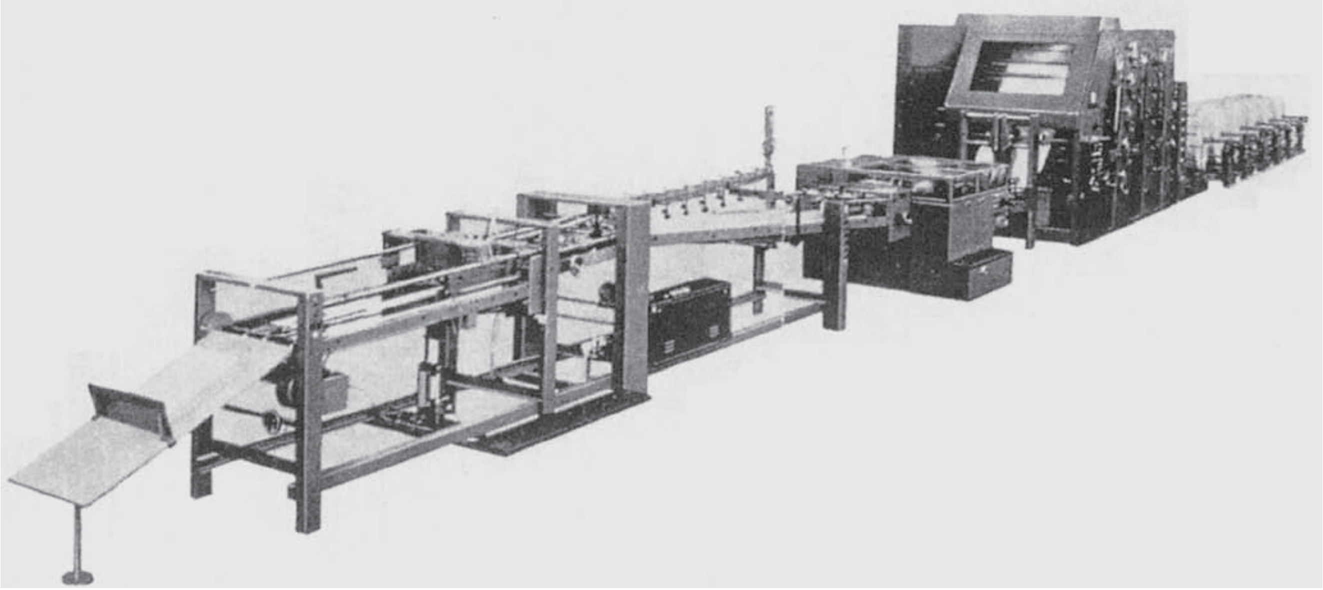

Figure 1. A universal tubing machine. Figure insert shows components: 1, flexoprinter; 2, unwind stations with reel-change arrangements; 3, automatic web brake; 4, web-guider path rollers; 5, web guider; 6, vertical auxiliary draw; 7, perforation; 8, cross pasting; 9, longitudinal register rollers; 10, seam pasting and auxiliary draw; 11, tube forming; 12, cut/register regulator; 13, cutting and tearoff unit; 14, variable-length drive-unit; 15, packet delivery unit; 16, takeoff table.

then snapped apart along perforations that were made prior to crosspasting. This snapping action is accomplished by sending the tubes through two sets of rollers, with the second set moving slightly faster than the first. Once the tubes have been flushcut or separated, they proceed to the delivery section of the line.

About one third of the multiwall-bag market is accounted for by bags with an inner, or intermediate, ply of plastic film. Flat film, used as an inner or intermediate layer, is formed into a tube along with the paper plies and pasted or, if necessary, hot-melt laminated in place. Another possibility is the insertion on the tuber of open-mouth film liners, the open end of which can project beyond the mouth of the paper sack. Stepped-end and flush-cut tubes are usually made on differently equipped tubers, but a universal model also can be adapted to produce either type.

Flush-cut vs. Stepped End. Flush cutting is the most inexpensive tubing method in terms of both original equipment investment and tubing productivity, but these gains are lost in the subsequent bagmaking operations. The bottom of a flush-cut tube is normally sewn, and sewing is also the traditional method of field closure for many products such as seed and animal feeds. There was some use of flush-cut tubes as valve bags, particularly in Europe, but they are not widely used today because a pasted flush-cut bottom is structurally weak. The gluing of the bottom takes place only on one ply. To compensate for this weakness, a patch would normally be added to the bottom of the bag. Sewing is a widely used bottoming method in the United States because there is a great deal of flush-cut tubing and sewing equipment in place, and replacing it in many instances would result in only a marginal return on investment. Unfortunately, sewing has many drawbacks. It is labor-intensive, and because the equipment has a large number of delicate moving parts, maintenance and repair costs are high. Also, the needle holes created by sewing weaken the bag, allow sifting, and make the bag more accessible to rodents and other pests.

The stepped-end tube makes the strongest bag. The ends of the bag have shingle-like stepping patterns that intermesh at the gluing points. In the bottoming process, ply one is glued to ply one, ply two to ply two, and so on. Generally speaking, all bag manufacturers have their own stepping-pattern designs.

Bottoming Equipment. The finished tube sections are converted into bags by closing one or both of the tube ends in any of the following three ways:

1. One end of the tube is shut, forming a sewn open-mouth (SOM) bag. After filling, the top of the bag is closed by means of a portable field sewing unit.
2. A satchel bottom is formed on each end of the tube, with one of the bottoms provided with an opening or valve through which the bag is filled by insertion of the spout of an automatic filling machine or packer. The valve is closed by the pressure of the bags contents. Additional means are available to make the bag more siftproof. In a valve bottomer (Figure 2), tubes advance from a feeder to a tube aligner and a diverting unit for removing incorrectly fed tubes. The tubes pass through a series of creasing stations, and needle holes may be added under

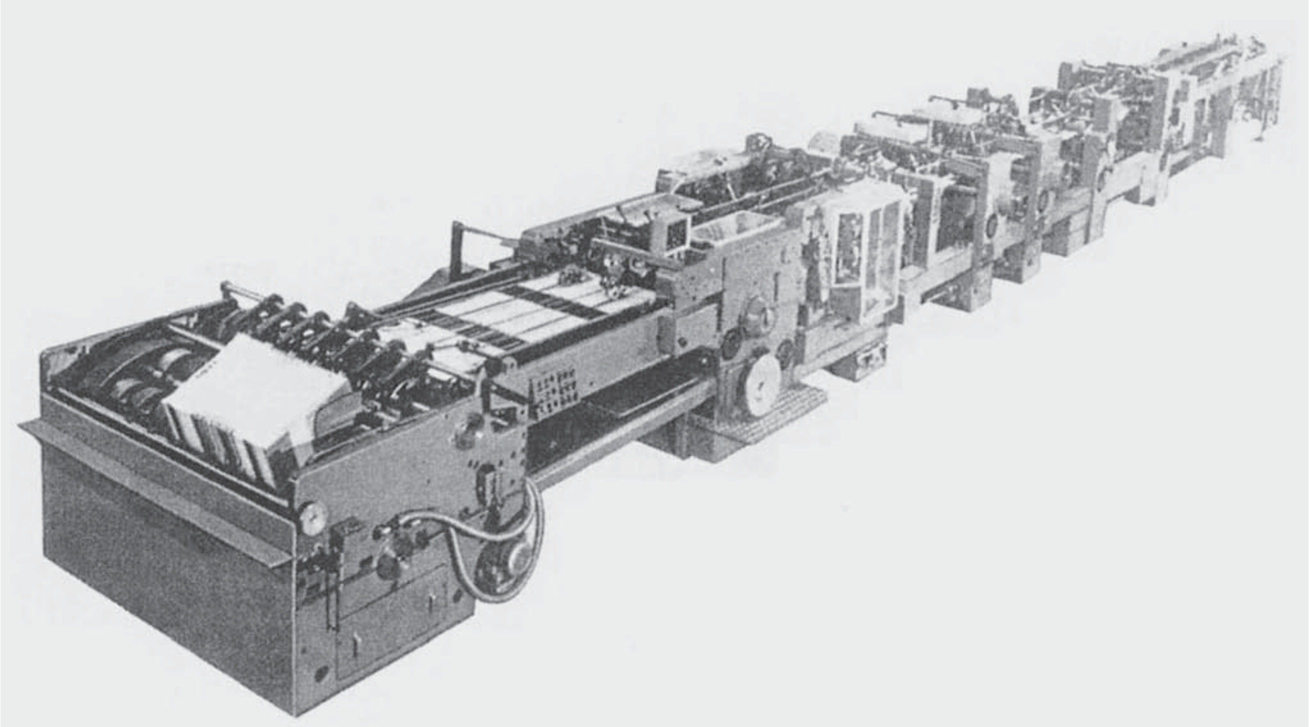

Figure 2. A valve bottomer. Figure insert indicates components: 1, rotary or double feeder; 2, tube aligner; 3, diverter for removing incorrectly fed tubes; 4, diagonal creasing and needle vent hole arrangements; 5, bottom center creasing stations with slitting arrangement for bottom flaps; 6, bottom opening station; 7, bottom creasing station; 8, unwind for valve patch; 9, bottom turning station; 10, valve unit; 11, bottom pasting; 12, bottom closing station; 13, bottom capping unit or intermediate pressing station; 14, flexo printers for bottom caps; 15, unwinds for bottom caps; 16, delivery, optionally with incorporated counting and packeting station.

the valve for proper venting of the bag during filling. At the opening section, the tube is opened and triangular pockets are formed. Valves are inserted at a valving station. Valves are automatically formed by a special machine unit and then inserted into the bottom. They may be inserted and folded simultaneously along with the bottom or performed and automatically inserted. Preformed valves permit the use of a smaller valve size in proportion to the bottom of the bag. In Europe, reinforcing patches are customarily applied to both ends of the bag for added strength. The bags are discharged to a press section where they are conveyed in a continuous shingled stream. Powerful contact pressure of belts (top and bottom) ensures efficient adhesion. In most instances, the final station is an automatic counting and packeting unit.

(3) Stepped-end tubes with gussets and a special step pattern can be converted into pinch-bottom bags on which beads of hot-melt or cold adhesives (see Adhesives) are applied to the steps in the bottom (see Figure 3(a)). These, in turn, are folded over and pressed closed to make an absolutely siftproof bottom (Figure 3(b)). Beads of hot melt applied to the steps at the top of the bag are allowed to cool and solidify. After the bag is filled, a field-closure unit reactivates the hot-melt adhesive, folds over the top of the bag, and presses it closed.

In most instances, bags are collected in packets or bundles palletized for shipment to the end user. However, it is also possible to collect the bags on reels for efficient loading of automatic bag-feeding equipment in the field. The reeled bags form a shingled pattern held in place by the pressure of two plastic bands that are wound continuously around the reel along with the bags.

Other Development. With conventional equipment, it usually takes two bottomers to keep pace with one tuber. This fact has generally discouraged the development of in-line multiwall bagmaking systems in the United States. For example, tubers for cement bags typically operate at speeds from 270 to 320 tubes/min, whereas old-style bottomers run at 120–150 bags/min. Newer bottoming equipment can achieve speeds up to 250 bags/min, enabling one-to-one operation of tuber and bottomer on an in-line system. The tuber operates at less than maximum output, but the in-line system still produces more finished bags because of the increased efficiency resulting from the bottomer being continually fed with fresh tubes. Tubes where the paste has dried become stiff and difficult to handle. As paper is unwound from a roll, it quickly loses its moisture content and becomes less workable. These types of problems are alleviated with in-line bottoming.

In-line tube forming and tube bottoming also lend themselves to significant improvements in manpower utilization. The U-shaped in-line pinch-bottoming system

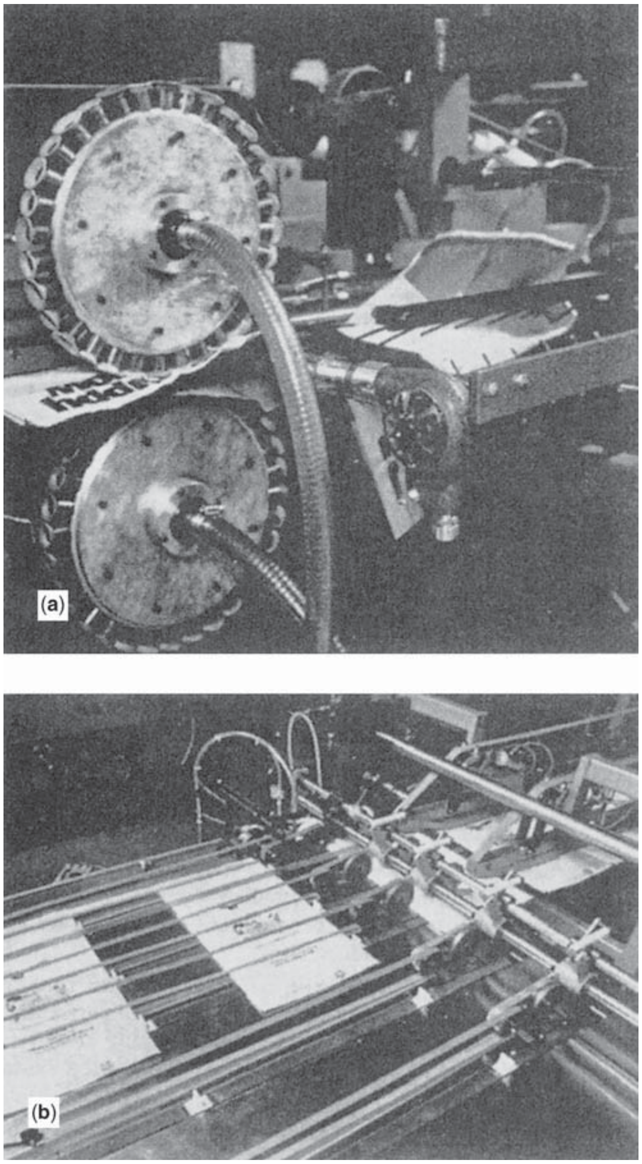

Figure 3. (**a**) adhesives being applied; (**b**) pressing station (bags are folded over and pressed closed).

shown in Figure 4 is capable of reducing the personnel requirements from nine to four. The key to the system is a unique turning station that rotates the axis of the tube by 90° for proper alignment with the bottomer. The "factory end" of the bottomer may be heat-sealed in-line (see Sealing, heat). On the "customer" end of the bag, hot melt or cold glue can be applied, or this end of the bag can be flush-cut for sewing in the field. A sewn top with a pinch bottom offers strength and siftproofness in this bottom style while allowing the customer to retain existing closing equipment. For a consumer product such as pet food, the pinch bottom allows the bag to be stacked horizontally on the shelf, still presenting a large graphics display area for the shopper.

An out-of-line double feeder-equipped pinch bottomer produces pinch-bottom bags for the manufacturers not anticipating having the volume to fully utilize the more productive in-line system. The trend for bag users to reduce inventories and place more small orders is expected to continue indefinitely. For the converter, this has meant decreased productivity because of a disproportionate amount of time being spent in changeovers. New computer numerical control (CNC) bottoming equipment promises to reduce changeover time from an average of about 3 h to about 30 min. All gross adjustments of machinery for a particular setup are stored in the microprocessor and made on the machine by way of stepping motors. Although minor fine-tuning is still required, the starting adjustment point of each operator is the same, and settings are optimized according to a logical sequence designed into the control (see Instrumentation). In addition to faster setups, standardization of tuning procedures should result in more consistent and improved product quality.

PLASTIC BAG MACHINERY

The procedure for making all-plastic, heavy-duty bags is similar to the procedure for multiwall bags; i.e., various bottoming techniques are used to transform a tube into a finished bag, generally either an open-mouth or valve bag, with or without gussets. The three basic differences are described below:

(1) Plastic bagmaking almost always uses a single ply of material, either mono-extruded film, coextruded film, or woven fiber instead of the multiple plies used in paper shipping sacks.
(2) All bagmaking operations are performed on a single converting line. If the bag is made from a flat sheet, the tubing and bottoming operations are integrated into a single bagmaking line. Bags are often made from tubes of blown film or circular woven fibers, and no tubing step is necessary.
(3) The plastic-bagmaking line may incorporate in-line printing, although the outer ply of kraft paper used in a multiwall bag is typically preprinted off-line.

Woven-bag Machinery. Economy of raw materials and toughness are two features that make the woven plastic bag an attractive packaging medium for goods mainly intended for export.

A typical line for converting woven high-density polyethylene (HDPE) or polypropylene (PP) material into heavy-duty shipping sacks includes the following: unwind units for sheet or tubular webs, jumbo or normal size; a flexographic printing machine (see Printing) designed for in-line operation; a wax-application unit (see Waxes) to apply a hot-melt strip across uncoated material at the region of subsequent cutting to prevent fraying; and a flat and gusseted tube-forming unit. The flat sheet of coated or uncoated material is longitudinally folded into tubular form. Some machines have the ability to do this without traditional tube-forming parts. A longitudinal seam is sealed by an extruded bead of plastic. Output of the extruder is matched to the web speed by a tachogenerator.

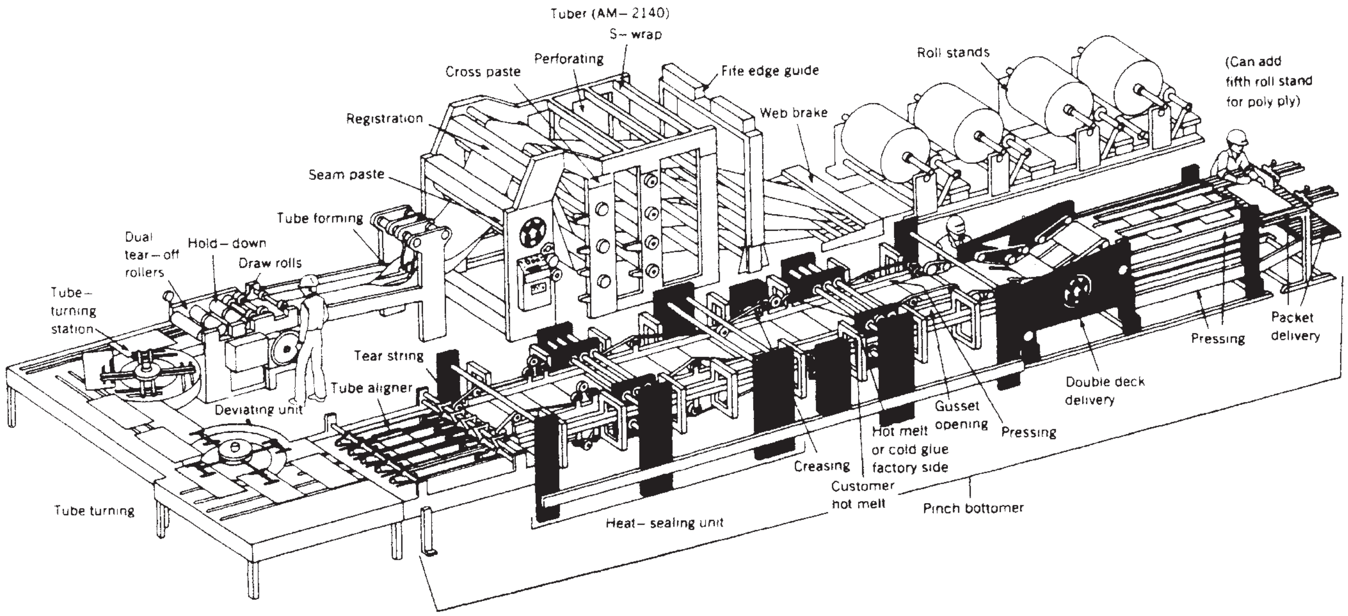

Figure 4. In-line tube forming and pinch bottoming.

A PE liner unit can be arranged above the tube-forming section to apply a PE liner to the flat web automatically. The principal element of this unit is a welding drum with rotating welding segments that provide the reel-fed PE with a bottom weld at the correct intervals. A Z-folding device enables a fold to be made in the crosswise direction for the provision of a liner that is longer than the sack. In addition, a crosscutting unit cuts the outer web and the PE insert, usually by means of heated rotating knives. In the bottoming unit, cut lengths are transferred to the bottoming equipment by conveyor. Bottoming is accomplished either by sewing or the application of a tape strip. Instead of folding the tape over the open end of the sack, the sack end can be folded once or twice and the tape can be applied in flat form over the folds. The delivery unit collects finished sacks into piles for manual or automatic unloading.

Plastic Valve Sack Machinery. Plastic valve bags operate by the same principle as multiwall valve bags. On filling, the pressure of the product closes a valve that has been inserted in either the bottom or the side of the bag. If the material is granular (not pelletized), channels along the bottom of the valve sack would allow some of the product to sift out. These channels can be made siftproof by closing them off with two beads of hot wax during the bottoming operation. Only 5–10% of the plastic valve sacks made in the United States require this feature. Therefore, most plastic valve sacks are produced on high-speed lines that produce sacks at about twice the speed of the siftproof machinery.

A typical system for the production of pasted PE bags from either flat film or blow tubes (Figure 5) consists of the following equipment:

1. An unwind unit for flat film or tubing incorporating automatic tension and edge-guide controls.
2. A tube former in which folding plates form flat film into a tube. A longitudinal seam is bonded by an extruded PE bead.
3. A rotary cross cutter in which the formed tube is separated into individual lengths by the perforated knife of the rotary cross cutter. Fraying of woven materials can be eliminated with a heated knife that bonds the tapes together.
4. A turning unit in which, after the cross cutter, the tubes are turned 90° to bring the cut ends into position for the following processes.
5. A tube aligner and ejector gate in which exact alignment of tubes in longitudinal and cross direction is achieved by means of stops affixed to circulating chains and obliquely arranged accelerating conveyor bands. Photocells monitor the position of the tube lengths. In the event of misalignment, leading to malformed bottoms and, therefore, unusable sacks, the photocell triggers an electropneumatic gate, which, in turn, ejects the tube length from the line.
6. Pasting stations in which each tube end is simultaneously pasted by a pair of paste units using a special adhesive.
7. An enclosed drying system evaporates and draws off solvent from the adhesive.

8–10. Creasing, bottom-opening, and fixing of opened bottom in which a rotating pair of bars hold the tube length ends by suction and the rotary movement pulls the tube ends open sufficiently to enable rotating spreaders to enter and complete the bottom-opening process. The diagonal folds of the pockets are fixed by press rolls to avoid subsequent opening of the pockets.

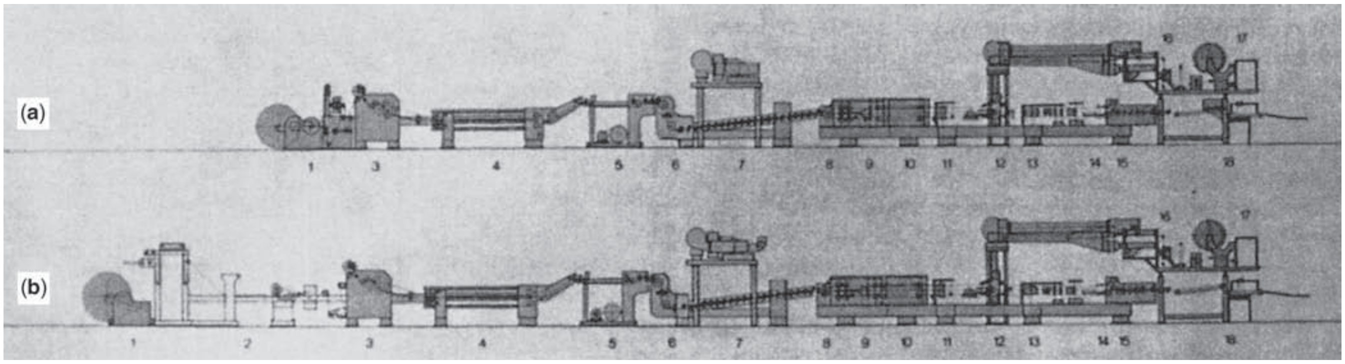

Figure 5. Systems for making all-plastic heavy-duty bags from (**a**) tubular film or (**b**) tubular or flat film. Components are described by number in the text.

11. A valve-patch unit forms the valve from rolls of flat film and places it in the leading or trailing pocket, as required.
12. The bottom-closing station, where, after the valve is positioned, the pasted bottom flaps are folded over, one to the other, and the sack bottom is firmly closed.

13–17. The bottom-patch unit, bottom-turning station, flexo-printing units for bottom patches, pasting stations with drying, and unwind for bottom-patch film, in which patches are formed from two separate rolls of film, flexo-printed (if required), and pasted to both sack bottoms. The bottom geometry is checked by photocells and faulty sacks are ejected through a gate. Just before they reach the delivery section, the bottoms are turned from a vertical to a horizontal processing plane.

18. Delivery with counter and packeting station, in which good adhesion of the cover patch to the sack bottom is assured by applying pressure to the shingled sacks with staggered spring-loaded disks. Having reached a predetermined count, the conveyor accelerates the shingled sacks to the packing station, where the counted sacks are collected into packets and discharged. To accommodate a user's automated filling line, equipment is also available to wind the plastic valve sacks onto reels.

Continuous Bagforming and Bagfilling. Plastic valve bags have been used extensively, especially in Europe, for products such as plastic resin. However, continuous systems for forming, filling, and closing flat and gusseted plastic bags are becoming increasingly popular in the resin market. Such systems typically use prefabricated tubing for high strength. The tubular material is usually preprinted with random printing. Since resin weight varies from day to day, depending on ambient conditions and other factors, random printing allows the bag length to be adjusted according to the prevailing resin volume—weight relationship. In this manner, a tight and graphically appealing package is formed.

An integrated system for forming, filling, and closing of shipping bags would contain the following stations: unwind unit; compensator roller; hot-emboss marking unit; sealing station for bottom seam; bag shingling; separation of bags; introduction of bag-holding tongs; bag filling; supply of the filling product; sealing station for closing seam; bag outfeed conveyor; and control panel. Such a system can produce up to 1350 filled sacks per hour.

One-way Flexible Containers. One-way bulk shipping containers are becoming very popular in Europe. These oversized bags are designed for handling by forklift trucks equipped with one of several specially designed transport devices. Called intermediate bulk containers, they range in capacity from 1100 lb to about a metric ton (0.5–1 t), and are constructed of woven PP or HDPE. Tubes are generally woven on a circular loom because elimination of the longitudinal seam gives the bag exceptional strength. The advantage of this bag is that it represents an exceptionally economical and efficient method of handling bulk quantities. Acceptance of the concept has been relatively slow in the United States because it requires bag producers, product manufacturers, and product customers all to invest in special equipment for bagmaking, product filling, or handling.

ELECTRONIC CONTROLS

Today's bagmaking equipment is following the overall industrial trend toward the use of programmable microprocessor control systems of increasing complexity. Ancillary equipment such as printing presses and extruders already have a high level of control, and other units on the bagmaking line are quickly being adapted to the computer. The first objective in conversion to programmable control is replacement of cumbersome mechanical logic. The next is storage of setup and processing parameters for subsequent reuse. Microprocessors are being used for controlling temperatures, web tension, surface-tension treatment, adhesive application, ink, and registration. The most recent stage of automation has been provision of multiple outputs so that lines may be monitored or controlled by hierarchal computers.

BAGS, BULK, FLEXIBLE INTERMEDIATE BULK CONTAINERS

Diana Twede

Bob Drasner
Senior Consultant, Packaging
Equipment Specialists
(Retired), Rockport, Texas

Intermediate bulk containers (IBCs) are *intermediate* between smaller packages, such as shipping sacks and drums, and the larger bulk truck and railcar quantities. IBCs fall into two general categories: Flexible and Rigid. Filled IBCs occupy about the same space as a typical palletized unit load.

Flexible intermediate bulk containers (FIBCs) are very big bags, made from fabric sewn into shape. They are often called *bulk bags* or *SuperSacks* (a registered trademark). Usually they contain about 1 ton of dry bulk product such as grains, powders, and pellets. There are also rigid IBCs, which may be called *Gaylords* (a registered trademark) when made of corrugated board or *Tote Bins* (another registered trademark) when they are made of stainless steel or plastic.

They are usually filled from the top, lifted from the top or bottom, and dispensed through the bottom (see Figure 1). Many are reused.

Flexible intermediate bulk containers (FIBCs), have been popular since woven polypropylene arrived on the scene in about 1963. Prior to that, bulk bags were made from PVC or rubber-coated cloth and were mainly used for shipping carbon black in 1- to 4-ton loads in each "bladder" to rubber manufacturers. They were filled to capacity and then weighed on a truck scale before loading onto a flatbed truck. They were usually lifted by overhead crane, and then discharged into hoppers through narrow inlets to reduce dust. They were reused over and over for many years, and they were shipped back to the carbon black manufacturer for repair, patching, and refilling. These huge "balls of black" needed no protection from the elements and weren't even covered with a tarp. They were just tied down securely, 6–8 to a flatbed truck.

Soon afterwards, FIBCs were adopted in other industries in Japan and Europe as an economical way to ship intermediate quantities in logistical systems where shippers and their industrial customers cannot handle a whole bulk tank truck or bulk railcar of product and prefer not to manually handle multiple shipping sacks or drums. Bulk bags have become increasingly popular for replacing 50- to 100-lb (25- to 50-kg) paper and plastic bags. Growth is expected to continue, especially given (a) the present trends of legislation to reduce the maximum weight that a person may lift and (b) the lower cost (and natural resource conservation) compared to smaller sacks or drums.

The advantages of bulk bags, compared to buying smaller packages, include reduced costs for package purchase (from about $8 per bulk bag), filling, and handling. They offer a customer service in handling savings because of the ease of dispensing the product. Bulk bags can also promote safety when handling hazardous materials, because they can be incorporated into sealed material handling systems where smaller bags that have to be cut open and shaken to be emptied cannot.

Another advantage of FIBCs is that they can be customized for the exact amount needed by their customers for a batch. Unlike other types of shipping containers, they can be made in any size and in heights from 24 in. up to the limiting height of a truck/container door.

TYPICAL USES

Bulk bags are used for a wide variety of dry products, primarily for ingredients intended for further processing. Typical products include chemicals, minerals, dyes, resins, feed, seed, grain, flour, sugar, salt, nuts, detergents, sand,

Figure 1. The most popular style of bulk bag: dispensed from the bottom. (Photo courtesy of Control and Metering Ltd.)

clay, cement, hazardous materials, building materials, pharmaceuticals, fertilizers, and other commodities in powder, pellet, flake, crystal, or granular form. Liquid products need more support than a flexible bag alone can provide, so intermediate quantities (200 gal) of liquids can be packaged in a “composite” IBC, with the bag supported by a metal frame, or in rigid IBCs, such as pallet boxes or small tanks that may be lined with a bag. However, some “flexible tanks” for over 5000 gal of liquid, without rigid supports but with transport restraint attachments, have been introduced in Europe.

The filled bag weight depends on the size of the bag and the density of the product. The heavier the product, the more strength is needed. The standard FIBC holds 1100–2200 lb, and bags from heavier fabric can contain up to 5 metric tons. FIBC manufacturers offer bags with a volume of 10–100 ft^3. Footprint sizes range from 29 in. × 29 in. to 41 in. × 41 in., with heights of $\leq$88-in. empty size. When bags are filled, they have a tendency to settle into a more circular shape. Examples of bulk bag use can be found in many industries. Sugar and flour are shipped to food processing plants in FIBCs. Sandblasters can receive sand in 5500-lb FIBCs. Plastic resin is shipped to converters in 1-ton FIBCs. About 80% of fertilizer in the United Kingdom currently goes into FIBCs. One of the largest markets in the United States is for exported commodities.

MATERIALS

Bulk bags are made of plastic fabric or films with a very high tensile strength. Most are made from densely woven polypropylene (PP) fabric and have sewn seams, but they can also be made from circular-woven fabric (see Film, nonoriented PP; Film, oriented PP). Other materials include high-density polyethylene (HDPE) and polyester. Some European FIBCs are made from fiber-reinforced paper or polyvinyl chloride (PVC) (see Film, rigid PVC). The most heavy-duty FIBCs are usually made from PVC-coated PE fabric. Bulk bags can be printed to identify the contents. Filled bulk bags are usually cube-shaped with a square footprint, but some have a circular footprint. Some designs have antibulging “baffles” as reinforcement features.

Selection of the appropriate materials and structure depends on the properties of the product and the distribution system. Waterproof FIBCs are coated with PVC or latex and have heat-sealed (rather than sewn) seams. If the bags will be stored outside, the fabric is formulated to resist ultraviolet degradation. Some products generate static electricity when they flow, and antistatic (or static conductive/dissipative) fabric or liners are available. If bulk bags are intended to be reused, they are usually stronger than those intended for a single trip.

Many bulk bags have plastic liners. Often the liner is disposable (for sanitation reasons) and the outer bag is reused. The choice of liner material depends on the barrier properties needed or the tendency of the products to dust or leak. Products that attract moisture, or are sensitive to water, require moisture vapor transmission resistance. Polyethylene (2–4 mils) is common, but it is not a complete moisture or gas barrier. Saran and aluminum foil laminate liners are better barriers and can be vacuum-packed. Liners are available in single or multiple plies. The liner construction matches the outer bag construction with respect to dimensions and placement of filling and dispensing ports. Liners come in tube shape or are custom-made to fit, with fill and discharge spouts. The liner can be designed to be manually or mechanically inserted.

There are various lifting and dispensing features available. For example, the most standard European FIBCs are for fertilizer, with single-point lifting and no discharge spout. The most common U.S. FIBCs have four lifting points and a spout. The choice of features depends on the application.

FILLING AND DISPENSING

Bulk bags are usually filled from the top and discharged from the bottom. Most bulk bags have a spout at the top and one on the bottom. The spouts are closed with a tie, clamp, tape, or stitching. Clamps or ties can also be used to tie off a partially discharged bag or to regulate the rate of discharge. Intermittent flow controls are also available. However, some bags have no spouts and are simply filled or emptied through an open “duffle” that is gathered and tied to close. Some single-use FIBCs have no discharge spout, and they are simply slit to empty.

Bulk bags normally require special filling and dispensing fixtures and equipment. Gravity directs the flow. Filling and discharge procedures and efficiency are influenced by the product’s angle of repose and flow characteristics. During filling, the bag needs to be suspended from the top so that the product will completely fill the corners. Some filling systems incorporate a vibrating or settling device, deaeration and dust control measures, or a bag squaring method (although they rarely stay square once they are handled). Most are filled to weight using either a batch weigh hopper above the bag or a load cell to monitor the bag’s weight as it is filled. Bulk bags are quick to fill; a two-operator filling station can fill a 2200-lb-capacity bag in about 30 s with a dense free-flowing product. But a light powdery product, which may require extra handling or vibration to compact, may take up to 30 min to pack.

A typical discharge fixture positions the bulk bag above the awaiting hopper, conveyor, pump, or tank receptacle where the bottom is opened so that the product can flow out. Special discharge equipment has been developed to reduce dust, improve flow, meter, and reclose, and improve sanitation (especially important for food products).

SAFE HANDLING, TRANSPORT, AND STORAGE

Bulk bag handling and transport require special systems to ensure safety and efficiency. FIBCs are very heavy and can be unstable during handling, storage, and transport. This instability can result in danger to materials-handling workers and can cause damage to the bag or its contents.

Bulk bags are lifted from the top or handled on pallets. The most common top-lifting design incorporates four loops at the cube-shaped bag's four top corners. These loops may extend from the top to cradle the bottom like a sling, sewn onto the fabric. There are also center-lift designs that incorporate (a) a single sleeve or loop on the top center and (b) two-sleeve designs with sleeves along two top edges. One-loop bags are more popular in the United Kingdom and France, especially for fertilizer. Some bags have a combination design with center-lift features to aid in discharge and corner lifting to aid in filling. The most heavy-duty FIBCs have steel lifting devices.

The loops or sleeves are lifted by the two forks of a forklift (or a single bar, in the case of the center-lift bags) that may be inverted to shorten the height of the lift. For most bags, it is necessary for one worker to position the loops onto the forks and a second worker to maneuver the forklift. Several can be lifted simultaneously by a ship's tackle and the appropriate stevedore fixtures. It is important for the loops or sleeves to be strong enough to support the weight during handling, including jerks caused by the lift equipment. Correct handling procedures are often printed on the bag or label.

Bulk bags can be transported by flatbed trucks, enclosed trailers, boxcars, flatcars, ship, or barge. Some restraint may be necessary to prevent shifting in transit. Typical restraints are made from straps and fabric, attached to the trailer and boxcar walls. Bulk bags must be strongly restrained if stacked in transit.

Stacks of bulk bags can be unstable. They can be stacked on pallets, but stacks more than 2-high should be supported by retaining walls. Even stacks of 2 should generally be pyramided (the top load spanning two lower ones) to lend stability. Handling a stack of two with a forklift is not recommended. One reason there are stability problems with stacking FIBCs is because they are often not filled with equipment that produces proper settling and material distribution to make the bag form a stable. FIBCs can also be used for temporary storage within a plant, and some can be used for outdoor storage.

DISPOSAL AND REUSE

Empty bulk bags can be discarded in landfills or incinerated if they have no hazardous residue, or they can be recycled (shredded and re-extruded) with compatible materials. But most bulk bags are returned and reused.

FIBCs have excellent return and reuse properties because they are strong when filled, and yet they are lightweight (usually < 10 lb) and can be folded small when empty. The life of a reusable FIBC depends on its construction, the nature of the contents, and the handling and transportation method used, but is typically 5–10 trips. Many shippers reuse the outer bag but discard the liner. Reusable FIBCs are usually stronger than one-way bags. Returnable packages add costs for return shipment, cleaning, tracking, and inspection. Most are reused in a closed-loop system. They require a close relationship with customers to ensure their timely return in order to minimize the packaging investment.

A hidden cost that is often discovered *after* a reuse system is put into place is that the filler of the FIBCs must inspect, clean, and repair the bags. This situation has spawned opportunites for third-party businesses to perform these functions.

In some cases, there is a market for used bulk bags, similar to the market for reconditioned drums. But an FIBC is usually designed for a specific type of product and use, and it is best reused for the same type of product. Buyers and sellers of used shipping containers should certify the identity and compatibility of previous contents and document that the package was cleaned, inspected, and certified as to its safe reuse capacity. For example, lime for steelmaking can be packed in used bags because the residue is burned up and vaporized (along with the whole bag, which is not emptied but is added to the furnace intact).

TESTING AND STANDARDS

Safety and performance standards have always been a concern of the FIBC industry, evidenced by the creation of the industry's self-policing associations such as the Flexible Intermediate Bulk Container Association (FIBCA) and the European Flexible Intermediate Bulk Container Association (EFIBCA). These associations work with other standards groups like the British Standards Organization (BSO), the International Standards Organization (ISO), the American Society for Testing and Materials (ASTM), the American National Standards Institute (ANSI), the United Nations (UN), and the European Technical Committee for Packaging Standardization (CEN/TC261/SC3/WG7 covers IBCs) to better control FIBC safety and quality. Performance standards for FIBCs vary by country and regulatory agency. The first performance standards were developed in the United Kingdom by the EFIBCA and were later incorporated into the British Standard Institute's BS 6382 (BSI/PKM 117). These form the basis for later standards adopted by other countries, including the United States, Australia, Japan, and throughout the European Economic Community (EEC). It is also the basis for the International Standards Organization's ISO TC 122/SC 2 N 238. The EFIBCA has also standardized the information that appears on each bag to include name, date, and address of manufacture, construction identification, standard to which the bag is produced, test certification, class of bag (e.g., single-trip), safe working load, safety factors, handling pictograms, and the contents' identification.

FIBCs used for hazardous materials are the most highly regulated. In 1990/91, the UN Chapter 16 for the carriage of dangerous goods accepted bulk bags for UN Class 4.1 flammable solids, Class 5.1 oxidizing substances, Class 6.1 toxic substances, and Class 8 corrosives, provided that they conform to the particular modal requirement and have passed drop, topple, righting, top-lift, stacking, and tear tests. In the United States, FIBCs have been accepted by the U.S. Department of Transportation (DOT) for Groups II and III hazardous materials, and performance specifications are given in HM 181-E (1). (See also Transportation codes.)

FIBC materials vary, so most standards are based on performance. Weight-bearing performance tests usually specify testing the bag's safe rated capacity with a much heavier weight—6 times more heavy for standard FIBCs, 8 times for more heavy-duty FIBCs, and 5 times for single-use FIBCs—than the expected contents. Filled bag performance should also be judged with respect to tear resistance, stacking, toppling, dropping (2–4 ft), dragging, righting (by one or two loops), and vibration. The most prevalent forms of damage are split side seams, broken loops, torn fabric, abrasion, and sifting. Damage can also be dangerous, if hazardous materials are spilled or if a stack topples onto a worker. In addition to performance tests, there are relevant material tests for the bag fabric and liner, including tensile strength and moisture vapor transmission. Material tests are used primarily for quality control.

CONCLUSION

Flexible intermediate bulk containers (FIBCs) provide a safe and cost-effective system for handling and transporting a wide range of bulk materials. They are "intermediate" between bulk handling and using shipping sacks for dry flowable commodities. FIBCs offer advantages compared to bulk handling and require a low initial investment compared to the special transport and handling equipment used for bulk handling. Some can be stored outdoors without the need for a warehouse or silo. They reduce product waste, and the contents can be easily and accurately metered. An FIBC can perform the function of a mobile hopper. Compared to conventional 50-lb bags, FIBCs are less labor-intensive and do not involve manual handling that can cause back injuries. They are less expensive and require less space to pack. They are quicker to fill, handle, and discharge. And they reduce the risk of product loss, contamination, and pilferage.

BAGS, MULTIWALL

ALLAN M. BAYLIS
Amber Associates, Jamesburg, New Jersey
Updated by Staff

INTRODUCTION

Multiwall bags are concentric tubes of 2–6 layers or paper with a choice in the type of end closure. Designs differ mainly with respect to whether the sack is to be filled through an open mouth or valve. This depends on the product or volume to be handled. Valve designs are closed automatically as a consequence of their design and there are various methods, including sewing and tying for the closing of the open mouth paper bag.

Prior to the United States Civil War, two industrious merchants in upstate New York, Arkell and Smiths, had been looking at cotton sacks to ship flour and grains to the larger southern cities; and from this vantage point, they were also investigating the use of paper sacks for marketing flour. Arkell received the first U.S. patent for paper sack making machines in the 1860s; this was just in time to permit paper sacks to replace the difficult-to-obtain cotton bag fabric during the war.

At the same time, salt was being packaged and marketed in cotton bags, until the 1890s, when Adelmer Bates developed a concept wherein a "valve" was incorporated into one corner of the cotton bags. Its advantages provided a faster method of filling cotton bags with salt, and it was patented in 1899. In 1901 John Cornell worked with Bates on the development of a valve sack filling machine, and in 1902 they were awarded a patent on a valve for paper sacks, but almost two decades passed before the paper shipping sack was widely used.

In 1919 R. M. Bates, Adelmer's brother, was visiting in Norway, where he saw a paper sack of a truly different construction. Having five walls made from long strips of kraft paper with each edge of the strip pasted to its adjacent edge, it formed tubes of paper. These were cut to length and were open at both ends. At the place where they were to be filled, one end was gathered together and tied off; when filled, the top end was also tied with twine or wire. These were flat paper tubes.

While Bates was working on his ideas of filling these tubes through the valve corner, his partner Cornell conceived the idea of having valve corners inserted into a gusseted tube, or “in-fold” feature. These were first made in the mid-1920s, and their advantages were promptly recognized. During the first year of production, millions were manufactured and sold, and by 1927 about 130 million were made annually.

While the cotton bags with their paper-filling sleeves had solved the bag-filling problem, the other problem of their return and reuse to reduce bag costs still existed. Into this breach came the multiwall paper sacks (either with or without filling sleeves), and thus the paper shipping sack industry was born.

Portland cement and masonry cement plants, grain products and flour factories, and saltworks were the earlier multiwall sack users, because these new bags solved the dusty conditions that had been so dangerous, healthwise. Now the workers were freed from breathing undesirable dust and airborne mineral deposits, and working conditions were greatly improved.

The terms *multiwall bags* and *paper shipping sacks* are often used synonymously. Other industries followed suit as soon as more producers of multiwall bags were established, and the shipping sack industry prospered accordingly. World War II caused severe shortages in burlap and manila fibers due to the extremely long distance from the primary sources in Southeast Asia; concurrently, cotton fiber for bags was in short supply, due to U.S. military and naval needs (as well as for civilian clothing). These shortages resulted in a large expansion of the use of paper shipping sacks, and the cotton bag never recovered its earlier dominance, just as cotton and burlap had replaced the rigid containers such as wood boxes, crates, and barrels.

During World War II the multiwall bag really came into common useage. With a wide range of special papers to control moisture and insect infestation plus the ability to tailor-make whatever package strength was required to fit the rough military handling, multiwalls came to be the approved specification packages for government purchasing.

From these early beginnings the sack industry has grown into a multi-billion-dollar business with shipments of over three billion sacks annually for over 2000 different products in the United States. Over four billion sacks are used annually in Europe (1). These end-uses fall into four major categories: agricultural products and supplies, food products, chemical products, and rock and mineral products.

The primary advanges of paper shipping sacks are low tare weight, flexibility, ease of filling and handling, low cost, minimum storage space, biodegradability, and good graphics. Other advantages include the basic material, which is a renewable resource; protection of contents from moisture absorption; control of contents from moisture loss; protection of contents from chemical action; control of seepage or penetration of hot-packed products; provision of loss of gas or vapor; prevention of product sifting or contamination; good stacking and utilization of warehouse space; FDA approval for human food products; excellent graphics; and ease of use in merchandising displays.

Multiwall bags exclude single-ply bags and bags of duplex construction, but do include those with three or more plies of paper or other barrier protectors. They are produced by combing several layers of paper (or other substrate) over a metal former that nests the walls into a long continuous tube (flat or gusseted). These walls are bonded together with adhesives so that each tube is independent of the other tubes, and therein lies the bag’s strength. The tubes may be cut straight (all at once) or in stepped-end formation where each wall is first perforated, then simultaneously snapped apart.

Next, in order for the tubes to be filled and used, the tubes are delivered to bottoming machines in the bag plant where they are either sewn closed at one or both ends. Or, the tubes may go to a pasting bottomer to form either pasted open-mouth, stepped-end pasted valve, or pinch-bottom open-mouth sacks (see Figure 1).

TYPES OF MULTIWALL SACKS

There are two basic multiwall types: the open-mouth type and the valve type bags. Multiwalls are custom-made to order according to the customer’s requirements and for adequate strength to ensure the safe arrival of their contents to the destination locations.

Whether the product is packaged with high-speed open-mouth weighing and filling machines with automatic closing and sealing machinery, or with even faster valve packers and automatic bag placers, a proper and successfully designed and printed multiwall bag may be readily developed.

Most multiwall bag suppliers have very well trained sales personnel, as well as experienced factory technical representatives with a wide range of user experience who are well qualified to recommend the best bag for any product requirement.

OPEN-MOUTH BAG TYPE

Sewn Open Mouth (SOM)

This style, with any number of walls, has a factory sewn bottom and open top, and may be either flat or with side gussets. These bags are used primarily to package granular or large-particle products. The product is delivered into the open top, and the top may be closed by sewing or other means. If a polyethylene liner ply is specified, this may also be heat-sealed. These types of packaging lines may be fully automated.

Pasted Open Mouth (POM)

This style has a pasted bottom and open-mouth top, and it is sealed after filling by folding and pasting, or, in some cases, sewing the top. This latter style is not preferred for packaging and shipping free-flowing products because a finlike (nonflat) package is obtained. But it is ideal for containing a number of previously filled and sealed unit bags–for example, 12.5-lb sugar or 5- to 10-lb bags of potatoes. These are called *master container or baler bags*.

Pinch-Bottom Open-mouth (PBOM)

This style has the plies cut in a stepped fashion with the bottom sealed by gluing or heat sealing at the bag factory.

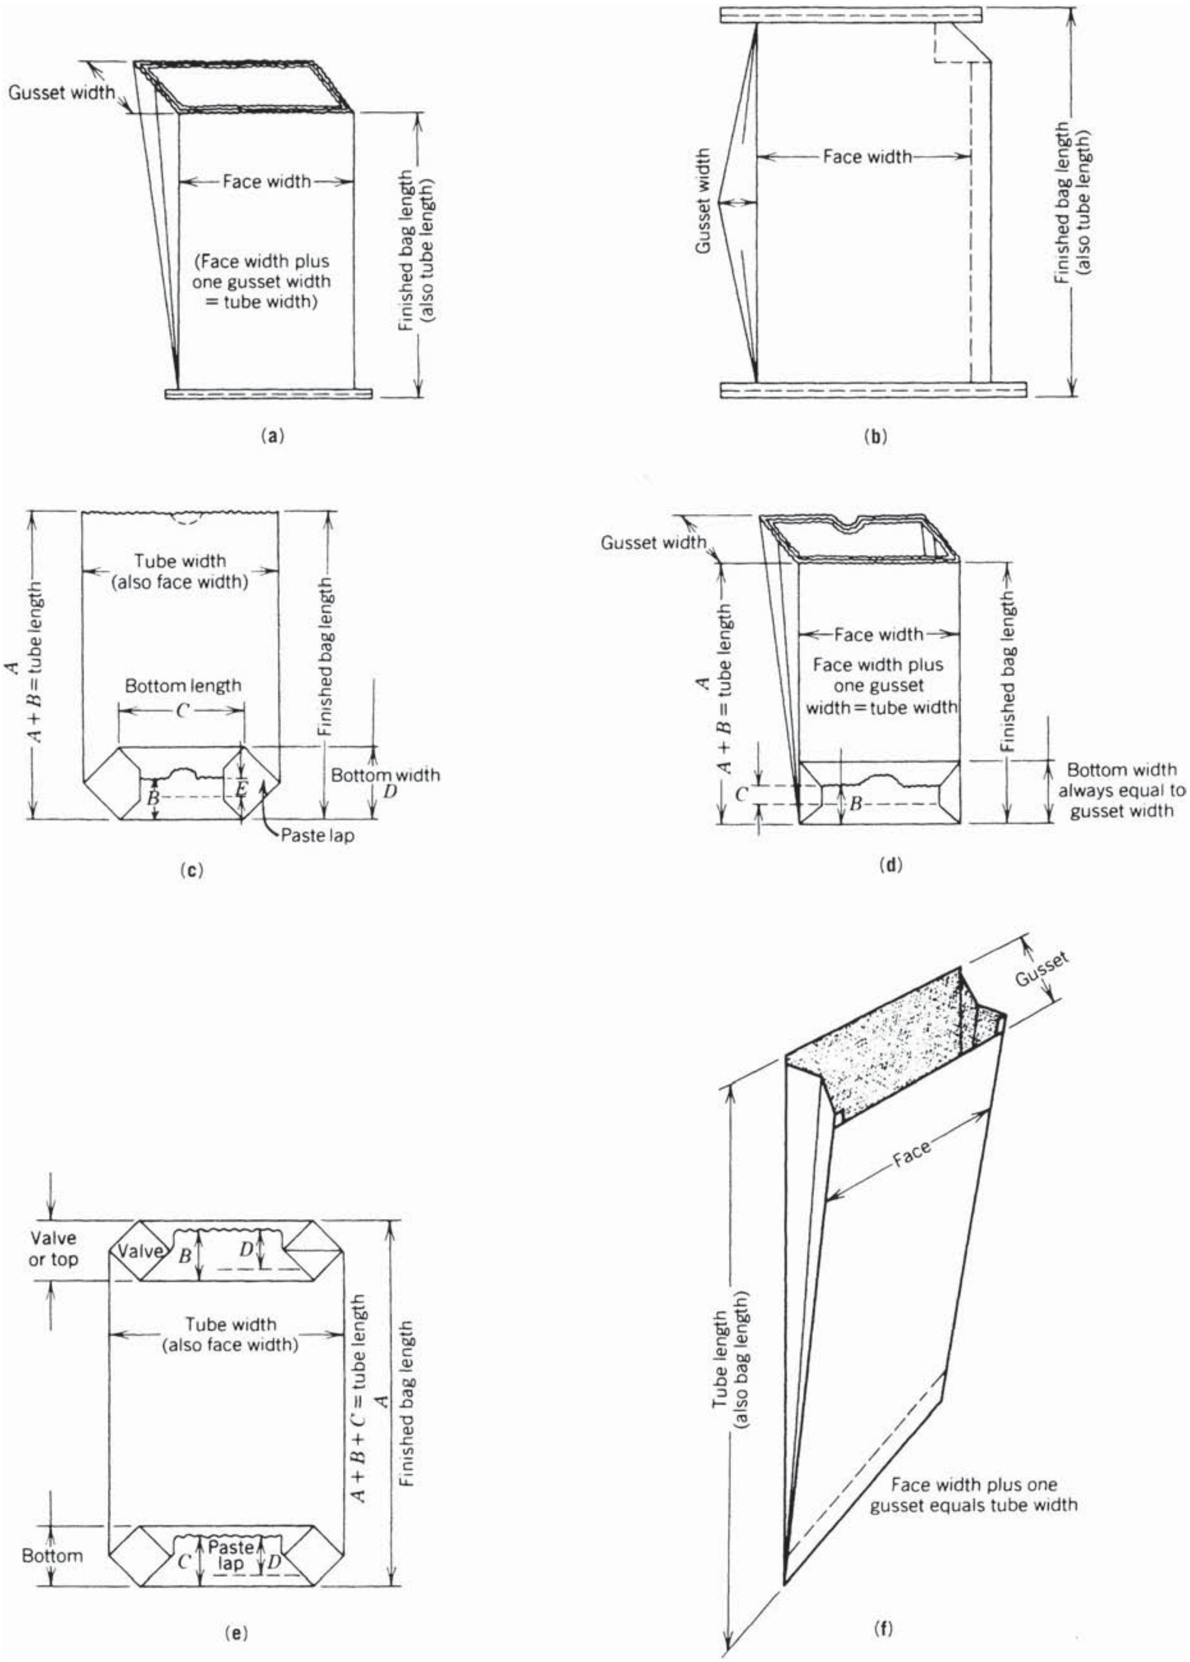

Figure 1. Common bag styles in current use: (**a**) sewn open-mouth; (**b**) sewn valve, (**c**, **d**) pasted open-mouth; (**e**) pasted-valve stepped-end; (**f**) pinch-bottom open-mouth.

After filling at the user's plant, the open mouth top is folded over and sealed by reactivating preapplied hot-melt adhesive. This style of bag provides completely moisture-proof and sift-proof packages. PBOM bags are the fastest-growing segment of the total multiwall bag industry because of the secure and strong closure ends, and full control of sifting or infestation.

VALVE BAG TYPE

Sewn Valve (SV)

These are made with the plies at the top and bottom ends sewn at the bag plant usually with sewn-through crepe paper tape. The bags are filled with a valve packing machine by forcing the product through a built-in valve corner. For small particles and large powders, the contents may be retained without any leakage, by hand-folding in the paper valve extension.

This old style with sewn tape at both ends has fallen out of favor in recent years, and the modern pasted valve style has supplanted it.

Pasted Valve Stepped End (PVSE)

As in the pinch-bottom open-mouth bag, the plies are cut off in a stepped configuration; then the bag factory bottoming machine folds and, with adhesive, seals both top and bottom ends of the tubes. An added valve sleeve is built into a corner, permitting rapid bag placement on a valve packer; and when the filled package falls to a take-away conveyor, the valve automatically is closed by the internal pressure of the product.

PVSE-type bags, introduced in 1956, are the present standard package for most automatic or high-speed operations such as cements, powders, feeds, fertilizers, or other chemical or building products. When stacked or palletized, they provide stable and attractive three-dimensional containers.

Valve bags may also be purchased with paper tuck-in sleeves that, when folded in, will control all possible leakage.

SIZING MULTIWALL BAGS

First, the weight to be packaged and the product density must be determined. This latter may be done by using a box of known dimensions (1 ft × 1 ft × 1 ft) or 1 ft^3 to determine the weight per cubic foot. With the known weight and volume requirements and with the bag type selected (by product characteristics), an educated estimated set of dimensions can be offered. A supplier can fine-tune these numbers by offering several handmade factory samples. When test-filled, these may be adjusted to supply a larger number of machine-made test packages to finalize all specifications such as dimensions, filling, handling and shipping, and palletizing conditions.

CONSTRUCTIONS

The paper most commonly used to fabricate multiwall bags is natural-colored virgin pulp brown kraft. Made primarily in the Southern U.S. states using a modified sulfate pulping process, it affords longer fibers that enhance the paper's cross- and machine-direction strength. Typically brown, it may be lightened through bleaching, or semibleaching sulfate pulping.

Kraft is usually designated in basis weights ranging from 40 to 80 lb per ream of 500 sheets of 24 in. × 36 in. in area. These grades are known as *multiwall kraft* and have higher strength specifications than grocery-bag kraft (NK) used for light-duty brown paper bags.

Other popular grades used in multiwall bags are extensible (XTK) and free-dry (FDK) process papers. These developments during the 1960s and 1980s resulted in improved cross- and machine-direction stretch specifications and greater overall bag strength. Other grades, such as high-finish, rough, calendered, machine-finish, and wet-strength, are available for specific end-use purposes (see Paper).

Subsequent to the mid-1940s with the development of tailor-made plastics, polyethylene (PE) films have been integrated into many bag constructions. Prior to this, asphalt laminated kraft (ALK) provided moisture barrier properties to multiwall bags, but it was difficult to fabricate on the tuber and bottoming equipment, and it is no longer in use.

Multiwall paper bags may be lightly coated with high-shear, low-stress adhesives to overcome bag slippage when stacked on pallets or in storage. This inexpensive treatment is invisible yet very effective.

Heavy-duty single-wall plastic film bags are also available, however, when compared in cost with multiple-ply kraft or a kraft paper ply plus a lightweight poly ply or polyethylene-coated kraft, the single-wall plastic bags are not cost-effective. They also are slippery, and palletized filled bags cause shipping difficulties (see Bags, plastic).

Depending on the physical characteristics of the product being packaged in multiwall bags, they can be custom-designed to provide all the protection that is necessary. Low-or high-density polyethylene, poly(vinyl chloride), poly(vinyl dichloride), nylon, saran, foil, and polypropylene are some of the available substrates.

Most multiwall bag suppliers have well-trained sales personnel and specially trained factory technical representatives who are well qualified to recommend the best construction for any particular requirement.

SPECIFICATIONS

With the complete knowledge of a product's physical and flow characteristics, a bag style may be selected. This is only a minor portion of the information required to design a new multiwall bag that will deliver the product in acceptable condition. The product density and the desired weight to be bagged must be known; from this, the required capacity (in cubic inches) is calculated.

General rules are usually followed to select the total kraft paper basis weight and the number of kraft plies. For instance, 50 lb of product might require three walls of 50-lb natural kraft to total 150 lb, and 80 lb would need three or four walls of combined 40- and 50-lb basis weight multiwall kraft, totaling ~180 lb.

The requirements for product protection must be carefully evaluated. This might include moisture protection and control, gas or odor control, grease or oil control, siftproofness, chemical resistance, mold protection, and toxicity or hazardous chemical protection.

Each of these factors can be controlled by the use of one or more of the following available sheets: low-density PE (LDPE), high-density PE (HDPE), polyethylene-coated kraft paper (PEK), saran, Tyvek, saran-coated polypropylene (SCPP), polyfoil–polykraft laminate (PE-AL-PE-K) biaxially oriented polypropylene (BOPP), or even poly-coated crepe kraft tape, or heat-sealed waxed kraft tape. About 25% of the multiwalls now being produced specify some kind of special liner ply.

Special barrier plies are commonly used in multiwall bags to protect the product from gaining or losing its intended moisture content. This is stated in terms of its water vapor transmission rate (WVTR). A wall of material may be laboratory-tested, to determine its WVTR rating in terms of g/m^2 per 100°F at 95% RH (relative humidity) in 24 h. The more effective barriers usually are the heavy 2.5–4.0-mil HDPE and LDPE, or 0.75-mil BOPP film, while those most frequently needed are the less expensive 0.5-mil HDPE and 0.8–1.0-mil. LDPE films.

Some products have specific needs, such as controlled porosity to permit proper air or moisture transfer, grease or oil penetration, wet-strength protection with urea formaldehyde, or melamine formaldehyde, which enable the paper to retain its original strength when saturated by water. All these and more—toxicity, hazardous nature, odor control, acidity, or alkalinity—can be controlled.

Or, for a really attractive consumer package, the manufacturer might select a supercalendered high-finish full-bleached white sheet with gravure-quality printing.

Multiwall prices are developed by applying cost factors for bag style, bag size (sheet width and tube length), basis-weight factors for kraft, and the plies of other substrates. To these the supplier adds the cost for printing by area and number of colors required. Bags are usually ordered by the carload or trailerload to obtain the lowest unit price.

In cases where a product is highly aerated and moisture protection is only nominal, one or more kraft plies may require allover pinhole perforations (AOPHP) of different diameter and spacing. These allow the internal pressure to be expended during bag filling and they prevent bag breakage.

Discussing the particular needs that are required for your product with a multiwall bag supplier will direct you to the correct and complete bag specifications from the weighing and filling stages to the customer's ultimate place of use.

PACKAGING EQUIPMENT

For each style and size of bag used, there is a wide choice of equipment available for weighing, filling, and closing the packages. There are two main styles of bagging equipment: open-mouth and valve.

Open-Mouth Packers

The older, original method of open-mouth bagging required a scale, a vertical delivery spout, and a closing function. With today's modern high-speed open-mouth equipment, there are automatic and accurate weighing scales, automatic bag placers, and finally, automatic bag closures.

These systems usually run up to 20 or more preweighed charges of up to 100 lb of material per minute with only token supervisory requirements. There are two preferred methods of closing open-mouth multiwall bags: sewn closure or heat sealing.

Most common of the sewn types is the stitching of the bag mouth with cotton or polypropylene sewing thread with an industrial sewing head. With more secure or special product requirements, either sewn-through tape, adhesive, or heat-sealed tape over sewing may be provided.

Valve Bag Packer

With the invention of the valve packer in the mid-1920s, the valve-style bag may be filled by forcing the product through a spout (usually horizontal) into the valve corner and then down into the bag. The product is either preweighed and then forced into the bag, or it is weighed in the package (gross-weighed).

Choices are available when weighing and filling valve bags, and they depend on the product's physical characteristics, price, and production speed requirements.

Most valve packers use either the impeller-wheel method or the belt-feed method. With the former, rotating high-speed paddles force the material into the package. This causes a great amount of aeration to occur, and the PV or PVSE bags must be capable of withstanding great pressure. One operator with a four-spout impeller valve packer may produce up to thirty 94-lb (206-kg) filled bags per minute.

With the belt valve packer, the product is thrust between a moving belt and a rotating grooved pulley and then into the valve opening. This is gentler on the material, but not as fast as the impeller method. Fertilizers and small-pelleted materials are usually packaged on belt-style valve packers.

Three other less popular valve packer styles are available auger, gravity, and airflow. The latter is more modern than the other two and has the advantages of handling non-free-flowing finely powdered materials, without degradation with much better accuracy. The auger packer utilizes a horizontal screw within a hollow tube. These work well for non-free-flowing products, and since the screw's rate of rotation can be adjusted, better weight accuracies are obtained. The last and least popular valve packing method is the vertical-gravity style. But, since it is used for very free-flowing or inexpensive materials, accurate bag weighments are sometimes difficult to obtain.

GRAPHICS

Previously, the fabrics of multiwall paper bags were printed with simple yet effective designs to identify the manufacturer, the product, the net weight, and some methods for using the contents.

Cotton and burlap bags had a second life, since they must either be returned, cleaned, and filled for reshipment or, in the case of the cotton bags, be washed and then sewn into towels or items of apparel at home.

With the conversion from fabric to paper bags came the important advantage of superior printing capabilities. With smooth surfaces and all-around six-sided printing of up to four colors, a company's marketing message could be extolled, thereby differentiating itself from all its competitors.

If brown kraft is not attractive enough, a supplier can readily furnish semibleached (SBW) or full-bleached (FBW) kraft. Smoother or brighter papers and coatings in conjunction with modern printing capabilities provide appealing and forceful advertising that make the bags effective billboards for marketing their contents. Whether they were small-unit consumer bags or large industrial-size bags, they can utilize flexographic printing to carry the intended messages.

If more definition is required, prepress gravure printing using up to six colors will result in photographic quality printing, with the following advantages: excellent product and protection; unlimited supplier capabilities; biodegradable materials; and proven shipping and storage environments

Pet-food and charcoal briquette bags are excellent examples of effectively printed packages found in all supermarket shelves today.

Multiwall bags are readily accepted and desirable as shipping containers in all domestic and export markets, including hundreds of uses for agricultural products, building materials, chemicals, food products, and minerals.

TRANSPORTATION

In the past 40 years the shipment of filled multiwall bags to the market where they are used has swung almost completely from railroad boxcars to over-the-road trailers or straight trucks. Also, pallets have replaced the individual handling of filling bags. Coincidentally, plastic film has in many cases been incorporated into the bag's construction. These changes have resulted in lighter basis-weight requirements and lower costs. Multiwall sacks are covered by the Uniform Freight Classification for Rail Rule 40; National Motor Freight by Truck Item 200; Hazardous Materials Regulations title 49 CFR; and Federal Specifications UUS-48, sacks for government shipment (2).

ENVIRONMENTAL CONSIDERATIONS

At present, the essential element in all paper sacks is virgin fiber. Secondary or recycled fiber is not an option because such material can result in an inconsistent pack that would be weaker and unsuitable for automated filling and in handling systems. The bags would be more costly to produce and in many cases would be unacceptable for direct contact with food. As a result of continuous research, there has been substantial reductions in the average construction weight of a multiwall paper sack. Recovered bags can be recycled. It has been suggested that specifications should be revised to maxmize the content of secondary fber. A levy on virgin fiber has been proposed in Europe.

USES

Some examples of products that are packaged in weights of under 20 lb are additives, animal food, baking products, cat litter, charcoal, chemicals, coffee, cookies, dried foods, grits, insecticides, microwave popcorn, plant food, theater popcorn, salt, and sugar. Industrial products weighing more than 20 lb and packed in multiwall bags are absorbents, abrasives, cement, lawn and garden supplies, and animal feeds (3).

Helpful Hints. The list below is meant to be of use to a packager in selecting an appropriate multiwall paper sack.

1. In the initial planning stage of a new use for multiwall shipping sacks, obtain the guidance of bag suppliers.
2. Develop accurate product physical and chemical properties.
3. Finalize decision on desired package weights.
4. Determine annual production requirements.
5. Select proper bag style and features.
6. Consider styles of packaging equipment available.
7. Decide on the transportation and distribution modes.
8. Determine probable bag sizes and constructions.
9. Plan bag transporting methods to provide minimum individual handlings.

BAGS, PLASTIC

Plastic bags, available in virtually all shapes, sizes, colors, and configurations, have replaced paper in most light-duty packaging applications. Paper has been more difficult to replace in heavy-duty applications (see Bags, heavy-duty plastic). Light-duty plastic bags are generally described in one of two ways: by the sealing method or by application. This article explains the methods used to produce plastic bags and defines the various types of plastic bags in terms of their intended use. A plastic bag is defined here as a bag manufactured from extensible film (see Films, plastic) by heat-sealing one or more edges and produced in quantity for use in some type of packaging application.

METHODS OF MANUFACTURE

By definition, all plastic bags are produced by sealing one or more edges of the extensible film together. The procedure by which this heat-sealing occurs (see Sealing, heat) is typically used to identify and categorize types of plastic bags. Three basic sealing methods are used today that include the following: sideweld, bottom seal, and twin seal.

Sideweld Seal. A sideweld seal is made with a heated round-edged sealing knife or blade that cuts, severs, and seals two layers of film when the knife is depressed through the film material and into a soft rubber backup roller. The materials are fused by a combination of pressure and heat (see Figure 1).

The sideweld seal is the most common bag-sealing method. Typical high usage bags, e.g., bread bags and sandwich bags, are produced using the sideweld technique. The term “sideweld” is derived from the fact that many of the bags produced in this fashion pass through the bag machine with the length (or depth) of the finished bag perpendicular to the machine floor. The film fed into the machine is either prefolded, i.e., J stock, or folded during the in-feed process (see Figure 2).

Bottom Seal. The bottom-seal technique seals the bag at the bottom only. Tube stock is fed into a bag machine, the single seal is produced at the bottom of the bag, and the bag is cut off with a knife action that is separate from the sealing action. A bottom seal is generally made by a flat, heated sealing bar, which presses the layers of film to be sealed against a Teflon (Du Pont)-covered rubber pad, i.e., seal pad (see Figure 3), or another hot-seal bar (see Figure 4). A separate cut-off knife is used to separate the bag from the feedstock while the seal is made or immediately thereafter. Both bottom-seal mechanism designs produce a bag with only one seal, unless the tube has been manufactured by slit-sealing (see below). The small amount of unusable, wasted film between the edge of the seal and the cutoff point, called the “skirt” of the bag, is an important factor in the total cost of the bag. Any disadvantages caused by the presence of the unwanted skirt are usually offset by greater control of the sealing process. The sideweld method actually melts through the plastic film, and overheating of the film resins can change the physical structure of the plastic molecules when the seal cools. In contrast, the bottom-seal method controls the amount of heat and the dwell time, i.e., the time that the heat is applied to the film, to produce a seal that does not destroy the film or change its physical properties. In addition, the total amount of film sealed together is usually larger, because the seal bar has a fixed width and none of the film material is melted or burned away.

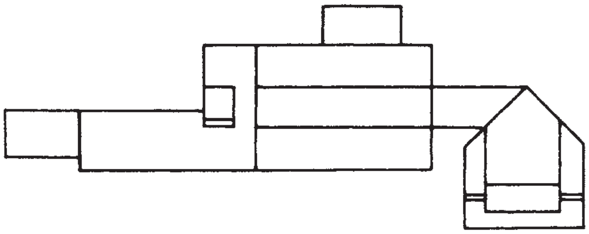

Figure 2. Sideweld process (top view).

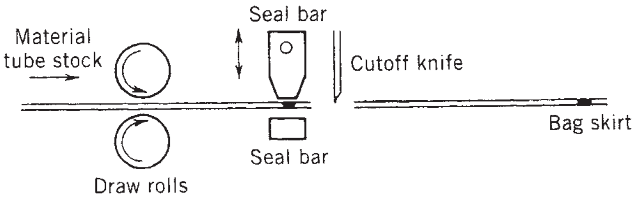

Figure 3. Bottom-seal mechanism (top heat only).

The bottom-seal method is commonly used to produce (HDPE) merchandise bags and (LDPE) industrial liners, trash bags, vegetable and fruit bags, and many other types of bag supplied on a roll. In contrast to the sideweld method, designed primarily for high-speed production of bags made from relatively light-gauge films — i.e., 0.5–2.0 mil (13–51 μm)—bottom-seal methods are often used to produce bags from film from 0.5 to ≥ 6 mil (13–$\geq 152\,\mu$m) at slower production speeds. Bags manufactured by bottom-seal methods are delivered through and out of the bag machine with the length (or depth) of the bag parallel to the machine direction. Because all of the bags

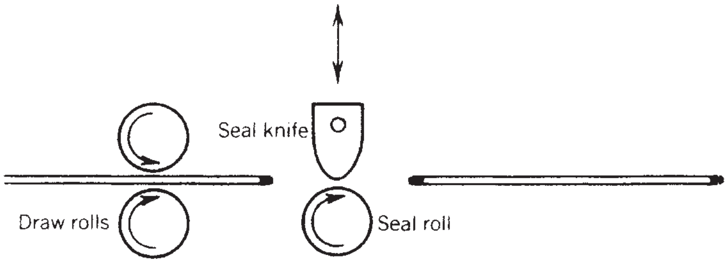

Figure 1. Sideweld-seal mechanism.

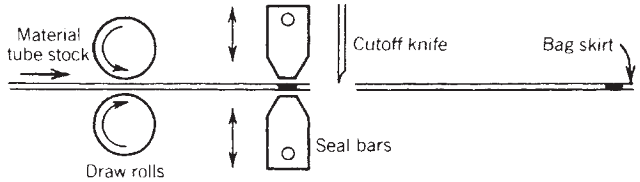

Figure 4. Bottom-seal mechanism (top and bottom heat).

are produced from tube sock, multiple-lane production of bags is limited only by the widths of the machine and the bags and the film-handling capability of the bag machine (see Figure 5).

Twin Seal. The twin-seal method employs a dual bottom-seal mechanism with a heated or unheated cutoff knife located between the two seal heads (see Figure 6). The unique feature of the twin-seal mechanism is that it supplies heat to both the top and bottom of the film material and makes two completely separate and independent seals each time the seal head cycles. Like the bottom-seal method, the twin-seal technique can supply a large amount of controlled heat for a given duration. This ability makes the twin seal useful in sealing heavier-gauge films as well as coextrusions and laminates. Because two seals are made with each machine cycle, the twin-seal method can be used to make bags with the seals on the sides of the finished bag, i.e., like sideweld bags, or on the bottom of the bag in some special applications, such as retail bags with handles. Many special applications call for the use of a twin-seal-type sealing method, but it most often is used in production of the plastic “T-shirt” grocery sack.

Slit Seal. Another type of sealing method, the slit seal, involves sealing two or more layers (usually only two) of film together in the machine direction through the use of a heated knife, hot air, laser beam, or a combination of methods. The slit-seal technique is usually used to convert a single large tube of film into smaller tubes. In the production of grocery sacks, for example, a single extruded 60-in. (152-cm) lay-flat tube of film (see Extrusion) can be run through two slit sealers in line with the bag machine. This process results in three tubes of 20-in. (51-cm) lay-flat material being fed to the bag-making system (see Figure 7).

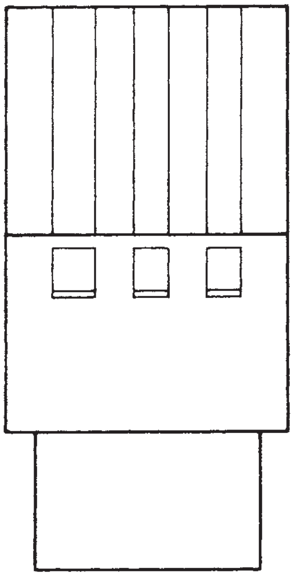

Figure 5. Bottom-deal bag machine, three-level.

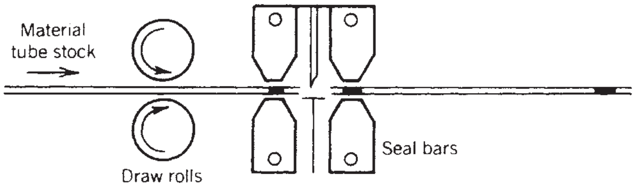

Figure 6. Twin-seal mechanism.

APPLICATIONS

Most plastic bags are characterized in terms of their intended use, e.g., sandwich bags, primal-meat bags, grocery sacks, handle bags, or bread bags. To provide some order to this user-based classification and definition system, it is convenient to separate the bags into commercial bags and consumer bags.

Commercial Bags. A commercial plastic bag is used as a packaging medium for another product, e.g., bread. Typical commercial bags and seal methods are listed in Table 1.

Consumer Bags. Consumer bags are purchased and used by the consumer, e.g., sandwich bags, trash bags. The plastic bag is the product. Typical consumer bags and seal methods are listed in Table 2.

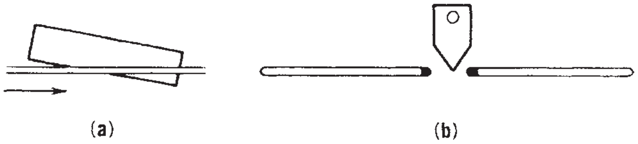

Figure 7. Slit sealer (hot-knife type). (**a**) side view; (**b**) top view.

Table 1. Commercial Plastic Bags

Sealing Method	Types of Bag
Sideweld	Bread bags, shirt and millinery bags, ice bags, potato and apple bags, hardware bags
Bottom seal	Vegetable bags on a roll, dry-cleaning bags, coleslaw bags, merchandise bags
Twin seal	Primal-meat bags, grocery sacks[a]

[a] With dual bottom seal.

Table 2. Consumer Plastic Bags

Typical Sealing Method	Types of Bag
Sideweld	Sandwich bags, storage bags
Sideweld or bottom seal	Trash bags, freezer bags, can liners
Bottom seal	Industrial liners

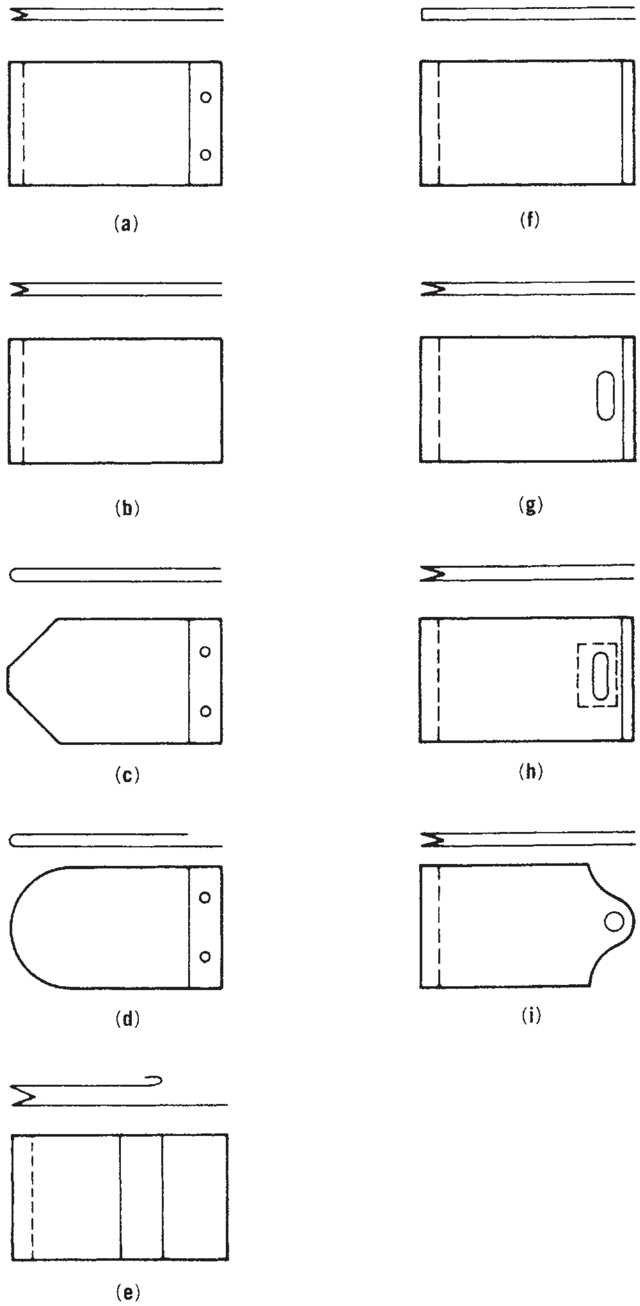

Figure 8. Bags, plastic: (**a**) conventional wicket bag; (**b**) conventional bag; (**c**) square-bottom bag; (**d**) round-bottom bag; (**e**) sandwich bag; (**f**) trash bag; (**g**) handle bag; (**h**) patch-handle bag; and (**i**) sine-wave bag.

In addition to the conventional bags, an enormous variety exists of special bags that have been created by bag producers to meet commercial and consumer needs. These bags are usually described as specialty bags, but they are all variations of the standard bags described above. Specialty bags include rigid-handle shopping bags, sine-wave handle bags, pull-string bags, patch-handle bags, double-rolled bags, square-bottom bags, round-bottom bags, deli bags, etc. Examples of both common and specialty bags are shown in Figure 8.

BANDS, SHRINK

David R. Kopsilk

Systems, Trevose, Pennsylvania
Updated by Staff

INTRODUCTION

Shrink labels, bands, and sleeves provide today's packaging companies with a unique and versatile method for labeling their products. Developed in Japan during the 1960s, shrink bands became popular in the United States in the early 1980s, mainly as unprinted or one-color tamper-evident neckbands. Today, the shrink band is used as a primary label, as a decoration, for multipack applications, and as a traditional tamper-evident feature. The high-quality printing and gloss inherent in shrink labels ensure packagers that their product will generate tremendous visual shelf appeal.

MANUFACTURING

Shrink bands are generally produced using special poly (vinyl chloride) (PVC) films, although PETG films, oriented polystyrene films, and poly(lactic acid) are also used (1). Film thicknesses generally run from 1.25 to 3.0 mils, with 1.50 and 2.0 mils the most prevalent. Material is available in two varieties: seamed film, and tubing. *Seamed film* is converted by bonding a flat sheet of printed or unprinted material into a sleeve configuration. This is achieved through a process of solvent seaming into the desired dimension or flat width. *Tubing* is extruded into the desired flat width before printing. Seamed film can be reverse printed with 360° graphics and generally provides more consistent dimensions in both flat width and gauge profile. Tubing is generally less expensive, and it is used for unprinted or one-color work.

Important dimensional measurements associated with shrink bands are (a) flat width, which represents the dimension relating to the diameter or circumference of the container, and (b) cut height or impression height, which represents the length of the container or the length of the section of the container to which the shrink band will be applied. These dimensions are usually expressed in millimeters.

The inherent shrink is imparted into the material in a heated stretching process. With tubing, this is achieved during the initial extrusion process. With seamed film, a process known as *tentering* is used. A tenter frame is a modified oven that uses a combination of airflow and temperature zones to orient the material. For example, a 30-in.-wide roll of 5.0-mil material will be converted into a 60-in. roll of 2.0- or 2.5-mil film. Shrink ratios of 50–70% can be achieved by adjusting the process. Various ratios are used, depending on the contour of the container being labeled.

Shrink bands are generally processed using the gravure printing method. Reverse rotogravure allows the image or copy to be printed on the back side of the film, which results in a glossy look to the package as well as protection of the image from scratching or scuffing that may occur in final packaging or distribution. Gravure printing provides excellent color reproduction consistency, high speed, and productivity, and it is an excellent method for printing smooth film surfaces. Flexo printing has made inroads into this market as the technology improves, but gravure is still dominant.

After printing, several other features can be added to the shrink band. Vertical and horizontal perforations, as well as tear tape strips, can be added to make the band removable for the consumer. Some packagers use a horizontal perforation to make part of the label removable, the tamper-evident feature is removed, and the primary label stays on the container. Some examples of this are toothpaste pumps, lip balms, syrups, and salad dressings. Bands can be provided in continuous roll-fed form, or in individual cut pieces for manual application.

APPLICATION

Bands can be applied manually or by automatic machinery. Machinery on the market today is capable of applying bands at speeds of 500 per minute or more, depending on container size, container contour, and label dimensions. For example, a lip-balm label of approximately 27-mm flat width and 60-mm length can be applied faster than a 190-mm-flat width, 40-mm length band for a large dairy container, due to both the label size and the container size. Machinery is dominant in the dairy, packaged-food, and pharmaceutical markets. Most machinery applies shrink bands in a horizontal method, but recent developments have allowed for vertical application of pen barrels, lip balms, and other small cylindrical objects. Most machinery requires material of 2.0 mils or more for processing, and the use of a wedge or other device to open the material before application is common. After application, the container is sent through a heat tunnel, which uses a combination of airflow and heat to shrink the band securely onto the container. A dwell time of 3 s at roughly 300°F is used for most applications, although some products require an elaborate system of varying temperatures and product rotation to achieve the desired effect.

Machinery is available to pack two containers together with one band. This process is used in lieu of an overall bundling method, which then may require the application of another printed label for bar coding or to convey the promotional message. Manual applications are used when product volume is small or in market trial introductions.

Since shrink bands adhere using shrink energy, no glue or glue applicating systems is required to apply shrink bands.

USES

Shrink bands are generally used in three ways: as tamper-evident neck bands, as primary labels and decorations, or for promotional multipacking (see Figure 1 for examples). Food and pharmaceutical packagers have been using neckbands as a tamper-evident feature ever since the Tylenol incident in Chicago in 1982. They are often used in conjunction with vacuum packaging, inner seals, and breakaway closures for product integrity. One advantage for consumers is that neckbands provide evidence of tampering before the consumer brings the product home, as any attempt at removal is evident on the store shelf. In the food-packaging market, yogurt, sour cream, salad dressing, mayonnaise, syrup, mustard, and jelly are just some examples of products that use neckbands (2). In the pharmaceutical and health–beauty arena, use of neckbands is even more prevalent. Eye care, mouthwash, cough syrup, pain relief, and vitamins as well as many ethical medicines are among the products that utilize this tamper-evident feature (see Tamper-Evident Packaging).

In the primary label and decorating market, shrink bands provide a versatile and unique way to package various products. The reverse printing capability allows graphics to stand out on the store shelf as well as provide durability. Batteries have been labeled using shrink film for years, because the fine copy and metallic look required on these products are achievable with shrink labels. Lip-balm labeling combines a primary and tamper-evident label using a horizontal perforation for easy removal of the tamper-evident feature. Since this product is often sold loose at drug and convenience-store checkout counters, the lip-balm package can be easily displayed without any further packaging. In recent years, writing instruments decorated with multicolor graphics have become popular, especially those with designs targeted to the teenage market. One advantage of shrink labels on this product is that the reverse printing protects the image from the oils and dirt that occur naturally on people's

Figure 1. Examples of commercial uses of shrink bands.

hands, which can erode an image directly printed on a writing instrument. Other products using shrink bands as primary labels or decorations are Christmas ornaments, Easter egg decorating kits, children's shampoos and soaps, deodorant sticks, plastic baseball bats, golf clubs, yarn and thread spools, craft paints, and tobacco containers. Seal-it Inc offers holographic labels (3).

Full-body sleeves cover 360° of a product from top to bottom., and they provide the maximum promotional area. Perforations are available that are easily removed, but the label remains on the containers. Up to 10 colors are available (2).

A third use of shrink labels is for multipacking purposes. Two or more products are bundled together using a shrink band. Printing the bands eliminates the need to apply a paper label later in the distribution process. Two products are placed side by side, and the label is applied vertically over the top. It is not uncommon to put two different products together. Examples of this would be 16 oz of shampoo and a trial size of conditioner, or mouthwash and a toothbrush. When three containers are banded, placing the products in a triangle configuration provides for a more secure package, because this prevents the third product from falling out of the middle. Just about any product can be packaged this way; some common uses are for packaging of hair-care products, vitamins, car-care products, lubricants, peanut butter, caulking compounds, and cooking sauces. Three tubs of baby wipes are stacked on top of each other and vertically sleeved using a shrink band. Most multipacks are done manually, and almost any product or container allows for this banding method. Basic uses for multipacks are trial sizes, values, twin packs, buy-one-get-one-free, and seasonal promotions (4).

Shrink bands will continue to provide packaging companies with a unique method of labeling their products. The double benefit of increased tamper evidence and integrity along with attractive graphic impact is beneficial for almost any product. Shrink bands will continue to grow as a labeling method in the beverage, industrial, and toy markets as well as maintaining an important position in the traditional food, health and beauty, and pharmaceutical markets.

BARRELS

Frank J. Sweeney
Sweeney Cooperage Ltd.

A barrel, or cask, is a cylindrical vessel of wood that is flat at the bottom and top, with a slightly bulging middle. The three primary parts of a barrel are heads (bottom and top), staves (sides), and hoops (rings that bind the heads and staves together) (see Figure 1). Specifications are contained in the Department of Transportation regulations (1).

In architecture and physics, the arch is probably the stongest possible structure. The more pressure or weight exerted on the top (keystone) of the arch, the stronger the arch becomes.

The wooden barrel is designed according to the double-arch principle of strength. Like an egg shell, it is doubly arched, both in length and girth. The bend in the stave's length is the first arch, and the bilge circumference of the stave's width is the second arch. These arches impart great strength.

There are three basic cooperage operations: logging the timber, milling the logs, and assembling the barrel staves and heading material. Saws reduce the logs to length, produce edge-grained pieces of cylindrically shaped and jointed wood for the staves, and produce flat pieces of wood for the heading. In recent times, staves have been quarter-sawn as opposed to earlier cylindrical-sawn staves. The

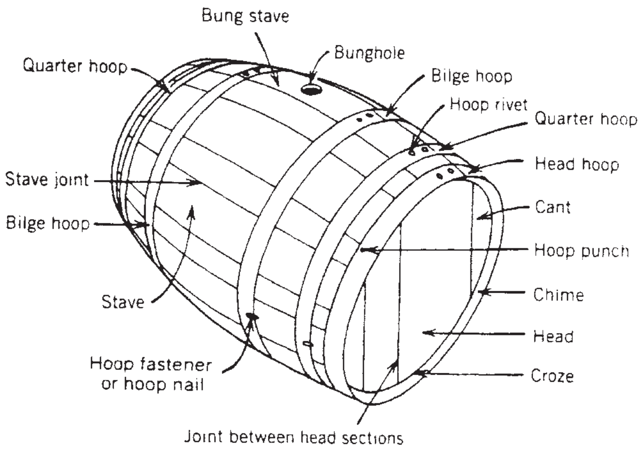

Figure 1. The wooden barrel.

quarter-sawn straight staves are planed interiorly and exteriorly throughout their thickness to achieve a stave of cylindrical width. After the wooden material has been air- and/or kiln-dried to approximately 12% moisture content, the staves and heads are assembled into steel-hoop-bound barrels. Assembly operations include: setting up staves; steaming and winching staves to achieve the belly, bilge, or circumference arch; heating to make wood pliable and give one last drying after being steam bent; tapping out for uniform thickness; trussing to tighten stave joints; crozing interior grooves in each end of the staves where the heads will be inserted; heading up by inserting heads in the croze at each end of the staves; hooping up by driving riveted-steel hoops onto exterior of staves; boring for testing, lining, and future filling; bunging up the bored hole; and rolling the barrel out to the marketplace.

Dozens of species of timber from all over the world have been used to make tight (for liquid) and slack (for non-liquid) cooperage. Hardwood barrels for spirits and wine include oak timber from Limousin and Nevers in France; Alastian and Italian oak; and fork-leafed American white oak, found principally in the slow-growing forest regions of the United States of Missouri, Indiana, Tennessee, Kentucky, and Arkansas. Virtually all of the wooden barrels made in the United States today [1–2 million (10^6)/yr] are 50-gal (189-L)-capacity barrels used by the bourbon whisky trade. Barrels for bourbon are charred interiorly about 1/16 in. (1.6 mm) of their 1 in. (25.4 mm) thickness to bring out the tannin in the wood. Tannin aids in the coloring and flavoring of spirits and wine.

Wooden barrels have had numerous names, depending on their size and use. A small sampling of these names include: pickled-pig's-feet kit; fish pail; one-quarter, one-half, and full-beer ponies; hogshead; salmon tierce; tallow cask; rum puncheon; and port wine pipe. A list of common international cask sizes is presented in Table 1 (2).

Just as the wooden barrel replaced the crude basketry used centuries ago, many other types of container have replaced the wooden barrel: steel and fiber drums, plastic pails, aluminum and steel cans, fiberglass and cement tanks, and so on; aluminum and stainless steel replaced wood for beer barrels (3).

Table 1. Wooden Casks for International Shipments of Alcoholic Beverages

Beverage	Name	Gallons[a]	Liters[a]
	Wine		
Sherry	Butt	137.5/140	500
	Hogshead	67.5/69	250
Port	Pipe	145/147.5	53
	Hogshead	72.5/74	265
Vermouth	Hogshead	67.5/70	250
Burgundy	Hogshead	57.5/60	215
	Spirits		
Rum	Puncheon	137.5/144	520
	Hogshead	67.5/72.5	255
	Barrel	50	180
Brandy	Hogshead	77.5/79	280
	Quarter case	39/40	140
Beer	Butt	135	500
	Hogshead	67.5	245
	Barrel	45	165
	Kilderkin	22.5	82
	Firkin	11	41
	Pin	6	20

[a] Gallon (U.S.) and liter sizes are not equivalent.

To date, no industrial engineer has come up with a blueprint to replace the strength of a wooden barrel. In tests involving high stacking, they can perform better than steel drums.

BARRIER AND OVERPRINT COATINGS

Michael W. Leonard
Sun Chemical—Functional
Coating Research, Kent, United
Kingdom

INTRODUCTION

Barrier coatings provide barriers to certain gases, liquids, radiation, or other substances. These may include oxygen, water vapor, aroma, light (including ultraviolet), and, in the case of food packaging applications, products such as oils and fats, and so on. The barrier is usually intended to prevent both penetration and loss from the package, which could otherwise cause advanced spoilage of the packaged product. There is an ongoing industry requirement to improve barrier properties in order to extend shelf life of packaged foods. This section deals only with barrier coatings, applied to flexible plastic packaging films, for the purpose of minimizing oxygen and water vapor transmission. In describing the various coating technologies, comparisons will be drawn with alternative methods of achieving these barriers, in order to provide a balanced view of this important property in relation to food packaging.

The ultimate packaging barriers to oxygen and moisture barrier are tin and glass closely followed by aluminum foils. These materials provide zero gas and vapor transmission and, in the case of glass, also visibility of the product, which is often an important point of sale marketing consideration. While these materials have served the food packaging industry very well for many years and are likely to continue doing so, they have certain drawbacks which leave the door open for new advances in barrier technologies. Glass and tin, while infinitely recyclable, are heavy and therefore expensive to transport, resulting in less environmentally friendly greenhouse gas (CO_2) emission compared to transportation of lightweight plastic packaging. Plastic packaging laminates including aluminum foils, while lighter than tin and glass, render the packaging difficult (if not impossible) to recycle, resulting in the need to dispose of it in landfill or by incineration, both of which are negative options in a world where sustainability is of increasing importance.

The gradual replacement of tin, glass, and more recently aluminum foils by plastic packaging materials has been evolving for several decades. The improvements to polymer film technologies, coupled with inorganic and organic surface treatments and coatings, continue to close the gap with tin and glass in terms of barrier performance, while ensuring that due attention is paid to the environmental impact.

BACKGROUND

There are limited choices for the packaging technologist who seeks the ultimate gas barrier in single or even multilayer plastic package structures. This becomes even more limited when there is a requirement for product visibility, reducing the options to structures that are aluminum foil or (Al) metallized film free. The common polymeric packaging films based upon polyethylene terephthalate (PET), oriented polypropylene (OPP), cellulose in many coated guises (e.g., MXXT/W, MS, etc.), and biaxially oriented nylon (BON/OPA) do not have sufficient oxygen or moisture vapor barrier properties for the many food packaging specifications that call for longer shelf life of foods that spoil if exposed to atmospheres depleted or rich in these gases. It is usual in many packaging situations to replace the atmosphere inside a package with an inert gas substitute. This is known as modified atmosphere packaging (MAP) or sometimes protective atmosphere packaging (PAP). Clearly, it is important that the substitute gas is retained for as long as possible. Typical MAP gases include nitrogen, oxygen, and carbon dioxide which as a rule of thumb permeate through polymeric films in the ratio 1:4:10. Since oxygen is the most reactive of these three, with respect to food degradation, it is seen as the most important, while combinations of nitrogen and carbon dioxide may be selected for reasons of control of microbial growth, ripening, or cost.

Permeability Data of Several Packaging Films

	Nitrogen	Oxygen	Carbon Dioxide	Ratio
Low-Density PE	0.7	2.2	9.5	1:3.1:13.5
PET	0.0108	0.0444	0.227	1:4:21
BON	0.00713	0.0285	0.066	1:4:9

The manufacturers of such polymeric films have over the past 60 years developed coatings for their products which, to varying degrees, improve the gas barrier properties as well as other specific performance properties such as heat-seal threshold, product resistance, gloss, and clarity. Such coatings include organic solvent and aqueous applied polyvinylidene chloride (PVdC), aqueous or extrusion-coated ethylene vinyl alcohol (EVOH), inorganic and organic sol–gels, and in a few instances aqueous polyvinyl alcohol (PVOH). Each of these technologies has certain compromises in performance. Certain polymeric films have an intrinsic barrier to moisture or oxygen, but rarely both. Cellulose, being a reasonable barrier to oxygen but poor moisture barrier, is one example.

Alternatives to aqueous or solvent-based coating applications have been available for some time now. These essentially inorganic layers are deposited either as vapor in a vacuum or by various electron-sputtering or plasma-enhanced chemical vapor deposition (PECVD) processes. The most common vacuum-deposited barrier coating is aluminum, but more recent developments include silicon oxide (SiOx) and aluminum oxide (AlOx) where the proportion of oxygen is nonstoichiometric. These coatings have one distinct advantage of being excellent barriers to both oxygen and water vapor. The oxide coatings are also completely transparent and most commonly used on PET and BON. Although improvements to the gas barrier of OPP are also achieved, this is less common due to the expensive nature of the process resulting in mediocre barrier performance. Since the important substrates are not heat-sealable, they are invariably used in multilayer structures, which also serve to protect the oxide coatings which are particularly susceptible to damage through physical abuse, which may result in a loss of barrier properties. Some oxide-coated films are also in-line coated, with sol–gel technologies, to enhance both barrier and abuse resistance properties. Post application of protective coatings is rare due to the risk of damage to the barrier before coating.

Very recently, there has been a resurgence in the interest shown by converters to apply barrier coatings in-line with the printing process for high-barrier packaging laminates. New organic polymer technologies combined with nano-particulate materials applied from aqueous or solvent-based systems that may not require extended drying conditions are at an early stage of commercialization and demonstrating certain advantages over existing technologies.

BARRIER COATING TECHNOLOGIES

The gas permeation process for any packaging film or coating is specific to the chemical structure and morphology of that material (1). The transmission of gases across a barrier usually involves several processes. After colliding with the barrier surface, the gas molecule must be adsorbed and subsequently dissolved in the voids of the barrier polymer matrix. Diffusion of the gas molecules then takes over and is governed by the kinetic energy of the molecules directly influenced by temperature. Diffusion of the gas generally proceeds through a barrier layer from a more to a less concentrated atmosphere or partial pressure. In all cases, permeation is controlled by the solution and diffusion steps, according to Henry's Law of Solubility and Fick's Law of Diffusion, respectively. This is why metals and the previously mentioned metal oxides exhibit such high barrier properties in exceptionally thin films, to both moisture and oxygen. Crystallinity in organic polymer barriers plays a less important role, although in coatings based upon PVdC copolymers, where the drying temperature is critical to imparting crystallinity, variation in oxygen and water vapor transmission has been reported previously by the author (2). An in-depth consideration of the theories governing gas transmission are dealt with elsewhere in this publication.

PVDC CO POLYMER COATINGS

PVdC was developed by Ralph Wiley and co-workers at the Dow Chemical Company during the period 1932–1939 (3). It was initially commercialized under the trade name of "Saran" in 1939. PVdC is still used today by both packaging film manufacturers and converters. Although it can be applied from solution, it is far more popular to use the aqueous dispersion form which enables much higher solids application at the required viscosities. One reason for the longevity of this technology is its undoubtedly unique properties that distinguish it from all other polymer dispersions, even today. It is fair to say that PVdC coatings are still the only organic polymers capable of providing both moisture and oxygen barrier. The fact that they also provide heat-sealability, high gloss, transparency, and flexibility are further reasons for its continued use. However, its use has gradually declined in various regions of the world as increased importance is placed on environmental factors. Chlorinated polymers are now excluded in many packaging structures due to the problems related to incineration and the difficulties associated with handling the toxic by products including dioxin. Furthermore, as higher barrier requirements have been introduced, partly driven by the need for longer shelf life, the need for alternative polymer technologies and inorganic barrier solutions has resulted in superior barrier technologies, albeit with their own set of compromises.

POLY VINYL ALCOHOL AND ETHYLENE VINYL ALCOHOL-BASED COATINGS

Ethylene vinyl alcohol (EVOH) copolymers are hydrolyzed copolymers of ethylene and vinyl alcohol. Polyvinyl alcohol (PVOH), made by the hydrolysis of polyvinyl acetate (PVAc), provides increasing oxygen barrier with the percentage conversion of PVAc, but this is accompanied by increasing water sensitivity. Consequently, the oxygen barrier of PVOH, while superior to polymers such as PVdC at low relative humidity, is drastically compromised under most ambient conditions that packaging must resist. Occasionally, PVOH coatings are used where the coating is protected by an efficient moisture vapor barrier such as that conferred by polyethylene or polypropylene films in multi-ply laminates. However, it is not suited, even in these structures, for high oxygen barrier specifications where relative humidity is above 50% or the processing of the packaged product involves pasteurization or autoclave steam cooking.

EVOH copolymers became commercially available in 1972 in Japan, although their use was very limited until some 10 years later. By copolymerizing vinyl alcohol with ethylene, the hydrophobic properties of the latter improve the resistance to humidity, while preserving much of the oxygen barrier. Copolymers with the highest oxygen barrier contain in the region of 27–32% ethylene and provide an environmentally acceptable alternative to PVdC under similar conditions of use. Again, the oxygen barrier properties are still sensitive to increasing levels of humidity, which limits this barrier in certain (e.g., tropical) specifications. The solubility of EVOH is troublesome; although some lower ethylene content copolymers are soluble in alcohol/water solutions, they have a tendency to gel upon storage, making them less than convenient to use. In fact, storage of the solutions at elevated temperatures is the only way to avoid gelation. Therefore, the use of EVOH in barrier packaging tends to be more commonly achieved by extrusion coating which is an expensive converting exercise.

INORGANIC COATINGS

Aluminum-metallized substrates such as PET, OPP, and cellulose are manufactured by the vacuum metallization process. These films have been available for around 30 years and provide high levels of barrier to oxygen and moisture vapor and have undergone an evolutionary process that has seen improvements to surface stability, film adhesion, and printing ink adhesion. The presence of aluminum (foil or metallized film) in food packaging is gradually being discriminated as environmentally unacceptable and will ultimately decline. The use of other vacuum metal oxide deposition processes such as plasma-enhanced chemical vapor deposition (PECVD) to lay down ultrathin layers of aluminium oxide or silicon oxide is also well-advanced, producing transparent films with equivalent barrier to the more common aluminum metallization or in some cases even better. The major disadvantage with these ceramic-type layers is their brittleness, which makes them prone to damage either during the converting process or in the final laminate structure during the packaging operation.

NEW BARRIER COATINGS TECHNOLOGY

Over the last five years, there has been considerable worldwide investment in nanotechnology. Some of this investment has been focused on the development of new barrier coating technology. In an effort to take cost out of the process whilst achieving the highest possible barrier properties combined with sustainability (low carbon footprint, compostability or recyclability) coatings applied via the conventional coating processes (gravure, reverse roll, flexo, blade coat, etc) from water or organic solvent are ready for commercialization. These coatings exhibit a balance of properties which makes them suitable for both film manufacturer and converter applied applications. Their performance in packaging will now be discussed with reference to the graphs referenced.

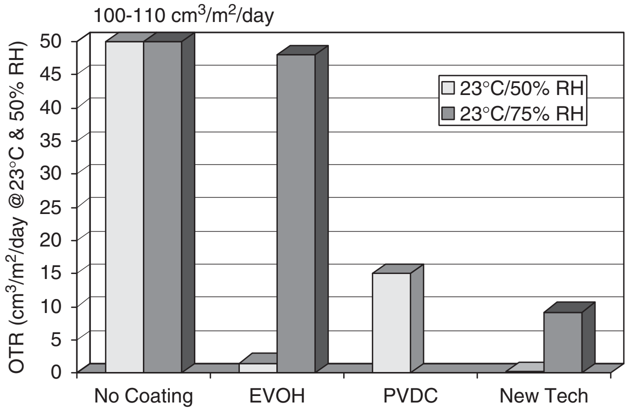

Figure 1. Comparison of new-generation oxygen barrier coating on PET with other barrier polymers.

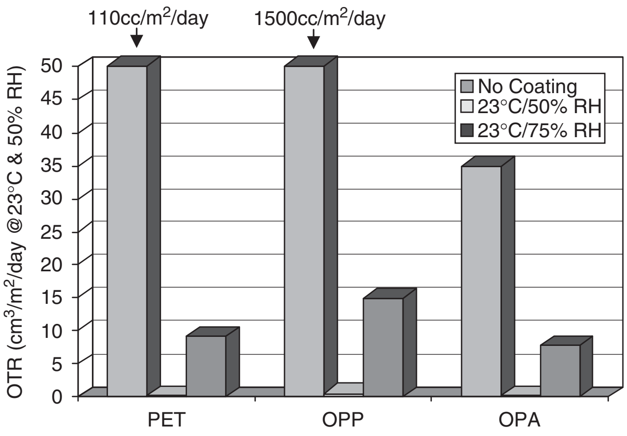

Figure 3. Comparison of new generation oxygen barrier coatings on common flexible packaging substrates.

Oxygen Barrier (see Figure 1). Compared to other well-known organic barrier polymers, this new generation of barrier coatings offers a superior oxygen barrier that is less susceptible to high levels of relative humidity. Compared to inorganic barriers the oxygen barrier is very similar, but inorganics still offer slightly better stability to high relative humidity. Owing to the combination of inert particle technologies and "green" polymer selection, the new-generation coatings are generally more sustainable and provide better abuse resistance as is demonstrated in Figure 2. Indeed the latest coating technology can be used to reinforce the performance of aluminium-metallized and oxide-coated films, achieving barriers of less than 0.1 cm^3/m^2/day as well as improving the flex resistance of these substrates. In Figure 3 it can be seen that significant improvements to the oxygen barrier of common packaging substrates is possible without the need for complex application/vapor deposition processes, opening up the potential for conversion of high barrier packaging at various points along the value chain (e.g., film manufacturer or converter). In many respects these coatings may be seen as a means to produce cheaper laminate high-barrier structures (e.g., using barrier-coated OPP) with equivalent barriers to those currently used (e.g., PET).

Compostable and sustainable substrates such as those derived from cellulose or poly lactic acid (PLA) are being

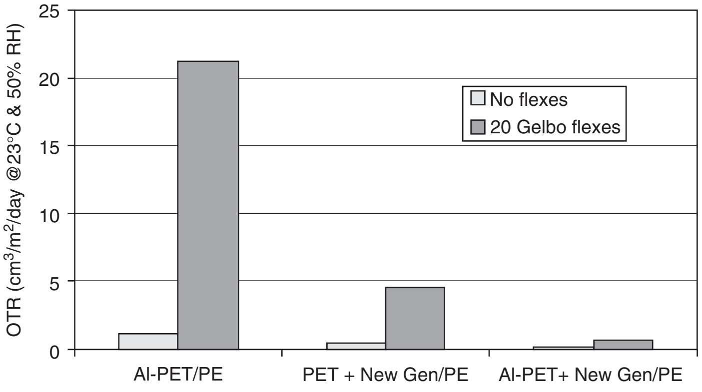

Figure 2. Oxygen transmission versus flex resistance (in Gelbo flexes)-new-generation barrier coatings in laminate structures.

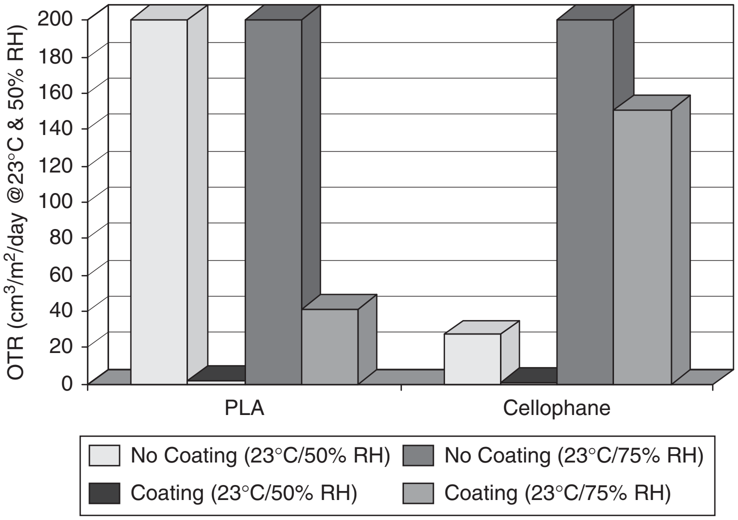

Figure 4. Indication of oxygen barrier improvements with new-generation technology on sustainable substrates.

specified more and more by the large retail outlets. These substrates do not have the appropriate barrier properties required for many perishable food types. Improvements through inorganic and new-generation-type coatings are presently a high priority. In Figure 4 the improvement to oxygen barrier on PLA is very significant. Cellulose, however, which has even higher sensitivity to moisture, shows less improvement.

Moisture Vapor Barrier. Combining oxygen and moisture vapor barrier in organic polymer-based coatings remains a target. Although nano particulate materials are capable of improving both barrier properties it is still necessary to apply separate coatings to achieve the highest barriers. In Figure 5, improvements to moisture vapor barrier on PET, PLA, and paper are compared with a commercial barrier board. With this type of coating technology, it is possible to confer moisture vapor barrier performance on substrates such as polylactic acid (PLA) and cellophane approaching that of polyethylene or OPP.

Present technologies include both water- and solvent-based products permitting applications from gravure, flexographic, and lithographic (tower) coaters.

NEAR FUTURE DEVELOPMENTS

The new-generation barrier coating technologies are set to evolve rapidly in-line with the requirement for a single coating combining both oxygen and moisture barriers, sustainability and high abuse resistance at low applied film weights. Heat-sealability and surface print

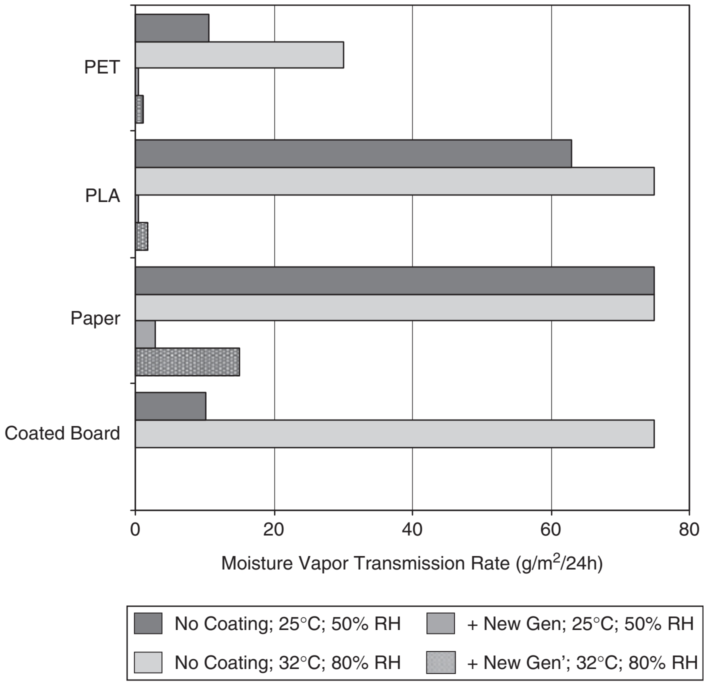

Figure 5. New-generation barrier coatings: moisture vapor transmission on sustainable substrates.

performance will follow. The use of barrier coatings, especially oxygen barrier types, will also allow consideration for simplifying or lightweighting complex laminates, resulting in waste reduction and a lower carbon footprint than is currently the case (4). Furthermore, these highly transparent and flexible coatings will allow new packaging design innovations where product visibility is an advantage. Combining these gas barrier coating technologies with UV light-curing barrier coatings will result in clear plastic packaging with the potential to supplant glass, cans, and conventional laminates in a wider variety of packaged produce.

BARRIER POLYMERS

Bradley Finnigan
Precision Fabrics Group,
Newport News, Virginia

Modern synthetic polymers have been used for over 50 years as barriers to mass transport of liquids and gases. Major applications of barrier polymers include food and pharmaceutical packaging. The growth in polymer-based packaging materials at the expense of metal and glass containers has seen the importance of barrier polymers continue to rise. Polymeric packaging offers the advantages of weight reduction, formability into useful and attractive shapes, reduced breakage, transparency, and cost savings. Recently, emphases on longer-term storage and convenience factors such as microwavability have become important. Research remains strong in industry and academia to offer improved polymer properties and fabrication methods and to address environmental issues including recyclability, source reduction, sustainability, and degradability.

Traditionally, the definition of a barrier polymer has been strongly attached to the oxygen permeability. Barrier polymers had oxygen permeabilities less than about 2.0 nmol/m · s · GPa (= 1.0 cc(stp) · mil/100 in.^{2} · day · atm). (See Table 1 for unit conversions.) This definition unnecessarily limits the range of barrier polymers. Some polymers with higher oxygen permeabilities are useful barriers for other molecules.

THE PERMEATION PROCESS

A basic understanding of the permeation process can help clarify the barrier characteristics of polymers. A permeant molecule moves through a barrier in a multistep process. First, the molecule collides with the polymer surface. Then, it must adsorb and dissolve into the polymer mass. In the polymer, the permeant "hops" or diffuses randomly as its own thermal kinetic energy keeps it moving from vacancy to vacancy as the polymer chains move. The random diffusion yields a net movement from the side of the barrier polymer that is in contact with a high concentration or partial pressure of permeant to the side that is in contact with a low concentration of permeant. After crossing the barrier polymer, the permeant moves to the polymer surface, desorbs, and moves away.

In virtually every case, the permeation is controlled by the solution and diffusion steps. The diffusion coefficient, D, is a measure of the speed of molecules moving in the polymer. The solubility coefficient, S, is an indication of the number of permeant molecules that are diffusing. Together, the diffusion coefficient and the solubility coefficient describe the permeability coefficient, commonly called the permeability, P.

$$P = D \times S \tag{1}$$

A low permeability may result from a low diffusion coefficient or a low solubility coefficient or both.

[a] Throughout the *Encyclopedia*, cm^3 (or mL) is used in preference to cc. However, the advantage of using cc here is an obvious visual aid in the complex units and there are further comments regarding cc versus cm^3 in the text.

The permeability for a given polymer–permeant combination can be used to describe the steady-state transport. Equation (2) is Fick's First Law adapted for packaging:

$$\frac{\Delta M_x}{\Delta t} = \frac{PA\Delta p_x}{L} \tag{2}$$

where $\Delta M_x/\Delta t$ is the steady-state rate of permeation of permeant x through a polymer film with area A and thickness L. P is the permeability, and Δp_x is the difference in pressure of the permeant on the two sides of the film.

Equation (2) shows why reliable tables of permeabilities are important. The packaging engineer has no control over the Δp_x since the conditions of the environment and the contents are fixed. Mechanical, economic, and containment requirements limit the allowable ranges of area and thickness. Only P has a wide range of possibilities.

One caveat must be considered before applying equation (2). The permeation must be at steady state. With small molecules such as oxygen, steady state is usually attained in a few hours or less, depending the polymer and the thickness. However, with larger molecules in barrier polymers, especially glassy polymers, the time to reach steady state can be very long, possibly exceeding the anticipated storage time. The time to reach steady state, t_{ss}, can be estimated with equation (3):

$$t_{ss} \cong L^2/4D \tag{3}$$

Equation (2) should only be used when t_{ss} is small compared to the storage time.

Water-vapor transmission is treated differently. The industry has arrived at a standard condition for reporting and comparing performance, 37.8°C (100°F) and 90% rh difference. Equation (4) shows how the rate of water-vapor transmission can be calculated using the value of the water-vapor transmission rate (WVTR) and the package geometry:

$$\frac{\Delta M_{\mathrm{H_2O}}}{\Delta t} = \frac{WVTR \cdot A}{L} \tag{4}$$

When the actual conditions differ from the standard, the WVTR can be adjusted with great care. Ideally, data have been reported at the actual conditions; otherwise, adjustments for both the relative humidity difference and temperature must be made. If the polymer is known to be insensitive to humidity, such as a polyolefin, the humidity adjustment is merely multiplication by the actual relative humidity difference on the two sides of the film divided by 90% rh. The temperature effect will be discussed later.

UNITS

The units for permeability are complex, and many correct combinations are used in the literature. Lamentably, many incorrect combinations are used too. Table 1 contains conversion factors for several common units for the permeability. Table 2 contains conversion factors for several common units for WVTR. In these units the quantity of permeant is a molar unit, typically a cc(stp). For the permeability of flavors and aromas, a unit using the mass of the permeant is useful. A modified unit, the MZU ($=10^{-20}\,\mathrm{kg\cdot m/m^2\cdot s\cdot Pa}$), can be converted to a molar unit according to equation (5), where MW is the molecular weight of the permeant in daltons (g/mol).

$$P\,\mathrm{in\,MZU} \times (10/\mathrm{MW}) = P\,\mathrm{in\,nmol/m\cdot s\cdot Gpa} \tag{5}$$

Table 2. Water Vapor Transmission Rate Units with Conversion Factors

Multiply → to obtain ↓	$\frac{\mathrm{nmol}}{\mathrm{m\cdot s}}$	$\frac{\mathrm{g\cdot mil}}{100\,\mathrm{in.}^2\cdot\mathrm{d}}$	$\frac{\mathrm{g\cdot cm}}{\mathrm{m^2\cdot d}}$
$\frac{\mathrm{nmol}}{\mathrm{m\cdot s}}$	1	0.253	6.43
$\frac{\mathrm{g\cdot mil}}{100\,\mathrm{in.}^2\cdot\mathrm{d}}$	3.95	1	25.40
$\frac{\mathrm{g\cdot cm}}{\mathrm{m^2\cdot d}}$	0.155	3.94×10^{-2}	1

PERMEABILITY DATA

Table 3 contains oxygen, nitrogen, and carbon dioxide permeability data for several polymers at 20°C and 75% rh. Generally, the permeabilities of N_2, O_2, and CO_2 are in the ratio 1:4:14. The polymers are ranked roughly in order of increasing permeability. This list contains polymers that meet the traditional criterion for barrier polymers and several that do not. The range of permeabilities here is more than four orders of magnitude. Table 4 contains diffusion coefficients and solubility coefficients for oxygen and carbon dioxide in many of the same polymers. Note that these values are useful for comparison with the flavor, aroma, and solvent permeation that is presented later in the chapter.

Barrier polymers are typically used as discrete layers, as coatings, or in blends. Depending on the packaging application, oxygen barrier polymers are frequently selected from the group consisting of ethylene–vinyl alcohol copolymers, polyvinyl alcohol, polyvinylidene chloride, polyacrylonitrile, polyesters, and various types of polyamides. Moisture barrier polymers include polyethylene (particularly high density polyethylene), polypropylene, polyvinylidene chloride, cyclic olefin copolymers, and polychlorotrifluoroethylene. OTR and WVTR data for selected polymers is shown in Table 5. A comprehensive list of permeability properties of polymers can be found in reference 4.

The increased demand for transparent packaging has seen a number of organic, inorganic and ceramic barrier coatings introduced as alternatives to metallized coatings and aluminum foil (3). Examples of commercially available barrier coating materials include polyacrylic acid, polyvinylidene chloride, polyvinyl alcohol, nitrocellulose, epoxy-amine and polyamino ether coatings, and nanocomposites thereof. In addition to high-barrier, transparency, and cost-savings drivers, retort and microwave packaging requirements contributed to the introduction of thin silicon oxide (SiO_x) and aluminum oxide (AlO_x) coatings. These coatings are typically applied to bottles and oriented polyester films via vapor deposition processes.

Table 3. Permeabilities of Selected Polymers[a]

	Gas Permeability (nmol/m · s · GPA)		
Polymer	Oxygen	Nitrogen	Carbon Dioxide
Vinylidene chloride copolymers	0.02–0.30	0.005–0.07	0.1–1.5

While SiO_x and AlO_x coatings are not polymeric, they offer an excellent combination of oxygen and moisture barrier properties to polymer-based packaging.

Multilayer barrier structures are commonly used for both flexible and rigid applications. These structures can be the result of coextrusion, lamination, or coating. Typically, one of the layers provides most of the barrier while other layers provide inexpensive mechanical integrity, printability, opacity, sealability, formability, adhesion, or merely a place to locate reground scrap. The total barrier performance of a multilayer structure can be estimated with equation (6):

$$\frac{L_t}{P_t} = \frac{L_1}{P_1} + \frac{L_2}{P_2} + \frac{L_3}{P_3} + \cdots \tag{6}$$

where L_1, L_2, and L_3 are the thicknesses of layers and P_1, P_2, and P_3 are the respective permeabilities of the layers. L_t is the total thickness, and $\mathrm{P_t}$ is the effective permeability of the multilayer structure. The quantity L_t/P_t is the “permeance.” L_t and P_t may be used in equation (2) to calculate the expected performance. An example of a seven-layer barrier film is shown in Figure 1.

NANOCOMPOSITE APPROACH TO BARRIER PERFORMANCE

Polymer nanocomposites containing nanometer-sized layered silicates (1 nm thick, 100- 500-nm-diameter platelets) have been the focus of considerable research interest in recent years (5). This is because significant improvements in mechanical, thermal, and barrier properties have been reported, particularly in nylon systems.

Improved barrier performance in nanocomposites can result from the high-aspect-ratio platelets providing a tortuous path for the permeant to travel through, or by the filler inclusions altering the diffusivity of the host matrix—for example, by decreasing the free volume of the polymer—or by changing the polymer crystal type/orientation. Improvements in barrier performance upon filler addition do not always occur.

A number of companies currently manufacture polyolefin and nylon nanocomposites for packaging applications. However, the use of these materials for barrier packaging has been limited to niche applications. At present, research is ongoing to overcome the challenges that are preventing widespread commercialization. These

challenges include processing methods and inexpensive surface modifications to ensure excellent particle dispersion and particle alignment, which are required in order to optimize property performance and reproducibility.

FLAVOR/AROMA/SOLVENT BARRIER

In addition to functioning as gas and moisture barriers, polymers are also utilized in packaging applications that require flavor, aroma, or solvent barriers. Table 6 contains data for the transmission of flavor, aroma, and solvent (F/A/S) molecules in a few polymers. These data are for 25°C at 0% rh and very low activity (or partial pressure) of the permeant. This list represents only a small fraction of the virtually limitless combinations of F/A/S compounds and polymer films. Reliable data at low activities, as typically encountered in foods, are difficult to find. However, the data in Table 6 are consistent with some general rules. First, polyolefins are not good barriers for F/A/S compounds. Second, vinylidene chloride copolymers and ethylene–vinyl alcohol copolymers are good barriers. A third rule is not apparent from Table 6. A polymer below its glass-transition temperature (T_g)—that is, glassy polymer—is an excellent barrier for F/A/S compounds. Data are extremely rare; hence, only a few data are given for an ethylene–vinyl alcohol copolymer. The problem is that the diffusion coefficients are so low that the experiments take too long to do with accuracy. The previous author and associates were unsuccessful in many attempts to test polystyrene, PET, and nylons.

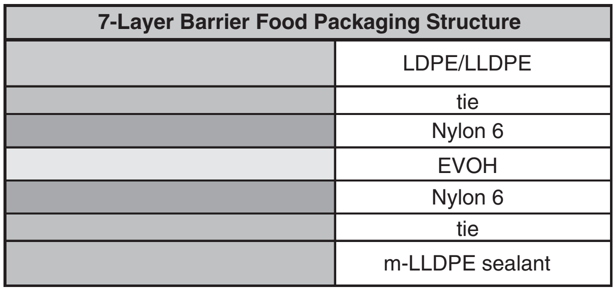

Figure 1. Seven-layer barrier film used in food packaging.

In these tables of data, different polymers occupy the top barrier positions. For oxygen, vinylidene chloride copolymers and ethylene–vinyl alcohol copolymers are the best barriers. For water vapor, vinylidene chloride copolymers and the polyolefins are the best barriers. For F/A/S compounds, vinylidene chloride copolymers remain good. Some glassy polymers that are not given are the best barriers. Yet of all these polymers, only a few meet the traditional definition of a barrier polymer.

FACTORS AFFECTING PERMEABILITY

The permeability increases with increasing temperature for all known cases. A plot of logarithm P versus $1/T$ in

[a] Values for vinylidene chloride copolymer and ethylene–vinyl alcohol are extrapolated from higher temperatures.

[b] Permeation in the vinylidene chloride copolymer and the polyolefins is not affected by humidity; the permeability and diffusion coefficient in the ethylene–vinyl alcohol copolymer can be as much as 1000 times greater with high humidity (1).

[c] MZU = $(10^{-20}\,kg \cdot m)/m^2 \cdot s \cdot Pa)$; see equation (5) for unit conversions.

kelvin yields a straight line with a slope proportional to the activation energy for permeation. Usually the slope is steeper above T_g than below T_g. Hence, knowledge of the permeability at two temperatures allows calculation of the permeability at a third temperature, provided that T_g is not in the range. For many polymers the oxygen permeability increases about 9% per °C above T_g and about 5% per °C below T_g. The temperature sensitivity is greater for larger-permeant molecules. The temperature sensitivity for the WVTR is theoretically a little more complicated; however, it is about the same as for the oxygen permeability.

Humidity can affect the permeability of some polymers. When a polymer equilibrates with a humid environment, it absorbs water. The water concentration in the polymer might be very low as in polyolefins or it might be several weight percent as in ethylene–vinyl alcohol copolymers. Absorbed water does not affect the permeabilities of some polymers including vinylidene chloride copolymers, acrylonitrile copolymers, and polyolefins. Absorbed water increases the permeabilities in some polymers including ethylene–vinyl alcohol copolymers and most polyamides. A few polymers show a slight decrease in the oxygen permeability with increasing humidity. These include PET and amorphous nylon. Since humidity is inescapable in many packaging situations, this effect cannot be overlooked. The humidity in the environment is often above 50%rh, and the humidity inside a food package can be nearly 100% rh.

Additives are blended into polymers to improve mechanical or chemical properties such as flexibility, cling, and thermal stability. When the additive is a small molecule and it is soluble in the polymer, the polymer is likely to be plasticized. This effect increases the diffusion coefficient for permeant molecules. The solubility coefficient is unaffected. The effect can be small if the additive is included at less than about 1 wt%. However, at larger concentrations the effect can be large. The oxygen permeability of poly (vinyl chloride) increases by about 10 times when enough plasticizer is added to make the resulting film flexible. The phenomenon of antiplasticization is under investigation. The potential exists that, for some small molecule additives, the diffusion coefficient can be decreased.

If the additive is not soluble in the polymer, the result is more complicated. For an inorganic filler, the permeability might increase if the polymer does not wet the filler. The permeability will decrease if the polymer wets the filler. However, the effect is likely to be small unless the loading of filler is greater than about 20 wt%. Loadings this high are avoided since these composites are typically difficult to handle.

Filler in the form of platelets can lower the permeability more than filler with a more compact shape. If the platelets tend to lie in the plane of the film, permeant molecules must make wide detours (tortuous path) while traversing the film. This gives a greatly reduced effective diffusion coefficient.

Crystallinity is an overrated contributor to barrier in polymers. First, if a polymer has crystallinity, the level of crystallinity typically exists within a narrow range with only modest variation allowed from fabrication variables. Hence, crystallinity is not a strong design parameter. Second, the same properties that lead to crystallinity also lead to efficient packing in the amorphous phase. Efficient packing in the amorphous phase gives a low diffusion coefficient. Polyolefins are glaring exceptions because they have considerable crystallinity and high diffusion coefficients.

Orientation is frequently cited as a contributor to barrier in polymer films. If the polymer molecules truly are oriented in the plane of the film, either uniaxially or biaxially, the permeability is probably lower than that in an unoriented film. However, sometimes the word "oriented" merely means that the film has been stretched. If the polymer molecules relax during stretching, little orientation results and little effect is expected. A few cases have been noted where stretching has created microfissures in the polymer and the permeability has increased. Table 7 contains permeability data for elongated films. The results vary. A practitioner is wise to test permeability before concluding that a fabrication involving elongation will lower the permeability. When elongation does lower the permeability, the causes are a combination of better packing among parallel molecules, difficulty in moving perpendicular to the alignment of the polymer molecules, and, when crystallinity is present, the tendency for crystallites to act as platelets aligned in the plane of the film. When performed correctly, orientation is an effective means of improving barrier properties and reducing material requirements.

Table 7. Effect of Orientation on Oxygen Permeability for Certain Polymers[a]

Polymer	Degree of Orientation, %	Oxygen permeability,[b] nmol/m · s · GPa)[c]
Polypropylene	0	300
	300	160
Polystyrene	0	840
	300	600
Polyester	0	20
	500	10
Copolymer of 70% acrylonitrile and 30% styrene	0	2.0
	300	1.8

[b] At 23°C.
[c] See Table 1 for unit conversions.

POLYMER COMPOSITION

Although a case has been made for a situational definition for barrier polymers, common practice still focuses on a rather small set of polymers. Figure 2 contains schematic chemical structures of polymers with low permeabilities to permanent gases, especially oxygen.

Finding common traits among this diverse group is difficult. However, each has some polarity which leads to chain-to-chain interactions that give good packing in the amorphous phase. Also, frequently, sufficient symmetry exists to allow crystallinity to develop. Again, this can lead to good packing in the amorphous phase.

AVAILABILITY

Barrier polymers are available as resins for extrusion, resins for dissolution and coating, and latices for coating. Each form has its own advantages and disadvantages. Resins for extrusion can be made into monolayers or multilayers with thicknesses to give adequate barrier for demanding applications. However, extrusion can give a severe thermal stress to the polymer which could lead to degradation. For semicrystalline polymers the extrusion temperature must exceed the melting temperature. When more modest total barrier is needed, a coating may be adequate. Typically, coatings more than 3 μm (0.1 mil) are difficult to achieve. However, semicrystalline polymers can be used in solvents well below the melting temperature. Hence, polymers with marginal thermal stability may be used. Solvent recovery and management must be considered. For latices, the particles are too small to allow crystallinity to develop; hence, semicrystalline polymers remain amorphous until after coating and drying. Latices cannot be stored indefinitely and must be used before coagulation occurs.

CONCLUSION

The choice of barrier polymer(s) for any given application is determined by economics, performance requirements, and the package format. A wide variety of barrier

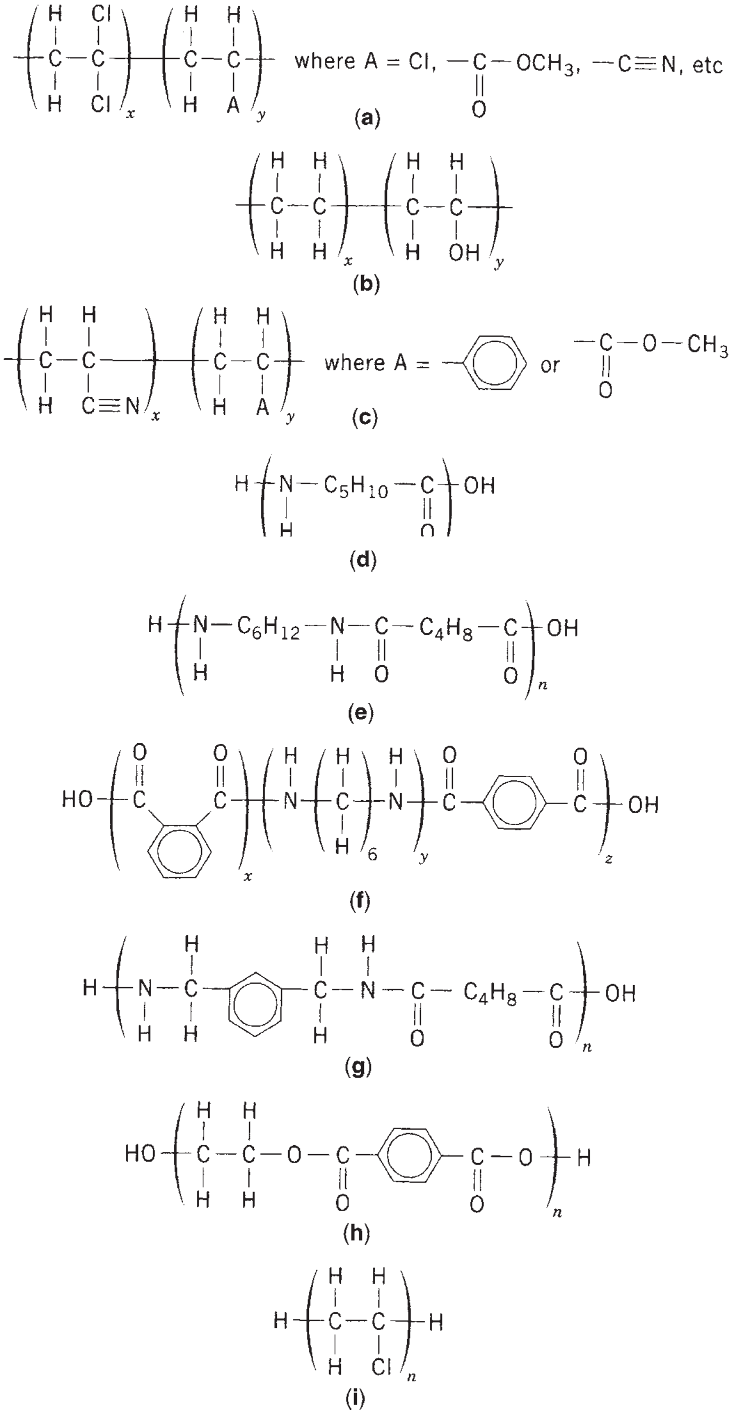

Figure 2. Chemical structures of barrier polymers. (**a**) Vinylidene chloride copolymers; (**b**) hydrolyzed ethylene–vinyl acetate (EVOH); (**c**) acrylonitrile barrier polymers; (**d**) nylon-6; (**e**) nylon-6,6; (**f**) amorphous nylon (Selar PA 3426), $y = x + z$; (**g**) nylon-MXD6; (**h**) poly(ethylene terephthalate); and (**i**) poly(vinyl chloride).

polymers are available for use, and the number of material options will continue to grow. In extreme cases, barrier requirements can be met without the use of foil by combining the correct barrier polymers, with technologies such as gas flushing and active packaging scavengers.

University, Beer-Sheva, Israel

The prefix “bio-” means life in Greek. Biobased materials indicate the substances obtained from living or dead animals or plants. Biobased materials are a large group of loosely related processing (or engineering) materials, which are mainly derived from substances originally existing in nature, such as in living tissues or organisms, but may also be obtained by synthetic methods. Accordingly, biobased materials include common commodities such as leather and wood, as well as those that have undergone more extensive processing such as pectin, oleic acid and carboxymethyl cellulose. In literature, the term “biobased material” is often used synonymously with the words biomass or biomaterial. The three words differ from each other slightly in definition and mostly in habitual uses. Biomass refers to animal or plant matter grown for uses for production of chemicals and fibers, but does not include their products after processing; and more commonly, biomass is frequently used in literature of energy production, emphasizing its status in the carbon cycle as a renewable fuel. The term “biomaterial” has an additional meaning. As a result of its long use for biomedical applications, it refers to materials that can perform biological functions and are biocompatible when in contact with living tissues. The study of biobased materials is now a large sector in material science and agrobusiness, as are (a) the study of biomaterials in biomedical and pharmaceutical sciences and (b) the study of biomass in renewable energy.

Based on their sources and production, biobased materials can be divided into three major categories (1, 2):

- Category 1 includes those removed (extraction, exuding, isolation after milling, etc.) from biomass. Examples are (a) polysaccharides such as starch and cellulose and (b) proteins such as collagen and casein.
- Category 2 includes polymers produced by a chemical method using renewable biobased monomers. Examples are some polyesters such as poly(lactic acid), which is produced from the polymerization of lactic acid, a fermentation product of carbohydrate feedstock. Category 2 biobased materials also include monomers or low-molecular-weight chemicals (so-called “building blocks”) obtained from biobased feedstocks by chemical or biochemical methods, such as rosin, castor oil, and terpene.
- Category 3 includes materials produced by microorganisms or genetically modified bacteria. Examples are bacterial cellulose and polyhydroxyalkonoates such as polyhydroxybutyrate.

Because of their overwhelming presence in the world and the versatility of their chemistry and architecture, biobased materials are the sources of many industrial products, such as medicinal, chemicals, fibers, and paint, as well as plastics, and so on. Although most of them can be used for packaging purpose, the consumption of biobased materials in the packaging industry is only about 1%; a large portion of these products are currently produced from petroleum-derived materials. The limitation of petroleum resources and the awareness of environmental protection have raised a new prospect that biobased materials may be once again the major contributor to the industries. Biobased materials are less dense than metal, and some petroleum-derived thermal plastics, are ideal components for many structural materials. Most biobased polymers perform in a fashion similar to that of conventional polymers. Unlike petroleum-derived materials, most biobased materials are biodegradable. This property enables the end-use products of biobased materials to be disposed of upon completion of their useful life without causing any environmental concerns. This is attractive in the production and applications of packaging materials and has become their main focus. The use of biobased materials also addresses other economic issues: the use of surplus stocks and the production of higher value-added material from agricultural products and by-products. Therefore, the use of biobased materials promotes agrobusiness development.

Scientists and engineers are developing new technologies that will provide competitive cost for products from biobased materials, meet the standards of various applications, and optimize their performance (3–9). Presently, important research areas include: (I) Reproducibility and quality of biobased materials. These not only depend on the methods and processing conditions of separation, purification and fabrication, but also dramatically rely on the sources of raw materials, such as where grown, when harvested, and how and how long they are stored. All these variations make product quality control more complicated and difficult. (II) In composites, water absorption can be considered a disadvantage. Migration of water through the polymer can lead to disturbance of the filler/matrix interface, reducing the overall strength of the composites. Most biopolymers are hydrophilic. It is a challenge to improve the water resistance of biobased materials in order to retain good mechanical properties when the composites are exposed to highly humid conditions. (III) The durability of biobased materials is related to their biodegradability. The degradation of biobased products should be controllable and their properties should be constant during the time of their useful life. (IV) Gas barrier properties have specific significance in packaging materials. In particular, food packaging requires specific atmospheric conditions to sustain food freshness and overall quality during storage. Biobased materials mimic quite well the oxygen permeability of a wide range of the conventional petroleum-derived thermal plastics. As many of the biobased materials are hydrophilic, their gas barrier properties are very dependent on environmental humidity. (V) Thermal stability. Most category 1 biobased materials are not stable at higher temperature, limiting applications and choices of processing methods. (VI) Safety. Biobased materials, particularly those come from biological processes, may support microorganism growth. Concerns have risen over the spread of novel trails in existing populations and the introduction of modified species.

CATEGORY 1 BIOBASED MATERIALS

There are a large amount of polysaccharides and proteins that are directly isolated from agricultural or marine plants and animals, and they can be used in packaging applications. Examples of category 1 biobased materials include starch, cellulose, pectin, alginate, collagen, soybean flour protein, and zein. Most category 1 biobased materials exhibit useful gas barrier properties; but they are hydrophilic and unstable at higher temperature, causing problems in processing.

Starch

Starch is a widely available raw material suitable for a variety of applications, including packaging (10–12). Starch is a storage polysaccharide found in the cytoplasmic granules of plant cells. Starch is a composite consisting mainly of amylose and amylopectin, and it is primarily derived from corn, wheat, potatoes, and rice. Due to its huge availability and low cost in processing, starch is economically competitive with petroleum-derived materials and is therefore a promising candidate for preparing compostable plastics. Starch is nontoxic, biologically absorbable, resistant to passage of oxygen, and semipermeable to carbon dioxide. On the other hand, starch granules are rigid, and starch blends are brittle. Plasticizers, such as glycerol, low-molecular-weight polyhydroxy compounds, polyethers, or ureas, can be included in starch blends to reduce the intermolecular hydrogen bonding and thus increase the flexibility. Because of the hydrophilic nature of starch, the performance of starch blends changes during and after processing as a result of water content changes with the changes in humidity. Side-chain modification to obtain more hydrophobic starch derivatives is a strategy to overcome this challenge.

Cellulose

Cellulose is the most abundant naturally occurring polymer. Cellulose is a high-molecular-weight $1 \rightarrow 4$-beta-linked polymer of D-glucopyranose, which displays a diverse range of conformations and crystalline packing arrangements, as well as fiber structure. Because of its regular linear structure and array of hydroxyl groups, cellulose-based films tend to be tough and flexible and resistant to fat and oil. Cellulose is hydrophilic; it swells, but does not dissolve in water. To produce cellulose films, an aggressive process is required that involves several strong basic, strong acid and toxic solvents. Although, the resultant films possess good mechanical properties, they are hydrophilic and moisture-sensitive (1, 13).

Cellulose derivatives are used for film forming, coating, and encapsulating applications. Cellulose derivatives, such as ethyl cellulose, methyl cellulose, carboxy methyl cellulose, hydroxyethyl or hydroxypropyl cellulose, and cellulose acetate, are commercially available. Cellulose acetate possesses relatively low gas and moisture barrier properties (1, 10, 14–16).

Pectin

Pectin is a cell wall polysaccharide. The majority of the pectin structure consists of homopolymeric partially methylated poly α-$(1 \rightarrow 4)$-D-galacturonic acid residues ("smooth" regions), but there are substantial "hairy" regions of alternating α-$(1 \rightarrow 2)$-L-rhamnosyl-α-$(1 \rightarrow 4)$-D-galacturonosyl sections containing branch-points with mostly neutral side chains (1–20 residues) of mainly L-arabinose and D-galactose (rhamnogalacturonan I). Pectins may also contain rhamnogalacturonan II with side chains containing other residues such as D-xylose, L-fucose, D-glucuronic acid, D-apiose, 3-deoxy-D-*manno*-2-octulosonic acid, and 3-deoxy-D-*lyxo*-2-heptulosonic acid attached to poly α-$(1 \rightarrow 4)$-D-galacturonic acid regions. The types and amounts of substructural entities in pectin preparations depend on their source and extraction methodology. Commercial pectin is mainly derived from citrus peels and apple pomace. It can also come from sugar beet pulp and sunflower heads. Commercial extraction causes extensive degradation of the neutral sugar-containing side chains. The pectin molecule does not adopt a straight conformation in solution, but is extended and curved with a large amount of flexibility. The carboxylate groups tend to expand the structure of pectin. Methylation of these carboxylic acid groups forms their methyl esters, which are much more hydrophobic and have a different effect on the structure of surrounding water. Thus, the properties of pectin depend on the degree of esterification (D.E.). High D.E. pectin ($>40\%$ esterified) tends to gel through the formation of hydrogen-bonding and hydrophobic interactions at low solution pH (pH ~ 3.0) to reduce electrostatic repulsions, or in the presence of sugars ($>70\%$ esterified). Low D.E. pectin ($<40\%$ esterified) gels by calcium divalent cations that bridge adjacent twofold helical chains to form the so-called "egg-box" junction zone structures so long as a minimum of 14–20 residues can cooperate (17).

In addition to its gelling properties, pectin is a well-established film-forming material. In isolated form, pectin readily reassociates or aggregates to form networks, and it interacts with proteins, other polysaccharides, and synthetic hydrocolloids via hydrogen bonding, ionic, or hydrophobic interactions. This character has led to applications of pectin in encapsulation, coating, packaging, and wrapping for food and pharmaceutical products (18–20).

Alginate

Alginates are mainly derived from seaweed. The alginic acid family of linear $1 \rightarrow 4$-linked glycuronans are copolymers composed of beta-D-mannopyranuronic acid (M) residues and alpha-L-gulupyranuronic acid residues (G) that are arranged in homopolymeric blocks (GG and MM) and heteropolymeric (GM) sequences in varying proportions and distribution patterns. Alginates possess good film-forming properties that make them particularly useful in food packaging applications. Divalent cations, such as calcium, magnesium, manganese, and aluminum, are used as gelling reagents in alginate film formation. Calcium ion appears to be more effective in gelling alginate than other divalent ions; calcium propionate provides acceptable flavor. Desirable properties of alginate films include the improved product texture, juiciness, color, odor, and appearance, along with moisture retention and shrinkage reduction. Sodium alginate is water soluble. Sodium alginate coatings are used to extend the shelf life of foods and fruits (21, 22).

Chitin and Chitosan

In its structure, chitin is a cellulose analogue and is comprised of 1→4-beta-linked N-acetyl-D-glucosamine units. Chitin is the second most abundant glycan after cellulose, being present in the exoskelton of invertebrates. Chitin occurs in several crystalline polymorphic forms, of which the alpha-chitin is the most common. Like cellulose, chitin chains adopt a 2_1 screw axis. All of the hydroxyl groups are hydrogen bonded, and the bonding between sheets accounts for the fact that chitin does not swell in water. The fully or partially *N*-deacetylated derivative of chitin, chitosan, has received considerable attention. Some desirable properties of chitosan include its film forming properties, its antimicrobial activity, and the ability to absorb heavy metal ions. Chitosan films exhibit good oxygen and carbon dioxide permeability, as well as good mechanical properties. Chitosan films and coatings show activity against bacterial yeasts and molds, and they inhibit the growth of a number of microorganisms. The cationic nature of chitosan allows for electronic interactions with anionic compounds during processing and can lead to the incorporation of specific properties into products (23–25).

Collagen and Gelatin

Collagen is a major structural protein in vertebrates. Most of the ectodermal and mesodermal tissues are composed of collagen. In this sense, collagen is similar to cellulose and pectin, which serve a somewhat analogues role in plants. Collagen has triple helix architecture, thus collagen is insoluble and difficult to process. Commercially available collagens are extracted from animal skin, bone, and tendons. By taking advantages of biotechnology and genetic engineering, collagen can be obtained not only from animal tissues but also from bacterial cultures and even from genetically modified plants. Collagen films have strong mechanical properties and have been proposed for use in food packaging. Edible collagen films can become an integral part of meat products, and thus they function to reduce shrink loss and to increase juiciness and smoke permeability to the meat products (26–28).

Gelatin is a substantially pure product obtained by either partial acid or alkaline hydrolysis of collagen. The denaturation treatments disrupt the tight, helical structure of collagen and release water-soluble fragments that can form stiff gels and films. Gelatin is a highly processable material and is moisture-sensitive. Gelatin gels or films show thermally reversible behavior and melt below body temperature. Gelatin films and coatings have been used to carry flavors or antioxidants in food packaging applications (29, 30).

Soybean Flour Protein

Soy proteins are commercially available as soy flour (50% protein), soy concentrate (70% protein), and soy isolate (90% protein). Flours are made by grinding and sieving flakes. Concentrates are prepared by extracting and removing the soluble sugars from defatted flakes, by leaching with diluted acid at pH 4.5, or by leaching with aqueous ethanol. Isolate soy proteins are obtained by extracting the soluble proteins with water at pH 8–9, precipitating at pH 4.5, followed by centrifugation and drying. Soy proteins consist of two major protein fractions, 7S (conglycinin, 35%) and 11S (glycinin, 52%). Both fractions are considered as storage proteins and contain cysteine residues leading to disulfide bridge formation. Soy proteins are adhesive- and moisture-sensitive. Soy protein coatings can reduce moisture loss and control lipid oxidation in coated samples. Soy proteins are also used as binders for aqueous inks and as pigmented coatings on paperboard. Furthermore, soy flour proteins are proposed for the use in food coating, encapsulation, and active packaging (18, 19, 31, 32).

Zein

Zein is a class of alcohol-soluble prolamine proteins, obtained from corn gluten meal. Pure zein forms a hard, edible, clear, odorless, tasteless, and water-insoluble material, making it invaluable in processed foods and pharmaceuticals. Zein is now used as a coating for candy, nuts, fruit, pills, and other encapsulated foods and drugs. Zein can be further processed into resins and other bioplastic polymers by extrusion or rolling into a variety of plastic products. Zein-based films can function as water barriers and, thus, have potential use for packaging materials (33, 34).

Casein and Whey

Casein and whey are milk-derived proteins. Both have high nutritional values, excellent mechanical, and emulsion and barrier properties, and they are available in large volume worldwide. They have been used in the manufacture of edible films. Due to its random coil structure, casein is easily processable. By controlling the types of plasticizers, casein films can be made with very different mechanical properties varying from stiff and brittle to flexible and tough materials. Casein and whey films can reduce moisture loss, delay lipid oxidation, and reduce peroxide value of packaged food products (35–37).

CATEGORY 2 BIOBASED MATERIALS

The use of classical chemical methods to produce polymers, monomers, and other chemical “building block” materials from biobased feed stocks have generated a wide spectrum of category 2 products. Theoretically, all the conventional packaging materials currently derived from petroleum can be produced from monomers obtained from biobased materials; however, due to their high cost, the production of those monomers is not economically feasible. Thus, these costs have been an obstacle on the road to broadening the application of biobased monomers. An exception may be poly(lactic acid) (PLA) production. As a result of the increase in both the efficiency of lactic acid fermentation and the market price of raw oil, the cost of making poly(lactic acid) from biobased materials is gradually approaching the price of PLA obtained from fossil fuel.

Poly(Lactic acid)

Poly(lactic acid) or polylactide (PLA) is a thermoplastic, aliphatic polyester derived from fermentation of agricultural products and byproducts such as corn starch and other starch-rich substances like maize, sugar, or wheat. Bacterial fermentation is used to produce lactic acid, which is oligomerized and then catalytically dimerized for ring-opening polymerization. It can be easily produced in a high-molecular-weight form, most commonly using a stannous octoate catalyst. The properties of PLA strongly depend on the ratio of the two mesoforms (L and D) of the lactic acid monomer. Poly L-lactide (PLLA) is the product resulting from polymerization of L-lactide. PLLA has crystallinity around 37%, a glass transition temperature (T_g) of 50–80°C, and a melting temperature (T_m) of 173–178°C. If a mixture of D- and L-PLA is used, a polymer with adjustable T_m and T_g, PDLLA, can be obtained. The physical blends of PDLA and PLLA are useful for producing loose-fill packaging, compost bags, microwavable trays, food packaging and disposable tableware. PLA can also be plasticized by blending it with its monomer or oligomer. The resultant blends possess lower T_m and T_g. PLA resembles conventional petrochemical-based plastics in its characteristics and has good water vapor barrier properties and relatively low gas transmittance. PLA can be processed into fibers, blown films, injected molded objects, and coatings on standard equipment that already exist for the production of conventional thermoplastics. To date, PLA has shown the highest potential for a commercial major-scale production of biobased packaging materials (38–41).

Monomers and Chemical "Building Blocks"

A number of monomers and chemical "building blocks," low-molecular-weight organic compounds or chemical precursors for preparing polymeric materials, can be obtained from biobased materials (1, 2, 42, 43). Examples include castor oil, oleic acid, molasses, furfural, multifunctional alcohols, multifunctional acids, and terpenes.

Castor oil is used for the preparation of polyurethane. The resultant polyurethane is water-resistant and widely used in the electronics industry. Unsaturated fatty acids and oils, such as oleic acid, linoleic acid, and ricinoleic acid, can be recovered from seed crops, castor beans, coconut, flax, and other agricultural origins and have found applications in water-proof coatings and multi-layered packaging materials. Furthermore, oleic acid can be chemically transformed to multi-functional alcohols and acids, amines and esters. The resultant azelaic acid and azelaic diacid are used in polyamide synthesis.

Furfural can be produced from woody biomass and molasses. Furfural can be transformed to furfuryl alcohol and to furan resin and a wide range of furan chemicals. Levulinic acid also can be produced from woody materials. Levulinic acid is a precursor for the synthesis of various lactones, furans, and other functional building blocks, which are used in the production of packaging materials.

Succinic acid and 1,3-propanediol are two examples of chemicals, which are prepared by fermentation of carbohydrate-rich materials using selected microorganisms. Succinic acid and 1,3-propanediol can be used to make polyesters, which, in turn, are used for preparation of packaging materials. Terpene chemicals are isolated from pine trees and have resulted in a number of terpene-based products, which are used to prepare resin materials, or as fragrances incorporated into resin materials for active packaging (1, 42).

At present, biobased monomers and "building blocks" may not be commercially attractive. However, with the progress in biotechnology and genetic engineering, these represent promising alternatives to petroleum-derived materials.

CATEGORY 3 BIOBASED MATERIALS

This group includes polymers produced directly from biomass by natural or modified organisms.

Bacterial Cellulose

Cellulose is an important starting material in many industries. Plants are the main source of cellulose. A harsh chemical treatment is required to isolate plant cellulose from lignin, hemicellulose, and pectins. The treatment severely impairs the chemical and physical characteristics of plain cellulose, such as molecular depolymerization and changes in crystal structure. Bacterial strains of *Acetobacter xylinum* and *A. pasteurianus* are able to produce pure cellulose that originally formed in plants (homo-beta-1,4-glucan) under ambient conditions. Bacterial cellulose is highly crystalline (70% in cellulose I form) and has a molecular weight 15 times higher than that isolated from wood pulp. Although the bacterial cellulose shows outstanding mechanical properties, the production cost of bacterial cellulose is high and hampers its application in current packaging industries (44, 45).

Poly(hydroxyalkanoates)

Poly(hydroxyalkanoates) (PHAs) are a family of polyesters that are produced by a large number of bacteria, in the form of intracellular particles, functioning as energy and carbon reserve. The properties of PHAs are dependent on their monomer composition. The specific monomer composition of PHAs depends on the nature of carbon sources used and the bacterial strains selected, providing a tool to control the properties of the resultant final products. PHAs of medium-chain length are elastomers with low melting point and low crystallinity. Poly(hydroxybutyrate) (PHB) is an important member of PHAs. PHB is a highly crystalline thermoplastic. PHB mimics the mechanical behavior of poly(isopropylene). The incorporation of hydroxyvalerate can remarkably change the mechanical properties of PHB, such as a decrease in stiffness and tensile strength and an increase in toughness. PHAs possess a low water vapor permeability, which is close to LDPE. The functional groups in the side chains of PHAs make it possible to chemically modify the polymers. PHA also can be produced from genetically modified crops, such as switchgrass. All these provide an enormous potential of the polymer for packaging applications (46, 47). A commercially available PHA product, *Mirel*$^{\text{TM}}$, can be obtained from Metabolix (Cambridge, MA, USA).

BIOFILM DEVELOPMENT ON PACKAGING MATERIALS

Paul Takhistov
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

INTRODUCTION

The term "microbial biofilm" or "biofilm" refers to the complex aggregation of microorganisms growing on a solid substrate such as a packaging material, not a film that is made of biopolymer. This article provides an introductory understanding of biofilm and its formation. Since a major function of packaging is to protect the product from microbial contamination and its associated heath risks, an understanding of biofilm is important, particularly for products which require aseptic packaging and retortable packaging.

Bacteria on the surface develop a biofilm-associated community with higher resistance to toxic compounds (1, 2) than their planktonic counterparts in the bulk. In general, biofilms result from physicochemical conditions and interactions in the bacteria/environment complex (3, 4). A biofilm consists of a living microbial biomass surrounded by an exopolysaccharide envelope (EPS), proteins, and nucleic acids, which the biofilm microorganisms produce. These components help bacteria to attach to surfaces, stabilize local environment, and spatially organize communities that need to collaborate to use the substrate effectively (5). The process of the microorganism's attachment to a surface is very complex, and the nature of both the microbial cell surface and the supporting surface (substratum) is critical for successful attachment (6). Surface adherence is an important survival mechanism for microorganisms. Moreover, the adhesion kinetics is the unique characteristic of a specific microorganism, differing even among phenotypes and strains (7). Several major factors affect attachment and consequently biofilm formation: the nature of the cell surface, the chemistry and texture of the attachment surface, the nature of the surrounding medium, and the temporal and spatial distribution of available nutrients (8–10).

A biofilm can be defined as a layer of microorganisms immobilized at a substratum held together in a multi-nature matrix polymer matrix (11). This matrix consists mainly of water (97%), microbial cells (2–5%), polysaccharides (neutral and polyanionic) (1–2%), proteins [including enzymes (1–2%)], and DNA and RNA from lysed cells (1–2%) (12). Usually, a mix consortium of microbes makes up this ecosystem, and they "team up" in order to protect themselves from stress and maximize nutrient uptake. One of the main components of a biofilm is the exopolysaccharide (EPS), which often consists of one or more family of different polysaccharides produced by at least some of the biofilm microorganisms. These components aid the attachment of cells to surfaces, stabilizing the local environment and spatial organization of the microbial communities, which may need to cooperate with each other to effectively use the available substrate (5).

BIOFILM ARCHITECTURE

A biofilm is a multiphase system. It consists of the biofilm itself, the overlying gas and/or liquid layer, and the substratum on which it (the biofilm) is immobilized. This system can be classified in terms of phases and compartments. The phases consist of the solid, liquid, and gas components, whereas the compartments consist of the substratum, the base film, the surface film, the bulk liquid and the gas. Biofilms are heterogeneous by nature, however, having stacks of cells scattered in a glycocalyx network with fluid-filled channels (13). Structurally, a biofilm is approximately two-dimensional, with its thickness ranging from a few micrometers to millimeters (5). This structure allows for the diffusion of nutrients and metabolic substances within the matrix.

Biofilm Organization. The microbes in a biofilm are typically organized into microcolonies embedded in the EPS polymer matrix (5). These microcolonies attain distinct 2-D or 3-D structural patterns. Initially, microcolonies are separated by void spaces, but ultimately they merge into unique structures forming a mature biofilm. This spatial organization is very important to the biological activity of the biofilm.

Extrapolysaccharide (EPS). EPS may vary in chemical and physical properties, but it is primarily composed of polysaccharides (11). Some of these polysaccharides can be neutral or polyanionic. Generally, this polymer can accommodate considerable amount of water into its structure by hydrogen bonding. Overall, the EPS has an important role of holding the biofilm together (14). As the EPS layer thickens, the biofilm microenvironment changes due to the activities of the bacteria. Therefore, a mature biofilm is a heterogeneous matrix. This heterogeneity concept is descriptive for both mixed and pure culture biofilms common on abiotic surfaces, including medical devices (15).

Quorum Sensing. Quorum-sensing gene expression has been proposed as an essential component of biofilm physiology, since biofilm typically contains high concentration of cells (16). Generally, the irreversible attachment of bacteria to a substratum triggers alteration to an array of gene expression and phenotypes of these cells (17). In the quorum-sensing process, cell–cell communication is accomplished through the exchange of extracellular signaling molecules (16). For most gram-negative bacteria, the quorum-sensing regulation involves a freely diffusible auto-inducer, acylhomoserine lactone (AHL) signaling molecule. For instance, the quorum-sensing ability in *P. aeruginosa* is dependent upon two distinct but interrelated systems, *las* and *rhl* (18), which directs formation of the AHL. In gram-positive bacteria, structurally diverse peptides act as quorum sensing regulators (19). The QS system is not necessarily involved in the initial attachment and growth stages of biofilm formation but is very important in the overall biofilm differentiation process (20). During biofilm formation, QS signaling molecule mutants may develop thicker, more acid-resistant (21) or "abnormal" biofilms (22) than do the wild-type strains.

BIOFILM LIFE CYCLE

Once immobilized on a contact surface, microorganisms have the potential to form a biofilm. Attachment to the surface is beneficial to the microbe for a number of reasons. First, the surface represents important microbial habitats because in the microenvironment of a surface, nutrient levels may be much higher than they are in the bulk solution (23). Second, it increases the microbes' resistance to mechanical and chemical stresses. Overall, biofilm formation is a dynamic process, comprised of four main stages (24): migration of cells to the substratum, adsorption of the cells to the substratum, growth and metabolic processes within the biofilm, and detachment of portions of the biofilm (see Figure 1). These steps can be divided into three phases: initial events, exponential accumulation and steady state.

Surface Conditioning Film Formation. The conditioning film is created when organic materials (polysaccharides and proteins) settle on the surface (11). It can be derived from the microbes in the vessel or from the bulk fluid. Adsorption of a conditioning film is relatively quick compared to the other steps. This film has the potential to alter the physicochemical properties of the substratum and thus greatly impacts bacterial attachment.

Cell Migration to the Surface. Migration of microorganism to the substratum is considered the second step in biofilm formation. This process can be mediated by different mechanisms depending on the system under consideration. Thus, transport can be (a) active, facilitated by flagella (25), or (b) passive, facilitated by Brownian diffusion, convection, or sedimentation. In quiescent systems (batch culture), sedimentation rates for bacteria are generally low due to their size and specific gravity (11), and microbes with a diameter of 1–4 μm^3 have small Brownian diffusivity. Therefore, motility may be the limiting factor of transport in such systems. In a laminar flow system, although motility affects transport, diffusion remains the controlling factor. In a turbulent flow system, Brownian diffusion has minute contributions to transport, but forces such as frictional drag force, eddy diffusion, lift force, and turbulent bursts are significant.

Factors that Impact Interactions of Bacteria with a Substrate

Microbial adhesion is mediated by specific interactions between cell surface structures and specific molecular groups on the substratum. Moreover, the adhesion process is determined by physicochemical and molecular interactions. It is believed that primary adhesion between bacteria and abiotic surfaces is generally determined by nonspecific (e.g., hydrophobic) interactions, whereas adhesion to living or devitalized tissue is accomplished through specific molecular (lectin, ligand, or a adhesion) mechanisms (26).

Physicochemical Interactions. Generally, two types of physicochemical interactions are used to describe the adhesion of a microorganism to a planar surface. The DLVO approach relates to the interaction energies (attraction and repulsion)—primarily to electrostatic and van der Waals forces—but chemical forces can operate (27). Typically, attraction between microbe and surface occurs either at a long range (5–8 nm), a secondary minimum, or at a shorter range, the primary minimum. Thus, adhesion can be reversible (at the secondary minimum)

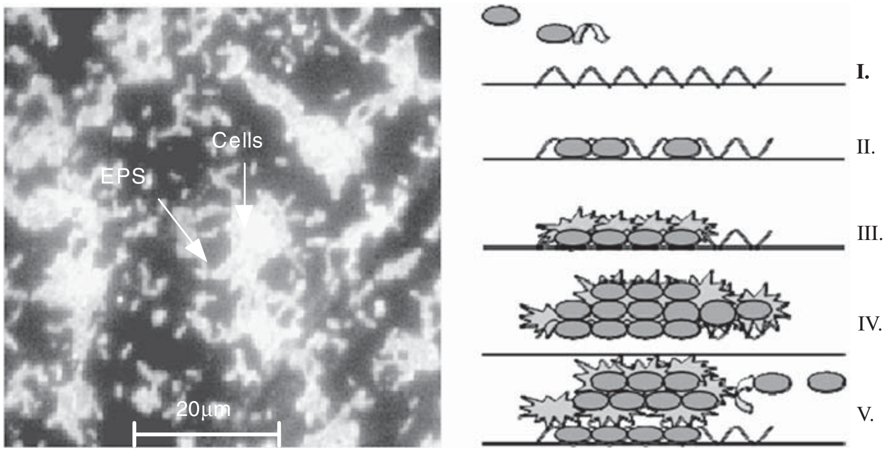

Figure 1. *Listeria* biofilm on the packaging surface and schematic representation of biofilm formation. Step I: Conditioning film formation. Step II: Bacteria migration to the conditioned surface. Step III: The cells start to produce extracellular polysaccharides (EPS), which cause an irreversible attachment. Step IV: Gradually, the biofilm increases through growth of the irreversibly attached cells and new ones from the solution. Step V: Cells near the outer surface can dislodge from the biofilm and escape to colonize new microenvironments.

or irreversible (toward the primary minimum) (11). In the DLVO approach, the ionic charge of the medium, the physicochemistry of both the bacteria and substratum surface, and the physicochemistry of biosurfactant determine the extent of adhesion.

Alternatively, in the thermodynamic approach, adhesion is described as the formation of a new interface between the substratum surface and adhering bacteria at the expense of (a) the interfaces between bacteria and the suspending liquid and (b) the substratum–liquid interface (5). Each interface contains a specific amount of interfacial energy (or surface tension). The extent of adhesion is determined by the surface properties of all three phases, the surface tension of adhering particles, of the substratum and of the medium (28). The more hydrophilic a substrate, the higher is its surface tension.

Molecular Interactions. Bacterial adherence is also mediated by molecular mechanisms. Bacteria are able to adhere to animal cells (29), such as muscle meats through protein–protein interactions on the surface. These proteins sometimes function as ligands to receptors when the bacteria invade target cells and/or have specific affinity for host components (30). The colony-opacity-associated (Opa) outer-membrane proteins or ligands (often called an a adhesion) confer intimate bacterial association with mammalian cells. Two classes of cellular receptors for Opa protein receptors have been identified: a adhesio-sulfate proteoglycan (HSPG) receptors and members of the carcinoembryonic antigen (CEA) or CD66 family (31). *Listeria monocytogenes* surface proteins Internalin A (InlA) and B (InlB) are involved in the attachment of this bacterium to host cells (32).

The magnitude of the cell substratum interaction forces, the chemical heterogeneity and the roughness of the substratum surface greatly affect the extent of microbial adhesion. As food traverses from the farm to the table, it comes in contact with fabricating equipments, utensils, gaskets, conveyor belts, packaging materials, storage containers, and chopping boards. These surfaces are usually metallic, plastic, rubber, or wood. Food processing equipments are often made of stainless steel, transport crates of high-density polyethylene (HPDE), conveyor belts of rubber, chopping boards of wood, and packaging materials of aluminum. Other storage and packaging-type materials include polypropylene, PVC, and Teflon. Sometimes the contact time between foods and surface may be 24–48 hours depending on the processing conditions including design of equipment cleaning and sanitation techniques.

Substratum Surface Hydrophobicity. The hydrophobicity of the substratum has substantial effect on bacterial adhesion. Typically, hydrophilic surfaces such as stainless steel and glass have a high free surface energy and thus allow greater bacteria attachment than do hydrophobic surfaces such as Teflon (25). For instance, a general trend of decreasing colonization density was observed for *Staphylococcus epidermis* and *Pseudomonas aeruginosa* with an increase in substratum hydrophobicity (33). In the above-mentioned study, the packaging materials used were stainless steel, poly(vinyl chloride), polystyrene, and glass. Likewise, biofilm formation by *L. monocytogenes* LO28 was faster on hydrophilic (stainless steel) than on hydrophobic polytetrafluoroethylene (PTFE) (34).

Substratum-Surface Roughness/Topography. Many reports have indicated that metal surfaces with a high degree of roughness serve as a better substrate for bacterial attachment than do smooth ones, since the surface area of the former is greater (33, 35). Arnold and others discovered that resistance to bacteria attachment decreased in the following order: *Electropolished > Sanded > Blasted > Untreated Stainless Steel*. Bower and Daeschel (1) illustrated that surface topography is extremely important in biofilm formation and resistance. Still studies such as that of Barnes et al. (36) claimed that the difference in bacteria attachment due to difference in surface topography is minimal.

Substratum Coverage with Organic Material. The layer of organic substances present on the surface can be favorable or unfavorable to bacteria adhesion. Barnes et al. (36) discovered that proteins that adsorbed to a stainless steel surface inhibited bacterial attachment. The dominating mechanism was suspected to be competitive inhibition, since the proteins were able to interact with the hydrophilic surface. The adhesion process begins, provided that the conditioning film is favorable to bacterial attachment.

Bulk Nutrient Composition. Generally, bulk fluid conditions influence surface hydrophobicity, adhesion expressions, and other factors that affect adhesiveness (37). Microbes are usually exposed to a range of nutrients concentrations from as low as 1 μg/L to 500 g/L, and this range has an effect on biofilm growth (5). At the highest nutrient concentrations, biofilms can appear to be uniform with few or no pores. This is common of biofilms associated with animal and food surfaces. Various reports suggest that the lower the concentration of nutrients, the greater the rate of attachment and biofilm development (38–40). *Escherichia coli* O157:H7 biofilms developed in minimal salts medium (MSM) developed faster and had thicker extracellular matrix, and cells detached much slower compared to those grown in trypticase soy broth (TSB) (38).

Temperature. Temperature effect is particularly important in the food industry, since food will experience differentials in temperature (temperature abuse) from farm to fork. This abuse is a consequence of changes in cell wall and attachment factors (41). Stopforth et al. (42) showed that a greater number of *Listeria monocytogenes* cells adhered to stainless steel templates at 59 °F and 77 °F compared to 41 °F and 95 °F. Moreover, Stepanovic et al. (43) suggested that a microaerophilic environment supports biofilm formation. Presently, there are few conclusive reports that support this claim.

Ionic Strength. The atomic ions present in the medium can indirectly affect attachment of the bacteria to other substratum. These ions may act as chelator, forming bridges between protein molecules on the bacteria surface and adsorbed proteins on the substratum surface. For example, with milk-treated steel, ferrous ions in solution increased *Listeria monocytogenes* attachment (36). Ions in the solution can also act as shields, shielding the surface charge of the substratum and the bacteria (44) and increasing bacteria attachment (45, 46). The ionic composition in the bulk may affect the composition of the metabolic by products of biofilm cells but not necessarily affect the physical property of the biofilm (47).

Hydrodynamics. The flow velocity in close proximity to the substratum and the liquid boundary (hydrodynamics) has marked influence on the cellular interaction and the biofilm structure. Cells behave as particles in a liquid, and the rate of settling and association with a submerged surface depends greatly on the velocity characteristics of the liquid (48). After the bacteria has attached, flow rate or shear force of the liquid affects the biofilm structure and content (25). More compact, stable, and denser biofilms were formed at relatively higher hydrodynamic shear force (49).

Atmosphere. The incubation atmosphere also influences biofilm formation. For instance, a microaerophilic and carbon dioxide-rich environment provided a relatively high rate of biofilm formation, whereas the least amount of biofilm was formed under anaerobic conditions (43). On the other hand, anaerobic growth favors maintenance of mucoid alginate (polysaccharide) production by *Pseudomonas* in cystic fibrosis airways (50).

BIOFILM FORMATION ON THE SURFACE OF THE PACKAGING MATERIALS

All “real-life” surfaces have substantial nonuniformity, with the surface irregularities (patterns) size ranging from nanometers to hundreds of microns. Although a number of studies have investigated the influence of the surface topography on biofilm formation by various microorganisms, including foodborne pathogens (1, 10, 51–53), most published results are devoted to the biofilm development in flow-through systems. It is difficult to separate the effects of surface patterns and those of the liquid flow on bacteria adhesion in such systems.

An ability to adhere to a surface provides an important survival mechanism for microorganisms (9). The process of microorganism’s attachment to the material surface is very complex, and the nature of both the microbial cell surface and the supporting substrate is important (6). For example, an electropolished stainless steel substratum showed significantly lower bacterial cells adhesion rate and delay in biofilm formation, compared with the sandblasted one (54). Planktonic microbial cells are delivered by diffusion and motility from a bulk medium to the surface, where a fraction of those cells adheres to the surface. The dynamics of bacterial adhesion is a unique characteristic of the specific microorganism; there may even be differences among the phenotypes and strains of the same bacterium (7).

Bacterial colonization of surfaces is influenced by two factors: First, a well-developed surface has higher adsorption capacity, and therefore the preconditioning organic film necessary for bacteria attachment is more likely to be formed on such a surface. On the other hand, surface topography influences bacterial attachment and proliferation, limiting the directions of colony growth and limiting nutrient access.

Surface topography was found to greatly affect the behavior and morphology of bacterial cells within colonies during the initial stages of biofilm development. In an effort to maximize their survival rate, bacteria form clusters of unique shapes, ranging from two-dimensional (2-D) single-layer colonies to three-dimensional (3-D) pillar-like structures within grooves. Hence, it is possible to control initial colony shape by varying the characteristics of surface constraints. Coupled with surface topography, starvation may play an important role in the attachment of bacteria to the surface, which is directly supported by our observations of bacterial behavior in the surface confines with limited nutrient access.

In general, surface patterns (i.e., roughness) impact microbial population in several ways: A well-developed (patterned) surface has higher adsorption capacity, whereas the presence of highly inclined regions (constraints) makes cell attachment more difficult. As follows from the obtained data, initial biofilm formation on rough surfaces occurs in two dimensions. If nutrient access is limited by the configuration of surface constraints and/or diffusion transport, bacteria can develop 3-D structures. On the other hand, if the tested surface is plain and smooth, bacteria always spread over it as a single-layer (2-D) colony. Maturing of the biofilm and corresponding total surface coverage lead to the development of three-dimensional structures, which have been previously described in the literature (4, 55, 56) and also observed in our experiments.

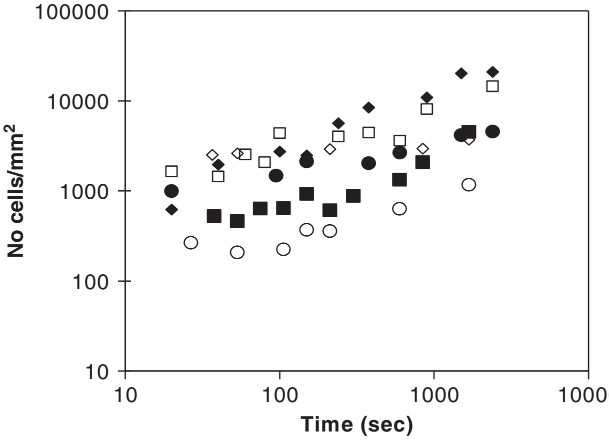

Figure 2. Effect of substratum type on the number of *Listeria monocytogenes* which become attached. The substrata are: ◆ aluminum; ☐ polypropylene; • poly(ethyleneterephthalate); ◇ high-density polyethylene; ■ poly(vinyl chloride); ○ poly(tetrafluorethylene).

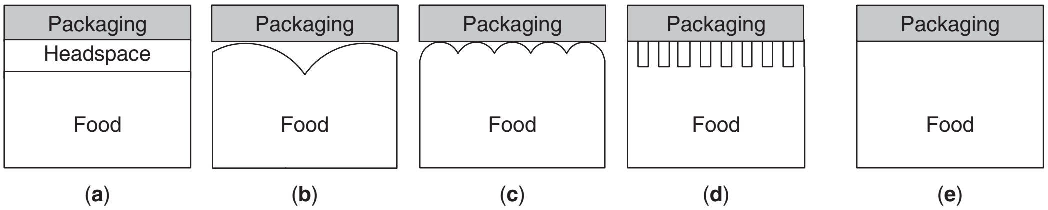

Figure 3. Spatial organization of AP as a function of food surface morphology: direct contact (**a**), partial contact ~1 cm (**b**), ~1 mm (**c**), ~10 μm (**d**), and direct contact (**e**).

Kinetics of bacterial adhesion onto surface of selected packaging materials is depicted in Figure 2. These results support data in the literature that adhesion of *Listeria monocytogenes* is material-dependent (34, 57).

FOODBORNE BIOFILMS AND ACTIVE (CONTROLLED-RELEASE) PACKAGING MATERIALS

The food market has growing demand on fresh and minimally processed foods. However, these foods are highly perishable and more susceptible to microbial spoilage. Thus, there is a strong need to develop new preservation methods to achieve a required level of safety, quality, and nutritional value of food during extended shelf-life period. The use of active packaging (AP) materials is one of the post-processing methods to preserve food products and meet consumers' expectations.

Antimicrobial packaging is designed to control microbial growth in a food product. It consists of an antimicrobial agent (AMA) immobilized onto the internal surface of a package or incorporated into packaging material (58). In the latter case, AMA is released into a food product over time. This permits us to extend shelf life of food products, helping to reduce the amount of AMA in food formulation.

AP materials have many parameters that influence their antimicrobial efficacy, which is thoroughly addressed in a number of studies: polymer processing, polymer morphology (59), polymer swelling (60), and AMA affinity to the packaging material (61). In all these papers the food product was considered as a homogeneous medium in full contact with the packaging. However, surface morphology of the foods is an important parameter that determines mass transfer of an antimicrobial agent through the interface between packaging and food.

Based on the nature of a food product and corresponding morphology of a food surface, one can distinguish five types of food-packaging contacts depicted in Figure 3.

If the surface of a food product is flat, direct contact between the packaging and the food exists. This AP system has maximum efficacy. An irregular food surface will cause only partial contact between the packaging material and the food product, developing noncontinuous headspace. This influences AMA transport from the packaging to the food. Depending on the dominating physical state of a food product, the packaging surface can be in contact with either solid or liquid food products, sometimes both. These contacts can be direct or indirect if headspace exists between the food surface and packaging material (see Figure 4). Depending on the type of the food product, the headspace can be liquid- or gas-filled.

Numerous parameters can influence the efficacy of AP, including the packaging material properties, the antimicrobial transport, the bacterial population response and the food matrix. Most of the published studies investigated antimicrobial activity of the controlled release compound by adding AMA directly to the foods or to the packaging materials. However, these two methods have significant disadvantages:

- When AMA is added directly to the food, obtained data provide important information on the antimicrobial activity of AMA and its interaction with the food matrix. But there is no time-dependent AMA release; therefore these studies are insufficient for the development of AP.
- On the other hand, if AMA is incorporated into the packaging material, there is no control over the antimicrobial release. The effects of packaging material properties on the AMA release rate cannot be distinguished from the effects of the AMA release rate on the bacterial inhibition.

There is a need to understand bacterial response to the AMA release without the influence of material-dependent properties of AP. No standard method has been established

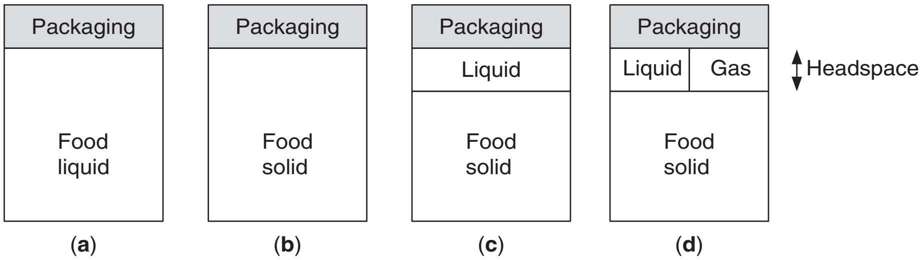

Figure 4. Dependence of a food/packaging interface on a type of food product.

to investigate the effect of antimicrobial agent's time-dependent release on the bacterial response.

BIOSENSOR TECHNOLOGY FOR FOOD PACKAGING APPLICATIONS

Paul Takhistov
Department of Food Science,
Rutgers, the State University of
New Jersey New Brunswick,
New Jersy

This article provides an introduction to the emerging technology of biosensors and its potential applications to food packaging. This biosensor technology may used to enhance the communication function of the intelligent packaging system (see the Intelligent Packaging article) to enhance the safety and quality of food products.

NEEDS OF FOOD QUALITY/SAFETY CONTROL

Food quality control is essential in the food industry; nowadays, an efficient quality assurance is becoming increasingly important. Consumers expect adequate quality of food product at a fair price, long shelf life, and high product safety, whereas food inspectors require safe manufacturing practices, adequate product labeling, and compliance with the U.S. Food and Drug Administration (FDA) regulations. Further more, food producers are increasingly demanding the efficient control methods, particularly through online or at-line quality sensors to satisfy consumers' and regulatory requirements and to improve the feasibility of automated food processing and quality of sorting. Also, food producers are demanding a reduction in the production time (increase throughput) and the final product cost.

Novel sensing technologies using biomaterials or nanomaterials can be used to detect quality and safety attributes in packaged foods. These sensing technologies range from rapid non destructive and noncontact to highly specialized microsensing and nanobiosensing structures. Micro- and nano-based sensors that use a variety of transduction mechanisms to sense microbial and biochemical changes in food products are being explored. Extensive development of biosensors for food safety and quality control were stimulated by acquiring several new food safety and key quality concepts during the last decade, such as Hazard Analysis Critical Control Points (see the HACCP article), Total Quality Management (TQM), and ISO 9000 Certifications. The wave of terrorist acts and foodborne disease outbreaks have raised the importance of the food traceability and authentication (1, 2). There are specific safety problems (pathogenic micro-organisms, BSE, GMF, pollutants, etc.) that require intensive control, data logging, and data treatments, which can be controlled effectively only with the new generations of biodetection systems (3). All these tasks require rapid responce sensors for new integrated data analysis systems and are an indispensable part of the modern supply chain operation paradigm.

There are several possible sources of undesirable contaminations and/or changes in food products that can be combined in five groups by their localization and occurrence. Three of them are food manufacturing-related as follows: technology (processing and sequence of process operations), industrial hygiene (food safety management at the plant level and HACCP), and formulation (product development, interactions of food additives/ingredients with food matrix, and bioavailability). The sources of food raw materials and their quality are the issue of biosafety/biosecurity in the agricultural processing including postharvesting technologies and logistics. The fifth source of biohazards is the environment in the broadest sense, which includes pollution, climate changes, and anthropogenic environmental factors.

The major types of changes in foods are caused by the sources of undesirable contaminants. They can be instrumentally controlled; hence, they represent the primary targets for biosensors development and design. Indeed, the great challenge is to develop the real-time and online sensors and data systems suitable for surveying processes and products, controlling automated processes and the raw material stream, sensing the final products quality, typing the product labels with nutritional and health information, and much more. Today, the most important quality parameters and concepts in food production control are as follows:

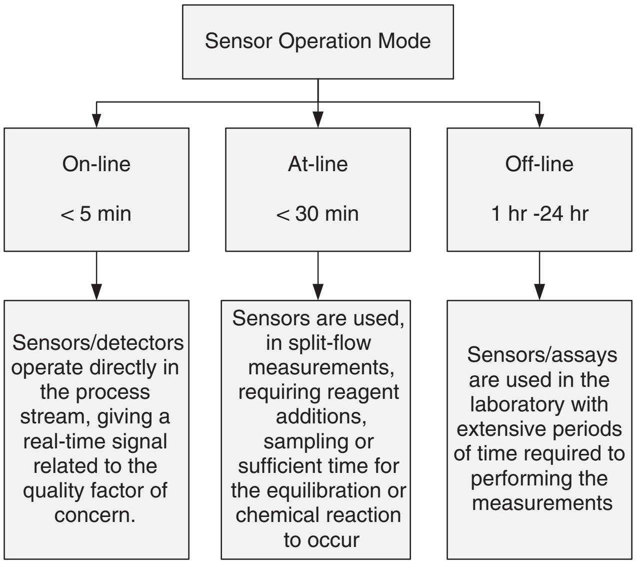
- *Sensory:* appearance, flavor, taste, texture, and stability
- *Nutritional:* including health implications, such as "high in fiber," "low cholesterol," and "GMF free"
- *Composition and labeling*: additives lists as well as quality and ethical claims (e.g., ecological information)
- *Pollutants record*: environmental pollutants, veterinary drugs, agricultural chemicals, BSE-prions, and mycotoxins
- *Detection of foreign bodies*: such as stones, glass or metal fragments
- *Microbial safety*: in particular *Listeria, Salmonella, Campylobacter, Escherichia coli* and *Yersinia*
- *Shelf life*: microbial, sensory, chemical, sterility testing, and F_0-values
- *Production hygiene*: cleaning and decontamination;
- *HACCP*: traceability and authentication
- *Process parameters control*: machine settings, temperature, pressure, flow, aseptic conditions, and many others
- *Packaging*: integrity, pinholes, gas permeability, and migration control

BIOSENSORS: GENERAL FACTS

The potential susceptibility of the food supply chain to natural or intentional contamination could result in compromised safety and quality of foods. Nano-bio sensors and integrated microsystems could play a significant role of detecting deteriorative changes in food packaging. In modern food packaging development, appropriate sensing technologies are required to detect substances in parts per trillion for food safety, quality, and process control. The development of new sensing devices may be achieved by taking advantage of miniaturization of electronics and nano-bio materials. These novel sensing systems can be used to facilitate the online analysis of food stuffs.

Biosensor technology is a powerful alternative to conventional analytical techniques, harnessing the specificity and sensitivity of biological systems in small, low-cost devices. Despite the promising biosensors developed in research laboratories, there are not many reports of real applications in packaging. A sensor is the device that can detect a property or group of properties in a food product and respond to it by a signal, often an electric signal. This signal may provide direct information about the quality factor(s) measured or may have known relation to the quality factor. Usually, sensors are classified according to their mode of use (see Figure 1).

Biosensors usually are small, analytical bioelectronic devices that combine a transducer with a sensing biological component (biologically active substance). The transducer,



Sensors/detectors operate directly in the process stream, giving a real-time signal related to the quality factor of concern.

Sensors are used, in split-flow measurements, requiring reagent additions, sampling or sufficient time for the equilibration or chemical reaction to occur

Sensors/assays are used in the laboratory with extensive periods of time required to performing the measurements

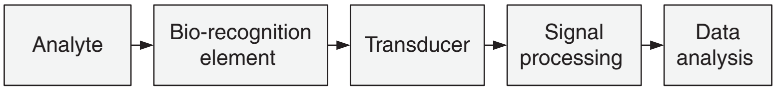

Figure 2. Schematics of biodetection process.

which is in intimate contact with the biologically sensitive material, can the measure weight, electrical charge, potential, current, temperature, or optical activity of the substance. The biologically active species include enzymes, multienzyme systems, antibodies or antigens, receptors, populations of bacterial or eukaryotic cells, or whole slices of mammalian or plant tissue. Substances such as sugars, amino acids, alcohols, lipids, nucleotides, and so on can be specifically identified and their concentration measured by these sensors. A schematic functional representation of a biosensor and the detection principle is depicted in Figure 2. The biosensor consists of a biological sensing element integrated with a signal transducer; together, they produce a reagent-free sensing system specific for the target analyte. The biological component of a biosensor used for the molecular detection is made of highly specialized macromolecules or complex systems with the appropriate selectivity and sensitivity. Biosensors can be classified according to the biocomponents used for the detection.

The biodetection principle can be schematically described as follows. A chemical, biological, or physical sensor produces a signal (e.g., voltage, absorbance rate, heat, or current) in response to a detectable event, such as binding between two molecules. In case of a biological or chemical sensor, this event typically involves a receptor (e.g., macrocyclic ligand, enzyme, or antibody) binding to a specific target molecule in a sample. Physical sensors, on the contrary, measure the inherent physical parameters of a sample, such as current or temperature, which can change because of reactions occurring in it. In any case, the signal is then transduced by passing it to a circuit where it is digitized. The obtained digital information can be stored in a memory, displayed on a monitor, or made accessible via digital communications port.

Because it is essential that the sensor's response be detected, it is necessary that an appropriate transduction mode for electrochemical signals, optical signals using changes in the fluorescence or absorbance rate of a sample, or plasmon resonance be available. With most sensors, transduction is accomplished electrochemically or optically.

The transducer transforms the physicochemical variations occurring in the biosensing element as the result of a positive detection event into an electric signal, which is then amplified by an ad hoc designed electronic circuit and used for the control of external devices. The transducers can be electrochemical (amperometric, potentiometric, and conductometric/impedimetric), optical, piezoelectric, or calorimetric. Often, this classification is used to identify the type of a biosensor (see Figure 3).

The bio-specific elements of the biosensor and transducer can be coupled together in one of the four possible ways (4), that are schematically shown in Figure 4: membrane entrapment, physical adsorption, matrix entrapment/porous encapsulation, and covalent bonding.

In the membrane entrapment scheme, a semipermeable membrane separates the analyte and the bio-element, and the sensor is attached to the bioelement [collagen

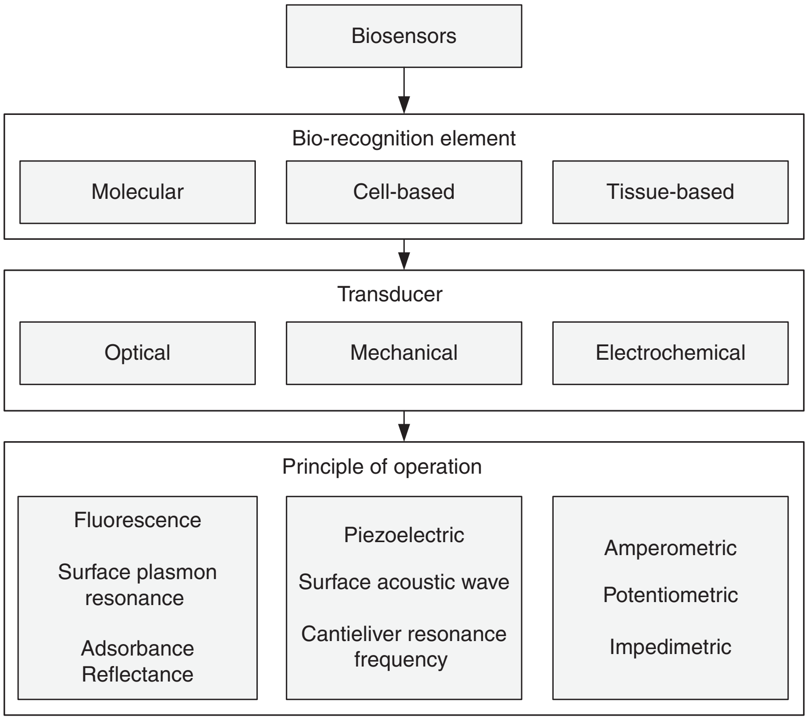

Figure 3. Biosensors classification.

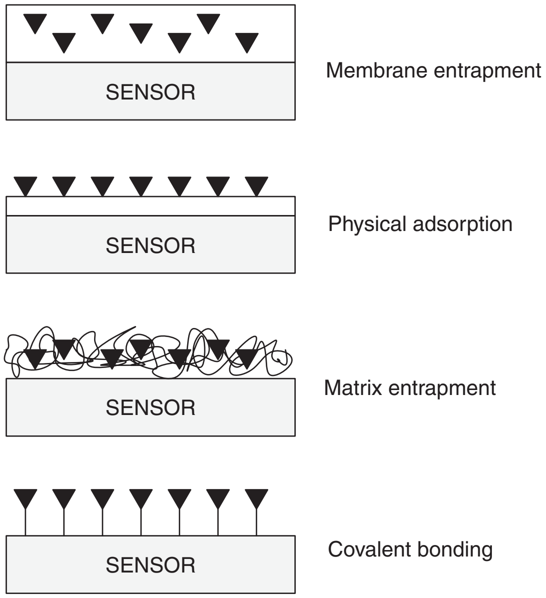

Figure 4. Coupling of biorecognition element (▼) with the transducer on a sensor substrate.

membranes, synthetic pre-activated membranes (5), and cellulose-acetate membranes]. The physical adsorption scheme depends on a combination of van der Waals forces, hydrophobic forces, hydrogen bonds, and ionic forces to attach the biomaterial to the sensor surface (6). The porous entrapment scheme is based on forming a porous encapsulation matrix around the biological material that helps in binding it to the sensor [nylon net (7), carbon paste (8), or graphite composites (9)]. In the case of covalent bonding, the sensor surface is treated as a reactive group to which the biological material can bind (10). One of the bioselective elements most frequently used in biosensors is an enzyme. These large protein molecules act as catalysts in chemical reactions but remain themselves unchanged at the end of reaction.

Mechanical (Resonant) Biosensors. In this type of biosensors, an acoustic wave transducer is coupled with an antibody (biosensitive element). When the analyte molecules (antigens) attach to the membrane (cantilever), the membrane mass changes, resulting in a subsequent change in the resonant frequency of the transducer (11). This frequency change is detected and measured (4).

Sensors Based on Electromagnetic Waves. Electromagnetic sensors may be classified by the wavelength of the electromagnetic waves they use: visible (VIS) (400–700 nm), ultraviolet (10–400 nm), infrared [700–30,000 nm: nearinfrared (NIR (12), FTIR (13), MRI (14)] waves, microwaves (15) (1–10 cm), radiofrequency (16) (1–10 m), and X-rays (17) ($100\,\mathrm{pm}^{-1}$ nm). Each sensor class may be subdivided even more according to the molecular information that can be obtained through the interaction. For instance, infrared sensors may be subdivided into near-infrared (700–2500 nm), mid-infrared (2500–30,000 nm), far-infrared (up to 1,000,000 nm), and thermography (1–15 μm) sensors, which all extract different information from the molecules (sample) interacting with the waves. We may also classify these sensors according to their precise type of interaction: absorbance, transmittance, or reflectance of light.

Sensors based on interactions with electromagnetic radiation waves have been on the market for many years, in particular for laboratory purposes. Online examples of such sensors are also numerous: X-rays used for foreign body detection (18), visible light sensors for color recognition or machine vision inspections (19), near-infrared sensors for quality inspection and temperature measurements (20), or microwave sensors for the detection of water content (21).

Optical Detection Biosensors. Strictly speaking, optical biosensors belong to the larger class of electromagnetic detectors, but because of their importance and broad use, they are usually considered as a separate group of biosensitive devices. The output signal measured in this type of biosensors is a light signal (22). These biosensors can be made based on optical diffraction or electrochemiluminescence (23).

Surface Plasmon Resonance (SPR). SPR is another optical phenomenon used in new sensors, often in those that involve antibodies or enzymes. The optical range used is most often in the visible part of the spectrum, but it may also be in the NIR range. Traditionally, SPR devices detect minute changes in the refractive index of the sensing surface and its immediate vicinity. They may detect these changes by a diffraction grating, with a prism on a glass slide, or through an optical waveguide carrying a thin metal layer (gold). The metal layer carries a sensitizing layer (e.g., immobilized antibodies or other molecules binding the analyte specifically; this layer is in contact with the sample). Inside the device, a collective excitement of electrons in the metal film occurs and leads at a specific wavelength to a total absorption of light at a particular angle of incidence. This angle depends on the refractive indices on either side of the metal film. Specific molecules binding to the sensitizing layer change the refractive index, which changes an angle of total absorption; this angle is measured and correlated to the concentration of the analyte.

The SPR detection technique has been used by Hellnaes (24) for online and at-line detection of veterinary drug residues (hormones and antibiotics) in dairies and slaughterhouses. Clenbuterol and ethinyl-estradiol in bovine urine, sulfamethazine (SMT), and sulfadiazine (SDZ) in porcine bile, as well as SMT, SDZ, and enrofloxacin in milk have been successfully detected by the technique. The developed biosensor operates in real time and can simultaneously detect up to 8 different veterinary drugs with a throughput of up to 600 samples per day. The project participants have established a new company to produce and develop the sensor systems, and several new and elegant designs of SPR sensors are now under study. The SPR sensor principle has also been used by Patel (25). The sensor developed as a result of this research has been applied to the quantification of mycotoxins, *Listeria,* and markers for growth hormones [recombinant bovine somatotrophin (rBST)].

Most current research is focused on the NIR/VIS sensors, SPR sensors and nuclear magnetic resonance (NMR) sensors (pulsed and low resolution); some work has also been done on fluorescence sensors, MIR and Raman sensors, Fourier Transform NIR sensors, thermography-based sensors, and sensors that combine two or more sensor principles.

Electrochemical Biosensors. Electrochemical biosensors are mainly used for the detection of hybridized DNA, DNA-binding drugs, glucose concentration, and so on. The underlying principle of these biosensors is that many chemical reactions produce or consume ions or electrons that in turn cause some changes in the electrical properties of the solution; these changes can be sensed out and measured (26). The electrochemical biosensor can be classified based on the measured electrical parameter as conductimetric, amperometric, or potentiometric (27).

Impedimetric/Conductometric Biosensors. Many biological processes involve changes in the concentrations of ionic species. Such changes can be used by biosensors, which detect changes in electrical conductivity. The measured parameter is the electrical conductance/resistance of the solution. When electrochemical reactions produce ions or electrons, the overall conductivity/resistivity of the solution changes (28). This change is measured and calibrated to a proper scale. Conductance measurements have relatively low sensitivity. The electric field is generated using sinusoidal voltage, which helps in minimizing undesirable effects such as Faradaic process, double-layer charging, and concentration polarization (29).

Impedimetric biosensors use changes in the electrical conductivity in the frequency domain (impedance) of a biological system for sensing and detection (6, 30, 31). Impedance spectroscopy provides a powerful tool for investigating a variety of bioelectric processes for both electrical and nonelectrical applications. In impedance spectroscopy, the current flowing through a sample cell that contains a nano-scale patterned bio-interface and the voltage across this cell are measured as a function of frequency (32–34). The design of impedimetric sensors is similar to conductivity-based sensors (26, 35–39). Enzyme/antibody immobilization on electrode surface makes these sensors highly selective and sensitive (40).

Amperometric Biosensors. This highly sensitive biosensor can detect electro-active species present in biological test samples. Enzyme-catalyzed redox reactions can form the basis of a major class of biosensors if the flux of redox electrons can be determined (41). Normally, a constant voltage is applied between two electrodes, and the current, which is caused by the electrode reaction, is determined. The first and simplest biosensor was based on this principle. It was for the determination of glucose and made use of the Clark oxygen electrode. In the case of amperometric biosensors, the measured parameter is an electric current. Some of the most recent applications of amperometric biosensors include glucose sensor for meat freshness (43); glucose sensor for use in fermentation systems (43); rapid cell number monitor (44); monitor for herbicides in surface waters (45, 46); amperometric enzyme-linked immunosorbent assay (ELISA) method based on the self enzyme amplification system (36); amperometric and novel fluorescent DNA probes (47).

Potentiometric Biosensors. In this type of sensors, the measured parameter is the oxidation/reduction potential of an electrochemical reaction (48). The simplest potentiometric technique is based on the concentration dependence of the potential, E, at reversible redox electrodes according to the Nernst equation (29) $E = E_0 + \frac{RT}{nF} \ln a_s$, where E_o is the standard redox potential, R is the gas constant, T is the absolute temperature, F is the Faraday constant, n is the number of exchanged electrons of the substance S, and a_s is the activity of the substance S. Changes in ionic concentrations are easily determined by use of ion-selective electrodes (48). This forms the basis of potentiometric biosensors (30). Many biocatalyzed reactions involve charged species each of which will absorb or release hydrogen ions according to their $\mathrm{pK_a}$ and the pH of the environment (49). This allows a relatively simple electronic transudction using the most common ion-selective electrode, which is the pH electrode (50).

Field Effect Transistors (FETs) and Ion-Selective Field Effect Transistors (ISFETs). Potentiometric biosensors can be miniaturized by the use of FET. ISFETs are low-cost devices that are in mass production (51). A recent development from ion-selective electrodes is the production of ISFETs and their biosensor use as enzyme-linked field effect transistors (ENFETs). Enzyme membranes are coated on, the ion-selective gates of these electronic devices, the biosensor responding to the electrical potential change via the current output. Thus, these are potentiometric devices, although they directly produce changes in the electric current. Reference shows a diagrammatic cross-section through an npn hydrogen ion responsive ISFET with a biocatalytic membrane. The buildup of positive charge on this surface (the gate) repels the positive holes in the p-type silicon causing a depletion layer and allowing the current to flow. In Abdelmalek et al. (52), Langmuir-Blodgett films that contain butyrylcholinestrase (BuChE) are fabricated to realize an ISFET for the detection of organophosphorus pesticides in water.

Cell-Based Biosensors. Cell-based biosensors have been implemented using micro-organisms, particularly for environmental monitoring of pollutants (53). Biosensors that incorporate mammalian cells have a distinct advantage of responding in a manner that can offer insight into the physiological effect of an analyte (54, 55). Several approaches for the transduction of cellular signals (56) are described in the literature: measures of cell metabolism, impedance (57), intracellular potentials, and extracellular potentials (58). Among these approaches, networks of excitable cells cultured on microelectrode arrays (53, 54, 59–61) are uniquely poised to provide rapid, functional classification of an analyte and ultimately constitute a potentially effective cell-based biosensor technology.

Keese and Giaever (62) have designed a biosensor that can be used to monitor cell morphology in tissue culture environment. The sensing principle used is known as electric cell-substrate impedance sensing (ECIS). In this process, a small gold electrode is immersed into the tissue culture medium. After cells attach and spread over the electrodes, the electric impedance measured across the electrode chamber changes. These changes in impedance can be used for understanding cell behavior in the culture medium. The attachment and spreading of the cells are important factors for successful use of this biosensor. Unfortunately, some types of cells, e.g., cancerous cells, can grow and reproduce freely in a medium without being attached to any substrate/surface, that makes them impossible to detect with these sensors.

Cornell et al. (63) proposed biosensor mimics biological sensory functions and can be used with most types of receptor, including antibodies and nucleotides. The technique is flexible and even in its simplest form it is sensitive to pico-molar concentrations of proteins.

Lab-on-a-Chip Systems and DNA Detection Devices. Significant advances have been made in the development of micro-scale technologies for biomedical and drug discovery applications. The first generation of microfluidics-based analytical devices [Lab-on-a-Chip (64)] have been designed and are already functional. Microfluidic devices offer unique advantages in sample handling (65–67), reagent mixing (68–70), separation (71–73), and detection (74). These devices include, but are not limited to are devices for cell sampling (75), cell trapping and cell sorting devices (59, 76–79), flow cytometers (67, 80, 81), devices for cell treatment: cell lysis, poration/gene transfection, and cell fusion devices (82).

Biosensors used for DNA detection are used to identify small concentrations of DNA (of micro-organisms such as viruses or bacteria) in a large sample. The detection relies on comparing sample DNA with a DNA of known micro-organism (probe DNA) (83). Because the sample solution may contain only a small number of micro-organism molecules, multiple copies of the sample DNA need to be created for proper analysis (84). This is achieved with an aid of the polymerase chain reaction (PCR). PCR starts by splitting the sample's double-helix DNA into two parts by heating it. If the reagents contain proper growth enzymes, then each of these strands would grow the complementary missing part and form the double-helix structure again. This happens after the temperature is lowered. Thus, in one heating/cooling cycle, the amount of sample DNA is doubled (85). In general, PCR is power consuming, so previously it was not possible to fabricate portable biodetectors that can perform PCR. But, using newly developed MEMS devices, such biodectors (also known as lab-on-a-chip systems) have been created. In these MEMS-based devices the amount of reagent used is scaled down (86).

DNA-Based Sensors/Assays. The general principle of DNA probe assay is similar to the immunoassay described in. Indeed, even the applications of DNA probes and monoclonal antibody immunoassay frequently overlap, thus establishing a "competition" between the two possible approaches.

One of the most important applications for DNA probes is the testing for virus infections (87). For probes of infectious disease, it is assumed that all strains can still contain a common DNA sequence region and thus be identified by a single probe. Recognized by the cell as a foreign body, viruses will induce an antigenic reaction causing antibody generation so they can also be detected in an immunoassay (88).

Another type of biosensor developed by the Naval Research Laboratory (85) uses magnetic field instead of optics or fluorescence. This sensor equipped with magnetic sensors and microbeads (89) can detect the presence and concentration of bioagents. The magnetic sensor (group of sensors) is coated with single-stranded DNA probes specific for a given bioagent or sample DNA. Once a single strand of DNA probe and a single strand of sample DNA find each other, they form a double-stranded (double-helix) structure, which in turn binds a single magnetic microbead. When a magnetic bead is present on a sensor surface, its resistance decreases, which can be detected and measured.

BIOSENSORS AND FOOD PACKAGING

Integrated Sensor-Packaging Systems

The basic function of sensors-packaging system is to monitor the package environment, product state/status, and perform data exchange with the external databases, providing information for decision making. Intelligent packaging is the integrated system of a complex structure with discrete/distributed sensor and data carrier elements. Technical realization of such a packaging system includes integration of sensitive elements into the packaging materials and/or labels, and integration of sensors' data into the intelligent packaging information flow, i.e., data layer. Such integration allows to perform online and "on-shelf" control of the internal and/or external package environments. Biosensors can be created by chemical modification and sensibilizing of packaging labels, embedding microdevices ("smart chips"), or depositing micro- and nano-sensitive elements into the label or the package itself. In the future, this system can be used to trigger the controllable release of bioactive components and targeted delivery of protective agents into the food product. One of the most important elements of the Internet Protocol (IP) concept is integration of sensors and detectors into the package itself. Examples of monitoring activities include visual observations/control and measurements of temperature, time, pH, and moisture levels. In the future, this system can be used to trigger the controllable release of bioactive components and the targeted delivery of protective agents into the food product.

Based on the type of the sensor and their location, it is possible to recognize three major types of sensor-packaging systems (see Figure 5):

- Off-package — remote sensing devices without requirements of direct contact with the package

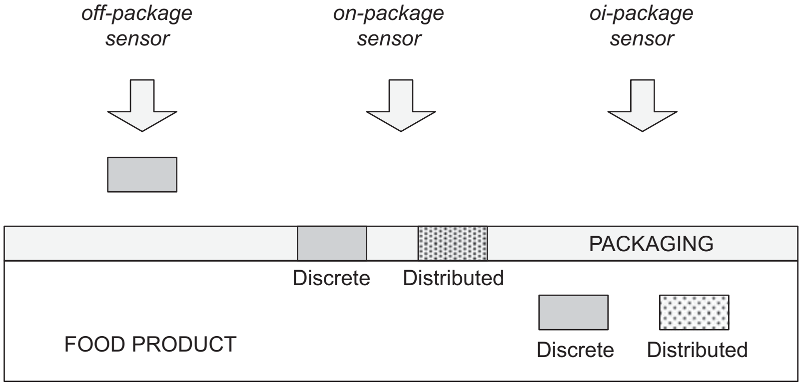

Figure 5. Sensor-packaging systems.

materials of packaging content, i.e., various spectroscopic devices (Raman, IR, NIR, and radiofrequensy).

- On-package — truly integrated devises that located on the packaging itself. RFID devices can be related to this category. Sensing packaging materials, which are sensors with distributed parameters, also belong to this type of sensors.
- In-package — sensing device is placed inside of the package. In some cases sensor can be part of the product formulation.

Integrated Sensor-Packaging Systems May Enhance Food Safety

Existing food distribution network includes producers, logistic operators, and processors. Timely detection of unsafe foods entering this network is the main issue that food safety system should address. The HACCP system, which has become the industrial standard for food safety management is designed to identify health hazards and to establish strategies and procedures to prevent, eliminate, or reduce their occurrence. Each stage of the food products flow is individually controlled, but there is no integrated food safety system that combines material and informational flows into one continuous food safety management process. There is a need to enhance the existing HACCP procedures by integration of material and information flows and to ensure early detection of deliberate food contamination at any point along the production pathway. In general the intelligent packaging framework is perfectly adapted to be used in the HACCP workflow and uses the principle of information system cyclic interactions with the environment (Figure 6).

The intelligent packaging framework enhances the existing HACCP system by incorporating its virtual data layer into the food safety management structure. Intelligent packaging can be integrated into the HACCP system as a data carrier, which delivers proper information about product history, establishes critical limits, and acts as a self-reporting data tag that creates natural link with an external knowledge base. Hence, the Critical Control Points that implement elements of an intelligent packaging will receive new functionality. Combining data of product properties and proper storage regimes with the

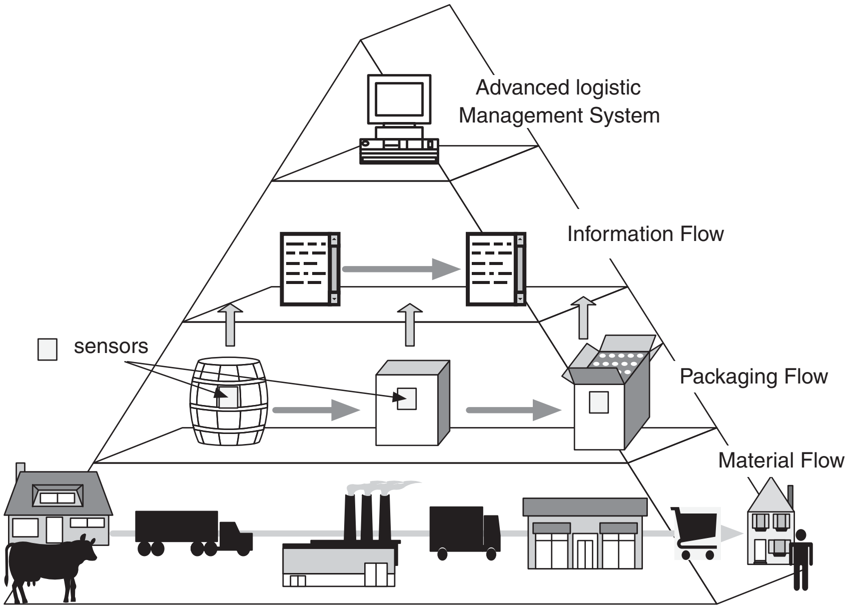

Figure 6. An integration of sensors into information/material flow in distribution network.

data generated by the packaging sensors, the IP system can direct the distribution/transportation network on proper operation sequence of product handling. In-time correction actions, continuous monitoring of product environment/quality, and record keeping are the main functionalities of the HACCP that can be realized within the intelligent packaging conceptual framework. Established critical limits can be stored in product labels. If progressive scan of sensors' data indicates the difference between established critical limits and current food product properties, then corrective actions will be performed. Intelligent packaging will be able to participate in these actions providing timely and sufficient information necessary for decision making.

An advanced food safety management system based on intelligent packaging will be able to correctly (a) identify potential hazards; (b) identify hazards which must be controlled; (c) conduct a biohazard analysis; (d) recommend controls, critical limits, and procedures for monitoring and verification; and (e) recommend appropriate corrective actions when a deviation occurs. This integrated food safety system combines data from multiple sensors (from different packages and/or products) and relates information about food environment and process conditions. Intelligent packaging is a unique entity that creates a dynamic link among the food product, environment, safety management system, and business operations. Its universality is determined by integration of information and data flows in one system.

APPLICATIONS OF BIOSENSORS IN FOOD SCIENCE AND FOOD PACKAGING

The need for fast, online, and accurate sensing, e.g., *in situ* analysis of pollutants in crops and soils, detection and identification of infectious diseases in crops and livestock, online measurements of important food processing parameters (90), monitoring animal fertility, and screening therapeutic drugs in veterinary testing are well described in another work (91).

Sensors for Pathogens Detection

The broad spectrum of foodborne infections keeps changing dramatically over time, as well-known pathogens have been controlled or eliminated, and the new ones have emerged. The burden of foodborne diseases remains substantial: One in four Americans is estimated to have a significant foodborne illness each year. Most of these illnesses are not caused by known pathogens, so more of them remain to be discovered. Among the known foodborne pathogens, the recently identified predominate, suggesting that as more and more is learned about pathogens, they would come under control. In addition to the emergence or recognition of new pathogens, other trends include global pandemics of some foodborne pathogens, the emergence of antimicrobial resistance, the identification of pathogens that are highly opportunistic and affect only the most high-risk subpopulations, and the increasing identification of large and dispersed outbreaks. New pathogens can emerge because of changing ecology or technology that connects potential pathogen with the food chain. They also can emerge by transferring the mobile virulence factors, often through bacteriophage (92).

Over the past decade, many improvements have been observed in both conventional and modern methods of pathogenic bacteria detection in foods (26). Modification and automation of conventional methods in food microbiology involve sample preparation, plating techniques, counting, and identification test kits. Adenosine triphosphate (ATP) bioluminescence techniques are increasingly used for measuring the efficacy of surfaces and utensils cleaning. Cell counting methods, including flow cytometry, and the direct epifluorescent filter technique are suitable for rapid detection of contaminating micro-organisms, especially in fluids. Automated systems based on impedance spectroscopy can screen high numbers of samples and make total bacterial counts within 1 day. Immunoassays in various formats make a rapid detection of as many pathogens as possible. Recently, there have been important developments in the nucleic acid-based assays and their application for the detection and subtyping of foodborne pathogens. The sensitivity of these methods has been significantly increased by employing the polymerase chain reaction and other amplification techniques. Alternative and rapid methods must meet several requirements concerning accuracy, validation, speed, automation, sample matrix, and so on. Both conventional and rapid methods are used in the frame of biohazard analysis critical control point programs. Additional improvements especially in immunoassays and genetic methods can be expected, including applications of biosensors and DNA chip technology (93).

In recent work by Bokken et al. (94), a surface plasmon resonance biosensor was used to detect *Salmonella* pathogen through antibodies reacting with *Salmonella* group A, B, D, and E (Kauffmann-White typing). In the assay designed, anti-*Salmonella* antibodies immobilized onto the biosensor surface were allowed to bind injected bacteria, followed by a pulse with soluble anti-*Salmonella* immunoglobulins to intensify the signal. No significant interference was found for mixtures of 30 non-*Salmonella* serovars at 109 CFU mL^{-1}. A total of 53 *Salmonella* serovars were successfully detected at 107 CFU mL^{-1}, except those from groups C, G, L, and P, as expected.

Another sensor technology recently developed uses a micro-electrophoretic system (mFFE) that separates and concentrates the analyte in question by several electrophoretic methods: preparative zone, interval zone, isotachophoresis, or isoelectric focusing. The mFFE system can be designed as a plain glass substrate 1.5 mm thick, and a cross-linked polydimethyl-siloxane (PDMS) top layer with micromachined sample channels. The central separation chamber ($12 \times 4 \times 0.15$ mm) is connected to 34 inlet channels for sample injection, and 36 outlet channels for sample collection. The detector unit can be based on several principles. In the case of *Listeria*, the detector unit may be a well-known ATP luminescence detector. For other analytes, the SPR detection system may be used with immobilized bio-specific layer, e.g., antibodies (95).

New ion-channel biosensor based on supported bilayer lipid membrane for direct and fast detection of *Campylobacter* species has been reported (96). The sensing element was composed of a stainless-steel working electrode, covered with an artificial bilayer lipid membrane (BLM). Antibodies to bacteria embedded into the BLM are used as channel-forming proteins. The biosensor has a strong signal amplification effect, which is defined as the total number of ions transported across the BLM. The biosensor has demonstrated a good sensitivity and selectivity to *Campylobacter* species.

A novel assay system for the detection of *E. coli* O157:H7 has been recently developed. The detection is based on the immunomagnetic separation of the target pathogen from a sample and absorbance measurements of p-nitrophenol at 400 nm from p-nitrophenyl phosphate hydrolysis by alkaline phosphatase (EC 3.1.3.1) on the "sandwich" structure complexes (antibodies coated onto micromagnetic beads – *E. coli* O157:H7-antibodies conjugated with the enzyme) formed on the microbead surface (97). The selectivity of the system has been examined, and no interference from other pathogens including *Salmonella typhimurium, Campylobacter jejuni*, and *Listeria monocytogenes* was observed. The sensor's working range is from 3.2×102 to 3.2×104 CFU/mL, with the relative standard deviation of 2.5–9.9%. The total detection time is less than 2 h.

An improved antibody-coated sensor system based on quartz crystal microbalance analysis of *Salmonella spp.* has been developed using thiolated antibody immobilization onto the gold electrode of the piezoelectric quartz crystal surface (98). The best results in sensitivity and stability were obtained with the thin layer of a thiol-cleavable, hetero-bifunctional cross-linker. The long bridge of this reagent can function as a spacer, facilitating antibody-*Salmonella* interaction on the gold electrode. The sensor's response was detected for the microbial suspension concentrations that ranged from 10^6 to 1.8×10^8 cfu/mL.

A label-free immunosensor for the detection of pathogenic bacteria using screen-printed gold electrodes (SPGEs) and a potassium hexacyanoferrate (II) redox probe has been reported by Susmel et al. (99). Gold electrodes were produced using screen printing, and the gold surfaces were modified by a thiol-based self-assembled monolayer (SAM) to facilitate antibody immobilization. In the presence of analyte, a change in the apparent diffusion coefficient of the redox probe was observed, that can be attributed to impedance of the diffusion of redox electrons to the electrode surface caused by the formation of the antibody–bacteria immunocomplexes. No change in the diffusion coefficient was observed when a nonspecific antibody [mouse immunoglobuline (IgG)] was immobilized and antigen added. The system has been demonstrated to work with *Listeria monocytogenes* and *Bacillus cereus*.

Sensors to Monitor Food Packaging and Shelf Life

In recent work by Yano et al. (100), a cell-based biosensor has been used to control meat freshness. Samples of fresh meat stored at 5°C were periodically removed from storage and washed with water for periods of up to 2 weeks. The water was then charged into a flow-injection analysis (FIA) system combined to the microbial sensor using yeast (*Trichosporon cutaneum*) as a sensitive element. This sensor has been specifically developed in this work for monitoring the freshness of meat. Relationships among the sensor signals obtained by the FIA system, the amounts of polyamines and amino acids produced from the meat, and the number of bacteria that had been multiplying in the meat during the aging process were investigated. The sensor response has been found to correspond to the increase in amino acid levels and viable counts in the meat during the first stage of aging. This is because amino acids produced initially by enzymes in the meat serve as a nutrition source for septic bacteria, and as a result, the amount of bacterial cells increases with increasing level of amino acids.

Foreign Body Detection. The presence of foreign bodies in processed food is of major concern to the producers. Mechanical separation techniques based on size and weight of different components have been used for many years to help finding foreign bodies in powdered and flowing products. Optical inspection techniques were able to extend the range of detectable foreign objects in free-flowing materials with regard to their shape and color. Metal detectors enabled metallic particles inside the product to be found. With recent achievements in sensor technologies advanced foreign body detection systems are becoming available (101).

The working principle and design of an ultrasonic transducer system with auto-alignment mechanism was first described by Zhao et al. (102). The proposed system has been used for detecting foreign bodies in beverage containers. Variations in reflection amplitude were analyzed as a function of the ultrasound beam incident angle to the beverage container surface. It has been concluded that a quadratic relationship exists between the strength of the reflected signal and the incident angle. Furthermore, a calculation for effective angular increment for searching the normal to a curved surface was introduced. Experiments conducted using the sensor prototype have demonstrated that foreign bodies are detectable in containers of various juices. This sensor design is also applicable to the non destructive inspection of canned food products for the foreign bodies presence.

Biosensors for Food Quality/Additives Control

Existing food packaging and packaging equipment may include microprocessors that are activated by electronic or biological sensors. Recent advances in electronic vision and computer technology have opened the research horizons for greater accuracy in process control, product sorting, and operation. The development of new sensors and instruments in this area is focused on measuring/evaluating the product internal and external quality and flavor (91).

The aim of food additives control and measurement is to develop, extend, and enhance the instrumental methods to improve consumer-perceived macroscopic quality factors. Several types of electronic sensors for quality assessment, grading, and sorting of food products have been investigated and described in literature.

A near infrared sensing technique can rapidly determine the sugar content of intact peaches. This technology has been extended to many other commodities, including testing avocados for oil content, and kiwifruits for starch and sugar content. The NMR method, for example, can be used for nondestructive detection and evaluation of internal product quality factors, such as the existence of bruises, dry regions or worm damage, stage of maturity, oil content, sugar content, tissue breakdown, and the presence of voids, seeds, and pits.

The machine vision for postharvest product sorting and grading is being investigated for several commodities. Recent research has included the development of a high-speed prune defect sorter, color and defect detector for fresh-market stone fruits, raisin grading, and flower grading machines. In this technology, electronic cameras are used for monitoring the product in various packing-line handling situations. Quality features are computed from digitized images, and the control system allows for product grading and sorting. The NIR/VIS region has been used in several different sensors. Thus, Crochon (103) has presented the design of a glove-shaped apparatus equipped with various miniaturized sensors providing information on fruit quality parameters, i.e., sugar content, maturity, mechanical properties (firmness and stiffness), and internal color. The sugar content and internal color were measured by a miniaturized spectrometer (NIR/VIS) coupled with optical fibers. A sound sensor evaluated the mechanical properties, and the size was measured by a potentiometer placed at the hand aperture. These sensors were coupled to a microcomputer that delivered processed information about the fruit overall quality grade, based on previously established variety and quality classes. The weight of the glove prototype was 400 g, and the electronic devices were held in a rucksack weighing 1000 g. The glove may be used before harvest to control the growth and to estimate the harvest date, at harvest to select fruits with specific qualities, or after harvest to control and measure the quality of the crop.

In Baendemaeker (104), chlorophyll fluorescence and reflectance in the NIR/VIS spectrum has been used for the mechanical quality factors assessment of green beans, broccoli, and carrots. Biosensors have been used for evaluation the effects of pasteurization on the vegetables quality by measuring the remaining enzymatic activity. Using MIR spectroscopy, as well as Raman scattering for online quality assessment in bakeries, breweries, dairies, and fruit farms has been reported (105).

Another method working in the NIR/VIS range, called time-resolved diffuse reflectance spectroscopy (TDRS) has been used to measure the internal quality of fruits and vegetables (106). The group has developed statistical models for the analysis of relationships between the TDRS signals and the firmness, sugar, and acid content of kiwifruit, tomato, apple, peach, nectarine, and melon. They have also developed the classification models to sort apples, peaches, kiwifruits and tomatoes into quality classes. Using a pulsed laser diode (70–200 ps/pulse), the single measurement time was about 100 ms. The absorption coefficient was related to the tissue constituents, whereas the scattering coefficient was related to the firmness and fiber content. A real-time sensors in the NIR/VIS range can be also used to measure product quality traits, such as maturity, flavor, or internal diseases and defects in potatoes, apples, and peaches (107).

Among the optical sensor systems developed and demonstrated in industrial environments are machine or artificial vision sensors. The system for olives sorting, using a traditional vision camera and three CCD color sensors for the shape, size, and color evaluation has been described (108). The new algorithm allowed the olives to be sorted into four classes with the speed of 132 olives/sec, and 6 images/sec.

The molecular imprinted polymers (MIP) technology is the new technology used for the development of biosensor substrates (109). The polymers are produced by imprinting the recognition sites of predetermined specificity into cross-linked synthetic polymers. The polymer is consequently able to selectively rebind the imprinted molecule (110). These sensor materials are called “artificial antibodies” (111). The MIP technology has particular strengths for small molecular analytes up to about 400 Dalton; it may be used to bind and detect many chemicals polluting food products, e.g., pesticides and veterinary drugs in meat and dairy products.

This technology has been successfully employed to develop and optimize plug-in detection cartridge supporting the molecularly imprinted polymer assay (112) for detection of different β-lactam antibiotics in milk. The sensor consists of a microfabricated column accommodating an optical detection window. Molecular imprinted polymers in the form of beads were used as packing materials and recognition elements; analyte binding was detected by the fluorescence. The same MIP technology has been used in several other studies, the overall objective of which was to develop novel and robust MIP-based technology that can be used in sensors for real-time measurements of food product contaminants (113–115). The results of the study indicate that MIP can be used to prepare both selective and general recognition matrices for either individual analytes or groups of compounds , with very good detection reproducibility and stability (115). SPR based sensor shows similar results for dairy product quality applications (116). The MIP developed for clenbuterol has been successfully applied in preparing a novel sensor comprising MIP as the selective element and amperometric detector as the transducer (109). The responses from several sensors were determined to have a variability of 10%. The feasibility for an oxacillin MIP-based sensor was also demonstrated.

At-line immunological sensors using amperometric detection of the resulting antibody-antigen complexes were described (117). The target quality factor assessed in this project was the presence of toxic chlorophenolic fungicides and their chloroanisole breakdown products in potable water, wine, and fruit juices. The electrochemical immunosensor uses monoclonal antibody preparations. The investigations of the effects of liquid food matrices on electrochemical transduction processes indicated that horseradish peroxidase is a suitable label for interrogation of the analyte–antibody immune complex, using amperometry and in-house fabricated screen-printed electrodes. The detection of hormonal substances for growth promotion, which is also based on immuno-sensors, has been recently reported by Guilbault (118). The sensor has to be used prior to slaughtering, and it can detect and measure testosterone, methyltestosterone, 19-nortestosterone, stanozolol, and trenbolone levels in biological fluids (blood). Analysis time achieved was about 30 min, compared with 24–36 h for tests used in laboratories today.

Biosensors for Sensory Evaluation of Food Products

“Electronic noses” (119, 120) and “electronic tongues” (121) are the common names of devices responding to the flavor/odor (volatiles) or taste (solubles) of a product using an array of simple and nonspecific sensors and the pattern-recognition software system (122). Historically, the sensors used were advanced mass spectrometers or gas/liquid chromatographs that produce unique fingerprint of the analyte. Nowadays, these sensors have been substituted by arrays of simple electric and/or frequency sensors, or sensors measuring changes in voltage or frequency as a response to the food contact.

Electronic noses and tongues are used in food production and quality control of different products, typically for laboratory tests or at-line control but may be further developed for in-line operation in the future. Testing times are often in the range of a few minutes, and the largest drawback of these devices is the lack of sensor stability. Examples of claimed successful applications include (123) the following:

- Discrimination between single volatile compounds
- Tracking of aroma evolution of ice-stored fish or meat
- Tracking of the evolution of cheese aroma during aging
- Classification of wines
- Determination of boar odor (androsterone) in pork fat
- Classification of peaches and other fruits
- Differentiation of spices by the area
- General raw materials control
- Testing of coffee, soft drinks, and whiskey
- Control of beer quality and faults

Essentially, each odor or taste leaves a characteristic pattern or fingerprint on the sensor array, and an artificial neural network is trained to distinguish and recognize these patterns (see Pattern recognition is gained by building a library of flavors from known flavor mixtures given to the network. Thus, e-noses and tongues are the devices intended to simulate human sensory response to a specific flavor, sourness, sweetness, saltiness, bitterness, and so on (123, 124).

The potentiometric chemical sensors such as ion selective sensors are most often used in the electronic noses. Considerable interest exists in the development of cheap, portable electronic noses to detect, online or at-line, the odor quality of many foods. For instance, olive oil producers would tremendously benefit from the possibility of detecting oil quality and shelf-life, and classifying the oils by their quality (e.g., extra virgin olive oil). This was the objective of a project in course of which scientists from olive producing countries have developed electronic noses especially for the olive production plants and tested them with great success (125).

In Dutta et al. (126), different tea samples were used to evaluate the applicability of electronic noses for sensory studies. A metal oxide sensor-based electronic nose has been used to analyze tea samples with different qualities, namely, drier month, drier month again overfired, well fermented normal fired in oven, well fermented overfired in oven, and under fermented normal fired in oven.

Electronic tongues are also widely used to assess the taste quality of various products. An electronic tongue based on voltammetry measurements, and a multichannel lipid membrane taste sensor based on potentiometry were compared using two aqueous solutions: detergent and tea (127). The electronic tongue consists of four electrodes made of different metals, a reference electrode, and a counter electrode. The measurement principle is based on pulse voltammetry technique in which an electric current is measured during the amplitude change of the applied potential. The taste sensor consists of eight different lipid/polymer membranes. The voltage difference between the electrodes and an Ag/AgCl reference electrode is measured when the current is close to zero. The multichannel electrochemical (potntiometric) sensors have demonstrated better sensitivity, faster dynamic response, but lower reproducibility of the results.

In study performed by Legin et al. (128) the electronic tongue based on a sensor array comprising 23 potentiometric cross-sensitive chemical detectors, and pattern recognition and multivariate calibration data processing tools has been applied to the analysis of Italian red wines.

Biosensors and Biosecurity

Food industry is one of the major potential targets for bioterrorism. The most damage can be attained through (a) final product contamination using either chemical or biological agents with an intent to kill or cause illness among consumers; (b) disruption of food distribution systems; and (c) damaging the food producing cycle by introducing devastating crop pathogens or exotic animal diseases such as foot-and-mouth disease, which could severely impact the food system.

Efforts to develop recognizing preparedness and response strategies for protecting the nation’s food supply pose substantial challenges for many reasons, including the following (129–131):

- The food system encompasses many different industries.
- A great variety of biological and chemical agents could potentially contaminate the food supply, and the possible scenarios for deliberate contamination are essentially limitless.

- The public health system is complex, and responsibilities for foodborne diseases prevention and control may overlap, or much worse, fall in the “gray area” between authorities of different agencies.

To achieve an adequate food supply chain and agricultural security, the improvement is needed in the activities on bioterrorism prevention, detection, and response. In addition, appropriate areas for applied research must be identified as follows:

- *Recognition of a foodborne bioterrorism attack*. This may be delayed because of background levels of foodborne diseases and potential wide distribution of the contaminated product or ingredient.
- *Rapid diagnostic methods* for identifying food-contaminating agents. They are not yet consistently available, and coordinated laboratory systems for pathogens detection are not fully operational.
- *Rapid trace-back procedures* for potentially contaminated products.

Biosensors and HACCP

Timely detection of unsafe foods is the main issue that the food-safety system should address, providing guidance for the design and integration of such system into the existing food safety management structures, i.e., HACCP. The preventive detection of the biohazard can be accomplished by direct measurements with the biosensors, or indirect detection by the process/environment monitoring and control. Such detection is based on the data from physical and chemical sensors, which are reliable and allow scale-down (meaning the possibility of easy integration into the existing information carriers). The HACCP system for food-safety management is designed to identify health hazards and to establish strategies to prevent, eliminate, or reduce their occurrence. An important purpose of corrective actions is to prevent potentially hazardous foods from reaching consumers. Where there is a deviation from the established critical limits, corrective actions are necessary. Therefore, corrective actions should include the following elements: (a) determine the disposition of non-compliant product, (b) determine and correct the cause of noncompliance, and (c) record the corrective actions that have been taken.

Currently, the use of HACCP is voluntary, but it is widely used in the food processing industry as a successful component of comprehensive food safety program. HACCP is a food safety management system in which food safety is addressed through the analysis and control of biological, chemical, and physical hazards from raw material production, procurement, and handling, to manufacturing, distribution, and consumption of the final product. The terms “HACCP” and “food safety” are used interchangeably in the food industry, implying that HACCP may be the only approach to achieving food safety. HACCP is designed for use in all segments of the food industry from growing, harvesting, processing, distributing, and merchandising, to preparing food for consumption (132).

However, there is a need for enhancement and integration of existing HACCP system into the total quality management system and food safety/biosecurity management on higher levels. This system currently includes the mechanisms to decrease the potential for contamination of or damage to the food supply from farm to table (i.e., prevention activities); systems to ensure early detection of deliberate food contamination at any point along the production pathway, including surveillance, rapid laboratory diagnostic and communication systems; and systems to ensure a rapid and thorough response if a bacterial contaminant is detected, including protection of workers and consumers (i.e., emergency response, control, trace-back, and mitigation activities).

The ultimate goal is the integration of sensors and sensor networks into the food-safety management structure. Such integration will allow to perform online and “on-shelf” control of the internal and/or external food product quality and package environment.

The integrated sensor information system combines data from multiple sensors (from different packages and/or products) and the information about environmental and process conditions to achieve highly specific information that cannot be obtained by using a single, independent microbiological assay. The emergence of new information carriers and advanced processing methods will make the food-safety management system increasingly dependable. A successful biohazard detection system should be able to (a) identify potential hazards; (b) identify hazards, which must be currently controlled; (c) conduct hazard analysis; (d) recommend control factors, critical limits, and procedures for hazard monitoring and verification; and (e) recommend appropriate corrective actions if a deviation occurs.

Based on a comprehensive model for multisensor data processing, developed by the U.S. Joint Directors of Laboratories (JDL) Data Fusion Group on Department of Defense (DoD) request (133), the integrated concept of multiple sensors data processing has been developed for the existing HACCP system of food safety monitoring and bio-hazard prevention. This model is specifically adapted to the HACCP workflow and uses the principle of information system cyclic interaction with the environment. The four major steps, including observation/ detection, hazard recognition, decision making and corrective actions strictly correspond to the seven HACCP principles. Integration of such system does not require the redesigning of existing manufacturing and control processes.

The new integrated sensors can monitor the HACCP control points with corresponding material packaging flow on a continuous basis or with predetermined monitoring frequency. Statistically designed data collection or sampling systems lend themselves to this purpose. Issues that need to be addressed when considering implementation of an integrated food safety monitoring system include where the system would be established; how it would be funded; how the data would be generated, analyzed, summarized, and disseminated; and how “snap surveys” could be used as a part of the system.

Microbiological tests are rarely effective for food safety monitoring because of their time-consuming properties and problems with assured detection of contaminants. Physical and chemical measurements are preferred because they are rapid and usually more effective for the control of microbiological hazards. For example, the safety of pasteurized milk is based on the measurements of heating time and temperature rather than on testing the processed milk for the absence of surviving pathogens.

To address the issues of connectivity between biosensor devices, the Connectivity Industry Consortium (CIC) has been formed to set up the standardized communication platform for all devices (134). The CIC has identified five requirements: bidirectionality, connection commonality, commercial software interoperability, security, and quality control and regulatory compliance (135). Under these standards, new devices should seamlessly link into the existing data management system without additional expenses.

Traditionally, food quality monitoring units consist of a sensor for the particular analyte, an electronic unit to convert the response into a digital signal, and a cable to communicate with the base station. Advances in technology now enable sensors to be integrated with the base station through wireless communication that frees sensors from being physically attached to it. An interest in such freestanding monitoring units is growing rapidly, because they offer the potential for developing integrated networks of sensing devices that can detect, diagnose, and monitor various food safety problems. The merging of computing with wireless communication systems and sensors has led to an increased accessibility to the real-time information in digital form. Because of achievements in communications and connectivity, data from these sensors can even now be easily accessed via personal digital assistants, personal computers, mobile phones, and networks. However, the communications network that has assembled over the past decade and continues to attract huge investments will fuel demands for more sources of health-related information and data.

New technologies do not come into existence easily. It is not just the matter of making conventional laboratory instruments smaller or putting a sensor into the human body. The new sensor devices and networks must satisfy food industry needs by delivering new benefits to users, offering new ways of monitoring food product properties/contaminations, developing tests that are cheaper, or creating devices that have significant advantages over those already available.

It has been predicted that the trend in biodetection systems development lies in the autonomous sensing technology with the next-generation handheld, portable sensing devices, "smart" sensing, and inline biodetection. The only limitation to the fast progress in this area is the fact that the sensors — especially chemical and biological ones — lag behind the electronics.

BLOW MOLDING

CHRISTOPHER IRWIN
Consultant, Michigan

Blow molding is a process for manufacturing containers, jars, and bottles. It is also a process for manufacturing other hollow objects such as double-walled tool cases, parts for toys, automotive ductwork, fuel tanks, flowerpots, flat cabinet panels, and so on.

Artisans have used the fundamental process for many centuries to fashion glass bottles, jugs, and urns. Archeologists discovered markings recording the glass blow-molding process on the walls of Egyptian royal tombs from 1800 B.C. (1). In the mid-20th century, with the discovery of more suitable thermoplastic materials—in particular, when low-density polyethylene became commercially available following World War II and high-density polyethylene became commercially available about a decade later, (2)—bottle manufacturers began to seriously consider thermoplastic materials as an alternative to glass. Bottles made of these materials have many benefits, including light weight, impact strength, and ease of use convenience.

This article provides an introductory discussion of fundamental container-manufacturing processes currently in use with thermoplastic materials. Primarily, the process involves first manufacturing a “pre-shape,” that is a parison or preform, using either extrusion-molding or injection-molding methods. While synonymous terms, “parison” generally relates to extrusion-based methods and “preform” relates to injection-based methods. Either of these molding methods or approaches generally involves a plasticizer that melts, pushes, and, with other tools, shapes the material into the parison or preform. A female mold cavity, having a shape of the container, captures (while still warm) and then a flow of pressurized air “re-shapes” the parison or preform to conform to this cavity. Figure 1 is an array of extrusion blow-molded bottles.

High-density polyethylene (HDPE) and polyethylene terephthalate (PET) are common thermoplastic materials for containers. Other container materials include: polypropylene (PP), low-density polyethylene (LDPE), polystyrene (PS), and polyvinyl chloride (PVC).

HISTORY

An early commercial attempt to blow-mold hollow plastic objects, a baby rattle, was in the later half of the 19th

Figure 1. An array of extrusion blow-molded bottles. (Courtesy of Graham Engineering Corporation.)

century using two sheets of cellulose nitrate material clamped between two mold halves (2). Steam injected between the sheets softened the material, sealed the edges, and expanded it against the mold cavity (3). Regrettably, cellulose nitrate is highly flammable, thus limiting practical use.

More useful cellulose acetate and polystyrene thermoplastics became available in the 1920s and 1930s (4). By the mid-1930s Owens-Illinois Glass Co. and PLAX Corp., a newly formed division of Hartford Empire Co., each began to develop proprietary plastic bottle manufacturing processes based in part on automated glass-blowing machinery then in use (2). Unfortunately, commercialized cellulose acetate and polystyrene bottles were significantly more expensive and, other than novelty, these bottles offered no other marketable advantages over glass.

Low-density polyethylene provided the necessary advantage; in the mid-1940s, following World War II, PLAX Corp. began blow molding the first commercial plastic container in high-volume, a squeeze bottle for Stopette underarm deodorant (2).

While commercial development of the squeeze bottle was a significant event, blow molding of thermoplastic materials in North America did not really begin until the mid-1950s when high-density polyethylene became commercially available (5); more important, commercial blow-molding machinery becoming available in the late 1950s (6). High-density polyethylene provided additional stiffness while retaining some “squeezability” when required, and commercial machinery provided an opportunity for other companies to establish blow-molding manufacturing operations. Until that time, a select few using proprietary machinery were the only companies manufacturing plastic containers. By 1960, over 55 builders were in the business of manufacturing blow-molding equipment (7). Many of these builders were unknown a year earlier and most do not survive today.

BASIC PROCESS

Figure 2 illustrates the basic blow-molding process using the extrusion molding method to create the parison.

In view Figure 2a, a blow-molding machine extrudes a hot tube-shaped parison typically in a downward direction from an extrusion head. Because the parison is tubular, it has two substantially open ends. The machine places the parison between two halves of a bottle blow-mold cavity. In this view, the machine has a blow pin with an end extending from the extrusion head and positioned inside the parison. The blow pin is actually a metal tube with a passage allowing a flow of air to enter inside the parison at the appropriate time. While this is a common blow pin placement, machinery builders and designers have developed several other arrangements with similar function.

In Figure 2b, once the parison reaches a proper length, the machine’s clamp system closes the two mold halves against each other to close off and seal the parison open ends. At one end, the mold pinches the parison flat. At the other end, adjacent to the extrusion head, the mold also pinches the parison substantially flat while sealing it around the blow pin. The pinching of the parison creates flash material. Machinery, later in the manufacturing

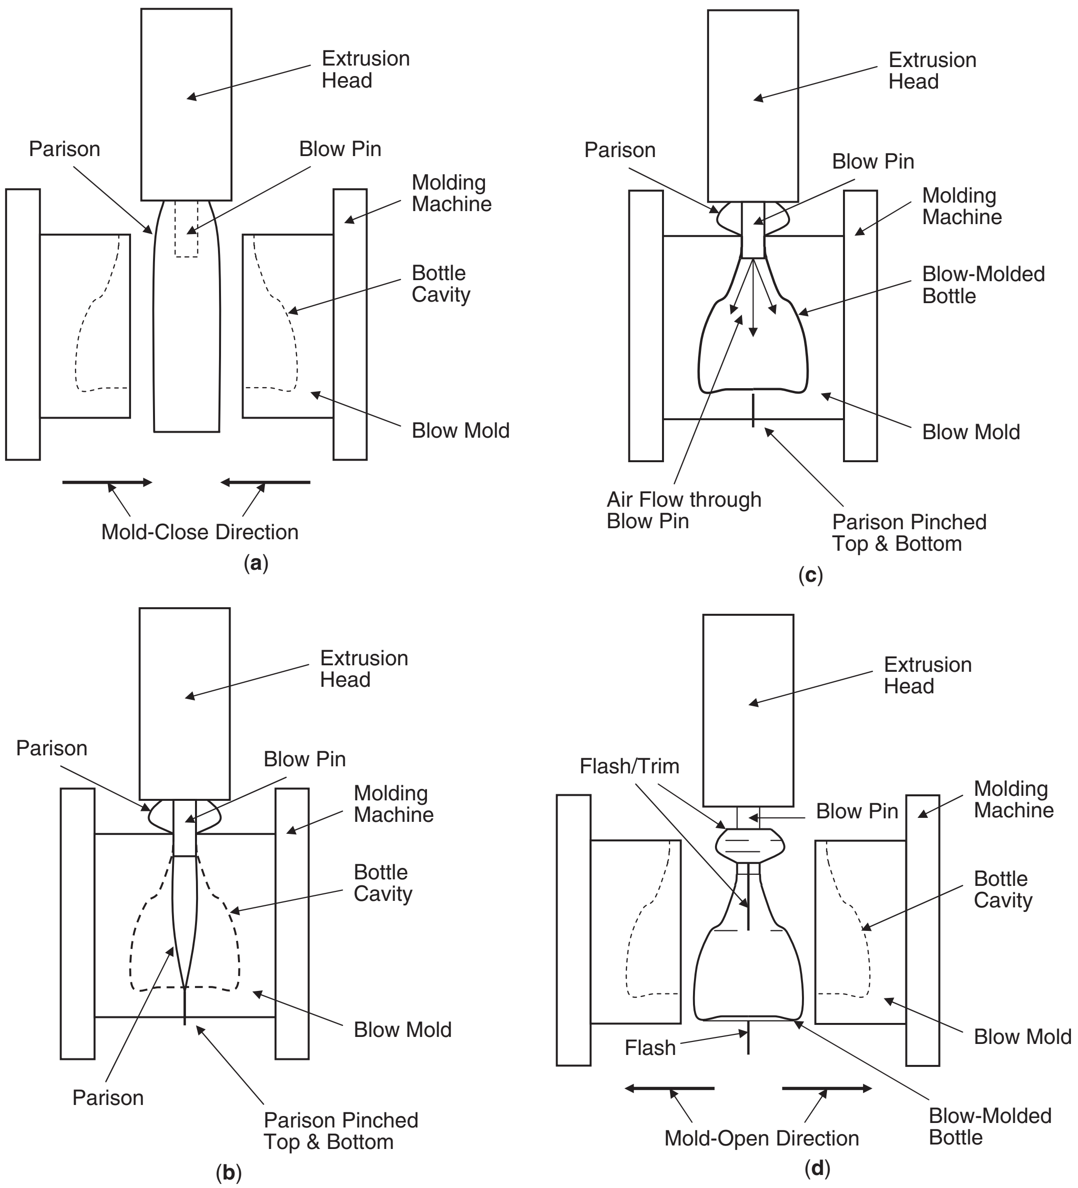

Figure 2. Basic blow-molding process sequence: (**a**) Parison extrusion; (**b**) mold close and parison pinch; (**c**) parison inflation and bottle cool; (**d**) mold open and bottle eject.

process, trims and recycles this flash. The flash portion is often 20–50% of final bottle weight.

In Figure 2c, air flowing through the blow pin at an elevated pressure inflates, thereby pressing and conforming the parison to the mold cavity surfaces. The machine holds the air pressure for a period sufficient to allow the mold cavity to cool the conformed parison, thereby retaining the molded shape of the container or bottle. Generally, machinery circulates water through channels in the mold, thereby maintaining a consistent mold temperature.

In Figure 2d, the machine ejects or removes the molded bottle from the mold cavity, usually to one side or downward. Typically, machinery trims away the flash still attached to the bottle in a secondary operation.

Although Figure 2 shows the extrusion method for creating the parison or preform, using the injection method does not alter process fundamentals—in particular, inflation of the parison or preform.

EXTRUSION BLOW MOLDING

Container manufacturers can make bottles, jars, or drums of nearly any size using extrusion-based blow-molding methods. Extrusion blow molding has two main process categories, that is, container manufacture using continuous extrusion machinery and intermittent extrusion machinery. Each category has machinery subcategories tailored to specific application requirements. Compared to injection-based blow molding, mold tooling for the extrusion blow process is relatively less expensive. In addition, the extrusion blow process has relatively few shape restrictions and is the only low-cost method for manufacturing a bottle with an integral handle.

Continuous Extrusion

Machinery continuously forms the parison at a rate equal to that required to blow, cool, and remove the molded bottle. To avoid interference with parison formation, the machine's mold-clamping mechanism or system must move quickly to capture the parison and return to a blowing station, thereby creating space for the next parison to form.

Builders have made machinery capable of molding large containers, such as a 35-gal trash container, using the continuous extrusion approach, but the approach is better suited for smaller containers, typically 10 L (2.5 gal) or smaller in capacity. In fact, most continuously extruded blow-molded bottles are 4 L or less in capacity.

The continuous extrusion process is capable of molding all commonly molded thermoplastic materials, but the process is particularly ideal for molding heat-sensitive PVC materials. Relatively low-pressure, slow uninterrupted flow of melted material through an extruder or plasticizer and parison extrusion head helps minimize thermal degradation of heat-sensitive polymers.

Several machinery configurations exist, but two approaches generally predominate: shuttle continuous and vertical rotary continuous. Less common approaches include rising-mold continuous and horizontal rotary continuous configurations.

Figure 3 illustrates the shuttle continuous extrusion approach. With this method, the blowing station is located on one or both sides of the parison extrusion head. As the parison reaches proper length, the blow mold and clamp (while open) quickly shuttle to a point under the extrusion head, closes to capture and then cut the parison from the head, and return to the blowing station where the blow pin enters to seal and then inflate the parison against the mold cavity surfaces. With dual-sided machine concept, as shown in the illustration, two clamp systems shuttle on an alternating basis. To increase production output, machines use multiple extrusion heads with multiple mold cavities—for example, a triple parison head with two triple mold cavity sets. Generally, the mold and clamp slides or swings on an incline. This provides extra clearance from the ever-advancing parison as the mold and clamp moves to the blowing station. An alternative means for providing additional clearance is by "bobbing" the extrusion head up during the return movement and then down following clamp movement.

The shuttle machinery configuration offers a number of advantages. The configuration allows critical dimensions of the bottle neck-finish to be "pre-finished" or "calibrated" in the mold with a water-cooled blow pin. This eliminates the need for post-mold secondary sizing or machining of the neck-finish area. Machinery operators also value the easy mold tooling and process setup. Job changes on shuttle continuous equipment can be relatively quick, making the equipment ideal for a short production run. On the other hand, the process has a relatively slow parison extrusion rate requiring the hot plastic material to have exceptional "melt" strength. That is, the parison must not appreciably change shape from material flow caused by its own weight as it extrudes from the head. Shuttle continuous extrusion machines, particularly single-sided machines, require the hot parison to hang for a relatively long time.

A number of machinery builders supplying shuttle continuous blow-molding equipment have begun offering "long-stroke" machines. These are either single-sided or dual-sided alternating shuttle machines with relatively large multicavity molds. These machines can have as many as 15 mold cavities in each mold set. Of course, the machine

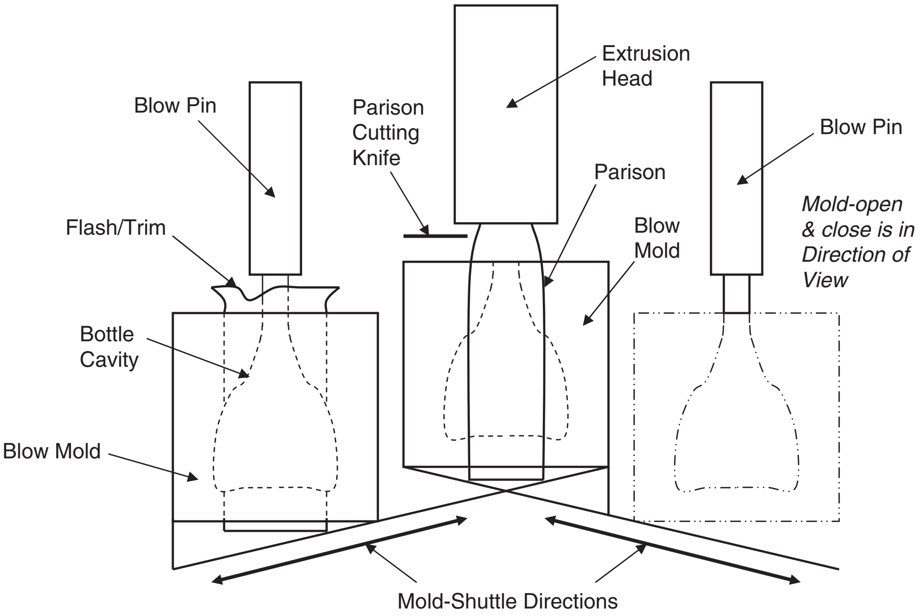

Figure 3. Basic alternating shuttle continuous-extrusion blow-molding machine.

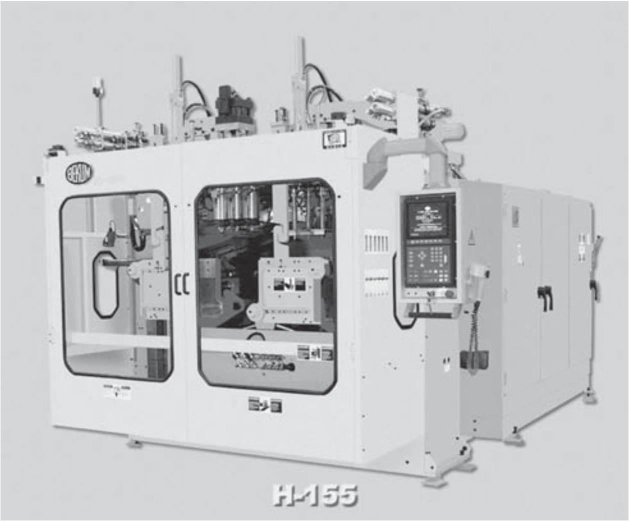

Figure 4. An alternating shuttle continuous-extrusion blow-molding machine featuring a three-parison extrusion head between two mold clamp mechanisms. (Courtesy of Bekum America Corporation.)

requires the extrusion head to extrude the same number of parisons. In comparison, a more conventional shuttle machine typically has six of fewer cavities in each mold set.

Relative to conventional shuttle machines, the long-stroke machine, predominantly in the dual-sided configuration, is capable of high production output per unit of factory floor space the machine occupies. Single-sided long-stroke machines can simplify integration of in-mold labeling equipment and downstream bottle handling equipment relative to dual-sided machines having similar production output. On the other hand, the large mold set and clamping system must travel a longer distance between the blowing station and parison extrusion head. Moreover, the mold set and clamping system has a greater mass; therefore, it is more difficult to accelerate and decelerate. All things equal, an alternating shuttle machine with half as many parisons, mold tooling with half as many cavities per side, and shuttle travel distance substantially half as much will provide a faster per cavity production rate than a single-sided long-stroke machine. Figure 4 shows a typical alternating shuttle continuous-extrusion blow-molding machine.

Recently, machinery builders have begun offering shuttle machines with tandem mold cavities. These machines have a production output that approaches that of a rotary machine while preserving the benefit of the pre-finished or calibrated neck-finish. Normally, at the blowing station the blow pin enters the parison from the top, primarily because the molded bottle leaves the machine in an upright position, greatly facilitating downstream handling. However, the blow pin can also enter from a bottom position, thereby blow molding the bottle upside down. A shuttle machine having tandem cavities produce two bottles from one parison, one in the upright position, the other in the upside-down position. Incorporated trim tooling later separates the tandem bottles.

Figure 5 illustrates the vertical rotary continuous machinery approach. The mold cavities circumferentially mount to a wheel having a horizontal axis of rotation like that of a Ferris wheel. In this approach, one of the mold sets on the rotating wheel captures the parison as it rotates past the parison extrusion head, in this case extruding the parison upward, while other mold sets simultaneously shape and cool bottles from previously captured parisons; another mold set opens, allowing bottle removal.

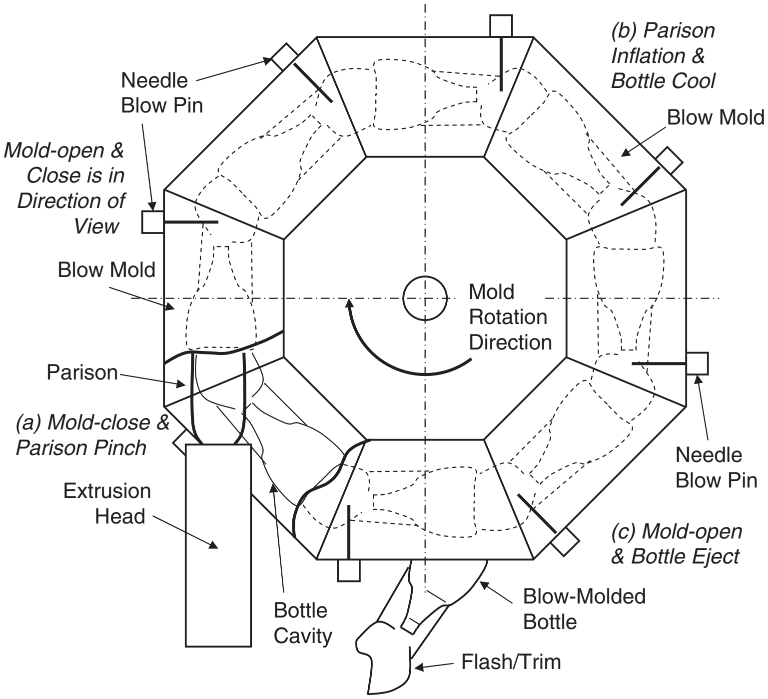

Figure 5. Basic vertical rotary continuous-extrusion blow-molding machine having a parison extruding upward.

Generally, the machine extrudes a single parison and each mold set has one cavity, but some machines have multiple parison and cavity sets. Specific configuration depends on mold and clamp design details—for example, two cavities inline, face-to-face made from a single parison; or two cavities side-by-side, each capturing its own parison extruded side-by-side and in parallel. Direction of mold open and close motion is either parallel to wheel axis, radial to wheel axis, or "book" where one mold half hinges from an edge of the other mold half. Once the mold cavity closes, a needle blow pin punctures the parison. Air flowing through the needle conforms the parison to the cavity surfaces. Figure 6 shows a vertical rotary continuous extrusion blow-molding machine having a single parison extruding in an upward direction a moment before the mold closes to capture. Note that the mold cavity in Figure 6 has a shape to form a bottle having an integral handle. In addition, Figure 6 shows a cylinder, (right-hand corner) for actuating the needle.

The rotary approach has many advantages, primarily for bottle applications requiring high production output. The single parison extrusion head helps to maintain bottle consistency between all mold cavities, particularly for applications requiring a complicated multilayer or coextruded polymer material structure. Another advantage is that in-mold labeling systems, when used, are less complicated because the same unit supplies labels for all cavities. In addition, the vertical rotary approach has a unique capability of holding the parison fast at the top and bottom, allowing an opportunity to manipulate parison material distribution in ways not as easily done with other processes where the parison's bottom end is free.

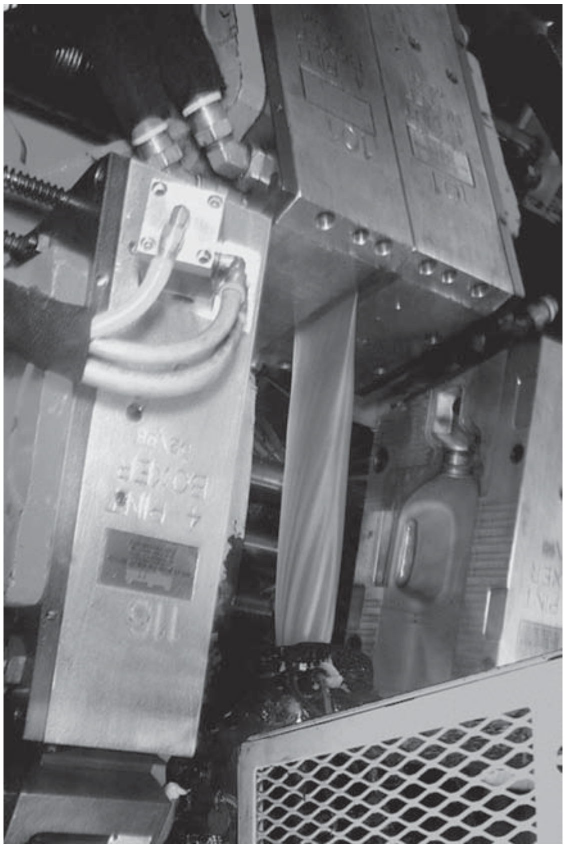

Figure 6. Mold cavity and upward extruding parison of a rotary continuous-extrusion blow-molding machine. Previous mold (now closed) holds the parison in position. Note, the needle blow-pin actuating cylinder near upper left-hand corner and mold cavity for a handleware bottle. (Courtesy of Graham Engineering Corporation.)

On the other hand, the vertical rotary approach, as mentioned previously, typically requires the needle blow pin to puncture the parison. For bottles, this puncture is into a molded dome area above the bottle neck-finish. A post-molding operation cuts off the molded dome with other flash trimmings. Establishing final neck-finish dimensions further requires a sizing or machining operation. Machining the neck-finish area can allow plastic chips to fall inside the bottle and potentially contaminate any filled product. In addition, tooling job changes are more complicated and typically take more time; however, this is not necessarily a problem for long-term high production applications.

Intermittent Extrusion

An intermittent extrusion blow-molding machine quickly extrudes the parison after bottle removal from the mold cavity. The mold-clamping system does not transfer to the blowing station. Bottle molding, cooling, and removal all take place under the parison extrusion head. This arrangement allows the clamping system to be more simple and rugged. Manufacturers typically use the intermittent extrusion approach to make containers from 100 mL (3.4 fl oz) to 210 L (55 gal).

Two machinery configurations predominate: reciprocating screw and accumulator head. A less common configuration is a side-ram accumulator or shot-pot approach. Polyolefin thermoplastic materials, particularly HDPE, are ideally suited for the intermittent extrusion; unfortunately, its start–stop–start character and extremely rapid parison extrusion rate is not best for heat-sensitive materials.

Manufacturers typically consider reciprocating screw machinery for containers less than 10 L (2.5 gal) in capacity. The plasticizer of the reciprocating screw blow-molding machine has an extruder screw that moves back as it helps to melt the thermoplastic material. That melted material, for the next parison, accumulates downstream of the screw's tip. During parison extrusion, the screw quickly moves forward to push the accumulated material through the extrusion head. Next, the mold clamping system closes on the parison and blow pin. The parison then inflates against the mold cavity while the reciprocating screw begins to accumulate material for the next parison. Once the molded container has cooled, the clamp opens allowing container removal. The process then repeats.

For many bottle design configurations, the reciprocating screw machine allows "pre-finishing" of critical bottle neck-finish dimensions during the molding process. Positioning the blow pin inside the parison before mold-close allows a choice of two pre-finishing approaches. The first, a so-called "ram-down" or "calibrated" pre-finishing

Figure 7. Typical reciprocating-screw intermittent-extrusion blow-molding machine. (Courtesy of Graham Engineering Corporation.)

approach provides a result substantially identical to the approach used with shuttle continuous extrusion. The second, a so-called "pull-up" pre-finishing approach, is unique to intermittent extrusion machinery. The blow pin for the pull-up approach moves upward a spit second before the mold opens. During this upward movement, the blow pin shears plastic material in a critical neck-finish inside diameter area to create a precise, round, and smooth inside surface for a closure to seal.

The pull-up pre-finishing approach is an innovation that perhaps is singly most responsible for the success of HDPE milk bottles. Substantially all of the HDPE milk bottles made in the United States feature a neck-finish made using the pull-up approach. The pull-up approach permits extremely lightweight containers that in turn reduces manufacturing cost from less material expense and faster (shorter) molding process from a reduced need for cooling. Bottles featuring the pull-up made neck-finish use a low-cost closure not requiring any secondary sealing material. Instead, the closure features a standing circumferential wedge that, when applied to the bottle, tightly engages the smooth precise inside surface of the neck-finish to establish a simple and highly effective seal. Figure 7 shows a reciprocating screw blow-molding machine.

The accumulator-head intermittent-extrusion process is ideal for heavyweight containers, such as 210-L (55-gal) drums, and noncontainer items, such as parts for toys, automotive ductwork, and the like. Generally, manufacturers will consider accumulator head machinery for containers larger than 10 L in capacity. The accumulator head features a tubular melt reservoir as part of the extrusion head itself. The machine's plasticizer feeds melted thermoplastic material into the reservoir on a first-to-enter, first-to-leave basis. Once a sufficient quantity of melted material accumulates, a tubular plunger within the head quickly extrudes the parison through a head tooling annulus.

Similar to the accumulator-head, the side-ram or shot-pot intermittent-extrusion process uses a single melt accumulator that receives melted thermoplastic from the plasticizer. The melt accumulator is not a component of the extrusion head; instead, it features a piston or plunger along side the plasticizer that pushes the material into a manifold and then through multiple extrusion heads. It is generally used for heavy container applications requiring an excessive amount of accumulated melt that is greater than the amount the reciprocating-screw process is capable of accumulating. Recently, machinery builders are offering the "shot-pot" equipment for classic reciprocating-screw applications, particularly in situations where a fine-mesh screen filters the melt to remove contaminates likely in post-consumer recycled material.

Head Tooling, Parison Programming, and Head-Tooling Ovalization

By definition, the extrusion process requires the parison to be a hollow tube having a diameter and wall thickness adequate to properly form the container. Head tooling consists of two components: a generally circular die substantially establishing, in cross-section, the parison's outer diameter and a generally circular mandrel substantially establishing the parison's inner diameter. In combination, these two components create an annulus through which the parison extrudes. The diametrical difference forms a gap between the die and mandrel that establishes parison wall thickness. For simple less demanding container applications, the gap remains uniform.

Parison inflation in the blow-mold cavity is not even. Some areas will expand more, thus tending to thin more. Parison programming is a technique to compensate particularly for more demanding container applications. Programming permits the molding technician to place extra material in the container where needed and remove material where it is not needed, ultimately allowing improved container performance while making container wall-thickness more consistent and likely reducing overall container weight and cost. Programming dynamically changes annulus gap size by moving either the die or the mandrel relative to the other to a specific profile as the parison extrudes to create axial circumferential zones or rings of thicker or thinner material in the parison corresponding to areas within the blow-molded container requiring more or less material.

Head-tooling ovalization is also a technique to compensate areas of the parison that tend to thin more. By changing the shape of either the die or mandrel from round to slightly oval, the corresponding gap of the annulus created by the die and mandrel circumferentially varies. During parison extrusion, ovalized tooling creates "stripes" of thicker or thinner material parallel to the parison's axis that correspond with areas of the container requiring more or less material. In other words, the parison in circular cross section has areas thicker than other areas within that cross section.

Generally, ovalizing head tooling is a fixed approach, not dynamic, as is the case with parison programming. While ovalized head tooling and parison programming separately or together can significantly improve material thickness distribution in the blow-molded container, some areas of the blow-molded container will always remain slightly thicker or thinner than other areas. The molding technician selects a degree of ovalization in combination with parison programming that is a compromise of wall thickness requirements in various container areas. For example, the container's sidewall may be slightly thicker than necessary to have adequate wall thickness in the container's chime area.

In general, it is not practical or cost effective for most container applications to have dynamic ovalization programmed to a specific profile as with conventional parison programming. However, in large somewhat heavy containers, such as the 210-L (55-gal) drum, dynamic ovalization is justifiable. Even with parison programming and fixed ovalization, a drum's chime area can still have significant differences in material thickness. Dynamic ovalization features a die having flexible lips. Applying a force to the lips during parison extrusion causes the normally circular die to slightly distort into various oval shapes as determined by a programmed profile suitable to specific container requirement, thereby reducing an otherwise necessary material thickness compromise in other parts of the container.

INJECTION BLOW MOLDING

In the classic injection blow-molding process, the plasticizer injects melted plastic into a closed mold having a cavity and a core rod to create an injected-molded "test tube"-shaped preform having an integral neck-finish. While still hot, the injection-molding machine transfers the preform on the core rod to a bottle blow-mold cavity. Pressurized air passing through a valve in the core rod inflates the preform, conforming it to the blow-mold cavity surface. Once cooled, the mold cavity opens and the machine removes the blow-molded bottle from the core rod.

Early injection blow-molding techniques were substantially two-position tooling adaptations of conventional injection molding machines (8). A shortcoming of these adaptations was that the injection and blow-mold stations stood idle during bottle removal. The blow-molding industry generally credits Angelo Gussoni with inventing a three-station injection blow-molder (9). A third station improved efficiency by allowing bottle removal while the other two stations molded either the next preform or the next bottle.

Initially, Gussoni also adapted this three-station concept to available conventional injection-molding machines. Later, purpose-built three-station injection blow-molders evolved that today have become an industry standard. Figure 8 illustrates the basic three-station injection blow-molding process. Note that the process requires three core rods for each preform-mold and blow-mold set.

The injection blow-molding process has a number of advantages. The process is flash- or scrap-free. Molded bottles do not require secondary trimming. Injection molding the preform accurately maintains critical neck-finish dimensions, an important consideration for complex child-resistant and snap-on closures common on pharmaceutical bottles. Bottle weight control is extremely precise, accurate within a range of 0.2 g or less. Bottle surface gloss and texture is pristine and consistent. For typical applications having a capacity less than 250 mL, the injection blow-molding process is generally less expensive than extrusion blow-molding processes. For vials—for example, 1, 5, or 10 mL in capacity—and other very small bottles, bottle manufacturers have only one cost-effective process choice, injection blow molding.

On the other hand, machinery configurations generally limit bottle size to 4 L (1 gal) or less capacity. Because of the relative high cost of mold tooling, the injection blow-molding process is usually not economically justifiable for typical bottle applications having a capacity greater than 500 mL. Finally, the process limits bottle shape and proportion. Although not a problem for most bottle applications, the process is not ideal for extremely flat, overly tall and thin, offset neck-finish, or handleware bottle shapes. Table 1 contrasts important advantages of injection blow molding versus extrusion blow molding.

Pharmaceutical and cosmetic product applications often require small bottles with precise neck-finishes. Furthermore, these products are often expensive, demanding an equally high-value, quality package that injection blow provides and not always available from the extrusion-blow alternative.

Many thermoplastic materials are injection-blow moldable, which could be difficult or impossible using extrusion-blow processes. General-purpose polystyrene is a good example of a thermoplastic that injection-blow-molding machines routinely process. Because the core rod helps to support the melted material during transfer to the blowing station, injection-blow process does not require the same degree of melt-strength that extrusion blow, particularly continuous extrusion blow, requires. In addition, the injection-blow process adds a degree of molecular

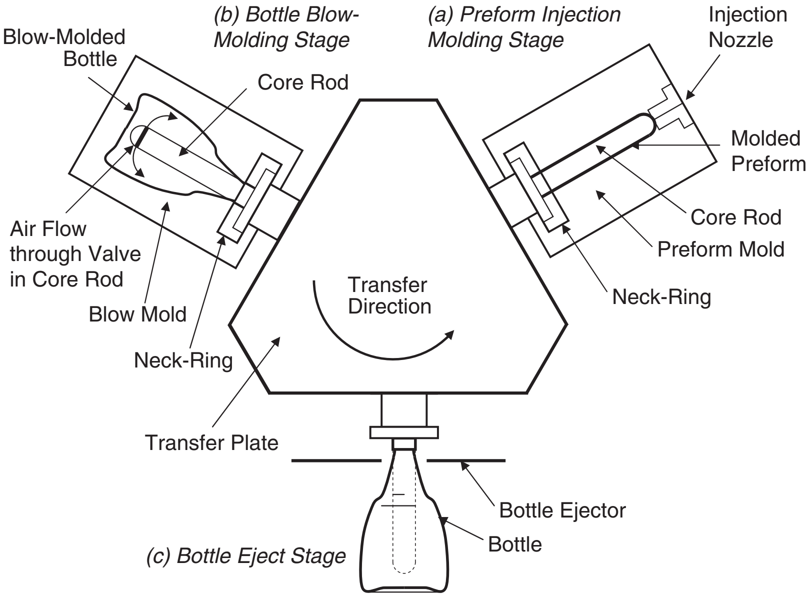

Figure 8. Basic injection blow-molding machine process sequence.

orientation to the general-purpose polystyrene bottle that enhances its impact resistance.

Other materials commonly molded with classic injection blow are high- and low-density polyethylene, polypropylene, polyvinyl chloride, and polyethylene terephthalate. While the injection-blow process approach provides beneficial molecular orientation to polystyrene, other thermoplastics such as polypropylene or polyethylene terephthalate, unfortunately, do not benefit. The core rod of the classic injection-blow process remains inside the preform; additionally, the preform length is approximately the same as the container is tall, conditions that inhibit beneficial molecular orientations of many other materials, particularly in an axial direction.

EXTRUSION—INJECTION-MOLDED NECK PROCESS

This unique hybrid process combines advantages of injection blow with extrusion blow. Originally developed by Owens-Illinois in the 1950s, the process is not much in use today for manufacturing bottles, but a version is in use for manufacturing constant velocity joint (CVJ) boots and parts for other automotive bellows applications. The hybrid process features an injection-molded neck with an extrusion-blow-molded body that provides a dimensionally accurate neck-finish without some of the bottle shape and proportion limitations of injection blow. The hybrid process can mold a flat oval bottle having an offset neck-finish and integral blown-handle configuration typical of extrusion blow with a high-quality neck-finish typical of injection blow. While machinery is not high output, it is ideally suited for integrating an in-mold labeling feature without production penalty.

STRETCH BLOW MOLDING

Thermoplastic materials are polymers of relatively high molecular weight—that is, of long polymer chains made of hundreds to thousands of linked individual monomer molecules. Normally, these long-polymer-chain molecules entangle with other in random complex coils. Careful, proper processing of some materials, such as polyethylene terephthalate (PET) and polypropylene (PP), will establish and retain partial molecular orientation of the polymer chains. In other words, the polymer chains become somewhat aligned with each other in uniaxial and biaxial directions.

While all blow-molding processes involve “stretching” the parison or preform in some fashion, “stretch blow molding” or biaxial-orientation blow molding is a modified process to achieve and retain polymer chain alignment in biaxial directions within the blow-molded bottle, in particular within the bottle sidewall. Biaxial orientation can significantly improve bottle impact strength, transparency, surface gloss, stiffness, and gas-barrier performance, particularly in bottles greater than 250 mL in capacity. Filled soft drink PET bottles, highly pressurized from carbon dioxide gas, are an everyday reality because of the stretch-blow process.

Fundamentally, the stretch-blow process requires precise conditioning of the preform to a temperature warm enough to allow rapid inflation and molecular alignment but cool enough to retard re-randomization of its molecular structure once aligned. Preform manufacture is by either extrusion molding or injection molding; however, dimensional precision provided by injection molding has allowed that approach to dominate in bottle manufacturing today.

Most common polymers biaxial-oriented are polyethylene terephthalate (PET) and polypropylene (PP). Other polymers include polyvinyl chloride, acrylonitrile-based copolymers, and a high-performance polyester, polyethylene naphthalate.

Figure 9 illustrates typical preform and bottle proportions. Note that the preform is significantly shorter than the bottle. In comparison, conventional extrusion-blow parison and injection-blow preform are substantially the

Table 1. Injection Blow Molding Versus Extrusion Blow Molding

Injection Blow Molding	Extrusion Blow Molding
Used for small, heavier bottles, typically less than 500 mL	Used for larger bottles, typically larger than 250 mL
Best process for polystyrene; ideal for most other thermoplastic materials	Best process for polyvinyl chloride; with adequate melt strength, ideal for many other thermoplastic materials
Scrap-free: no flash/trim to recycle; no pinch-off scar on bottle; no post-mold trimming required	Fewer bottle shape limitations permitting extreme dimensional ratios: long and narrow, flat and wide, doubled-walled, offset neck-finish, molded-in handle, and other odd shapes
Injection-molded neck-finish provides more accurate neck-finish dimensions that better address special shapes required for complicated safety and tamper-evident closures	
Precise and repeatable bottle weight control from injection-molded perform	Low-cost tooling often made of aluminum; ideal for short- or long-run manufacturing applications
Excellent and consistent bottle surface texture	Adjustable weight control ideal for prototyping applications

same length as the bottle is tall. The flow of air at elevated pressure stretches the preform in a "hoop" direction—that is, a direction substantially perpendicular to the preform's axis. At the same time, the flow of air, often in combination with a stretch rod, stretches the preform in an axial direction—that is, a direction parallel to the preform's axis. Needed air pressure is extreme; for example, PET applications often require 600 PSI (4100 kPa) to properly inflate the preform. In comparison, most extrusion blow-molding applications require about 90 PSI (600 kPa).

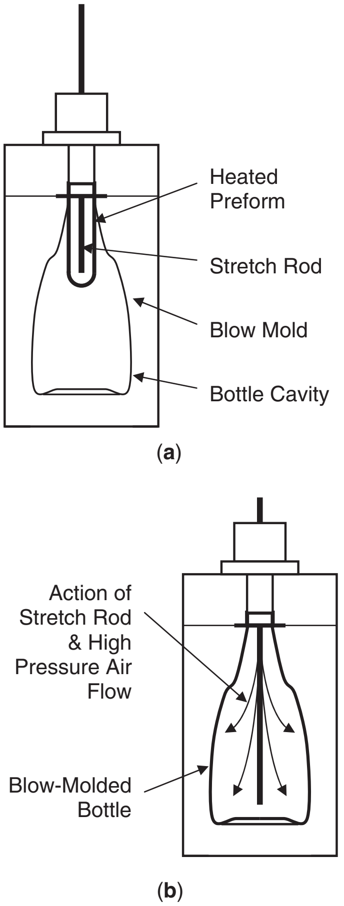

Figure 9. Basic stretch blow-molding process sequence: (**a**) Mold close on preform; (**b**) stretch blow molding. Note that for many PET applications, preform length is typically about one half the bottle height.

There are two basic stretch-blow methods: one-step and two-step. While at least one machinery builder has produced a one-step machine capable of producing a 20-L container, most stretch-blow containers are less than 4 L in capacity.

One-Step Method

Production stages of preform injection molding, heat conditioning, and blow molding take place in the same machine. Molding technicians generally consider it better for manufacture of wide-mouth jars and better for bottles having extreme oval or other unusual cross-sectional shapes. The one-step method minimizes blemishes to provide a pristine bottle-sidewall surface appearance. In addition, the preform does not require a handling ring, as the two-step method requires. Eliminating the handing ring can improve the bottle's overall aesthetic appearance. Tooling and machinery setup is relatively easy, making the method ideal for short-run production applications. In addition, the method potentially saves energy in that the preform does not require reheating from room temperature (see Figure 10).

On the other hand, one-step machinery typically has an equal number of preform cavities and blow-mold cavities. Dictated by specific preform and bottle shape, weight, and performance requirements, rarely is an optimum process or ideal production rate for preform molding stage in perfect balance with that needed for bottle blow molding stage. Accordingly, one process stage, usually preform injection molding, will govern overall machine productivity while retarding productivity of the other process stages. Sometimes process technicians are tempted to make compromises, usually in preform configuration, that reduce overall bottle performance in exchange for greater overall production output.

There are three general variations of one-step machinery. One variation features a four-station rotary table. Preform injection molding in station one. Unlike injection blow molding, the machine removes the preform core rod before transfer to the next station. The preform is heat

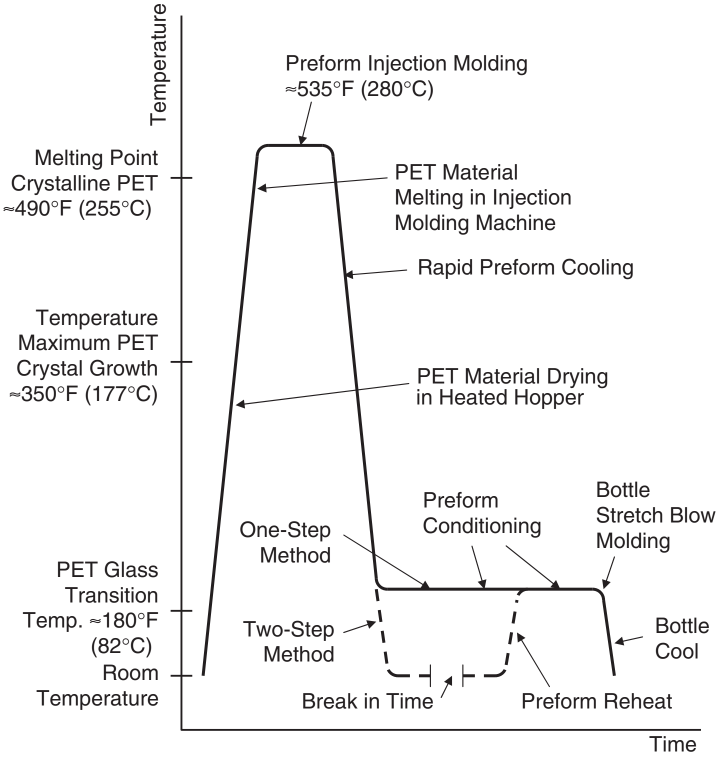

Figure 10. Comparison of basic one-step and two-step stretch blow-molding processes of PET.

conditioning in station two by heating and/or cooling specific areas within the preform. Preform blow molding into the bottle occurs in station three and bottle removal occurs in station four. The second variation features a three-station rotary table. Some machines combine preform injection molding with heat conditioning in stage one. Other machines combine bottle blow molding and bottle removal in station three. The third variation combines in one machine a substantially conventional preform injection-mold tooling and apparatus with a substantially conventional bottle blow-mold tooling and apparatus connected by a preform transfer mechanism that includes a short preform reheat oven. Preform injection-mold cavity count is higher than bottle blow-mold cavity count, allowing a more balanced operation.

Two-Step Method

Production stage of preform injection molding is separate, taking place in a separate machine from heat conditioning and bottle blow molding stage. Molding technicians often refer to the two-step method as “reheat and blow.” The method allows technicians to optimize preform and bottle design and overall production efficiency. Equipment with extremely high output is available. Figure 11 shows a high-output PET preform injection-molding machine; although not evident in the figure, these machines have a robotic takeout that includes a post-mold cooling system. Figure 12 shows a typical high-output PET preform injection mold.

Figure 13 shows a high-output horizontal rotary bottle stretch blow-molding machine with a preform oven for heat conditioning. Bottle manufacturers often link a group of injection molding machines producing the preform with a group of blow-molding machines producing the bottle with conveyors that reduce part handling and “work-in-process” inventory. Nonetheless, manufacture of the preform and the bottle can be separate and in different facilities.

Molding technicians tend to use the two-step method for containers having a substantially round cross-sectional configuration; however, with improved reheat ovens capable of heating regions within the preform to a different temperature than other regions and precise preform positioning in the blow-mold cavity, two-step machinery is often suitable for containers having a substantially oval or rectangular cross-sectional configuration.

MULTILAYER

All materials—whether metal, glass, paper, or plastic—have certain strengths and weaknesses. Layering two or more materials can economically overcome individual material shortcomings. Multilayer blow molding is a way to combine the strengths of two or more thermoplastic materials to economically manufacture bottles that can package a product far better than any of the materials could individually. In recent years, multilayer structures and related barrier polymers and machinery has been an active development area within the blow-molding industry, particularly for PET bottle applications. Thermoplastic materials in bottles now routinely protect sensitive products previously not feasible.

Ideal characteristics of many bottles include: low cost, strength, clarity, product compatibility, and gas barrier. Polypropylene, for example, is a relatively low-cost material suitable for food contact and having acceptable clarity,

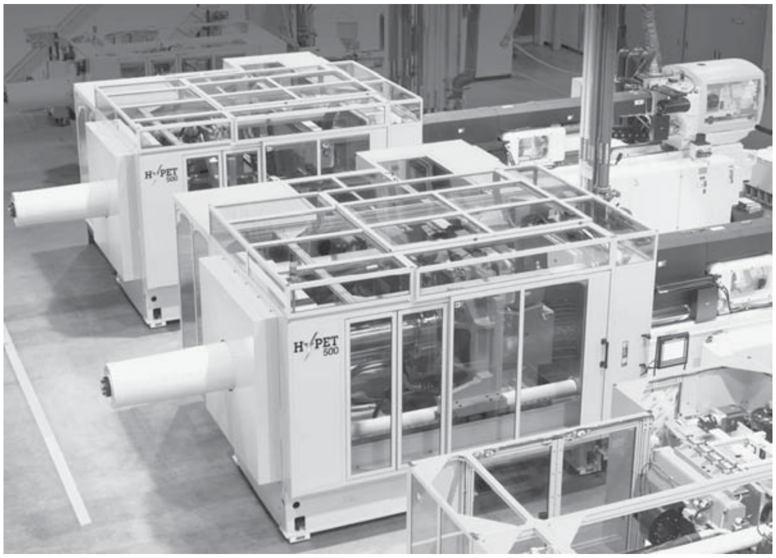

Figure 11. Typical high-output preform injection-molding machine. (Courtesy of Husky Injection Molding Systems.)

excellent water-vapor barrier, good heat, and impact resistance. Polypropylene is also a poor oxygen barrier, making the material unsuitable for packaging oxygen-sensitive foods requiring long shelf life. An oxygen molecule can easy permeate through a wall made of polypropylene. Ethylene vinyl alcohol (EVOH) copolymer, on the other hand, is a high-cost thermoplastic material with excellent oxygen gas barrier but sensitive to water, which can significantly deteriorate its barrier performance if unprotected. In combination, a thin layer of EVOH protected by the polypropylene can greatly enhance bottle performance, making it suitable for packaging products previously not practical. Ethylene vinyl alcohol copolymer does not generally adhere well to polypropylene, polyethylene, or polyethylene terephthalate. Accordingly, multilayer structures often use a mutually compatible adhesive between layers. Multilayer bottles not having the adhesive can easily delaminate and separate its layers.

There are several methods with several variations for establishing the multilayer bottle structure. These multilayer methods generally fall into four broad groups: (a) extrusion molding of a multilayer parison, (b) injection molding of a multilayer preform, (c) coating the injection-molded preform or blow-molded bottle interior or exterior, and (d) bottle treatment.

Extrusion Multilayer

Blow molding machinery form the multilayer parison by simultaneously extruding two or more thermoplastic materials in continuous layers within the parison's wall (at least for packaging applications, for example, automotive

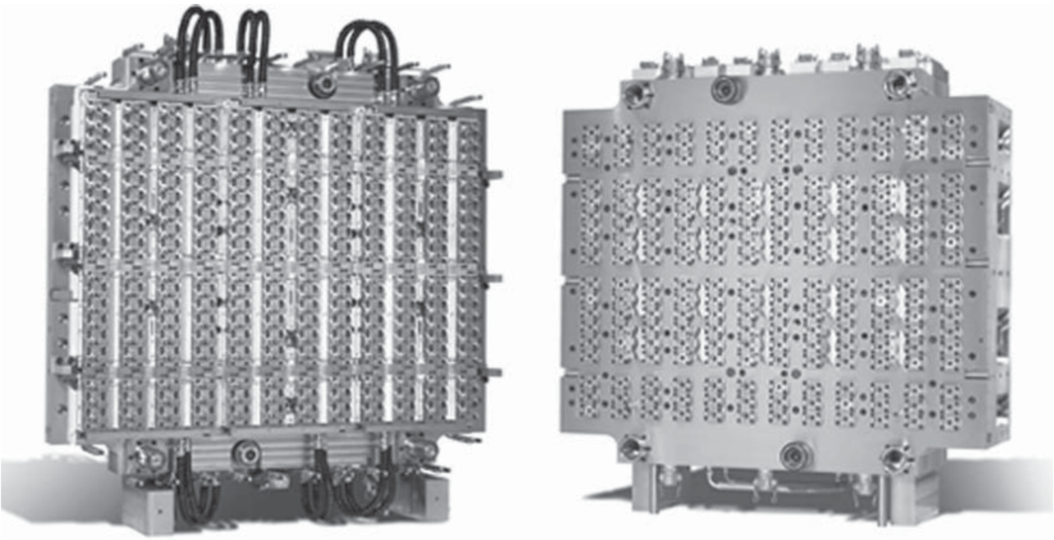

Figure 12. Typical high-output preform injection-mold having 216 cavities for manufacturing a PET preform. (Courtesy of Husky Injection Molding Systems.)

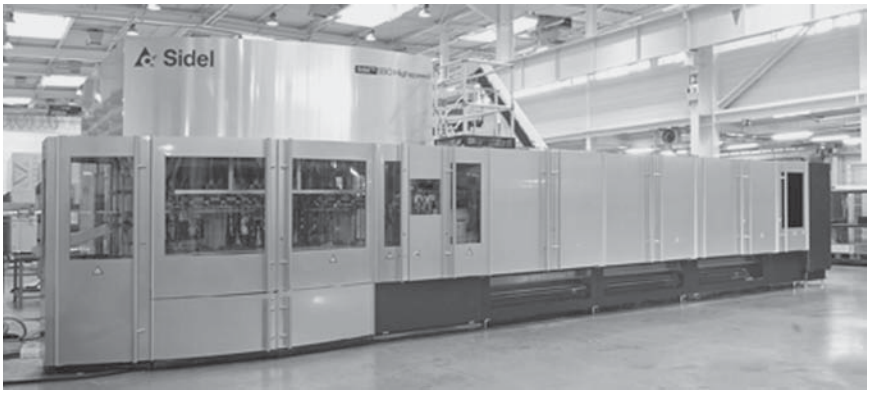

Figure 13. A horizontal rotary two-step blow-molding machine with preform oven. This is a high-output machine featuring 34 blowing stations capable of manufacturing over 61,000, 0.7-L carbonated soft drink PET bottles per hour. (Courtesy of Group Sidel.)

part blow molding of an under hood duct might employ intermittent and/or discontinuous layers). Creating the multilayer structure is relatively straightforward because melted thermoplastic materials flow in a laminar fashion, and the high-molecular-weight materials will not mix while passing through the extrusion head. Figure 14 illustrates a cut-away schematic of a typical six-layer extrusion head.

Most high-performance extrusion multilayer containers use polyethylene or polypropylene for its structural layers and, as the gas barrier layer, ethylene vinyl alcohol copolymer or a polyamide, typically poly-*m*-xylylene adipamide or nylon-MXD6 developed by Mitsubishi Gas Chemical. Product applications include: automotive and small-engine fuel tanks, juice bottles, and ketchup bottles. Figure 15a illustrates a typical extruded multilayer container wall structure for food products. If we change the polypropylene to high-density polyethylene, the structure becomes typical of fuel tanks.

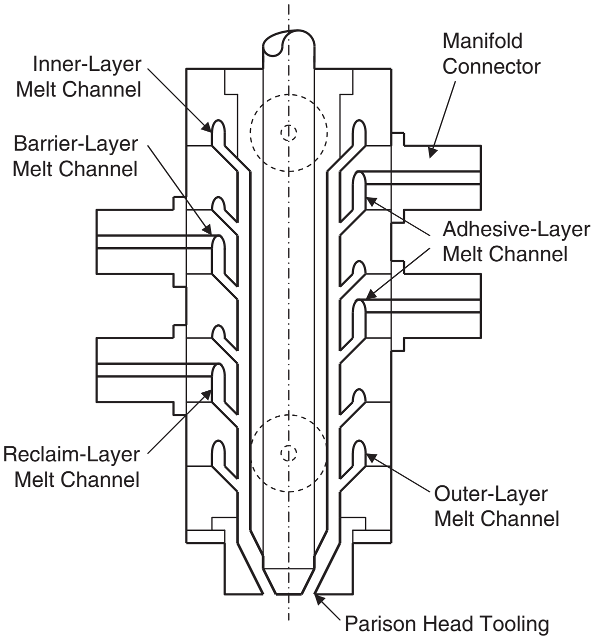

Figure 14. Cut-away schematic of a typical multilayered parison extrusion head.

However, high-performance gas barrier applications are not the only use for extruded multilayer structures. Multilayer blow molding has become a significant means to recycle postconsumer high-density polyethylene scrap where all of the layers are substantially the same material. Containers for household chemicals and motor oils are typical uses. A common structure is an inner product contact layer of virgin high-density polyethylene, an outer layer of pigmented virgin high-density polyethylene, and middle layer of postconsumer commingled reclaim high-density polyethylene (see Figure 15b). The commingled HDPE is a mixture of homopolymer and copolymer HDPE in a rainbow of colors that becomes an unpleasing yellow-greenish-bluish gray color when molded. The commingled material provides poor chemical stress-crack resistance, a critical product requirement particularly for many household and automotive chemicals. The virgin HDPE copolymer inner product contact layer provides the required stress-crack resistance. A pigmented HDPE outer layer provides a pleasing overall bottle appearance hiding the middle layer.

Although technically not multilayer extrusion, some extrusion heads for high-density polyethylene applications have a coextrusion feature for creating a “view stripe” in an otherwise opaque pigmented container. As the extrusion head establishes the tubular cross-sectional form of the parison from a flow of pigmented thermoplastic material, before the parison exits the head, the pigmented material flow splits at one point with a secondary flow of unpigmented material from a separate plasticizer, thus creating a pigmented parison with an unpigmented translucent stripe. The stripe is in a position usually corresponding with a side of the blow-molded bottle. Graduation marks on the bottle in a position along the view stripe allow consumers to easily judge content volume.

Injection Multiplayer

As with extrusion multilayer, injection multilayer also relies on laminar flow of thermoplastic materials entering the preform cavity to create individual layers. Although there are subtle process variations between several techniques, two or three individual plasticizers inject material into the preform cavity through concentric injection

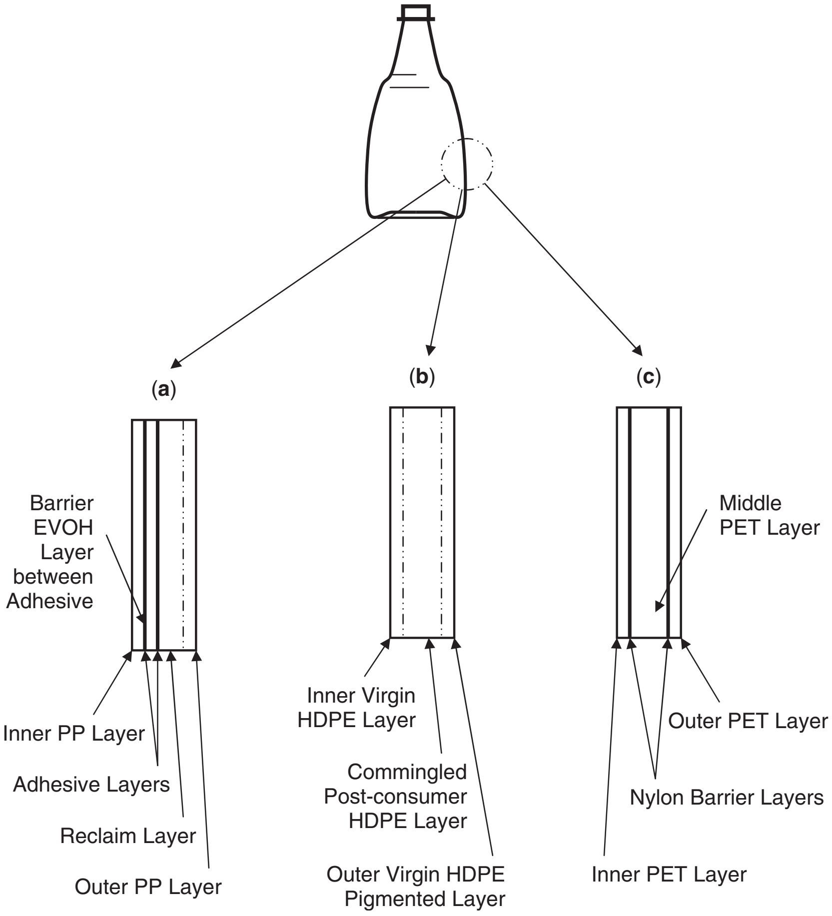

Figure 15. Common multilayer bottle wall structures: (**a**) Typical PP barrier food packaging application; (**b**) typical post-consumer recycled HDPE application; (**c**) typical stretch PET barrier food packaging application.

nozzles, in generally either a simultaneous or a sequential manner, to establish substantially three- or five-layer structures (see Figure 15c). Usually based on polyethylene terephthalate, a typical structure has a PET layer, a gas barrier layer, and another PET layer. The barrier layer is likely polyamide such as poly-*m*-xylylene adipamide or nylon-MXD6. Ethylene vinyl alcohol copolymer is another choice for barrier layer material, but the PET/EVOH is more susceptible to layer delamination.

Creating an injection-based two- or four-layer structure requires an insert or insert equivalent approach; that is, an apparatus usually places the insert made of at least one layer of material onto the injection cavity core, where then the plasticizer of the injection molding machine injects a second material over the insert to complete the multilayer preform. Process technicians often refer to this approach as “over-molding.” In general, the over-molding approach is not as common or as efficient, but it does have an interesting advantage in that the insert can be thermoformed, injection molded, or even extrusion blow-molded.

Development of price competitive multilayer bottles has allowed package designers to consider thermoplastic materials, particularly PET, as a viable alternative to glass and metal where high gas barrier is required. While development of machinery processes is significant, these bottle opportunities would not be feasible without ongoing development of high-performance barrier thermoplastic materials both passive and active in nature.

Poly-*m*-xylylene adipamide or nylon-MXD6 is one of many such materials. Nylon-MXD6 provides excellent passive barrier to oxygen; however, eventually, enough oxygen molecules can permeate through to change highly oxygen-sensitive products. Interestingly, nylon-MXD6 can become active by adding a “transition” metal salt such as that based on iron, cobalt, or other “transition” metals. The salt becomes a catalyst or oxidation promoter that causes the nylon-MXD6 material to oxidize or attract oxygen, thereby allowing the material to actively scavenge oxygen molecules permeating through the bottle sidewall before the oxygen molecule can react with the product contained.

Sometimes an added filler, such as a dispersion of nanoclay material, creates a tortuous path for the permeating oxygen molecule forcing that molecule to travel a greater distance and effectively improving barrier performance. In addition, some barrier materials combine oxidation promoter and tortuous path techniques in a nanocomposite material.

Preform or Bottle Coating

While not a multilayer structure in the sense of extrusion or injection-based approaches, applying a coating indeed creates multilayered structures. All of these coating approaches seek to improve oxygen and/or carbon dioxide gas barrier performance of polyester or PET bottles.

Makers of carbonated beverages, for example, are using coatings to improve carbon dioxide retention in small bottles, less than 500 mL (16.9 fl oz) in capacity, where bottle surface area relative to bottle capacity is too great. Smaller bottles allow a greater rate of gas permeation than larger bottles having less bottle surface area relative to bottle capacity. For example, an uncoated 2000-mL capacity PET bottle provides adequate 16-week shelf life for a cola beverage, but shelf life for an uncoated 300-mL bottle could be less than six weeks.

At least one company has developed a water-based flow coating material and process for covering preform exterior surfaces for improved gas barrier in the blow-molded bottle. Stand-alone apparatus applies and then cures the coating on the preform before the blow-molding machine reheats and then expands that preform into the bottle.

Given that coatings tend to be thin, most approaches apply these coatings to the bottle instead of the preform. Polyvinylidene chloride (PVdC)-based organic coatings were an early barrier material. A more recent organic coating development uses epoxyamine chemistry to create a tough, glossy thermoset polymer film on bottle exterior surface. Stand-alone apparatus typically inline with the blow-molding machine sprays or dips the bottle and then cures the coating material.

Another coating approach uses a form of plasma-assisted or -enhanced chemical vapor deposition process to create an extremely thin inorganic film on either the exterior or interior bottle surfaces. Silica-based film depositions create a silicon oxide (SiOx) barrier film from gas precursors containing, in part, silicon and oxygen. Carbon-based film deposition create an amorphous carbon barrier film using an acetylene gas precursor. Fundamentally, the deposition process involves placing the bottle in a vacuum chamber, introducing appropriate quantities of certain precursor gases into the chamber, exciting those gases with energy and creating a plasma that causes a compound (such as silicon oxide or amorphous carbon) to form that normally would not form if not for the plasma, and allowing the compound to condense on the bottle surface. Specially built machinery for depositing these coatings on bottles are often inline with blow-molding machinery.

Bottle Treatment

Again, while not a multilayer structure in the sense of extrusion- or injection-based approaches, bottle treatment approaches seek to improve gas barrier of volatile hydrocarbon chemicals in polyolefin bottles by allowing polymer molecules at or near the container's surface to react with certain gases, thereby creating a thin integral gas barrier layer on the surface. There are two approaches: fluorination and sulfonation.

The fluorination approach is either downstream or part of the blow-molding process. When part of the blow-molding process, the molding machine uses pure nitrogen gas to initially inflate the parison in the blow mold cavity, quickly followed by a mixture of a small amount of fluorine gas with nitrogen gas to complete the blow-molding process. The fluorine gas easily and quickly reacts with the polyolefin material still hot from parison extrusion. Chemically, the fluorine replaces hydrogen atoms within the polymer molecules that are on the interior surface. To promote reaction, the downstream approach requires reheating the bottle before fluorine exposure. Fluorine is a dangerous gas requiring special handling by trained technicians.

Fluorination makes high-density polyethylene and polypropylene bottles suitable for packaging nonpolar chemicals, such as those in cleaners, mineral spirits, turpentine, solvents such as carbon tetrachloride, and gasoline additives, insecticides, herbicides, and the like.

Although treatment barrier is not quite as effective, the sulfonation approach introduces sulfur trioxide to the inside surface of the bottle or container downstream of the blow molding machine. The sulfur trioxide reacts with the HDPE, causing sulfonic groups to form on the container's surfaces. The approach then introduces ammonium hydroxide to neutralize any acidic byproducts followed by a water rinse.

HEAT-RESISTANT PET BOTTLES

Conventional stretch or molecular biaxial-oriented blow-molded PET thermoplastic bottles cannot withstand temperatures much above 55°C (130°F) without significant bottle distortion or shrinkage from release of molded-in molecular strains and stresses created during the blow molding process. Modified processes make heat-resistant PET polyester bottles (molding technicians also call these "heat-set" or "heat-stabilized" bottles), which in part relieve stresses and "locks-in" remaining stresses with an increased crystalline molecular structure that prevents any significant bottle shrinkage at desired product fill temperatures.

Product applications for heat-set bottles include high-acid foods, such as fruit juice and isotonic drinks. Suppliers using a modified "canning" process often fill these juices and drinks at an elevated temperature capable of sterilizing the bottle, typically 68°C to 96°C (155°F to 205°F) and usually at 85°C (185°F). Patent literature is full of bottle manufacturing process and equipment descriptions further extending bottle heat-resistant performance for low-acid foods requiring higher-temperature pasteurization or retort sterilization processes (10). Heat-set PET bottles are now routinely for packaging products previously not feasible.

Molecularly, polyethylene, particularly high-density polyethylene, is considerably crystalline in nature. On the other hand, polyvinyl chloride is amorphous. Crystalline thermoplastic materials tend to be opaque. Amorphous thermoplastic materials tend to be clear or transparent. Polyethylene terephthalate is a unique thermoplastic material in that, with relative ease, it can assume a substantially amorphous molecular form or a significantly crystalline form depending on molding and processing conditions. Moreover, PET having crystalline structure can be either clear or opaque. Molding technicians take advantage of this unique PET material capability to manufacture high-performance, transparent heat-set bottles.

Polyethylene terephthalate crystals are generally either spherulitic in shape or rod-like in shape. Spherulitic crystals are heat-induced in substantially amorphous PET, and formations of these relatively large spherulitic crystals cause clear PET material to become a white opaque color. Fundamentally, the spherulitic crystal is larger than light wavelength. Consequently, the crystals reflect light attempting to pass through the PET material. Rod-like crystals initially form in PET material from molecular strain or biaxial orientation and continue to grow with heat. Rod-like crystals are relatively small, permitting light to pass without significant reflection.

A conventionally molded PET bottle—for example, a transparent carbonated soft drink bottle sidewall—is about 20% crystalline. These crystals are substantially rod-like in nature. Clear heat-set PET bottles for typical hot-fill applications have at least a 28% crystalline level. Higher-performance heat-set bottles may have crystalline levels around 30–32%. Theoretically, crystalline levels of $>50\%$ percent are possible.

A crucial area of the heat-set bottle is the neck-finish. The neck-finish cannot deform in normal use. Generally, the PET thermoplastic material within the neck-finish is amorphous, that is, noncrystalline. The amorphous structure is often not acceptable for higher performance bottle applications. One means to gain additional heat-stability is to deliberately crystallize the neck-finish with heat to create spherulitic crystalline structure. These bottles are easy to recognize in that its sidewall is clear and its neck-finish is opaque white. An alternative approach, for typical applications requiring slightly less performance, is to increase overall wall thickness of the neck-finish, permitting it to retain its amorphous structure. While this approach adds weight, it is often less expensive overall. The alternative approach works because in a filling-line environment, using a post-fill cooling tunnel and coupled with a generally poor thermal conductivity of the thermoplastic, the heaver neck-finish does not become hot enough, long enough to allow the neck-finish to appreciably deform.

While there are several variations, machinery builders have developed two fundamental heat-set bottle-manufacturing approaches. First is a single-mold method where the machine stretch blow-molds the heated preform into a mold having a temperature of about 120°C to 130°C (248°F to 266°F). Air pressure holds the molded bottle against the mold cavity for about 3 s, which is sufficient time to allow stresses to relieve slightly and promote required additional crystalline growth. Second is a dual-mold method where the machine stretch blow-molds the preform into a first mold having a first shape slightly larger than final bottle form. The machine then reheats this first shape in an oven to relieve molecular stress but not alter biaxial orientation. Heating the first shape causes it to shrivel into a second shape while increasing crystalline levels. The second shape is then blow-molded in a second blow-mold cavity to produce the final bottle form.

Besides heat resistance, another consideration for heat-set, hot-fillable PET bottles is collapse from vacuum-related forces after fill, seal, and cool to room temperature. As the bottle and contents cool, it contracts reducing volume that in turn creates a negative pressure or vacuum inside. This contraction is different from shrinkage that might occur from molecular stress relief in a poorly heat-set bottle. Vacuum-related forces acting against the bottle can often slightly distort bottle shape, particularly in a lightweight bottle. To maintain a pleasing overall appearance, clever hot-fillable bottle designs have “vacuum panels” or other surfaces that manage these distortions in a uniform fashion.

ASEPTIC BLOW MOLDING

While any blow-molding process can directly or indirectly link with a filling machine that sterilizes the bottle and maintains an aseptic filling environment, aseptic blow-molding usually involves the extrusion blow-molding method where the bottle is blow-molded in a commercially sterile environment with highly modified equipment. Often the product-filling process is an integral part of the blow-molding machine. Generally, aseptic blow-molding machines use one of two fundamental approaches.

Blow-and-Hold Approach

This is substantially a two-stage approach. The blow-molding machine seals the bottle interior before removal using moving plates in the mold to seal the blow-pin opening after pin withdrawal. Following removal from the machine, the bottle exterior is no longer in a sterile environment, but the seal maintains sterile conditions inside. In the second stage, a stand-alone aseptic filling machine, with its own sterilized environment, sterilizes the bottle exterior and then removes the seal, thereby exposing the bottle interior. Next, the machine fills the bottle with sterilized product and reseals before removal and distribution.

Blow-Fill-Seal Approach

This fundamental approach has two variations. In one variation, the blow-molding machine molds and then fills the bottle within the blow-mold cavity. One or two seconds after initial parison inflation, a measured quantity of product flows in to fill the bottle. A few seconds later, the blow pin and product filler tube withdraw and another small mold cavity, just above the main bottle mold cavity, closes to seal the bottle and product inside. Bottles made and filled, using this variation, often have a molded-in twist-off seal that one can easily remove without a knife or scissors. In another variation, the blow-molding machine uses conventional means to manufacture the bottle and then immediately transfers it to a filling station where the machine fills and seals the bottle with a conventional closure. Bottle manufacture, filling, and sealing all take place in the same controlled commercially sterilized environment.

Aseptic blow-molding machinery modifications generally include extensive use of stainless steel and plated materials throughout. Special "clean-in-place" fixtures sterilize all internal surfaces, passageways, hoses, blow pins, valves, and so forth. A cabinet encloses the molding and filling area, and a flow of sterilized, filtered air having laminar flow characteristics maintains sterilized conditions inside. Once molding process begins, nothing inside the cabinet is touchable by human hands.

OTHER SECONDARY BLOW-MOLDING PROCESS ADDITIONS

As well as those already discussed, three other additions are commonly part of the blow-molding process.

In-mold labeling

In-mold labeling (IML) is a process addition where a robot-like arm places a paper- or plastic-based preprinted label onto the blow-mold cavity surface just before mold close and parison inflation. A series of vacuum holes in the mold cavity hold the label in place until the expanding hot parison can contact and establish a 100% bond with the label's heat-activated adhesive.

Internal Cooling

Normally, cooling of the blow-molded bottle occurs from the outside only—that is, from the blow-mold cavity itself. Consequently, heat energy must travel through the entire thickness of the bottle sidewall. Usually, this is not a major problem for most applications; however, cooling of heavy containers, such as a drum (or cooling heavy sections within the container), can take a significant amount of time. Assuming that the blow-molding machine plasticizer is capable of delivering thermoplastic melt for the next parison at a higher rate, removing some of the heat-energy from inside molded container can improve molding efficiency.

With varying cost effectiveness, molding technicians have developed several internal-cooling approaches, including injection of liquefied gas, super-cold air with or without injected water vapor, and air exchange. Effectiveness highly depends on specific application conditions; often apparatus and related gas or excess air delivery expense is greater, offsetting any cost benefit from higher productivity.

Post-Mold Cooling

Post-mold cooling is another means that molding technicians use to shorten molding time. Here the blow-molding machine removes the partially cooled bottle from the mold cavity, placing it into a typically water-cooled nest where cooling continues. At least a portion of the nest mimics the bottle contours. In addition, the nest may have a series of fine nozzles directing a flow of high-velocity air toward hotter areas. Often the nest is part of the trim tooling used for removing bottle flash.

BOTTLE DESIGN GUIDELINES

Figure 16 illustrates a number of bottle and neck-finish terms. Good product design begins with a clear understanding of bottle manufacturing process and tooling limitations. Consider injection blow molding, for example; as a rule, available strength to minimize core rod deflection will generally limit its length to about 10 times its diameter. In other words, height of the bottle should be about 10 times or less its neck-finish diameter. Limits in preform wall thickness and ability of tooling to properly heat-condition the preform restricts preform blowup ratio; that is, the bottle diameter or largest dimension perpendicular to the core rod axis should be about three times or less than the neck-finish diameter. For consistent wall thickness, bottle cross-sectional shape also has limits. Oval cross-sectional configurations require the oval's major diameter to be about two times (or less) its minor diameter.

In comparison, extrusion blow molding is not as limited as injection blow molding. For most thermoplastic materials, molding technicians limit parison to bottle diameter blowup ratio to about four times or less. This general rule applies not only to overall bottle shape but also to isolated

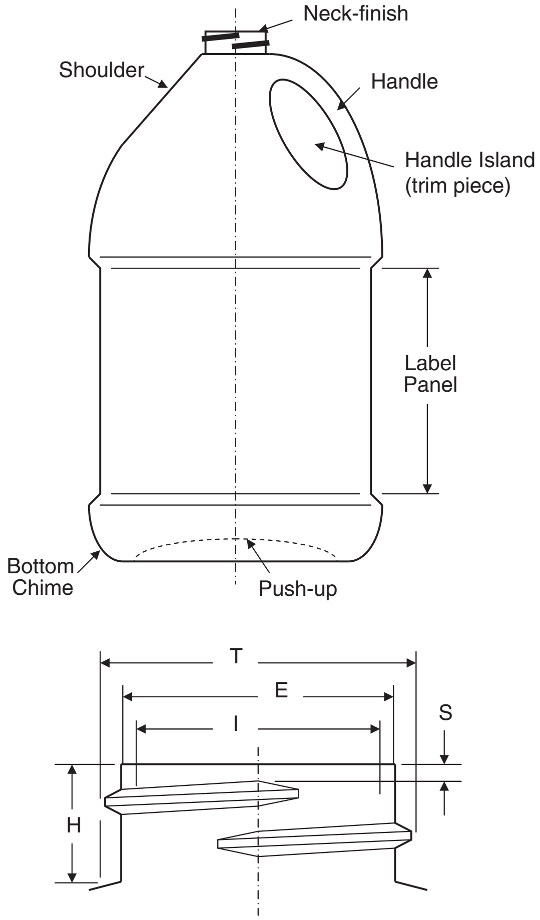

Figure 16. Common bottle and neck-finish terms. T, thread diameter; E, external diameter; I, inside diameter; H, finish height; S, thread start.

sections within the bottle. For example, bottle handle designs that are deeper than wide across mold parting face, particularly at the handle's outer end, are difficult to mold while maintaining a reasonably consistent wall thickness.

Generally, most blow-molded bottles perform better when its sidewall has uniform or nearly uniform wall thickness. Designers can help achieve this uniform thickness by remembering to "radius, slant, and taper" all surfaces. Bottles having square, flat surfaces with sharp corners will not likely perform well. Sharp corners will usually become thin and weak. In contrast, flat side panels often are relatively heavy and thick and likely distorted.

Flat, square shoulder configurations offer little top-load strength, an important consideration for bottle storage and warehousing. Ribs do not always stiffen. Rib configurations create more surface area for the parison to cover, which, in turn, thins bottle wall thickness, potentially creating a bellows or accordion effect that flexes easier. Good designers think about the bottle as a whole structure and attempt to determine how various forces acting on the bottle impact performance. For example, what areas of the bottle are likely to flex when subjected to forces anticipated with double or triple stacked pallets of filled bottles in a warehouse.

Blow-mold process conditions can influence bottle dimensions or, more important, bottle capacity. Consider high-density polyethylene milk bottles, for example. By tradition, U.S. dairies fill milk bottles to within one half inch (13 mm) of the top of the neck-finish. In other words, the milk bottle has very little headspace above its fill level. Because the dairy fills to this level, it requires the bottle capacity to be exact. To avoid overfilling or underfilling, naturally, the dairy does not want its bottles too large or too small.

Technicians at Dow Chemical determined that several process conditions could significantly change bottle capacity (11). High-density polyethylene bottles shrink over time, with about 80% occurring within the 24 h after manufacture, but small amounts of measurable shrinkage still occurs after 10 days. Lightweight bottles are bigger because of less thermoplastic material on the inside and because the bottle bulges more from product weight. A 5-g bottle weight reduction of a typical 1-gal (3.78-L) milk bottle increases capacity by about 12 mL (5 mL for plastic, 7 mL for bulge). Faster manufacture cycle time, lower parison inflation air pressure, and higher parison and/or mold temperature also reduce bottle capacity. Lastly, empty bottle storage temperature is an important consideration. A significant reduction of bottle capacity occurs after 10 days of storage at 140°F (60°C), a condition that could easily occur in a semi-trailer on a hot summer day.

BOTTLE DESIGN, PLASTIC

Andrea S. Mandel
Andrea S. Mandel Associates,
Packaging Consulting Services,
West Windsor, New Jersey

Like many of today's popular packaging techniques, blow molding of plastic bottles became popularized soon after World War II (see Blow molding). The original applications took advantage of the flexibility of plastic material to create squeeze bottles for dispensing of deodorants or medicines. The availability of reasonably priced higher-density polyethylene for rigid containers in the 1950s led to the widespread use of plastic bottles for detergents (1).

As both molding and plastic material technology developed, conversion to plastic bottles expanded beyond household products into health and beauty aids, foods and beverages, and general goods. By the last decade of the twentieth century, most soft drink bottles were converted from glass to plastic, and oil and other automotive product containers were changed from metal to plastic. The 1990s and early twenty-first century brought technical breakthroughs in materials and manufacturing that allowed the economical production of high barrier, multilayer and high temperature resistant plastic bottles. As a result, foods and drugs requiring hot fill and good flavor, odor, oxygen, and vapor barriers (such as sauces and baby food) began to be packaged in plastic bottles and jars in increasing quantities.

The advantages of plastic over glass bottles are abundant. They are safer, lighter, easier to handle for consumer and manufacturer, and easier to manufacture, and they offer improved versatility in design. However, many of the earlier conversions suffered because of the marketer's attempt to imitate the original glass bottle as closely as possible. It was feared that the consumer (especially in beauty aids) would perceive the change to plastic as strictly a cost-savings measure resulting in reduced quality. Today, the majority of plastic bottles are designed to take advantage of the material's unique properties, and the consumer has come to expect all the inherent advantages in the items they purchase.

In the 1970s and 1980s, plastic bottle designers and manufacturers were faced with widely fluctuating plastic material and additive costs and availability. The latter 1980s and 1990s added the additional challenge of environmental concerns. The early twenty-first century has brought us dual concerns: high energy prices with increased costs and the potential for shortages, along with a renewed interest in environmental considerations. The package must not only minimize material usage to reduce costs and environmental impact, it must also take into account its eventual disposal.

BASIC STEPS IN THE PLASTIC BOTTLE DESIGN AND DEVELOPMENT

There are several basic steps for the proper design and development of plastic bottles. They can be summarized as follows:

1. Define bottle requirements—product to be contained, use, distribution, aesthetics, and environmental issues.
2. Define manufacturing and filling requirements—types of molding available and filling and packaging systems.
3. Select materials.
4. Rough drawings.
5. Part drawing.
6. Model and/or rapid prototyping.
7. Mold drawing.
8. Unit cavity.
9. Unit cavity sampling and testing.
10. Finalize drawings.
11. Production mold.
12. Production mold sampling and testing.
13. Production startup.

This is a basic list of steps for bottle production. Some items may be done in a different order, and some can be performed concurrently to save time. Many items will be performed more than once as the design is refined. In addition, mating fitments and secondary packaging are frequently being developed in the same timeframe and become part of the critical path.

DEFINING BOTTLE REQUIREMENTS

What Will the Bottle Hold?

Information about the product to be contained is of primary importance for bottle design, particularly in the selection of material and neck finish. Will the product be liquid, powder, or solid? What is its viscosity? Is it homogeneous, or does it tend to separate out? Will the product have to be shaken to be used? What plastic materials and additives is it compatible with? How sensitive is it to moisture or oxygen gain or loss? Does the product have components (such as those found in detergents) that could make the bottle prone to stress cracking? Will the product outgas into the headspace and cause a pressure buildup? Will the product absorb oxygen from the headspace and tend to collapse the bottle? Will the product be filled into the bottle hot or cold? How much product should the container hold (in weight or volume)? Is the product considered hazardous or in some way regulated?

WHAT ARE THE SPECIAL REQUIREMENTS FOR BOTTLE PERFORMANCE?

Product End-Use. How will the product be used by the ultimate end-user for dispensing and storage? Examples of this are squirt bottles, roll-on bottles, trigger-spray bottles, drainback closure/measuring cup systems, bottles with integral funnels, and bottles that are stored on their caps. What are the storage conditions (temperature, humidity, pressure) of opened and unopened containers?

Secondary Packaging. Will the primary package be sold in an intermediate secondary package? Examples of this are carton, blister, and tray.

Distribution Requirements. Will the unitized product be sold in shipping case or partial-height tray? What type of inner partitions or shrink wrap can be used? Do intermediate customers require smaller unitized packs and if so, of what type? Will the bottle itself contribute to stacking strength? Does the final outer package have to fit on a standard GMA 40-in × 48-in. pallet (consider load optimization and stack heights)? Will cases be shipped in mixed loads at any time? Will shipment generally be by full truckload, partial truckload (LTL), or individual shipment by ground or air (such as United Parcel Service or Federal Express)? Does the product travel in a rack system or bulk package for any part of its distribution? Are there shelf size requirements for the retail market or for storage? Will the distribution system require the product to be shipped over high altitudes or in unusually hot temperatures or low and/or high humidity environments? Will international shipment lead to special conditions or requirements?

Aesthetic Requirements. The plastic bottle is frequently required to act as a salesperson at point of purchase and after the sale. Common concerns include:

1. Shelf facing size—maximization of width and/or height vs depth while maintaining package stability
2. Clarity, opacity, and color
3. Label area and label qualities
4. Requirement for recycled and/or recyclable material

WHAT ARE THE SPECIAL REQUIREMENTS FOR BOTTLE MANUFACTURING AND FILLING?

Options for Bottle Manufacture

Ideally, the designer should be able to select the best manufacturing technique for the particular bottle. However, because of cost, available capital equipment, and other factors, it may be necessary to compromise if possible. The major choices are:

1. Molding process—injection blow, extrusion blow, stretch blow (with variations)
2. New or modified molds (or parts of molds and mold bases)

The various advantages and disadvantages of the different plastic bottle manufacturing methods and molding processes are summarized as follows:

1. *Process:* extrusion blow molding
    a. *Description:* A tube (parison) is extruded through an annular die. Two halves of a bottle mold are clamped over the parison, sealing the top and bottom except for a hole for air injection. Air is injected, expanding the parison to match the mold. Clamped material (excess material at the top and bottom commonly called necks and tails) is removed and generally put back into the system as regrind.
    b. *Advantages*
        i. Relatively inexpensive mold, mold modification and equipment costs for a basic system.
        ii. Multilayer bottles and extruded side stripes possible.
        iii. Larger size containers are economical.
        iv. In-mold labeling available.
        v. Good for handleware or other designs requiring a molded-in “hole.”
    c. *Disadvantages*
        i. High built-in waste due to necks and tails.
        ii. Requires in-mold or postmold trimming of necks and tails.
        iii. Finish (neck area that typically receives a cap or fitment) dimensions and quality are not as consistent.
    d. *Variations*
        i. Extrusion dies can be ovalized to improve material distribution in oval or rectangular bottles.
        ii. Extrusion dies can be programmed to open and close while extruding, providing a top to bottom variation in wall thickness.
        iii. For high-volume large-container production, continuous wheel machines can be used instead of molds that shuttle in and out.
        iv. Instead of direct blow into a bottle, a dome may be created that must be trimmed off the finish. A calibrated neck, on the other hand, uses the blow pin to help mold the finish. The top of the finish may be further improved by posttrim reaming.
        v. High blow ratio (finish to maximum width) or off-center neck bottles can sometimes be improved by blowing “outside” the neck; a wide parison is used and waste is trimmed off the sides of the finish on the parting line.
2. *Process:* injection blow molding
    a. *Description:* The neck finish and “cigar”-shaped body are injection molded in the first phase. This parison mold preform is then moved to a blow station containing a mold shaped like the bottle body. Air is injected through the finish, and the completed bottle is removed from the pin. The injection molded performs can either be premade and stored for later transport to be reheated for the blow molding process, or can be molded and then blow molded all in one continuous process.
    b. *Advantages*
        i. Good quality and control of finish dimensions due to injection process.
        ii. Capability of control and design inside the finish area (as long as there are no undercuts).
        iii. Economical for large volumes of smaller containers.
        iv. Waste not built into molding process (injection mold is hot runner).
        v. Can use PET as material.
        vi. Finished container does not have a “pinchoff” area at the tail (the line where the extruded parison is actually cut off the container during the manufacturing process) that can provide a weak point for drop test or stress-crack failure.
    c. *Disadvantages*
        i. Additional need for injection molds increases cost and lead times (although existing preform molds can sometimes be used to save costs and time).

   ii. In-mold labeling and handles (with "holes") not generally available.
   iii. Not good for larger containers or high blow ratios.
3. *Process:* stretch blow molding
   a. *Description:* This is a variation on injection blow molding wherein the hot parison mold, or preform, is stretched in length by a push rod placed in the bottom prior to blow molding. The preforms can be premade and stored for later transport to be reheated for the blow-molding process, or it can be molded and then blow molded all in one continuous process.
   b. *Advantages*
      i. Improved bottle impact and cold strength.
      ii. Improved transparency, surface gloss, stiffness, and gas barrier.
      iii. Good for pressure containers such as soda bottles.
      iv. Opportunity to save plastic material by optimizing strength through stretch process and good control.
   c. *Disadvantages*
      i. Commonly used PET requires special handling and drying process.
      ii. Extra step required in process.
      iii. High capital equipment costs.
      iv. Additional need for injection molds increases cost and lead times (although existing preform molds can sometimes be used to save costs and time).
      v. In-mold labeling and handles (with "holes") not generally available.

Bottle Filling and Packing

Bottle design needs to take into account the filling and packing operations for the bottle. Important criteria include:

1. *Current equipment and change parts*. There are frequently size limitations (height, width, and depth on equipment). Likewise, change parts and changeover times can be minimized by determining common critical dimensions or easier adjustments (frequently height) with other bottles that might run frequently on the same line.
2. Forces and conditions imparted by the filling and packing operation on the bottle. Common conditions include downward compression due to insertion of items in the neck (such as plugs and balls) or on the finish (such as snap-on closures); bottle body torsion and neck distortion due to high-torque cap application; side-to-side compression due to labeling and starwheel pinch points; multidirectional compression and abrasion due to bulk handling such as in a bottle unscrambler; and bottom drop impact due to automatic drop packing into cases or trays (Figure 1). In addition, aesthetic damage can be done at various points to a labeled or unlabeled bottle due to abrasion at transfer points and handling throughout the line. In some cases, machinery can be selected or modified to reduce these conditions or insure that they occur at protected or strong points on the container. If this is cost prohibitive or not possible, the bottle needs to be designed with these requirements in mind (see Bottle Design and Specification).

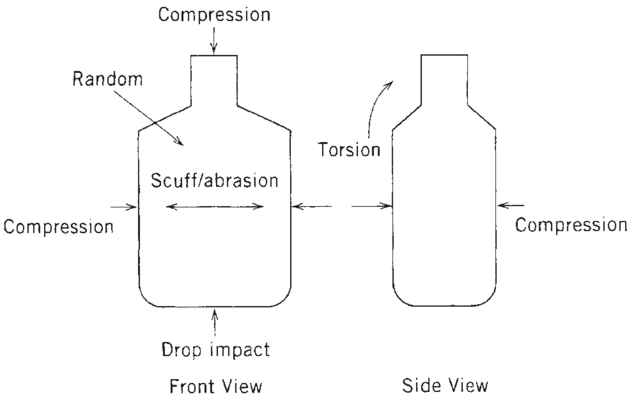

Figure 1. Common stresses on a bottle on a filling and packing line.

BOTTLE DESIGN AND SPECIFICATION

Once the special requirements for the bottle have been determined, sketches and models of various bottle designs meeting these criteria can be produced. As the process continues, the finalists need to become more detailed (dimensions, angles, finish) and begin to incorporate good plastic bottle design principles. Computer modeling and rapid prototyping can be used as part of this process.

GENERAL DESIGN CONSIDERATIONS

1. *Sharp Edges and Changes in Direction Should Be Avoided.* Surfaces should be blended and generous radii used as much as possible at bends and corners (2). Sharp edges can lead to thin and high-stress areas, resulting in stress cracking or failure on drop testing.
2. *The bottle must have minimal or no undercuts.* Thought must be given to how the bottle is to be removed from the mold. The inside of the finish must be stripped from the core rod or blow pin, and the front and back halves of the mold need to open up from the outside of the bottle. Any plastic that would hook onto the tooling or molds can cause the bottle to distort or even break. Very small and rounded undercuts, such as small retaining rings on the inside of the neck, can sometimes be successfully molded; trial and error may be necessary for a particular design and process to see how much is possible.
3. *Wall Thickness Minimum and Distribution Should Be Considered.* Thin spots can lead to stress

cracking, failure on drop test, and even pinholing; thick sections can act as heatsinks after the bottle is molded, and the uneven cooling and shrinkage can lead to bottle distortion. In the case of product that will cool or outgas after the container is sealed, there is a potential for distortion due to negative or positive pressure. This can require special molded-in structures, expansion areas, or controlled wall thickness to minimize these effects. The preciseness of wall thickness guidelines should be determined by how critical it is for performance of the bottle.

4. *Bottle Stability Is Critical.* This is especially true for many of the tall, thin (depth) bottles frequently used in consumer products to maximize shelf impression. In injection blow molding, the height of the pushup (the center of the base of the bottle) can be adjusted. The center of the bottle base must be high enough to not “belly out” for a full or empty bottle, or the bottom of the bottle will be a round surface. Various aids to stability include molding bottom rings (radiused or with a flat land area) or feet (three or four). It is a good idea to put a slight depression in the vicinity of the parting line so that a slightly raised parting line will not contribute to instability. The best solution depends on the bottle’s general shape and center of gravity and on the controls available in the molding process.
5. *Embossed or Debossed Decorations.* These include logos, which can be a free or inexpensive way to add information to the bottle. However, care should be taken to avoid thin spots, undercuts, or sharp edges.
6. *Information that Is Frequently Molded into the Bottom of the Bottle.* This includes material identification symbol (recycling logo, legally required to be on the bottle in several states), mold and cavity number (for quality checks and troubleshooting), and a molder or company logo. Placement should be planned ahead of time, especially because this may affect bottle stability. These should generally not touch or cross the parting line.
7. *The Bottle Sealing Area Should Be Closely Specified.* For standard continuous thread closures, lined or unlined, the land seal area at the top of the container is critical. It needs to be flat, horizontal, and free of dips or nicks. If the flat surface is going to be angled, care should be taken to specify a continuous surface that will create a seal. A minimum land width (flat neck thickness at the top) can be specified. If a valve seal closure is to be used, the circumference inside the finish where it meets the valve is critical.
8. *Anticipate Pressure Differentials.* Special product, filling, and distribution circumstances can lead to pressure differentials between the inside and outside of the filled and sealed container over the course of product life. Examples of this include hot fill, product outgassing, product migration through walls causing suckback, and changes in external pressure and temperature during distribution, storage, and handling. Flexible panels or more flexible materials will not prevent dimensional change, but can prevent damage to the container and allow it to be aesthetically acceptable. Variations in wall thickness support ribs, and stiffer materials can strengthen containers against dimensional changes to some extent. Depending on the product, one- or two-way valves can be added to the closure or inner seal.
9. *Labeling and Decoration.* These are a major consideration in bottle design. A label panel must be flat or have a surface that curves in only one direction. Many label areas are recessed or provide top and bottom “bumpers” to protect the label against scuffing during normal handling and distribution. The maximum label area is determined by a combination of the tolerances of the label placement equipment, the label dimensions, and the usable label panel dimensions. The additive tolerances need to be subtracted from the specified label panel size. Major labeling or decoration methods include the following: (a) In-line labeling (filling line)—labels (generally pressure-sensitive or plain-paper and glue) are applied on the filling line; (b) postmold labeling—labels (generally pressure-sensitive or heat-transfer) are applied soon after the bottle is molded (further shrinkage in the bottle, particularly over the next 24 hours, must be taken into account); (c) in-mold labeling—labels (either plastic or paper) are applied inside the mold during the molding process (bottle versus label shrinkage must be designed into the bottle tooling, especially for paper labels); and (d) direct application to bottle—instead of applying a label, the container is decorated by printing or silk screening directly onto the bottle.

HDPE or PP bottles usually require flame treatment prior to decoration or labeling. Round bottles may need a rotational guide in the bottom to help control them during either process. (See also Labels and labeling machinery.)

Industry Standards

As in any purchased item, specifications and tolerances should be set up between the customer and the supplier. However, the designer is greatly aided by industry standards. Currently, ASTM publishes D2911-94(2005) Standard Specification for Dimensions and Tolerances for Plastic Bottles with standard screw closure neck finish dimensions, threads, and tolerances, and tolerances for various ranges of bottle capacity (up to 5 gallons) and body dimensions. These standards are modified on an ongoing basis and should regularly be checked for updates. In addition to dimensional standards, there are procedures for stress crack resistance, crush strength, drop impact and additional tests (3). The existence of standard finishes greatly facilitates the interchangeability of various stock and custom closures that might be available. The standard tolerances also provide a good starting point for specifications. The designer might wish to tighten some of these tolerances as required, but should be prepared to work

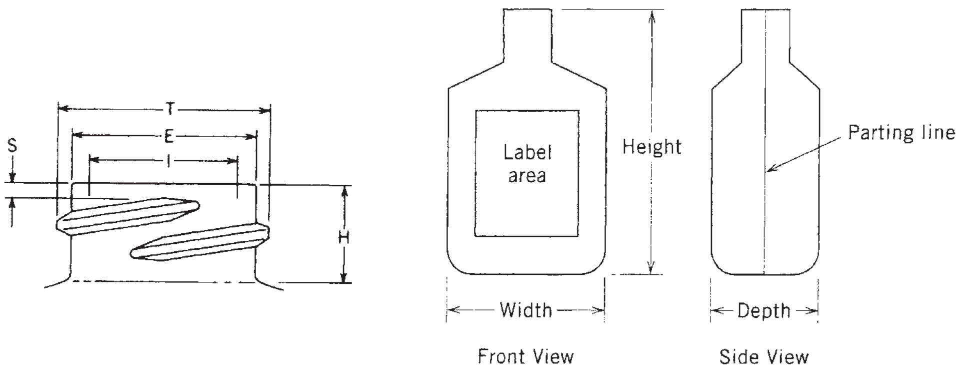

Figure 2. Typical dimensions of a plastic bottle. Bottle and finish nomenclature. T, diameter of thread; E, diameter of root of thread; I, diameter of inside; S, distance of thread start to top of finish; and H, height of finish.

closely with any vendors ahead of time to ensure manufacturing capability.

A typical dimensioned bottle is shown in Figure 2. Table 1 describes a typical container's dimensions and their importance. The sample given is a standard continuous thread finish container, which uses a standard screw-on/screw-off closure that is common on many consumer bottles.

Materials and Colorants

Critical criteria for selection of bottle materials include the following:

1. Cost and availability—should be calculated by the bottle, not just the pound.
2. Environmental—recyclability and availability of recycled material, toxicity or biodegradability.
3. Clarity or opacity.
4. Stiffness or squeezability.
5. Water or moisture vapor transmission rate (WVTR or MVTR).
6. Gas permeability.
7. Chemical resistance to type of chemicals required.
8. Temperature range.
9. Impact strength.
10. Environmental stress—crack resistance (ESCR)

Materials generally used for bottles in the United States include high-density polyethylene (HDPE), polypropylene (PP), low-density polyethylene (LDPE), linear low-density polyethylene (LLDPE), polyvinyl chloride (PVC), polyethylene terephthalate (PET), and polystyrene (PS). Of these, HDPE and PET make up the great majority of

Table 1. Bottle Dimensions

Dimension	Description	Purpose
T	Thread outer diameter	Cap fit and torque control.
E	Diameter between threads	Cap fit and torque control.
H	Height from shoulder to top of finish	Bottom of closure must clear shoulder at maximum torque for proper sealing. The maximum minus minimum H (ΔH) should also be specified to limit neck "cocking," which will also adversely affect the seal.
S	Height from top of thread to top of finish	Thread engagement.
I	Inside diameter of finish	Minimum is for filling tube clearance only. Custom detail should be added for placement of special fitments.
Ovality	$T_{\max}-T_{\min}$ or other area	Ovality in the finish can affect closure fit, torque control, or fitment integrity and fit. Specification should be based on requirements and manufacturing capabilities.
Land width	Sealing width on top of finish	Cap seal and torque control. Specification should be based on requirements and manufacturing capabilities.
Overflow capacity	Volumetric capacity of bottle to top	Consistent filling of bottle with proper amount of product and correct aesthetic fill height.
Overall dimensions	Height, width, and depth at maximum point	Proper machinability on filling line and fit in secondary packaging. Additional dimensions are specified in article drawing.
Weight	Weight of empty bottle	Cost control, to ensure sufficient material, and fill weight control.
Wall thickness	Thickness of wall at minimum and specified points	Thin spots can lead to drop failure or stress crack. Wall thickness should be specified at the absolute minimum found on the bottle (this can vary as to location) and at other critical locations if necessary.

containers by number and weight. Other materials, including engineering plastics such as polycarbonate, are used for special applications. Individual material properties can be found in detail under their separate articles. Many materials can have their properties significantly modified by additives such as plasticizers, fillers, impact modifiers, antistatic agents, and UV (ultraviolet radiation) inhibitors. Copolymers and multilayer coextrusions can further enhance a material.

Colorants are added to provide color and/or opacity to the material. Pigments, an opacity agent (such as titanium dioxide), and a compatible base material are compounded and added to the regular plastic during the molding process. The colorant loading, wall thickness of the plastic, and color and opacity of the product all affect the final aesthetics of the filled bottle (see Colorants, plastic).

Different materials and to some extent different colorants all affect the shrinkage and final performance of a bottle. This must be taken into consideration for testing and qualification.

Computer Utilization in the Design Process

The computer is an integral part of the bottle design process, and new ways of using it are being added continuously. Uses include:

Specifications. Bottle specifications are computerized at both the customer and supplier level.

Computer-Aided Design/Manufacturing (CAD/CAM). Bottle drawings are performed on CAD systems, with improved opportunity for analysis and exploration of options and variables. Mold makers frequently use a CAM system for production of the mold. Some forms of rapid prototyping can also be performed.

Analysis and Data Recording. Test data can be both directly recorded and analyzed on the computer. Sophisticated engineering programs, such as finite-element analysis, can be used to compute and visualize stresses at various points.

Pallet Loads. Several programs, such as those produced by CAPE (4) or TOPS (5), allow quick calculations of finished pallet options based on bottle sizes. This allows for pallet load optimization at the initial design stage.

In addition, there is various software to do everything from evaluating heat transfer in mold design to visualizing product placement on the supermarket shelf.

PROTOTYPING AND TESTING

Once the bottle is designed and unit-cavity samples have been produced in the proper materials, a testing program must be initiated. A testing protocol should be established that checks bottles against both their specifications and the requirement list that was generated.

SPECIALTY BOTTLE REQUIREMENTS

A number of specialty bottles have distinctive requirements. Some of these include:

Roll-On. A round ball is inserted in the finish; rolling the ball against a surface (clothes, parts of the body) dispenses a liquid. The ball is held in place between two rings in the finish. The most common method of sealing is to torque the cap so that it pushes the ball down tightly against the lower ring (Figure 3).

Plug. A small orifice plug is placed into the finish so that product dispensing can be controlled (eye or nose drops, creams). The plug must be inserted without crushing the bottle body or neck finish and yet be difficult to remove. Controlled dimensions or retention rings are some of the solutions.

Drain-Back Closures. These fitments provide pour spouts and matching caps for detergents and fabric softeners. The drain-back section is sometimes

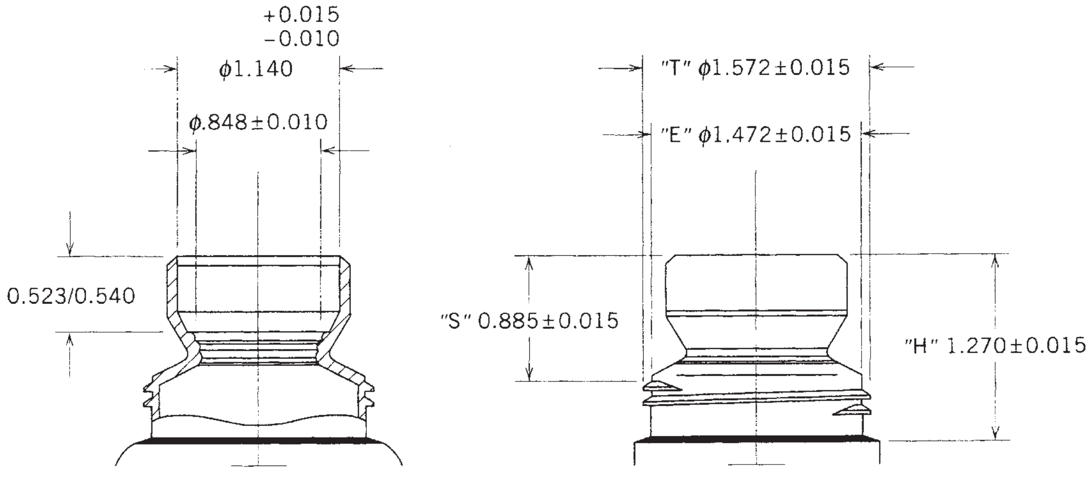

Figure 3. Typical special rollon finish.

placed inside the finish similar to a plug, but frequently before filling.

Child-Resistant Closure (CRC). There are a number of different types of these closures on the market, generally requiring special finishes. The popular "push and turn" instruction requires sufficient H dimension to allow the cap to be pushed down for thread engagement. The "line up the arrows" instruction requires a ring with an interruption under the arrow. Protocol testing includes both closures and containers (see Child-resistant packaging).

Nonremovable Closure. Some dispensing closures are designed to prevent removal. One design has ratchets that can easily be overridden for tightening but prevent loosening (see Closures, bottle and jar).

Tamper Band. Many products (drugs and foods) have tamper bands to show tamper evidence. The band must be able to anchor itself to something on the bottle—a ring is sometimes added to the outside under the finish area (see Bands, shrink; Tamper-evident packaging).

ENVIRONMENTAL CONCERNS

Whether driven by legislation, consumer preference, or the desire to be a good corporate citizen, today's packager has to take environmental concerns into account when producing a package. A new plastic bottle presents a special challenge and opportunity. The following is a brief look at plastic bottles and the ways of handling solid waste other than the landfill:

1. *Reduce.* The preferred way of handling the problem—creating less waste in the first place—has another major advantage. The less plastic we use, the more money we save. This can be accomplished through optimizing structural design, eliminating oversizing, and taking advantage of the best materials for the job.
2. *Reuse.* Although returnable bottles may seem like an obvious answer, this is not necessarily the case: "to withstand the process of return and refill, a refillable container must be about twice as heavy as a one-way container of the same material." This adds impact to energy usage and eventual disposal also (6). However, a number of consumer products, notably detergents and cleaning products, are sold in bottles that the consumer refills without having to undergo this process. The refill packages are designed with less plastic and frills, or are made of lighterweight or more easily crushable materials.
3. *Recycle (Recyclable).* Everything can be recycled by somebody, somehow, somewhere. However, unless a substantial percentage of the bottles can realistically be recycled in the near future, this doesn't mean too much. Although the percentages of bottles that are recycled or could be from programs in place changes constantly, the bulk of recycling is with PET (mostly soda bottles, although some areas have added capabilities to accept other bottles) or HDPE (mostly homopolymer milk bottles, although some areas now accept other containers including copolymer detergent bottles). Plastic containers can be recycled into plastic lumber, piping, or even carpet liner as well as packaging containers. The recycling rate for plastic containers has been estimated at 24.3% for 2005, based on pounds of resin sold (7). To aid in potential recycling, as well as comply with the law in most states, a material identification logo, such as the SPI resin identification code, (8) should be added to all containers.
4. *Recycle (Recycled).* The relatively high cost of collecting, sorting, cleaning, and processing good-quality post-consumer HDPE generally makes it more expensive pound for pound than virgin resin. As the process becomes more efficient and if the cost of virgin continues to climb, this may change. Because of the unpredictability of the color and properties of much regrind, it is frequently used as a middle layer in a multilayer coextruded bottle or as a small percentage in a dark bottle holding nonaggressive product. Food and drug primary packages may not be permitted to use reground plastic directly, although repolymerization or special considerations can be investigated.
5. *Incineration and Conversion to Energy.* Plastics produce heat when burned, which, in turn, can be converted to other forms of energy. The presence of heavy metals (such as lead or cadmium used in some colorants) in a bottle will leave toxic waste residue. Several states have outlawed the use of these materials, and it is critical to avoid them. Older incinerators may also have a problem with chloride containing materials such as PVC (9).

BOXES, CORRUGATED

Gene A. Foster
Middlesex Container Company,
Inc., Milltown, New Jersey
Updated by Staff

INTRODUCTION

Corrugated containers (erroneously termed *cardboard boxes*) became the shipping package of preference in the early 1900s as a replacement for wooden crates. Corrugated fiberboard packaging is, in terms of tonnage, by far the most common type of paper and paperboard-based packaging (1).

The corrugated shipping container and related inner packaging is multifunctional. Its varied uses include wrapping, enclosing, protecting, cushioning, indexing, stacking, and displaying. The basic function of the packaging is to protect the product during distribution until the product is removed from the package. The growing use of palletization in warehousing and distribution requires corrugated boxes with good stackability. Corrugated board is an appropriate material for obtaining high stackability. Product containability and cost-effective adaptation to logistics systems are important issues in corrugated-board transport design. Today's packaging is used not only for protection, but also for promotional and adverstising support. It is a communication medium carrrying information and artwork. Printing quality has been developed to meet these needs (1).

RAW MATERIALS

Kraft linerboard derives its name from the Swedish word *kraft*, meaning strength. It is produced for its facial stiffness (stackability) and puncture resistance. These characteristics are achieved through use of soft-wood fibers that are long and resilient. Linerboard becomes the facings of corrugated board.

The basic raw material for liner is cellulose fiber extracted from wood chips. The chips are digested in a cooking liquor to remove lignin and resin, leaving the fiber that is fibrilated to enhance the tendency for the fibers to mat together. The fibers are pulped with water and spread onto the screen of a Fourdrinier paper machine. Water is drained, leaving the mass of fiber to form a sheet of paper that is dried and wound into rolls. Many Fourdrinier machines are over 20 ft (6 m) wide. Linerboard is graded by *basic weight*, which will be explained in the section on liner grades.

The natural color of pulp is tan or kraft. A small percentage of the pulp is bleached white in a chlorine bath and then converted into fully bleached white paper. Bleached white pulp is also furnished as a topping for kraft liners to produce mottled white linerboard. Paper mills sell linerboard to corrugated converting plants in units of tons.

The medium is the paper rollstock that is converted into the fluted portion of corrugated board. The medium is also known as “nine point” because it calipers 0.009 in. It is also termed “semichem” because the pulp is cooked with chemicals and then mechanically ground into fibers. The pulp, like linerboard, is converted into paper on the Fourdrinier machine; however, pulp for the medium is selected from hard-wood trees that have short fibers that hold a set better when they are steamed and fluted on the corrugator. Technical advances have made possible the use of roots and recycled containers as percentage additives to medium stock. Recycled fiber from recovered paper and board is a major source of fiber for the corrugating industry.

The universal weight for the medium is 26 lb/1000 ft^2 (11.7 kg/90 m^2); however, minimum quantities (33 and 40 lb) of medium are used to improve flat crush, stacking, and moisture resistance in finished board.

Adhesives

Contemporary corrugator adhesives are starch-based with additives and are selected for their flow, tack, absorbtion, evaporation, and set qualities. Specialty additives may be blended with the base adhesive to improve wet strength and moisture resistance. Borax is added because it causes the starch to become a more highly branched polymer chain with higher viscosity and tack (1). Modern corrugators use as little as 2 lb (0.9 kg) of adhesive per 1000 ft^2 (90 m^2) to combine single-wall board. Fingerless single-facers have eliminated the old problem of adhesive buildup lines (finger lines) in the finished product. The manufacture of corrugator adhesive is highly technical and is controlled through a series of extreme specifications.

Joint adhesives can be plastic based hot melts or starch-based cold melts. Both are used successfully to produce high-speed manufacturer's joint closure (see Adhesives).

Inks

Are a product of earth elements and chemical formulations. The base carrier for modern flexographic printing inks is water laced with additives designed to enhance drying speed, produce image clarity, inhibit smearing, and eliminate spotting or blotching. Inks must be carefully scrutinized for their pH factor because acidic inks differ in performance from base inks. For example, basic inks tend to smear. Ready-to-run inks are supplied to the corrugated printers in drums of 50-lb (22.5-kg) pails. In-house ink kitchens afford the converting plant the flexibility of mixing raw materials delivered from the ink manufacturers into custom batches in which the corrugated printers can control tones, viscosities, additive selections, and many other custom characteristics that will enhance the final printed image (see Inks).

The industry's modern ink kitchens use the Pantone Matching System (PMS) Service. An endless range of available ink colors has been opened up. The color of the print is measured by the CIE system.

Printing Plates

Modern printing plates are supplied to the corrugator mounted on poly backing, ready to be locked into the press. The industry has moved from a rather slow, methodical art form to a highly technical and efficient producer. The engraved rubber plate (die) has been replaced by a photopolymer plate that is rapidly produced through a series of computer imaging, and photoprocessing. The photopolymer plate is presently subject to ultraviolet (UV) deterioration; however, chemical suppliers of the base poly material will solve this problem soon.

Cutting Dies

Corrugated products with scores or slots with angles other than 90° must be die-cut. Cutting dies are produced for the purpose by imposing an image onto a plywood sheet, jigsawing or laser-cutting the imaged lines, and filling the eradicated space with a cutting knife or scoring rule as desired. The dies are made on curved or flat plywood, depending on the style of diecutter to be used. Stripping forms accompany cutting dies if they are to be used on automatic equipment.

Labels

High-graphics products incorporate the use of labels in conjunction with or in lieu of printing. Labels are supplied to the corrugated converters by label manufacturers. Typical specifications requested for labels are number of printed colors, paper basis weight, stock color, finish, and grade. Labels are adhered to the corrugated stock manually, semiautomatically, or fully automatically.

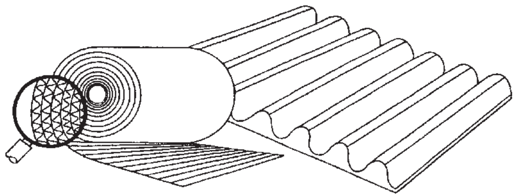
Additives

Finished corrugated blanks may be treated by many additives or coatings to improve water repellency, scuff resistance, and petrochemical resistance. Waxes and polymers are favored additives.

BOARD CONSTRUCTION

Corrugated board is a sandwich of one or more linerboard sheets adhered to a fluted medium. Single-face construction incorporates one linerboard adhered to the medium. Double-face, better known as *single-wall*, has a linerboard adhered to both sides of the medium. Additional media and linerboards yield double-wall and triple-wall (see Figure 1).

Combinations of linerboard grades and flute configurations are used to generate the many variations of corrugated board. Liner weights are increased to improve board bursting and stacking strength, and flutes are modified to accommodate various compression, stack, and printing



Single face corrugated

Figure 1. Various examples of corrugation.

features. Two important requirements of corrugated board are flat crush and stacking strength. *Flat crush* measures the pounds per square inch (psi) resistance to pressure applied at a 90° angle to a horizontal sheet, thus establishing the rigidity of the flute structure. This property is changed by varying the flute outline and linear density. It can also be revised by changing the basis weight of the fluted medium. Flat crush supplies the internal resistance to squeezing forces such as feed rollers in presses and gluers. It also supplies resistance to gravitational forces imposed upon bottom sheets in stacks and bottom cartons in units.

Stacking strength measures the ability of a vertical panel to resist bowing, buckling, or collapsing from pressure exerted in line with that panel. This is regulated by varying the linerboard weights, changing flute heights, or both. Stacking strength is probably the most sought-after characteristic in corrugated cartons.

Flutes

Flutes are most essential to the characteristic of corrugated board. They supply the rigidity to the board that imparts strength with minimal weight and density. Fluting makes the product economical. Flutes are designed by height (thickness) and density (number per linear foot). Higher flutes produces a physically stronger columnar stack in line with the flutes. Denser flutes—that is, flutes that present more images per linear foot—produce more resistance across the flutes. C is the most used flute size, followed by B and E. The C flute is considered a compromise between A and B. Other, minimally used flutes include J (jumbo), which is larger than the others, as the name suggests; S flute; and F flute, which is the lowest flute height.

Higher (less dense) flutes in addition to stacking strength provide softer cushion characteristics, while lower (more dense) flutes provide greater flat crush resistance, smoother print surfaces, and crisper score lines. Flutes are often used in combinations such as BC double wall, which provides an overlap of required characteristics. B and C flutes are the most commonly produced flutes, and E is considered sparingly. Flute selection is determined by shipper needs. A fragile-decorations shipper would choose C flute for its stacking strength and cushioning qualities. A canned beverage filler would choose B flute for its end-to-end compression attributes; and a point-of-purchase display designer would select E flute for its superior printing surface. (See Table 1.)

MULLEN VERSUS EDGE CRUSH

Carrier regulating agencies require a board upgrade to accommodate increased loads and increased box sizes analogous to the idea that a 3/4-in. (19-mm) plywood sheet is stronger than a 1/4-in. (6.35-mm) sheet. Paper mills fulfill this requirements by producing various-weight liner grades, corrugated converters combine board using proper heavier grades to accommodate the need for stronger containers.

Liner Grades

The universally accepted test for corrugated board has been the *Mullen test* (TAPPI test method T-810), which measures the resistance of the board to withstand a puncturing pressure measured in pounds per square inch (psi) or metric kilopascals (kPa). Linerboard grades have been manufactured to meet specific Mullen requirements. Increased Mullen demands increased linerboard strength, which is accomplished by increasing the mass of the linerboard measured in pounds per thousand square feet (lb/1000 ft^2) (kg/90 m^2).

A major modification to containerboard was initiated in the 1980s, when paper mills developed a process that enhanced linerboard material, giving it an ability to withstand crush or compression examinations at lower basis weights. Table 2 compares STFI crush performance of standard to high-performance liners. Note the improved STFI in high-performance liner.

The product *high-performance linerboard* provides a serious potential for user satisfaction and improved economics. New linerboard concepts prompted the corrugated industry trade associations to sponsor proposals to truck- and rail-carrier committees to consider classifications recognizing edge crush as a test criteria. Proponents for the new test methods argued that edge crush is more customer-oriented and that it permits more latitude for manufacturers to design and supply boxes that meet customer performance criteria. Rules committees of truck and rail carriers accepted the proposals, and in 1991 they approved the edge-crush test (ECT) as an alternative test method for containerboard.

Edge-crush Test

This measures the resistance of the *containerboard* to edgewise compression. Ring-crush and STFI tests measure the resistance of the *linerboard* and medium. These tests are performed to give the linerboard and corrugated manufacturers relative material comparisons. The

Table 1. Standard U.S. Corrugated Flutes[a]

Flute Designation	Flutes per Linear Foot	Flutes per Linear Meter	Flute Thickness, in. (mm)	Flutes per Cross Section
A flute	33±3	108±10	3/16 (4.8)

26	11.8	11	12.8
33	14.9	15	17.4
40	18.0	19	22.0
High-Performance Liner			
35	15.8	20.3	23.6
45	20.3	27.5	31.9
57	25.8	33.7	39.1
72	32.6	45.0	52.2

edge-crush test includes the value of the medium's resistance to compression as well as the linerboard. It should be noted that these tests can, and are, performed on standard weight liners as well as on high-performance liners (see Edge-crush concept).

Medium Grades

General industrial principle requires use of the same medium weight (26 lb/1000 ft^2) (11.7 kg/90 m^2) for all board grades; that is, liner weights change to generate increasing board tests, but the medium remains the same. There are some approved exceptions that call for upgrading medium to improve flat crush and moisture resistance. Two upgraded medium weights are 33 and 40 lb.

REGULATIONS

Freight carriers and government agencies control the regulations for the container industry. The major regulation is encompassed in Rule 41 (*Uniform Freight Classification*) established by the National Railroad Freight Committee (2). This regulation is closely paralleled by Item 222 (National Motor Freight Carriers). Table 3 outlines minimum standards. Triple-wall and solid-fiber standards have not been included in this chart.

Rules prescribed by these agencies outline requirements that determine proper liner weights and manufacturing specifications. All corrugated boxes made to conform to the regulations carry a printed certificate identifying the boxmaker and appropriate board grade as shown in Figure 2. Note the apparent difference between the burst-test and the edge-crush certificates.

CONVERTING OPERATIONS

Corrugated fiberboard boxes are manufactured in a corrugated board plant or in a sheet feeder plant. The corrugated board plant consists of the corrugator, which produces flat sheets of corrugated fiberboard, and the converting equipment where the corrugated sheet is converted into corrugated board boxes by printing, cutting, scoring, and gluing. Sheet feeder plants are smaller factories that convert board into packaging for shorter run length orders, for quick deliveries, and for a local market.

Contemporary box plants vary widely in size and capability. A small sheet plant may ship one truckload of cartons per day while the megacontainer plant will ship 50 truckloads per day. Corrugated requirements are so diverse that a wide variety of company sizes is a desirable asset to the industry.

Corrugator

This is the major piece of equipment in a box plant. The machine converts mill-supplied roll stock (linerboard and medium) into flat sheets. It varies from 50 to 100 in. plus (12.7–25.4 m) in width, and most are over 300 ft (91.5 m) long. Wide computer-managed corrugators operating at speeds of up to 1000 lineal feet per minute are capable of producing four truckloads of corrugated board per hour.

The single-facer (wet end) of the corrugator converts the medium into fluted paper and adheres it to the inside liner of the corrugated sandwich. Next, a double backer roll is applied as the outside liner, and finally the sandwich is run over dryer plates and delivered to the dry end. Cross-corrugation scores may be applied and the board is trimmed into two-dimensional blanks in preparation for delivery to the plant for further conversion into a box.

Scheduling (trimming) a corrugator requires skill and training because variations of liner combinations, quantity requests, and blank dimensions are endless. Modern computer-trimmed corrugators are capable of producing several hundred setups per day.

Printer-Slotters

These machines print, slot, and score flat banks in preparation for folding and joining into finished boxes. Sized blanks are delivered from the corrugator prescored for flap and depth dimension. The operator, generally one of a two- or three-worker crew, sets scoring and slotting heads at proper dimensions to cut required length, width, and joint dimensions into the carton. The operator then hangs the premounted printing plates on the print cylinders, fills the ink wells with desired colors, and begins production.

These machines are referred to by the number of colors they are capable of printing in one pass plus cylinder diameter and machine width. Small-dimension machines are obviously better suited for producing small boxes, and so on. A majority of presses today are two-color; however, presses in up to six colors are available.

Corrugated printer-slotters are letterpress printers; however, most current equipment is a flexographic variation that incorporates the use of an analox roller with water-base inks versus the old doctor and impression rollers with oil-based ink. Flexographic printing offers many advantages over letterpress, including operating speed, clarity, registration, trapping, drying, and cleanup. Printer-slotters employing flexographic printing can produce an average size-box (e.g., a 24/12-oz beverage box) at approximately 15,000 per hour.

Flexofolder-Gluer

The Flexofolder-Gluer (FFG) incorporates the addition of an automatic folder–gluer system with the printing unit, which permits the completion of most cartons on one machine. The equipment has been available since the 1960s, when flexographic printing with high-speed drying made it possible for cartons to be folded immediately after printing without smearing. These machines may also be equipped with automatic bundeling and unitizing systems. The most advanced FFG can run up to speeds of 26,000 boxes per hour. Boxes can be produced for any application.

Folder–Gluers

These are designed to finish boxes in a straight line or right angle. Both are extremely efficient at folding panels and applying adhesive to produce finished cartons that require minimum or no final sealing. Predecorated, slotted, and or die-cut blanks are belt fed through the folding sections; glue is applied at required spots; and finished cartons are stacked at the finish end. Most equipment is designed to accept a wide variety of sizes both in the machine direction and across the machine.

Die Cutters

Die cutters are required for all parts that are scored or slotted other than 90° or in line with press direction. Intricate die cut interior parts and box designs are a very common part of the industry.

Flatbed die cutters are designed to produce accurate products. They vary from small hand-fed machines that are limited in speed to the operators performance (about 500 blanks per hour) to high-performance automatic equipment that include multicolor printing selections. Flatbed cutting dies are reasonably priced. The process for flatbed die cutting closely resembles cookie cutting. The die board is locked into a chase that holds it in a firm position. Corrugated board is registered under the die; and the machine is closed, striking the die impression into the board.

Rotary die cutters are best used to produce parts at high speeds. They are not as accurate as flatbed machines; however, they can be designed to accept large blanks. Rotary cutting rule is inserted into curved plywood and then locked onto the die-cutting cylinder. An impression is made into the board when a blank is passed between the cut die cylinder and an opposing thick polyblanketed impression cylinder.

Slitters

Slitters have a series of wide rotating shafts to which scoring and slitting collars (heads) are attached. These heads can be moved by the operator to change dimensions. Most slitters are manually fed; however, some are equipped with automatic feed sections. Slitters are used to reduce large sheets to smaller blank dimensions, add scores to existing blanks, and prepare small runs for further processing. Slitters are very versatile machines. Small sheet plants may be totally equipped with a slitter a printer–slotter and a taper.

Partition Slotters

These machines slot corrugated pads in preparation for assembly into partitions.

Partition Assemblers

These machines automatically assemble slotted racks into cell-divided partitions for use in separating delicate parts such as glass bottles.

Tapers

These machines apply tape fed from rolls onto prefolded cartons to form a manufacturer's joint. Standard tape widths are 2 in. (5.08 cm) or 3 in. (7.62 cm). Tapers are handfed semiautomatic or hopper-fed automatic. The machine is an economical piece of equipment that can be adjusted and set very quickly. Taped joints represent a minimal amount of todays production because of their relatively slow production speeds and higher costs compared with glued joints. Glued joints also perform better in regulatory transit tests.

Stitchers

These devices apply staples cut from a roll and are driven into the joints of prefolded boxes. Stitched joints have limited use in today's market; they are used mostly with government-grade boards and specialty wet-strength containers.

Coaters

These machines are operated at box plants or, in many cases, at specialty plants that process coatings on finished containers. These specialty plants function as a separate entity to the corrugated industry; that is, they seek customers for their process, mostly from the fish, poulty, and produce industries; purchase finished containers from corrugated converters; and add the required coatings (waxes and plastics) to the containers. The industry specializes in wet-strength and moisture-barrier containers.

Curtain coaters feed box blanks under a curtain of liquid coating (molten poly) that coats one side of the blank and passes it to a drying section. Some coaters are capable of flipping the blank to deposit a coating on both sides. *Cascaders* pour wax coatings onto finished containers. *Wax dippers* immerse finished containers into tanks of molten wax and then hang them to dry. The process looks very much like your local laundry.

Laminators

Litholaminators have become an important adjunct to the high-graphics corrugated producer. This equipment rolls adhesive onto a printed litholabel, registers the label under the substrate, drops the substrate onto the label, and rolls the combined stock to achieve 100% adhesion and eliminate air bubbles. Litholaminators are designed to feed flat banks, including joined (knocked-down) boxes.

Stock-laminators are designed to laminate varied substrates together to achieve added thickness or uncommon stock variations. They simply pass a flat blank over a surface roll that is revolving in a pan filled with adhesive, register the now adhesive coated substrate with a second substrate, and pass the combined sheet through compression rollers. The finished product is usually stacked immediately, flipping every other handful to reduce warp. Single-face laminate is a is a hybrid process that begins as a traditional fluted medium adhered to a single linerboard; but in the place of a second board, a preprinted sheet of paperboard is laminated to the outer surface.

Miscellaneous Equipment

A well-equipped corrugated plant will require additional materials handling and finishing equipment, including lift trucks, conveyors, bundelers, unitizers, bailers, load turners, eccentric slotters, quick sets, strippers, and band saws, plus many custom machines such as riviters.

MANUFACTURER'S JOINTS

Joints applied by the corrugated manufacturer provide the most practical way to convert a two-dimensional product into a third-dimensional one. *Manufacturer's joints*, as the name implies, are created by the box manufacturer. Box users torque containers open, fill them, and seal them closed by gluing, stapling, or taping. Edges that meet during closure are called *seams*.

Joints are glued, taped, or stitched. Glued and stitched containers employ a 1 1/4-in. lap that is a contiguous part of a length or width panel that will be glued or stitched to the opposing panel when the panels are folded to meet. Glued joints became the joint of preference in the 1960s. Almost all high-speed flexo presses and folders are equipped to run glued joints. Some volume box users are equipped with wraparound machines that fold flat blanks around a product and seal joints and seams in place. This process eliminates the need for a manufacturer's joint from the box manufacturer, which in some cases saves cost and in all cases produces a more tightly wrapped package. Stitching is not used in food packaging products.

Glued and stitched joints are produced with the lap on either the inside or the outside of the container. Both have their advantages. Inside laps present a finished outside edge that presents a better appearance and allows more print area. Outside laps leave a smooth surface on all four inside panels of a carton. (See Figure 3.)

DIMENSIONING

Three-dimensional cartons are designated by length × width × depth. Length and width are the longer and shorter dimensions of the opening of a box, and depth is the third dimension. Two-dimensional parts are designated by supplying the flute direction as the first dimension. Dimensions can be specified for either the inside or the outside of a box. Accurate inside dimensions must be determined to ensure the proper fit for the product being shipped or stored. At the same time, palletizing and distributing the boxes depends on the outside dimensions. The box manufacturer must be informed as to which dimension is most important to the customer (3).

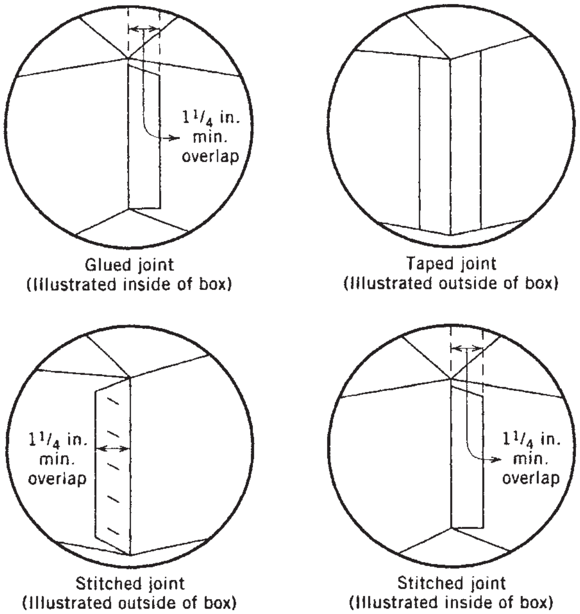

Figure 3. Examples of joints.

Corrugated board has a definite caliper, which was noted in Figure 1; consequently, scoring allowances must be considered when dimensioning boxes and interiors. One-half thickness of board is lost for each 90° bend. See an example in Figure 4.

CORRUGATED ECONOMICS

Carton economics demands that solid geometric figures (pertaining to three dimensions, $L \times W \times D$) must be reduced to plain geometric figures (pertaining to two

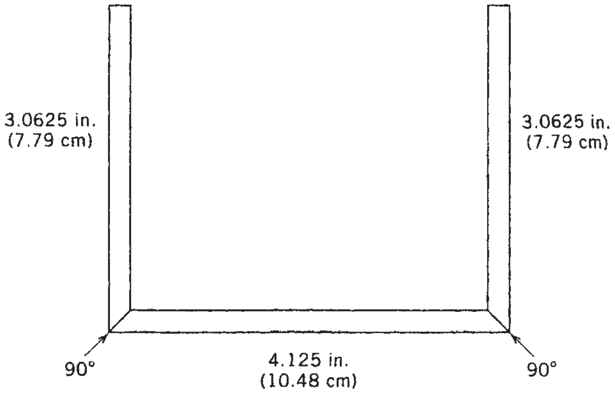

Figure 4. Score and fluting. Score B flute 1/8 in. (3.175 mm) thick at 3 1/16 in. × 4 1/8 in. (7.79 cm × 10.48 cm × 7.79 cm) to achieve inside dimensions of 3 in. × 4 in. × 3 in. (7.62 cm × 10.16 cm × 7.62 cm).

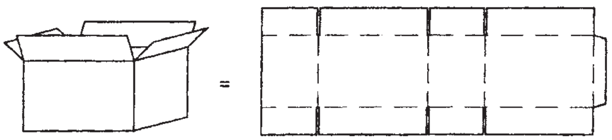

Figure 5. Example of reduction to plain geometric figure.

dimensions, $L \times W$) for manufacturing specifications and cost analysis. (See Figure 5).

Having established the single-plane dimensions of a container ($L \times W$), the area per piece can be established. This area is calculated in square inches per piece, which is generally referred to in square feet per 1000 blanks, that is, L in. × W in. divided by 144 × 1000 = square feet (ft^2)/1000 pieces.

Corrugated box costs are functions of *raw material*, plus manufacturing, administrating, and delivering costs; consequently, a major objective in box design is to maximize fill area and minimize the blank dimension required to do so. Several principles to consider that will accomplish this maxim follow:

1. The most economical RSC (regular slotted container) formula is $L = 2W = D$.
2. Rectangular RSCs are more economical than square RSCs.
3. Square tubes are more economical then rectangular tubes.
4. Width is the least economical dimension of an RSC.
5. Depth is the most economical dimension of an RSC.

BOX STYLES

Box styles and interiors are too numerous to discuss in this article, and can best be referred to in the *Fibre Box Handbook* (4). Most designs are designated by their closure feature. The most used box is the *regular slotted container* (RSC), which features the most economical use of board from the corrugator. All flaps are equal in depth, and the width of the outer flaps equals one-half that of the containers, so they meet to form a seam at the center of the box when folded. An alternative to the RSC is a wraparound design. The manufacturer supplies a flat blank to the packer. This is folded around the product and overlap is sealed. One-piece packaging to meet specific market needs, such as the carry-home pack for bottles of wine, shows considerable design ingenuity (1).

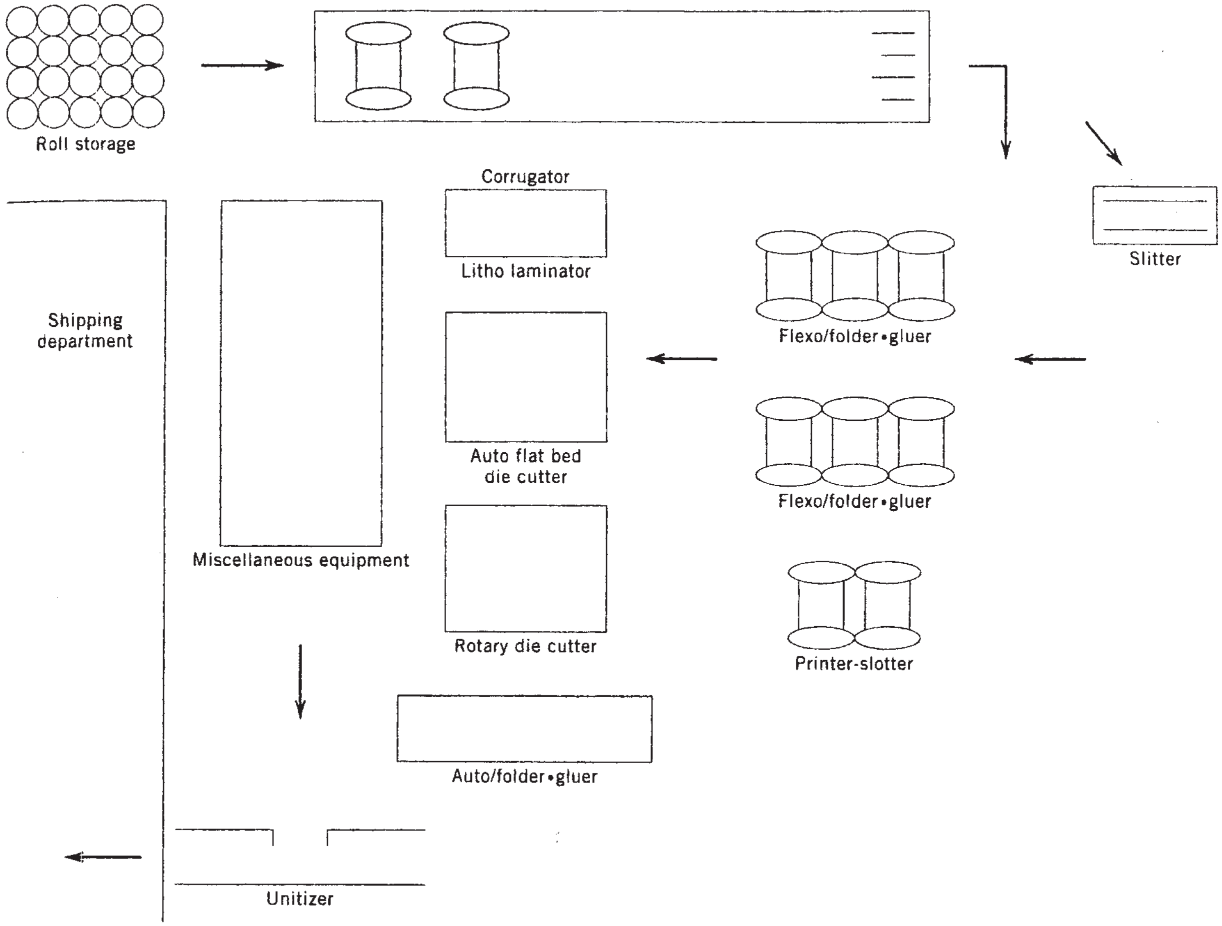

Figure 6. Typical plant floorplan.

Carton designers using CAD/CAM computer programs generate intricate new designs that enhance packing programs and support marketing schemes. Today's world of discount stores requires containers that function as sales tools that fully describe the product enclosed as well as protecting the product for delivery to the consumer.

RECYCLING

Corrugated material, made from a natural renewable resource, is frequently manufactured from recycled fiber, is often reused many times, and then is recycled for use in other packaging materials. Used corrugated containers are very adaptable to recycling; in fact, they represent the major source of recycled paper today. Over 76% of recycled containers are reclaimed for paperboard used to make more corrugated boxes (5). Box manufacturers have learned to make stronger boxes using less raw material. This is called source reduction. Corrugated packaging also allows for significant source reduction by eliminating the need for overwraps and secondary packaging (5). The industry is working on problems that occur during the repulping process. New adhesives are being developed that will help prevent "stickies" from forming that can clog the papermaking equipment. Stickies can originate from wax coatings, labels, and adhesives. Figure 6 illustrates a rough floorplan of a typical box plant.

INDUSTRY FUTURE

The corrugated industry is mature, meaning that it has developed a full share of the possible market and that most volume advances come through volume increase in existing markets. An unavoidable outcome of the globalization of the world economy is an escalated need for distribution of goods in terms of ready-made products from the globabl enterprise to its customers in the global market as well as extensive transport of materials, parts, and subsystems from external and/or internal suppliers to assembly plants. Effective packaging and logistics solutions have become key factors in order to maintain or improve competitiveness of these enterprises. These patterns also affect national and small- to medium-sized enterprises. A significant driving force is the quest for the optimal package. It is not only necessary that the package provide fundamental functions, but also that it be accomplished at the lowest possible cost with a minimum of environmental impact. A key factor is to minimize the mass of the package. A benefit to the industry would be the reduction of the amount of raw material used. An additional important factor is to realize that in the future the sources of raw materials may change and vary in quality. These factors emphasize the necessity to use effectively the fiber strength of the raw material, and current research is aimed in this direction (6).

Undoubtedly the most beneficial adjustment the consumer will receive is the move to high-performance linerboard and the corresponding change from burst test to edge-crush test. This very significant change will ultimately result in not only lower direct costs but also lower freight and handling costs. The combination of stronger paperboard at lower basis weights will also result in a reduction of waste tonnage and pulp consumption. High-performance linerboard will improve machine efficiencies and printing capabilities.

High-graphics containers are claiming a larger share of the market. Packagers are accepting the corrugated container as a sales tool in addition to its use as a shipping container. Exotic labeling equipment and preprinted liner laminates are becoming more common to the industry, and the trend continues toward faster in-line converting machines that incorporate printing, slotting, die cutting, folding, and gluing into one piece of equipment.

BOXES, RIGID, PAPERBOARD

Larry Lynch
Julia Anderson
National Paperbox and
Packaging Association
Updated by Staff

INTRODUCTION

Rigid-paperboard boxes are also called "setup" boxes. Unlike folding cartons (see Cartons, Folding), they are delivered to the packager setup and ready to use. The rigid box was originally used by the Chinese, who were among the earliest to discover a process for making strong and flexible paper from rice fiber. The first known use for a paper box was tea. The word *box* generally means a receptacle with stiff sides as distinguished from a basket, and boxes were so named because they were first made from a tree called *Box* or *Boxwood*.

Boxes for gift-giving became popular over 2000 years ago when the Roman priests encouraged people to send presents during the seasons of rejoicing. The paperboard box of current use originated in the 16th century, with the invention of pasteboard. In Europe, one of the earliest types of paper boxes was commonly known as a *band box*. It was a box highly decorated by hand and was used to carry bands and ruffles worn by the Cavaliers and Ladies of the Court. It was not until 1844 that setup boxes were manufactured in the United States. Starting with a machine that cut the corners of the box, Colonel Andrew Dennison soon found that manufacturing boxes by hand was tedious work and developed the Dennison Machine, which led to the creation of the Dennison Manufacturing Company. The Colonel's invention was revolutionary, but until the Civil War, most consumer products were packaged in paper bags or wrapped in paper. There were only about 40 boxmakers in the country, and most boxes were made by hand. For these 40 craftsmen the box business was merely an adjunct to other lines of business, which varied from printing to the manufacture of the consumer items they would eventually pack.

In 1875, John T. Robison, who had worked with Colonel Dennison and others, developed the first modern scoring machine, corner cutter, and shears. These three machines still form the machinery basis for most box shops, but it was not until the end of World War II that significant progress was made to improve the production of machinery for the industry. Today's machinery takes a scored piece of blank boxboard through to the finished covered box.

DESIGN

A defining characteristic of the rigid box is the freedom it allows with respect to shape, materials, use of accessories, and overall presentation (1). Rigid boxes may be large, small, square, rectangular, or elliptical in shape. The basic form is the lift-off-lid box. Examples of other forms are the shell and slide book style, combining trays with different hinged lids (for jewelry boxes) and combining rigid board jackets with pockets for DVDs. The two major factors in the appeal of the rigid box are quality and perceived luxury. In marketing terms, a product must be shown to its best advanatage. This is sometimes achieved by making the product visible, especially when displayed at the point of purchase. More is usually achieved by graphics, window patching, and the use of transparent plastic lids (2). A simple lift off box with good graphics may be enough of an appeal, but a round, oval, or heart-shaped box may be required for packaging chocolates.

MANUFACTURING PROCESS

The process starts when sheets of paperboard, made principally from recycled fibers, are sent through a machine known as a *scorer*. The scorer has circular knives that either cut through or partially cut through the paperboard and form the box blanks from the full sheet. The scorers must be set twice, once for the box and once for the lid, since there is usually a variation of 1/8–3/8 in. (3.2–9.5 mm) between the box and the lid. After the individual box blanks are broken from the full sheet, they are stacked and prepared for corner cutting. Once the corners are cut, the basic box blank is ready. Die cutting, usually performed on a platen press and an alternative method of cutting blanks, is economically justifiable for large orders.

The blanks are now ready for staying. For small quantities the box blanks can be sent through a single stayer where an operator must first bend all four sides of the blank to prebreak the scores. The single-staying machine will then glue a strip of 7/8-in. (22-mm)-width kraft paper of the required length to each corner of the box. For greater quantities the boxmaker uses a quad stayer. The quad stayer feeds the box blanks automatically under a plunger that has the same block size as the box or cover to be formed. With each stroke of the machine, the box blank sides are turned up and stay paper is applied to all four corners at one time.

After staying, the box is in acceptable form, requiring only an attractive outer wrap. In most operations, the paper box wrap is placed onto the conveyor gluer, which applies hot glue to the back of the wrap and then places it on a traveling belt. The wrap is held in place by suction under the belt. As the wrap travels on the belt, either it is removed from the belt by a machine operator, who manually spots the paperboard box on the wrap, or it is automatically spotted by machine. After spotting, the box and wrap move on to another plunger mechanism where the wrap is forced around the box. Simultaneously, nylon brushes smooth the paper to the four sides of the box. Just before the plunger reaches the bottom of the stroke, the wooden block splits, allowing metal "fingers" to push the paper in the box. The wooden block then closes together and completes its downstroke where felt-lined blocks press the sides and ensure the gluing of the paper to the inside as well as the outside of the box.

The manufacturing process described above is for the simplest box, but the setup box can accommodate unusual requirements with regard to windows, domes, embossing, platforms, hinges, lids, compartments, and other variations. Standard variations of the rigid box include the telescope box, the ended box, the padded-cover box, special shapes (e.g., oval, heart-shaped), slide tray, neck or shoulder style, hinged cover, slanted side, full telescope, box-in-box, specialty box, interior partition, extension bottom, three-piece, slotted partition, and interior platform. This versatility is extremely valuable in meeting the merchandiser's demands for quality, quantity, and convenience. Figures 1 and 2 show a familiar candy box and an unusual configuration for cosmetics.

MATERIALS

Four primary materials are needed for manufacturing the rigid box: chipboard (for the rough box), stay paper (to hold the sides of the box together), glue (to hold the outer

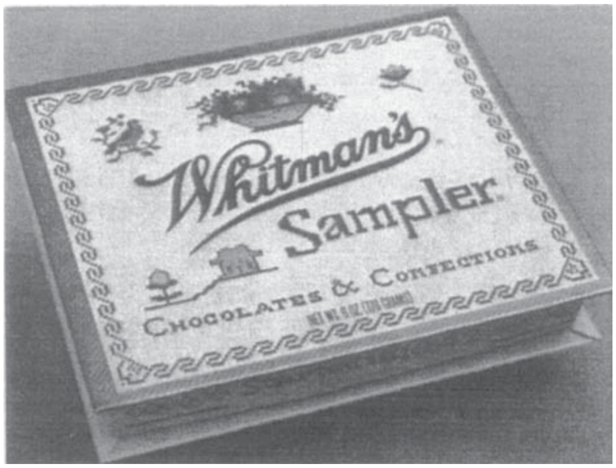

Figure 1. A familiar example of a rigid paperboard box.

wrap to the box), and outer wraps (for the decorative appearance).

There are four common types of chipboard used in boxmaking: plain, vat-lined, book-lined, and “solid news.” Plain chipboard is made entirely of waste paper, with the minimum of selection or de-inking of waste. Vat-lined chipboard provides a cleaner appearance. It is primarily chipboard with a liner (made of low-grade white waste paper) that is applied on the board machine at the mill. Book-line chipboard is chipboard with a liner of book or litho paper pasted to one or two sides as a separate operation. “Solid news” differs from plain chipboard in that the waste used in this sheet is a little more selected and is made mostly from newspaper waste that has been de-inked. Other boards are available, including glassine-lined, foil-lined, and folding grades of boxboard, but the four listed above are those that are primarily used.

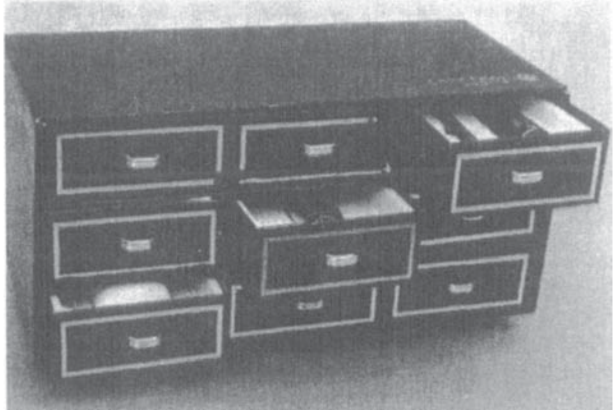

Figure 2. The high-fashion look of a lacquered wooden box is copied with style in the glossy finish and fine detail work of this rigid box designed for Lancôme cosmetics. Especially noteworthy is the registration of the gold-stamped border on the wrap of each separate drawer. Brass drawer-pulls complete the illusion. Shelves are sturdy and wrapped, allowing the drawer to slide in and out smoothly.

To properly serve the customer, a boxmaker must stock various sizes and weights of board. Setup boxboard is measured in basis weight: A 50-lb (22.7-kg) bundle of 50-basis-weight boxboard contains 50 standard 26 × 40-in. (66–102-cm) sheets; a 50-lb (22.7 kg) bundle of 40 basis weight boxboard contains 40 sheets. The larger the basis weight, the thinner the sheet.

Stay paper is almost always 7/8-in. (22-cm)-wide kraft or white paper. Glues are either animal- or starch-based, formulated to dry fast or slow. They are available in dry form for mix-it-yourself, or flexible form to melt as used. Most glue is hot-melted to give a faster drying and lay-flat quality to the paper with minimal warping (see Adhesives).

The final ingredient in box manufacturing is the outer wrap. There are thousands of stock papers, most of them available in 26-in. (66-cm) or 36-in. (91.4-cm) rolls. The wraps are generally paper, but foil and cloth wraps are also used. Through the use of artwork, photography, and good printing, a boxmaker can also produce a distinctive custom-made wrap.

Modern boxmakers make extensive use of CAD systems for samples and limited production runs, which are often cut on computer-driven plotter tabes (2).

APPLICATIONS

The rigid (setup) box has stood the test of time and competes well within its selected markets. It protects, it builds image, it displays, and it sells. The setup box possesses unique qualities that satisfy the specific needs of all four segments of the marketing chain: the consumer, the retailer, the marketer, and the product packager. The boxes are delivered setup and ready to load. Small “market-test” or emergency quantities can be prepared quickly at low cost, and individual custom designs are available without expensive investment in special tools, jigs, or dies. The rigid “feel” creates consumer confidence, and the manufacturing process permits utilization of varied overwraps to reflect product quality. The boxes are easy to open, reclose, and reuse without destroying the package. Rigid boxes are recyclable and made from recycled fibers. Production runs can be small, medium, or large, and volume can fluctuate without excessive economic penalities. In addition, these boxes provide lasting reuse features for repeat advertising for the seller. They are customized to provide product identity. Rugged strength protects the product from plant to consumer. Reinforced corners and dual sides provide superior product protection and minimize damage losses.

The markets for rigid boxes are as follows: tableware, jewelry and watches, perfumes and cosmetics, music and video games, stationery and office supplies, luxury beverages, chocolate and confectionery and gifts, boxed greeting cards, photographic trade products, engineering and DIY tools, and medical equipment (2).

BOXES, RIGID, PLASTIC

Richard M. Brasington
Buckhorn, Milford, Ohio

Rigid plastic containers have been used for many years in a wide variety of consumer and industrial applications. Some of the more familiar uses have been as the bread trays, milk crates, and beverage cases that one might see in a supermarket; as cosmetic and shampoo bottles; or as medicine bottles or blister packs used to display consumer goods on a store rack. Some of these and less-familiar uses are touched on in this article, and the processes used to produce this wide range of containers are covered as well. Finally, container configurations and applications in the emerging category of reusable shipping containers are described in some depth.

There are five major *processes* used to manufacture rigid plastic containers: injection molding, compression molding, blow molding, rotational molding, and thermoforming. Each process is suited to the production of a range of geometries with a variety of materials at different costs. A complete description of these processes, materials, and applications is beyond the scope of this article, but an overview is possible and will be helpful for later discussions.

TYPES OF MOLDING

Injection Molding

In this process a heated, softened plastic material is forced from a cylinder into a cool mold cavity, which results in a plastic product matching the geometry of the cavity of the mold. Generally, molds are expensive, but they produce the widest variety of part shapes at very high rates of production (see Injection Molding).

Compression Molding

This process uses preheated thermosets and high mechanical pressure to shape the material between male and female portions of a die. The mold cavities are preheated themselves, and the parts are removed after they have been cured under pressure. Many fiberglass and polyester parts are made with this method in which tooling costs are moderately expensive and production rates are moderately high. (see Compression Molding).

Blow Molding

This is most often used to shape hollow items like bottles. A tube of hot melt, called a *parison*, is extruded between the open halves of a chilled mold. The mold halves are clamped together, pinching off the tube at the ends. Air or an air and water mist is injected into the cavity, inflating the soft tube against the mold surfaces. Cooling time is quick, tooling costs are moderate, and production rates are extremely high (see Blow Molding).

Rotational Molding

This is also a process for producing hollow, seamless products. In this method, a powder or liquid plastic is placed in a mold; the mold is heated and rotated about two perpendicular axes simultaneously and then cooled. After the material solidifies, the mold is opened and the part is removed. Tooling and equipment costs are low, but production rates are slow, and the geometry of the parts produced is limited.

Thermoforming

This involves elevating the temperature of a thermoplastic sheet material to a workable level and forming it to shape. The forming process draws the sheet by a vacuum into an open, chilled mold. Like rotational molding, the tool costs are low, but production rates are slow, and there are limitations to the complexity of the part geometry.

REUSABLE SHIPPING CONTAINERS

All of these processes can be used to manufacture reusable shipping containers, but by far the most often used method is injection molding. This process is best suited for reusable shipping containers because it allows intricate shapes to be molded at high rates of production. The molds last a long time, and relatively low unit costs can be achieved.

The reusable shipping container (RSC) concept is simple: A container is loaded with product and shipped to its destination, where it is emptied. The empty container is sent back to the supplier, refilled with product, and then shipped again to its end-user destination. The cycle is then repeated over and over again.

While the concept is not new, its application in a wide variety of industries has spurred increased usage. Replacing expendable corrugated packaging with RSCs saves money, reduces worker injuries, and helps the environment. Money is saved by purchasing plastic containers once and reusing them instead of buying corrugated cartons each time a shipment is made. Worker safety and health are improved by providing easy-to-lift boxes with ergonomic handles. And the environment is helped by using recyclable plastic in the containers and eliminating the dumping of corrugated cartons in the landfills.

APPLICATIONS

Plastic reusable shipping containers have been used for years by wholesale bakeries shipping bread, by dairies shipping milk, and by soft-drink bottlers shipping 2-L bottles into supermarkets. More recently, drug chains, hardware stores, chain restaurants, and durable goods manufacturers have realized the benefits of reusables. Drug and grocery wholesalers pick from their incoming bulk shipments into reusable hand-held totes for split case shipment to individual stores where the contents are then unloaded onto retail shelves. Much of the recent growth in this category can be attributed to the automotive industry and their suppliers that ship component parts into assembly plants. The produce industry is another large user, harvesting into reusable containers in the field, shipping to the packing houses, and then sending them to supermarkets in the same container. This eliminates the cost of corrugated packaging and the double handling associated with repacking into corrugated boxes.

A relatively new application for reusable plastic shipping containers has been with bulk liquid loads. These are referred to as intermediate bulk containers (IBCs), and they are collapsible bulk containers with a plastic film liner. They have been used to ship tomato paste, liquid eggs, syrups, and cosmetics, to name a few. To provide the strength to carry liquid loads, these IBCs are made from either (a) an engineered resin or (b) hot-plate-welded high-density polyethylene (HDPE), or polypropylene. In hot-plate welding, two halves of the base and wall units are welded together with steel, fiberglass, or pultruded rods sealed inside the walls for rigidity.

TYPES OF CONTAINER

Various container types can be used in these applications, and most are injection-molded from HDPE, or polypropylene. Generally, there are four categories of RSCs: nest only, stack only, stack and nest, and collapsible. Each type has its advantages and disadvantages as outlined in the remainder of this article.

Nest-Only Containers

Nest-only containers (see Figure 1) have tapered walls that allow them to fit inside each other or “nest” when they are empty. These are inexpensive containers to make, but they require racks or shelves to sit on when they are full of product.

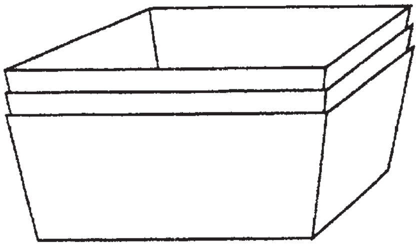

Figure 1. Nest only.

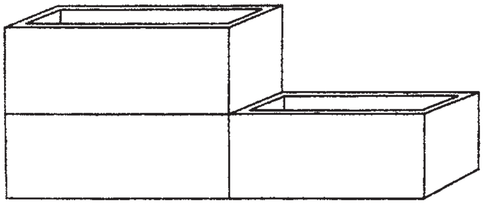

Figure 2. Stack only.

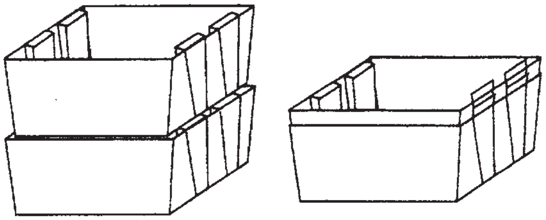

Figure 3. 180° stack and nest.

Stack-Only Containers

Stack-only containers (see Figure 2) have straight walls and good interior room for optimal utilization of interior space. They have excellent stacking stability and make good over-the-road containers. Because they stack only, they take up a lot of space and are inefficient when stored empty. Lids are not necessary for stacking, but could be used to keep dirt out of the containers.

Stack-and-Nest Containers

There are five types of stack-and-nest containers:

1. *90° Stack-and-Nest*. By turning a container 90°, containers can either stack on top of each other or nest inside one another. They do not need a lid and are generally inexpensive. Depending on the configuration, they can be good for over-the-road transport.
2. *180° Stack-and-Nest Containers*. (see Figure 3). Similar to the 90° version, with a 180° turn a container can be either nested when empty or stacked when full. Stacking posts on the inside ends of the container allow this versatility, but they take up interior room and take up potential product space.
3. *Attached-Lid Containers* (see Figure 4). These are nest-only containers with lids that are attached, usually by a metal hinge wire. They are ideal

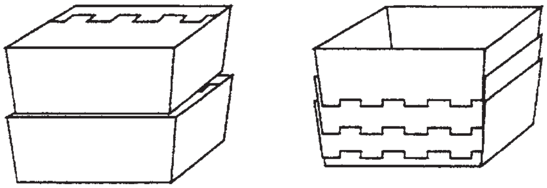

Figure 4. Attached lid.

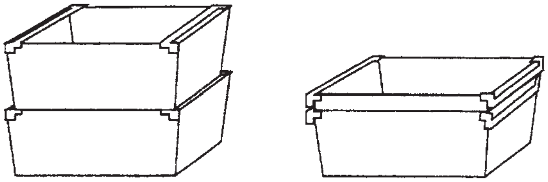

Figure 5. Bail.

over-the-road shipping containers and provide an excellent unitized load. They stack when the lids are closed and nest when the lids are open and are one of the most popular RSC.

4. *Detached-Lid Containers*. These are basically nest-only containers with lids that make excellent over-the-road shipping containers. They stack when the lids are snapped on, and, they nest when the lids are removed. These are the easiest lidded containers to clean, but do require keeping track of both boxes and separate lids.
5. *Bail Containers* (see Figure 5). These are nest-only containers with "bails" that flip in to allow stacking and flip outside the container to allow nesting. They make good transportation containers, are easy to clean, and do not require the tracking of separate lids and boxes.

Collapsible Containers

There are several types of collapsible containers. For bulk boxes (see Figure 6), which are generally built on a pallet base **and 30 in. high**, the most efficient design has side and end walls that are hinged at the base and fold inward flat on themselves. With straight walls, these offer excellent interior space utilization, and when they are empty and collapsed, they offer efficient storage. They generally come with optional detached lids.

Smaller collapsible totes (see Figure 7) offer the same interior space efficiencies and collapsible storage benefits as do bulk boxes. They are more commonly designed like collapsible bulk boxes, but some are designed accordion style as in Figure 7; both have collapsing design and can be open-topped or have a detached or attached lid. The accordion style can accommodate an attached lid as well.

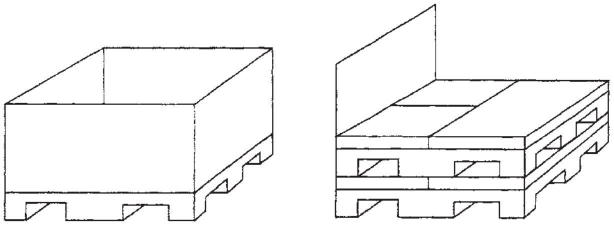

Figure 6. Collapsible bulk box.

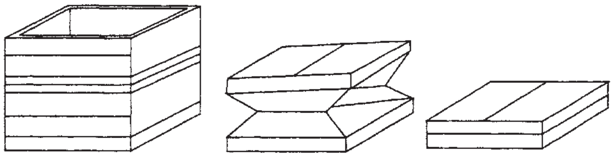

Figure 7. Collapsible tote.

BOXES, SOLID-FIBER

Robert Quinn
Union Camp Corporation
Updated by Staff

INTRODUCTION

Solid-fiber containers are used almost exclusively for applications in which container return and reuse are desirable and where return can be controlled by the distributor. Without such control, the impetus to use the multitrip shipping containers, which are more costly than corrugated boxes, would not exist.

As a rule of thumb, the solid-fiber box costs two to three times as much as a comparable-size general-purpose corrugated shipper. However, the solid-fiber container can be used an average of 10–15 times before retirement. The economics are obvious, but only in a "closed-loop" distribution system.

Solid fiberboard differs from corrugated board in several significant respects (see Boxes, corrugated). As its name implies, the former is a solid (nonfluted) structure consisting of two or more plies of containerboard. Four plies generally are used to manufacture board from which solid-fiber boxes are to be produced. Standard quality solid fiberboard is more resistant to water and damp conditions than are standard corrugate fiberboards.

FABRICATION

Solid board is made either on a multi-ply paperboard machine forming with vats or by a combination of forming methods. It is also made by multi-ply lamination. Solid fiberboard packaging is manufactured primarily from recycled material. It is both recyclable and biodegradable at the end of its useful life (1).

Solid-fiber sheets are constructed by gluing roll-fed containerboard plies together on a machine called a *laminator*. The plies are bonded under controlled pressure to form a sheet that comes off the line as a continuous strip that is subsequently cut to predetermined lengths (2).

Caliper of the finished board is the result of the number and thickness of individual plies. It varies according to the needs of the customer market. For most applications, finished sheet thickness ranges between 0.035 and 0.135 in. (0.089 and 0.343 cm). (In the industry lexicon, 0.035 in. is called 35 points). For special heavy-duty applications, solid fiberboard of 250-point thickness can be produced. This, however, is the exception. For the largest market (shipping containers), board thickness averages 70–80 points (0.18–0.20 cm).

When the continuous web of solid fiberboard exits the laminator, it is cut to length. Converting equipment prints, diecuts, and, if needed, coats the material with polyethylene or other protective finish. Solid fiberboard packaging is supplied flat to save space in storage and distribution. It can be erected by the packer manually or with mechanical assistance (1). When product volume is high and a high packing speed is required, fully automatic machinery is used for erecting, packing, and closing.

A principal difference in construction between solid-fiber and corrugated boxes is that rail and highway shipping-authority rules limit solid-fiber boxes to only two styles of manufacturer's joints; stitched and extended-glued. Standard methods for testing solid-fiber boxes have been developed and published by the American Society for Testing and Materials (ASTM) and the Technical Association of the Pulp and Paper Industry (TAPPI). Common-carrier requirements for solid-fiber box performance (burst strength, size, and weight limits) have been established and are fully detailed in Rule 41 of the Uniform Freight Classification (rail shipment) and Item 22 of the National Motor Freight Classification (truck shipment) (see Laws and regulations).

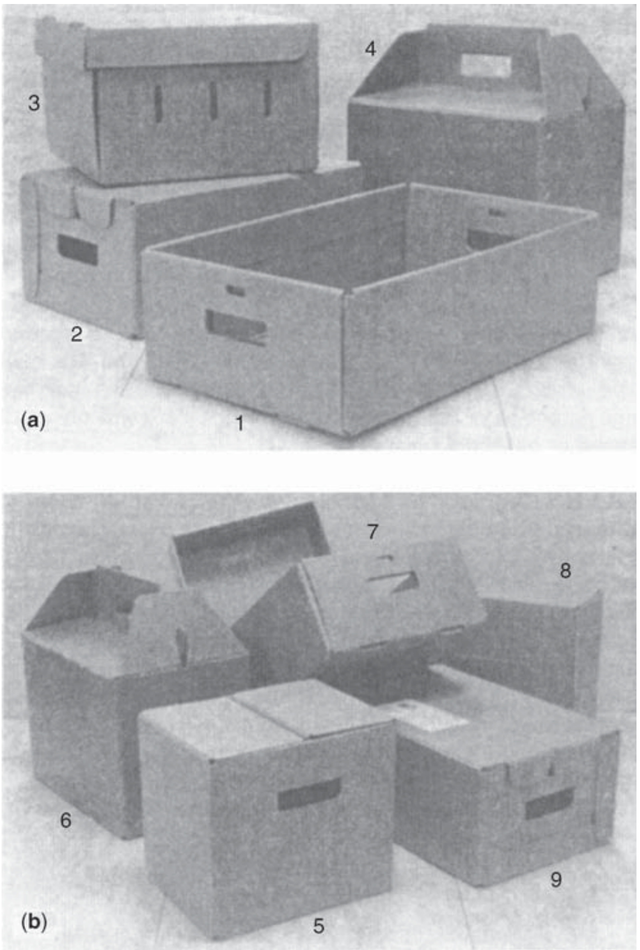

Figure 1. Solid-fiber beverages cases and tote boxes. (a) 1, One-piece bin box with locking feature; 2, three-piece 24/12-oz. (355 mL) beverage case; 3, one-piece vegetable box; 4, attache-style tote box. (b) 5, one-piece 4/1-gal (3.785-L) beverage case; 6, attache-style tote box; 7, one-piece lidded tote box; 8, one-piece self-locking tote box; 9, three-piece 24/12-oz. (355 mL) beverage case.

APPLICATIONS

Solid fiberboard is used in a wide range of packaging and display applications such as the packaging of horticultural produce, meat and poultry, and fish. Beer bottles and cans are packed in a wrap-around lithioprinted multipack. Compartmentalized machine-erected trays are typically used for multipacks of plastic yogurt cups. Solidboard is also used in shoe box packaging. Products that are heavy, are likely to shift during transportation, require protection, and possibly have protruding parts need the protection of puncture-resistant solid board. It is also used for export packaging (1).

After containers, the largest use of solid fiberboard is for slip sheets. Slip sheets are used in materials-handling applications, chiefly as replacements for bulkier and more expensive wood pallets. Designed for forklift handling and requiring minimal warehouse space, solid-fiber slip sheets are easy to use and store. Slip sheets are made from three plies of kraft. Polyethylene-lined board and hard-sized board can be used for wet/damp conditions. An anti-skid varnish can be applied to the slip sheet to assist load stability (1).

Divisions or partitions of solid fiberboard are used to create cells in a case or box wherein individual items and packaged products can be placed. It is superior to corrugated board for this purpose and does not indent with the shape of the upturned container. Other uses include point of purchase displays, furniture (sheets are affixed to the wooden framework to provide a firm backing for upholstery), and mirror backing. Automative applications include non-load-bearing interior bulkheads. Drums, railcar dunnage, and wire- and-cordage reels, are other miscellaneous uses in which solid fiberboard's strength, damage resistance, and machinability are cost-effective.

See Figure 1 for some examples of solid-fiber containers.

BOXES, WOOD

The use of wooden boxes and crates dates back to the Industrial Revolution, when the building of roads and railways led to their development as the first "modern" shipping containers (1). (See also Boxes, wirebound; Pallets, wood.) They still are used today for products that require the strength and protection that only wood can provide. The difference between a box (or case) and a crate is that a box is a rigid container with closed faces that completely enclose the contents. A crate is a rigid container of framed construction. The framework may or may not be enclosed (sheathed) (2).

BOXES

Box styles. Wooden boxes are of either “nailed construction” or “lock-corner construction.” Of the eight basic box styles shown in Figure 1 (3), Style 6 is the only lock-corner construction. The others are nailed (cleated).

Wood. Specifications for wooden boxes refer to the categories developed by the US Forest Products Laboratory, which relate to strength and nail-holding power (see Table 1). Groups 1 and 2 are relatively soft; Groups 3 and 4 are relatively hard. For a given box of a given style, the thickness of the wood and cleats depends on the type of wood.

Fastenings. The strength and rigidity of crates and boxes are highly dependent on the fastenings, which are as follows: nails, staples, lag screws, and bolts. Nails are the most common fastenings in the construction of boxes. The size and spacing of the nails depends on the type of wood (5).

Loads. The type of load is determined by the weight and size of the contents and its fragility, shape, and capacity for support of, or damage to, the box. Load types are classified as Type 1 (easy), Type 2 (average), or Type 3 (difficult). Descriptions and examples of each load type are contained in Ref. 5.

CRATES

A wood crate is a structural framework of members fastened together to form a rigid enclosure that will protect the contents during shipping and storage. The enclosure is usually rectangular and may, or may not, be

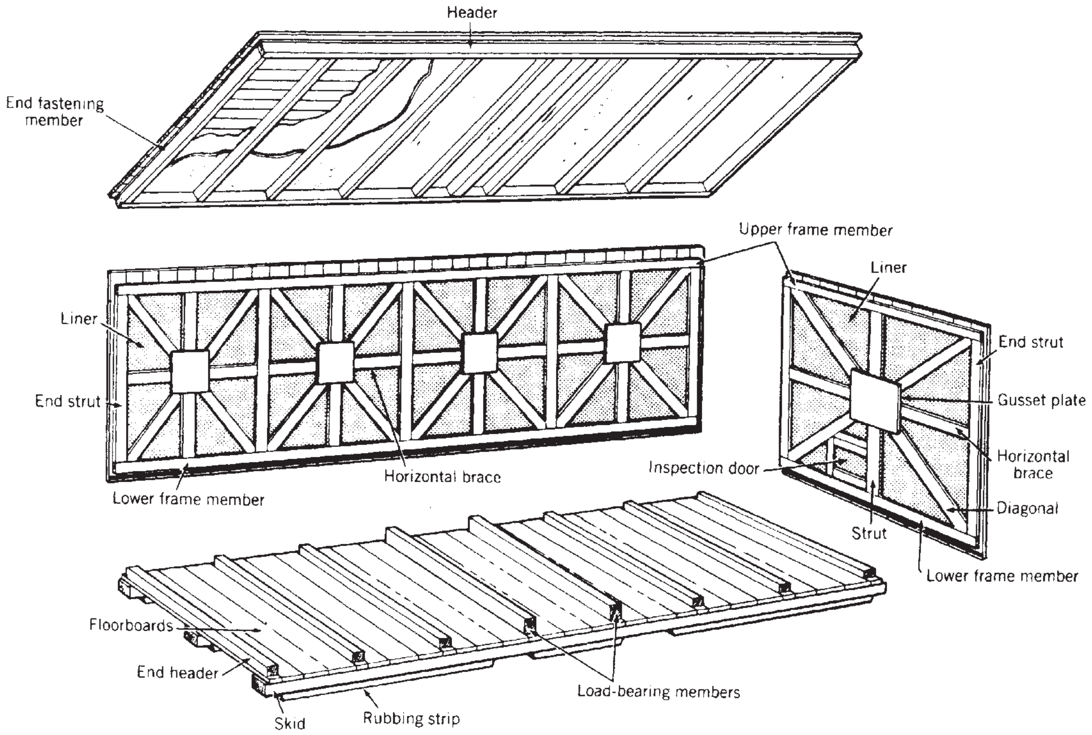

Figure 3. Plywood-sheathed crate.

sheathed (4). A crate differs from a nailed wood box in that the framework of members in sides and ends must provide the basic strength. For its strength, a box relies on the boards of the sides, ends, top, and bottom. A crate generally contains a single item, and its dimensions are not subject to standardization. The function of a crate is to protect a product during handling and shipping at the lowest possible cost. A simple enclosing framework is shown in Figure 2 (4).

Some products and shipping conditions require greater protection. The value of the contents or the likelihood of top loading may dictate the use of a sheathed crate (6). The sheathing can be lumber or plywood. A plywood-sheathed crate is shown in Figure 3 (4).

BULK PACKAGING

Peter Henningsen
Minnetonka, Minnesota

Bulk packaging is an economical solution for the shipment of many different types of product. Continuing advancements in the materials applicable to constructing bulk containers contribute to increasing acceptance in their use. These factors, together with lower materials-handling and freight costs, combine to create an effective shipping container system that meets the needs of the product, the shipper, and the customers.

BULK PACKAGING CONSIDERATIONS

Almost all types of product present possibilities for use of bulk containers. Successful applications include chemicals, liquids, pastes, metallic powders, resins, food items, automotive parts, and grains. Although metal, plastic, and fiber drums are a form of bulk containers, these materials are not included here as they are specifically covered in other articles of this encyclopedia. Planning for use of bulk containers should include the following analysis.

Product Needs. These needs include physical and chemical properties, such as sensitivity to moisture gain or loss, flow characteristics, loading and unloading, compatibility with packaging materials, vapor emissions, protection from oxygen, retention of various gases, physical protection, and normal production volumes.

Product Weights. Depending on the product and the container used, shipping weights of 2000 lb (907 kg) and more are common, and some dry, flowable products that weigh up to 8000 lb (3629 kg) are being sucessfully shipped.

Container Costs. Weight and size of product, production volumes, loading and unloading requirements, and methods of storage and transportation are all key elements in the design process. It is essential to design for optimum cube in storage and in the transportation vehicle to realize the most benefits.

Lightweight products may reach vehicle weight limits before cubing out. For heavy products, stacking strength to use warehouse space effectively is a major point. Container base dimensions must relate efficiently to both storage and transport vehicle size and incorporate a solid base for handling. Typical sizes are 48 in. × 40 in. (1219 mm × 1016 mm) and 44 in. × 35 in. (1118 mm × 889 mm). Many other sizes are used, which depend on distribution requirements.

Container Types. Markets served and distribution needs determine selection of the most cost-effective container. Woven plastic films, corrugated containers, rigid plastics, metal, and wood products are materials commonly used. Reusability reduces total costs, and the ease of disposability at the end of container life is important. The automotive industry makes great use of returnable bulk containers for parts and assemblies feeding their production lines. Ingredient packaging for food products is another major use.

Customer requirements for use of the product are important. Special features can be designed into containers to facilitate filling and emptying. All containers must be equipped to accept applicable materials-handling devices—forklifts, cranes, hoists, slings, pallet jacks, etc.—used to load, store, move, and unload the containers at all points in the distribution cycle.

MATERIALS USED FOR BULK CONTAINERS

The most commonly used materials are described below. Table 1 shows a comparison of some attributes of various container materials.

Corrugated. Widely used for bulk containers, corrugated containers can be designed to compensate for bulge resistance, puncture resistance, and stacking strength as needed. Variations in board construction that provide necessary properties include one-piece liners, two-piece inners, as well as three-ply and/or eight-sided (octagonal) shapes. Board used can be single, double, triple wall, or

Table 1. Comparative Attributes of Container Materials

General Material Category	Reuse	Disposability	Tare Weight	Durability	Resistance to Shipping Environment	Container Cost Advantage	Freight Cost Advantage
Corrugated	Good	Best	Best	Good	Good	Best	Best
Bags	Better	Good	Best	Better	Better	Better	Best
Rigid plastic	Best	Good	Better	Better	Best	Good	Better
Metal	Best	Best	Good	Best	Best	Good	Good
Wood	Better	Better	Good	Better	Better	Better	Better

combinations thereof. Within supplier equipment limitations [up to ~180 in. (4572 mm) in perimeter and 55 in. (1397 mm) in depth], many different sizes and shapes are possible. Box liners are used as needed to ensure product protection. Containers are easily disposed of and can be designed for reuse. Container surfaces readily accept graphics for product and company identification.

Bags. Many uses for bags are possible because of the multitude of films and laminations available for fabrication. Woven polypropylene fabrics are most common. Use of rubberized plastic films greatly increases bag strength. If needed, then special extrusion coatings or additional protective liners can be used for special product needs. Most uses are for dry products. Bag handling is usually accomplished through four corner lifting loop straps sewn into bags at the top. Common bag sizes are usually up to 66 ft^3 (7.8 m^3). However, recent designs that use rubberized nylon and DuPont Kevlar provide the ultimate with bags up to 9 ft (2.74 m) in diameter and 10 ft (3.05 m) high, which hold up to 25 tons (2268 kg). Bags are collapsible when empty, light in weight, and can be designed for reusability (see Bags, plastic).

Rigid Plastics. Designs for rigid plastic containers can be made to meet all expected requirements for bulk packaging. They can be collapsible, lightweight, and usually up to 34 in. (864 mm) in depth. They are adapted to product needs by selection of compatible plastic resins for molding and/or addition of protective liners. These containers are generally more costly than other types but can be justified in a total system concept through recycling and reuse. Plastic containers are resistant to normal environmental hazards such as moisture and water. Temperature extremes—low or high—are addressed by specific material selection. Some plastics may be adversely affected by exposure to sunlight. Plastics often are used in captive systems for handling and moving product between multiple plants of a single parent company.

Metal. Metal containers in the form of drums were among the first types of bulk container. The possibilities for metals to meet many different product needs—high or low temperatures, corrosion resistance, longevity, chemical compatibility, shipping weight and cube, etc.—are significant. They can be closed-wall, cage-wall, collapsible, and even expandable by adding tiers to a base container. Metal returnables commonly are used for handling and shipping automotive parts and assemblies from suppliers to assembly plants. The quantities involved make disposing of packaging materials costly. Efficient container design, which includes internal components, provides for reuse and physical protection. Metal containers are usually heavier than other container types.

Wood. Wood is adaptable to the design of bulk containers to meet many different product demands. Styles include open crates, cleated plywood, and wooden boxes. Containers can be designed for knocked-down shipment when empty to reduce space and freight costs. Reusable fastening devices are available to close many types of box construction. Box liners in various types are used to satisfy special product needs. Wirebound boxes represent a specially designed box or crate to reduce weight and increase strength and are successfully used in bulk product shipments.

CONTAINER TESTING

ASTMD-4169 provides for definition of test elements and the applicable test procedures for shipping units to meet specific distribution patterns. Performance can be measured against any one of three assurance levels as determined by the shipper. Preshipment testing is essential for bulk container validation.

CAN SEAMERS

Otto L. Heck
Richard Cabori
Angelus Sanitary Can Machine
Company, Los Angeles,
California

Can seamers are machines that mechanically attach component ends to can bodies in a reliable manner. Around 1900, the sanitary can made its appearance in Europe, where both top and bottom ends were double-seamed to the can body. The term “sanitary” indicated that solder was not used in the ends being double-seamed, but only on the outside of the can body side seam (1). In 1910 Henry Louis Guenther, inventor and manufacturer, introduced can seamers for double seaming that met the requirements of modern food and beverage processing. His products, which are sold under the trade name of “Angelus,” were so well introduced that they are now used by the largest food, beverage, and can manufacturing companies in the United States as well as abroad (2). Basically, there are two categories of can seamer: In can manufacturing they are called *can shop machines*, which attach the first end on a three-piece can, and in product filled cans they are called *closing machines*, which attach the last end on either a two-piece or three-piece can.

THE DOUBLE SEAM

The preservation of canned products requires hermetically sealed cans. The process of creating an airtight closure by attaching the can end component to the can body is called double seaming. This double seam is a metal-to-metal joint formed by mechanically interlocking five layers of metal together: three from the can end and two from the can body (3). These layers are then compressed and ironed tightly to form the hermetic seal (see Figure 1). The can seamer sometimes referred to as a double seamer requires two seaming operations to produce a quality seam formed by the machine’s seaming rolls as the can body and can end are held together by a vertical load applied between the lower lifter and the seaming chuck as the can parts move through the machine. During this seaming cycle the can end and can body meet, and the first-operation seaming roll contacts the can end and begins curling the can end around the can body flange. A second-operation seaming roll follows, which tightens and irons out the seam between the can body and can end forming an airtight hermetic seal between the two parts (see Figure 2).

The double seam is a critical can component for a proper seal. Every angle, radius, and dimension must be correct to ensure a hermetic seal (4). The double seam is defined as follows: “The curl on the can end containing sealing compound and the flange on the can body are indexed and rolled flat, forming five folds of metal. Sealing compound between folds gives an airtight seal (5).”

METHOD OF SEAMING

There are two basic seamer designs: can spin and can stand still. Practically all closing machines designed in the early years were of the can stand still type incorporating up to four seaming heads and operation at speeds ranging from 25 to 275 cans per minute. The can-stand-still design is still used extensively and in many cases is a necessity due to the products being closed, such as shortening or some fine powders. In this design the nonrotating can body and can end are assembled between the knockout rod pad and the lower lifter or base plate table. The knockout rod pad keeps the can end firmly in place as the lower lifter (which is synchronized with the knockout pad) raises the can body and can end into the seaming position on the seaming chuck. First operation seaming rolls, which are diametrically opposite each other in a seaming head, revolve around the stationary seaming chuck, and pressure is applied through cam action to form the first operation. After the first operation is completed to the proper thickness, the second-operation seaming rolls, which are diametrically opposite each other, iron out the double seam to the proper thickness. After the seaming operations are completed and the second-operation seaming rolls have been released, the knockout rod follows the seamed can away from the seaming chuck as it is being lowered to the discharge position by the lower lifter (6).

As canning speed requirements increased, can spin or rotating-can-type seamers were developed using a multi-station design. Machines with 4 to 18 seaming stations are in use, providing production speeds of 100–2300 cans per minute (see Figure 3). Can ends are automatically separated and mated with the can bodies in the seaming

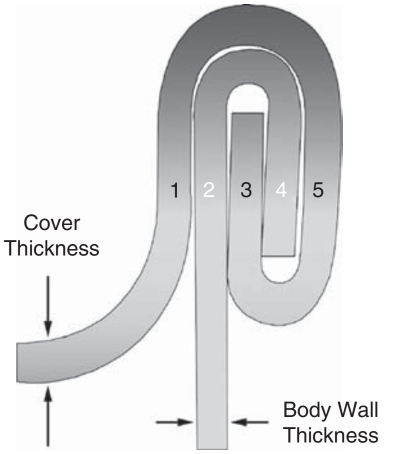

Figure 1. Double seam made of five layers compressed and ironed tightly to form a hermetic seal.

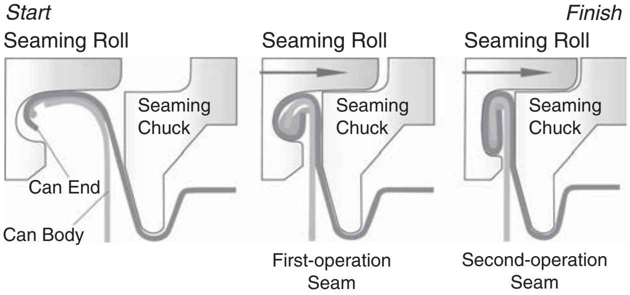

Figure 2. A schematic of the double-seam process.

position. The knockout rod pad contacts the can end while the lower lifter, synchronized with the knockout rod pad, lifts the can body and can end into position on the seaming chuck. On thin-walled lightweight cans the machine design incorporates driven seaming chucks and driven lower lifters to prevent *can skid* or *can buckling*. One first operation seaming roll actuated by a cam forms the first operation seam. After completion of the first operation seam, the second operation seaming roll actuated by a similar cam action irons out the seam to the proper thickness.

MACHINE TYPE BY APPLICATION

Can seamers are typically manufactured in five machine types for seaming can ends to can bodies: can shop, atmospheric, mechanical vacuum, steam vacuum, and undercover gassing.

1. *Can shop*. For can manufacturing: this attaches the first end on three-piece cans.
2. *Atmospheric*. For can closing products not requiring removal of oxygen for preservation—that is, soaps, petroleum products, frozen products, and hot products > 180°F.
3. *Mechanical vacuum*. Evacuates oxygen from headspace of can for preservation of product at slow speeds—that is, vegetables, specialized powdered products.
4. *Steam vacuum*. Evacuates oxygen from headspace of can with steam for preservation of product at high speeds—that is, fruits, vegetables, soups, fish, meat products, and juices.
5. *Under-cover gassing*. Displaces oxygen in headspace of can with a gas, such as carbon dioxide or nitrogen, to extend shelf life and/or increase internal can pressure for thin-walled aluminum cans—that is, beer and soft drinks.

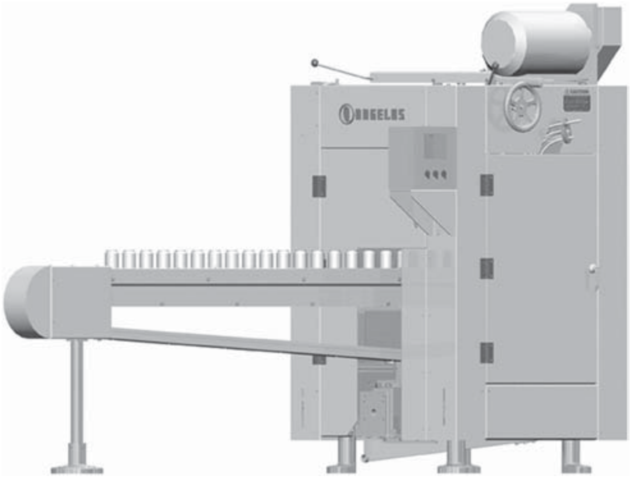

Figure 3. Can seamer.

Generally, during the process of a modern automated canning operation, cans are filled with a measured amount of product, then transferred from the filler to the can feed table of the seamer. This transfer from the filler to the seamer is critical and must be timed in such a manner to avoid can damage, product spill, or extreme product agitation, thereby rendering a smooth flow of cans and product into the seamer. As the cans move into the seamer, they are sensed by a mechanical, electrical, or optical device that triggers a signal to separate one can end from a stack and feed it in a synchronized rotary manner to an incoming can. Generally, the timing of machine operations is mechanically controlled by cams and there is a dwell period for steam vacuum and undercover gassing applications as stream or gas is injected between the top of the open can and the can end prior to their contact. Filling the headspace of cans with steam or gas displaces the air, preserving the quality of the canned product. After the can parts meet, they move through the seaming cycle of the first and second seaming operations and then the cans are discharged from the machine.

MACHINE SETUP

Can seaming machines are designed to double-seam a given range of can diameters, can heights, and speeds. Can diameters and can heights are expressed in both inches and millimeters, but generally use an industry nominal diameter, such as 200, 202, 206, 207.5, 209, 211, 300, 303, 307, 401, 404, 502, and 603. Industry nominal diameters are defined as follows: The first digit equals inches; the second and third digits equal 1/16 fraction of an inch. For example, a can with a nominal 211 diameter would be the equivalent of $2\frac{11}{16}$ in. and a can with a nominal 307 diameter would be the equivalent of $3\frac{7}{16}$ in.

It is very important that the machine be setup to the correct specification for the type of can end and can body, diameter of the can end and can body, and material thickness of the end and can body. Important setup procedures include the following:

1. Checking the fit of seaming chuck to can end.
2. Initially installing only the first operation seaming rolls. Remove second-operation seaming rolls if in place.

3. Installing seaming chucks and checking that the first operation seaming rolls do not interfere with the seaming chucks when in the seaming position.
4. Setting lower lifter assemblies to correct height relationship with can feed table.
5. Setting lower lifter spring pressure to proper load with an appropriately calibrated instrument, such as a Dillon force gauge or force cell gauge.
6. Setting pin height with an appropriately calibrated instrument, such as a pin height gauge or planer gauge.
7. Setting the first operation seaming rolls on each station to a specified seam thickness using a wire gauge of the proper diameter. Run samples of first-operation seamed cans to verify quality of seam. Visually inspect seam while measuring the seam thickness, seam width, and countersink depth.
8. Installing and properly adjusting the second operation seaming rolls to the seaming chucks on all stations to the specified seam thickness. Run samples of the finished second operation seam. Visually inspect the seam while measuring the seam thickness of the finished seam to given specifications using a properly calibrated seam micrometer. Finally, tear down the second operation seam for further inspection.

KEY FEATURES AND ATTACHMENTS

Depending on the application and production requirements, can seamers are equipped with features and various attachments to meet the demands of industry processors.

Automatic Stops. For safety reasons, machines are equipped with mechanical, electrical, or optical sensors that cut power to the motor, actuate the clutch release unit, and apply the brake to stop the machine rapidly. These safety devices are located at critical areas on the machine.

Filler Drive Seamer Safety Clutch. A safety overload clutch is used to protect the can seaming machine in case of a severe can jam or mechanical failure in the filler.

In-Motion Timer. This is a timing attachment located between the seamer and filler that synchronizes the transfer of cans from the filler pockets to the seamer feed chain fingers during machine operation.

Can Coding Markers. There are two types of markers—mechanical and ink-jet—used to place the processor's identification code on can ends. Mechanical markers use type dies that are capable of debossing and embossing identification characters on can ends. Debossing is where the characters are indented into the top of the can end, and embossing is where the characters are raised on the top of the can ends. Mechanical markers are driven by the seamer and have speed limitations up to 1000 cans per minute. They are used primarily on sanitary food cans. Ink-jet markers are not driven by the seamer and use a nozzle assembly device to print droplets of ink to make up characters forming alphanumeric or bar codes. Ink-jet markers apply clear codes to virtually any surface at nearly any production speed, using a programmable controller and software to monitor the ink quality, size, font, and lines of print.

Automatic Lubrication. Metered amounts of grease and/or oil are automatically delivered by pumps to designated machine areas requiring lubrication while the machine is operating.

Automatic Oil Lubrication Recirculating and Filtration System. This system continually filters water and particles from the recirculating oil. The lubricating oil is pumped and recirculated through the machine, reducing the amount used and the environmental concerns of discarding cycled oil.

Programmable Controller. This provides electrical monitoring of seamer functions and operates auxiliary equipment.

Driven Lower Lifters. Also referred to as *driven lower chucks or driven baseplate tables*. They accept incoming can bodies or product-filled cans from can infeed devices before being raised by a cam action to meet can ends to be seamed at the make up area. They are gear-driven and rotating in a synchronized design with the seaming chucks to provide stability and enhance can control during the seaming cycle process. Driven lower lifters use a preset spring pressure, which is a vital component in the formation of a double seam.

SEAM TIGHTNESS EVALUATION

Generally, in order to stand the rigors of processing, handling, damage by abuse, and distribution, as well as to ensure product shelf-life, the tightness of the seam is critical and should be evaluated carefully. During the formation of a double seam the proper tightness assures that the sealing compound will fill all the spaces not occupied by metal.

Seam tightness is normally evaluated by the degree of waviness or wrinkle found in the cover hook. This wrinkle is formed by compression of the curled outer edge of the can end as it is folded back under the body flange. By increasing the pressure of the seaming rolls, the wrinkle can be ironed out to a smooth strip; and by loosening the rolls, the wrinkle is increased (7). Wrinkles may be classified by a tightness (wrinkle) rating as shown in Figure 4. A 70% wrinkle rating equates to a 30% wrinkle in the cover hook or 70% of the cover hook is wrinkle-free. Less than 70% tightness is considered too loose. There are other numerical cover wrinkle rating systems used: The Dewey and Almy wrinkle rating uses a 0–10 scale in which absence of wrinkle rates as 0 and a full-width wrinkle rates as 10: another uses a 0–3 rating system. The rating for each end component is based on the worst or deepest wrinkle, because it is at this point or area that the seam is

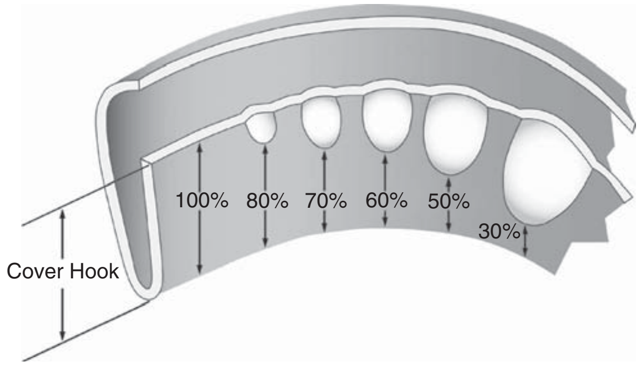

Figure 4. Wrinkles are rated by the percentage of tightness.

most vulnerable to abuse, leakage, and penetration by bacteria.

In hemming a straight edge of metal, no wrinkles are formed. On curved edges, wrinkling increases as the radius of curvature decreases. For this reason, different wrinkle ratings are specified for small-diameter cans as compared to large-diameter cans (8). A 100% wrinkle rating of a 211 diameter can indicates that the seam may be too tight and should be watched for possible defects such as cutovers, droops, and unhooking. A 100% wrinkle of a 603 diameter can would not necessarily be too tight. With most can seamers using standard seaming roll profiles, the ideal seam almost invariably shows a slight wrinkle, except on 603 diameter and other large-diameter containers.

MEASUREMENT OF PERCENTAGE OVERLAP

The overlap of a double seam is expressed as a percentage of the maximum possible overlap. A minimum percentage of 55% is considered acceptable. The percentage overlap of the seam is established by first measuring the internal seam length, a measurement between the inside of the cover hook and the inside of the body hook, and rating this length as 100. The measured length of the actual overlap is then a portion or percentage of that length calculated (B/A × 100 = percentage overlap) (see Figure 5).

PROFILES OF SEAMS

A properly formed first-operation and second-operation double seam requires the correct adjustments of pressure of the seaming rolls and lower lifter or base plate table. The shape and conformity of the finished seam is determined by the taper and fit of the seaming chuck to the top of the end component and the contoured profile of the seaming rolls. The seaming roll profile is a groove around the circumference of the roll which varies with the diameter of the can to accommodate variations in material, material thickness, cover curl, body flanges, and seam specifications of the user. For any given can diameter, there may be a number of roll profiles, which will properly form the double seam. First-operation and second-operation roll profiles are uniquely different. As the first operation seaming roll profile contacts the cover curl, the flange of the can bends over to form the body hook and the edge of the cover tucks underneath to form the cover hook. The second-operation seaming roll profile completes the seam formation by compressing the seam so that the hooks interlock tightly and any metal voids or spaces are filled with the sealing compound.

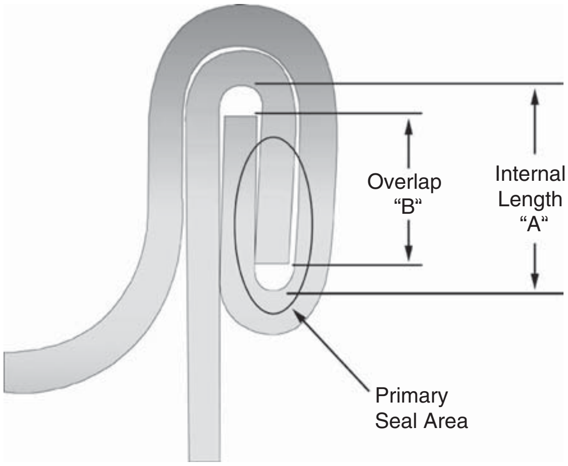

Figure 5. Overlap measurement.

CAN, COMPOSITE, SELF-MANUFACTURED

Two basic types of self-manufactured composite cans are produced in-house by packagers. One is the traditional spiral-wound or convolute composite can, the familiar form used for motor oil, orange juice, and cocoa-based products (see Cans, composite). A more recent development is the use of folding-carton material for the production of self-manufactured paperboard cans that use composite materials in the folding-carton base stock. A newer innovation is a paperboard can that is hermetically sealed and capable of holding a gas environment.

Composite Cans. A typical example of self-manufacturing of a traditional composite can is a system known as Sirpack. This system, from Sireix (France), installed in the packager's manufacturing facility, produces composite cans that can be round, square, rectangular, or oval. The cans are produced from a continuous form-and-seal process from four reels of material in a horizontal fashion. The materials are shaped around a forming mandrel and sealed, generally by a hot-melt adhesive (see Adhesives). The inside liner is heat-sealed for excellent moisture and liquid tightness (see Sealing, heat). The reels of material are slightly staggered to each other so that the sealing lines on the four materials do not superimpose. The inside materials that provide moisture and liquid tightness are generally made from a plastic film or aluminum foil (or both), according to the protection needed for the product. The outside laminate can be printed by web rotogravure, or web offset (see Printing).

The bottom is generally a metal end, but it can also be made of a composite material matching that of the sidewall. It also can be one of the many plastic closures available. Generally, the top is a heavy injection-molded plastic that is heat-sealed to the upper edges of the container. In most cases, the cover incorporates an easy-open device that allows a separation or opening of the lid and can be reclosed after removing a portion of the product.

The main advantages of the in-plant Sirpack system are that it permits the option of various sizes (material options) and the ability to save the conversion cost normally paid to the converter of the composite cans. Added to this benefit are other savings, such as the savings in floor space and warehousing of empty composite cans prior to use in the filling and closing process. The machinery is relatively compact and easy to maintain. It has been designed for in-plant production with the average mechanic in mind.

Paperboard Cans. Several companies provide systems for in-plant manufacture of paperboard cans. They include folding-carton companies such as Westvaco (Printkan), International Paper (CanShield), and Sealright (Ultrakan). All of their packages are low-to-moderate barrier paperboard cans that can be manufactured in the packager's facilities. Another paperboard can, Cekacan, offered in the United States by Container Corporation of America, provides a high-barrier, gastight supplement to the paperboard-can list. All the paperboard cans are formed from a flat blank and assembled into either a straight-wall can or a tapered-wall can. In some cases, e.g., CanShield, the use of paper-cup technology has been employed to develop the vertical-wall paperboard can.

A paperboard can is described as a semirigid container with the body sidewall fabricated from a single sheet of folding-carton-based material, wound once and sealed to itself, with either or both ends closed by a rigid or semirigid closure. The typical paperboard can has three pieces, which are as follows: a single-sheet single-wound body, a single sheet of base material fixed to one end, and a closure. The system almost always is made in line with the packager's filling and closing operations, but it also is possible to manufacture to storage. The can body can be cylindrical, rectangular, or combinations thereof, but most are cylindrical. Commercial or prototype paperboard cans range in size from 2 to 10 in. (0.8–3.9 cm) high, and up to 6 in. (2.4 cm) in dia, but mostly are confined to a maximum 5.25-in. (2-cm) dia and 3–10-in. (1.2–3.9-cm) heights.

In the CanShield construction, the paperboard sidewall is rolled into a cylindrical shape and the two edges are overlapped and sealed. Continuous thermofusion along the seal is effected by bringing the coating on one or two edges of the blank to a molten state, i.e., by direct contact with a heated plate, or more recently, by blowing hot air onto the edge, bringing the two edges together, and applying pressure. Usually a polyolefin, e.g., polyethylene, is used on the surface of the board to provide the adhesive factor. A disk of paperboard with a diameter approximating that of the cylinder is crimpfolded around its perimeter to form an inverted shallow cup. This base piece is positioned in one end of the hollow cylinder so that the bottom edge is about 1/4 in. (0.64 cm) below the edge of the cylinder. The edge of the inner periphery is heated and crimpfolded over to lock and seal the disk in place. In this manner, the outer peripheral of the base is sealed to the inner perimeter of the cylinder wall. The segment of the outer wall extended beyond the inner disk then is heated and folded over to come in contact with the inner side of the disk. A spinning mandrel applies pressure to the base of the cylinder to effect the final seal.

The result is a primary seal between the bottom disk and the sidewall and a secondary seal, wherein the sidewall is folded over, which captures the disk with an additional seal. For the rectangular version, the base piece is forced against the body wall under pressure using an expanding mandrel to seal the base to the body. Here too, the material for sealing is usually polyethylene, and hot air is used to bring the material to a molten state to act as a sealant. On the round containers, the top is usually rolled out and the closure, e.g., a foil membrane, is adhered to the top rolled edge after the product has been placed into the paperboard can. On the rectangular version, the top rolled edge is generally closed by a rim closure that clamps onto the periphery of the opening and is sealed into place by induction or by glue. The rim then acts as a holder for a full panel closure.

The Ultrakan concept is similar to the CanShield in that the body wall is wrapped around a mandrel and the two edges are overlapped and heat-sealed to each other. The bottom disk is inserted in the container, and the body wall and bottom disk are heated and crimped or rolled together. Thermoplastic hot-melt adhesive may be used for added security and seal strength. The interior edge of the sideseam can be skived to enhance WVTR or greaseproofness of the container, or both. The top of the Ultrakan container can be finished in a variety of ways that include the following: rolled outward (to accept a membrane seal); flared (for a variety of seamed metal ends); rolled inward (for special thermoformed or injection-molded plastic closures); or gently flared (for insert rotor/dispenser style closures). The Ultrakan system also provides the option of customizing by special bottom techniques, which offer dispensing features for granulated products, powders and paste, or semiliquid sauces or condiments.

A high barrier paperboard can has been introduced from Sweden (Cekacan). By incorporating the use of polyolefin

Table 1. Comparative Water-vapor Transmission[a]

Product	Conventional Package	Rate of Moisture Pickup at 75°F (24°C) and 100% rh, wt % per Week	
		Conventional Package	Cekacan
Dehydrated sweetened beverage powder	26.5-oz (751-g) composite can	0.03	0.0075
Powdered soft-drink mix	34.0-oz (964-g) composite can	0.02	−0.0025
Sweetened cereal product	12.0-oz (340-g) bag-in-box	0.2	0.04
Snack	7.5-oz (213-g) composite can	0.01	−0.01

laminates (see Laminating) along with foil and a special means of sealing the package, a hermetic seal has been demonstrated, which makes the package virtually impermeable to gas, liquid, fat, etc. (see Table 1). The Cekacan system involves both a canforming operation and a can-closing operation. In the forming operation, the sidewall is wrapped around a mandrel and butt-seamed (not overlapped). Just prior to the wrapping operation, a foil-laminated tape is induction-sealed to one edge of the blank. With the seam butted, an induction sealer affixes the tape to the interior of the can in such a way as to provide a continuous hermetic seal along the longitudinal seam.

The package is transfered to an end-closing device, wherein a top or bottom closure is affixed. In this case, the closure is inserted into the can with the closure sidewalls flanged to the vertical position. Through the use of pressure and induction sealing, the disk is hermetically sealed into place. The package is then discharged for filling and brought back to the second piece of equipment, which inserts and hermetically seals the final closure. Closures are available that provide easy opening without compromising the gastight integrity of the package. Through the use of a butt seam, held together with sealable tape, no discontinuous joints to bridge exist. Ends are inserted, and fused by induction sealing, to the smooth interior wall. During the induction-sealing process, the fluid flow of the internal coating, usually polyolefin, fills any short gaps that may occur. The equipment is simple to operate and does not require special expertise.

A special attribute of all the in-plant paperboard-can packaging systems is the reduction of materials storage and handling. Because the body walls are shipped flat along with the bottom disk and top closures, a minimal amount of storage space is necessary. The average space needed to contain the paperboard can in its flat form represents approximately 97% savings over a similar number of composite or metal cans or glass jars. Additional savings are realized by the reduced cost of shipping the container components to the plant and also in the weight of the final product.

Materials. Basic paperboard-can-body structures are made of laminations of paperboard, aluminum foil, and polyolefins. End structures are analogs that might omit the paperboard for some applications. The generalized structure is paperboard/bonding, agents/aluminum, foil/polyolefin (outside-to-inside). Engineering the components to each other and the structure to the package has been a significant advance. The material components must be functional, economic, structurally sound, and compatible with the contained product.

The paperboard component of the lamination is not critical to the hermetic function of the Cekacan, but it is essential to the commercial value of the system. The exterior surface must be smooth and printable and the interior surface must be sufficiently tied to ensure adhesion to the adjacent layer. Because the paperboard-can body is composed of a single-ply material (as opposed to the multiple plies in composite cans), ranging from 0.016- to 0.032-in. (406–813-μm) finished caliper, the appropriate finished caliper must be chosen to meet the physical stress. At the same time, the economics of the additional caliper board must be weighted against the cost.

Structures can be engineered for each product's specific requirements. Interior polyolefins may be polyethylenes or polypropylenes. They can be applied by extrusion, coextrusion, extrusion–lamination, or adhesion–lamination (see Extrusion coating; Laminating). In the case of a gastight container, a crucial variable is the bonding of the interior polyolefin to the aluminum foil or paper substrates. This adhesion must be maintained above preestablished minimums in converting, body erecting, sealing, and operation. This process is a demanding requirement.

CANNING, FOOD

Joseph H. Hotchkiss
Cornell University,
Ithaca, New York

INTRODUCTION

Canning may be defined as the packaging of perishable foods in hermetically sealed containers that are to be stored at ambient temperatures for extended times (months or years). The objective is to produce a "commercially sterile" food product. *Commercially sterile* does not mean that the food is free of micro-organisms, but rather that the food does not contain viable organisms that might be a public health risk or might multiply under normal storage conditions and lead to spoilage. Canning processes do not necessarily kill all micro-organisms present in a food, and it may be possible to isolate viable organisms from canned foods. The food product may be made commercially sterile either before or after filling and sealing. Three conditions must be met for canning safe and wholesome food:

1. Sufficient heat must be applied to the food to render it commercially sterile.
2. The container must prevent recontamination of the product.
3. The filled and sealed container must be handled in a manner that prevents loss of integrity.

Canning was invented as a means of food preservation in 1810 in response to a prize offered by Napoleon. The original containers were corked glass; handmade tinplate "canisters" (shortened to "cans") were introduced shortly afterward. Cans used prior to 1990 were manually produced from a cylindrical body, an end unit or disk, and a top ring. All seams were formed by dipping in hot solder. The food was filled through the hole in the top ring and a plate that contained a small hole was soldered over the opening. Cans were heated to exhaust the headspace so that a partial vacuum would be created after sealing and cooling. A drop of solder was used to seal the small hole, and the can was then thermally processed.

Around the turn of the century, the process for manufacturing the three-piece open-top can became widely available. This container used the same double-seamed ends that are in use today. The second end was not put on until the can was filled, which meant that food no longer had to be forced through the hole in the ring.

Today the tin-plated steel double-seamed can is still the predominant food canning package (see the Can seamers; Cans, steel article in this encyclopedia). Glass is also used for some products (see the Glass container design article in this encyclopedia). Recently, flexible pouches (see the Retortable flexible and semi rigid packages article), rigid plastics (see the Cans, plastic article), and thin aluminum (see the Cans, aluminum article) cans have been used to can foods. Processes have also been developed in which the food and container are commercially sterilized separately, often by different methods, and the container is filled and sealed without recontamination (see the Aseptic packaging article).

Food canning accounts for just over 30% of U.S. metal can shipments (1) and just under 30% of glass container shipments. Approximately 1700 canning plants process about 36 billion (10^9) pounds (16.33×10^6 metric tons) of food per year (2). The importance of canning in marketing food products varies widely. Virtually all tuna is canned, as is 90% of the tomato crop (2). Other foods rely less on canning.

PROCESS DESCRIPTION

The processing of canned food must produce a commercially sterile product and minimize degradation of the food. The container must also withstand the process and prevent recontamination of the product after processing and up to the time of use, often months or years after processing. The most common sequence of events in canning is that the food product is prepared for canning, the container is filled and hermetically sealed, and the sealed container is thermally processed to achieve commercial sterility. The thermal process necessary to commercially sterilize a canned product depends on the acidity of the food.

Role of pH. High-acid foods such as fruits and fruit juices, pickled products, and products to which acid is added in sufficient amounts to give a pH of 4.6 or lower require considerably less heat treatment than low-acid foods ($pH > 4.6$). Low-acid foods include most vegetables, meats, fish, poultry, dairy, and egg products. High-acid foods may be processed at boiling water temperature (212°F or 100°C) after sealing. High-acid liquid foods, such as fruit juices, may also be sufficiently processed by "hot filling" the container with product near the boiling point and allowing slow cooling after sealing. Low-acid foods ($pH > 4.6$) must be processed at temperatures above the boiling point of water. Most often this is accomplished in a pressurized vessel called a retort or autoclave, which contains water or steam at 250°F at 15 psi (121°C at 103 kPa).

Time and Temperature Requirements. The process or scheduled process refers to the specific combination of temperature and time used to render the food commercially sterile. Several factors affect this process, including the nature of the product, shape and dimensions of the container, temperature of the retort, the heat-transfer coefficient of the heating medium, the number and type of micro-organisms present, and the thermal-death resistance of these micro-organisms.

The relationship among the heat destruction of specific organisms, heating time, and temperature has been intensely studied since the 1920s, and equations have been derived for several organisms, the most important of which is *Clostridium botulinum* (3). This spore-forming organism is found in soil, is ubiquitous, and grows in anaerobic environments such as canned foods; it produces a deadly toxin. Its spores are also highly heat resistant. When commercially sterilizing a canned product, it is the temperature profile of the coldest spot in the container, which must be known before the correct process can be calculated. This is accomplished by placing a thermocouple inside the can, usually at the geometric center for products heated by conduction or in the lower portion of the can for products heated by convection. The temperature is recorded during heat processing and used to calculate the proper process time under the given conditions of product, container size and geometry, and retort temperature. This information coupled with the thermal death characterstics of *Cl. botulinum* or a more heat-resistant organism is used to determine the correct process time. Often these processes are described in terms of F values.

***F* Value.** An F value is the time in minutes to heat-inactivate a given number of certain micro-organism at a fixed temperature (4). If the temperature is 250°F (121°C) and the organism is *Cl. botulinum*, then the F value is called F_o. This value is the number of minutes required to kill a given population of *Cl. botulinum* spores at 250°F (121°C). Combinations of times and temperatures other than 250°F and F_o minutes can inactivate the same number of spores; temperatures lower than 250°F for longer time periods or temperatures greater than 250°F for shorter times have an equal ability to inactivate the spores. An $F_o = 2.45$ min reduces the population of *Cl. botulinum* spores by a factor of 10^{12} (5). In practice, F_o values of greater than 3 are used as a safety measure. To prevent overprocessing (overcooking) of the food, the spore inactivation (called lethality) is summed up during the time the coldest spot in the can is coming up to the retort temperature. Some viscous conduction-heated foods may never completely reach the common retort temperature of 250°F (121°C) yet still receive the proper F_o treatment. The Food and Drug Administration (FDA) regulations require that these tests and calculations be carried out only by recognized authorities (6).

Interest in thermal processes resulted in techniques that commercially sterilize fluid foods in continuous-flow heat-exchange systems before packaging (7). The thermal death calculations described above still apply to these processes, and proper F values must be achieved (8). The continuous-flow commercial sterilization procedures have the advantage that products can be heated and cooled more rapidly for shorter times with equal lethality. This can give a higher quality product. These products must be filled into presterilized containers (see the Aseptic packaging article).

CANNING OPERATIONS

The canning process requires several unit operations that normally take place in a set sequence (9).

Product Preparation. As soon as the raw agricultural product is received at the canning plant, it is washed, inspected, sorted to remove defective product, and graded. Often, the edible portion is separated from nonedible as in the case of peas or corn. Fruits and vegetables are subjected to a blanching operation by exposing them to either live steam or hot water at 190–210°F (88–99°C). Blanching serves to inactivate enzymes that would otherwise cause discoloration or deterioration in the product. It also softens, cleans, and degases the product. Peeling, coring, dicing, and/or mixing operations may be carried out next. These operations prepare the product for filling into the can.

Container Preparation. Containers must be washed thoroughly immediately prior to filling. Cans are washed inverted so that any foreign objects and the excess water can drain out. The container is now ready for filling. Accurate and precise filling is necessary to meet minimum labeled fill requirements yet leave sufficient headspace for development of the proper vacuum after closure. Too large a headspace results in an underweight container, whereas overfilling can result in bulging or domed ends after processing. Excessive headspace may also suggest that large amounts of oxygen remain in the can, which accelerates product deterioration and can corrosion. Liquid or semiliquid products including small pieces are filled by automated equipment. Larger, more fragile products, such as asparagus, are packed by hand or by semiautomated equipment. In most products, brine, broth, or oil is added along with the product. This liquid excludes much of the air between the particles and provides for more efficient heat transfer during thermal processing.

Vacuum. Proper application of the closure after filling is one of the most critical steps in the canning operation. The two-step seaming operation not only must produce a sound, well-formed double seam at speeds of several hundred cans per minute but also must produce an interior vacuum of 10–20 in. Hg (34–68 kPa) (10). This vacuum reduces the oxygen content, retards corrosion and spoilage, leaves the can end in a concave shape during storage, and prevents permanent distortion during retorting. A proper internal vacuum can be achieved by several methods. Containers that are sealed while the food is at or near the boiling point develop a vacuum when the product cools. This preheating or hot fill also serves to sterilize the container when high-acid foods are packaged. Products that are cool when filled can be heated in the container prior to sealing with the same result as the hot fill. This is often termed "thermal exhaust." An internal vacuum may also be achieved by mechanical means. The filled, unsealed container is fed into a vacuum chamber by means of an air lock, and the closure is sealed while under vacuum. This system has the disadvantage that flashing of the liquid may occur if air is entrapped in the food or high levels of dissolved air are found in the liquid. The most common method of producing internal vacuum is by displacing the air in the headspace with live steam prior to and during double seaming the cover. The steam in the headspace condenses and forms a vacuum as the container cools.

Retorting. In conventional canning operations of low-acid foods, the sealed containers are next thermally processed at 250°F (121°C) in retorts. Recent regulatory agency rule changes allow specific flexible containers to be processed at 275°F (134°C).

Several distinct types of commercially manufactured retorts are available for thermally processing canned food (11). Although all, by necessity, operate at pressures above 15 psi (103 kPa), the design characteristics of each type are considerably different. At least six design variables exist: (a) discontinuous (batch) types versus continuous container processing, (b) the heating medium used to transfer heat to the container, (c) the agitation or nonagitation of containers during processing, (d) the layout of the pressure vessel (vertical vs horizontal), (e) the method used to load and unload the containers from the retort, and (f) the cooling procedures used after thermal processing.

The simplest retorts are batch (discontinous) retorts that use pure steam as the heating medium and do not have provisions for mixing (agitation) of the container contents during processing. These retorts are termed still retorts (Figure 1). Temperature inside still retorts is maintained by automatic control of the steam pressure.

Loading and unloading the containers from discontinuous still retorts are accomplished by preloading containers into crates, baskets, cars, or trays. “Crateless” systems randomly drop containers into the retort vessel, which is filled with water to act as a cushion and prevent container drainage (Figure 2). The water is drained prior to processing. The orientation of the retort depends on the type of container handling system. Systems that use crates or baskets and the crateless systems, by necessity, use vertical vessels, whereas car handling necessitates a horizontal orientation.

Glass, semirigid, and flexible containers must be processed in still retorts that have been designed to accommodate the fragility of these containers at retort temperatures and pressures. These retorts operate at pressures greater than the 15 psi (103 kPa) of steam required to reach 250°F (121°C) to counterbalance the internal pressure developed in the container. This is termed “processing with overpressure.” The pressure buildup inside individual containers during processing would result in the loss of seal integrity in heat-sealed containers (see the Sealing, heat article) and could loosen the covers of glass containers or permanently distort semirigid plastic containers. Four design changes in still retorts must be made to process with overpressure:

1. Either steam or air overpressure must be automatically controlled. Pressures of 25–35 psi (172–241 kPa) are typical.
2. Control of the retort temperature must be independent of retort pressure.
3. Mixed heating media of either steam—air, water–air, or water–steam are used in place of pure steam. Heat transfer is less efficient in these mixed-heating media. For this reason, some means of circulating or

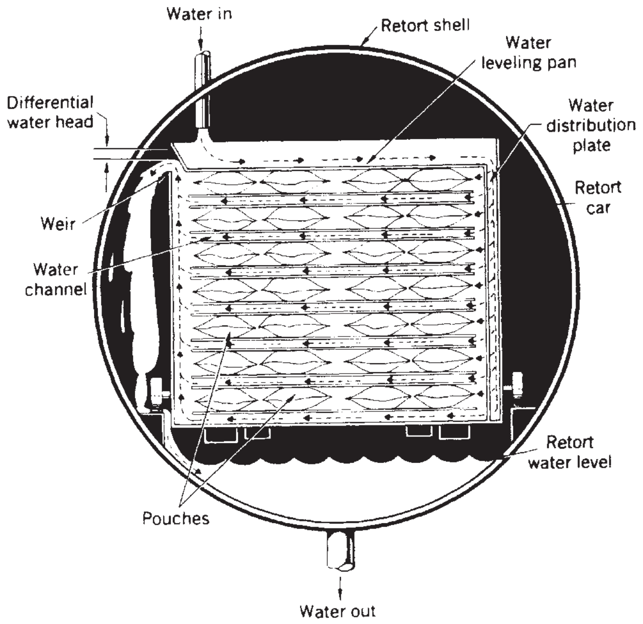

Figure 3. FMC convenience foods sterilizer, showing water flow and pouch restraints. (Courtesy of FMC Corporation, Food Processing Machinery Division.

mixing the heating medium is necessary. For steam–air mixtures, fans may be provided. Water–air and water–steam systems use circulating pumps.

4. Provisions to prevent stress on the containers caused by motion during processing are made.

These designs may be incorporated into either vertical or horizontal retorts depending on how the containers are handled. Glass containers are typically loaded into crates or baskets for processing in vertical water–air or water–steam retorts. Flexible retortable pouches are often loaded into trays and cars (which also serve to maintain the proper shape of the pouch) and moved into horizontal retorts for water–steam or steam–air processing (see Figure 3).

Still retorts, whether designed for metal cans or other containers, are batch (discontinous) systems. The hydrostatic retort is technically a still retort (product is not agitated) that continuously processes containers. The retort operates at a constant temperature (and pressure) as the containers are carried through the retort by a continuously moving chain (Figure 4). The required 15 psi (103 kPa) of steam pressure inside the retort (or steam dome) is maintained by two columns of water, which also serve as pressure locks for incoming and outgoing containers. These columns of water (called feed and discharge legs) must be greater than 37 ft (11.3 m) high to maintain at least a minimum 15-psi (103-kPa) steam pressure. Hydrostatic retorts have the highest throughputs; are efficient in their use of floorspace, steam, and water; can process a variety of container sizes and types (including flexible); and are highly automated. They have the disadvantage of high capital costs and are therefore applicable only to high-volume operations.

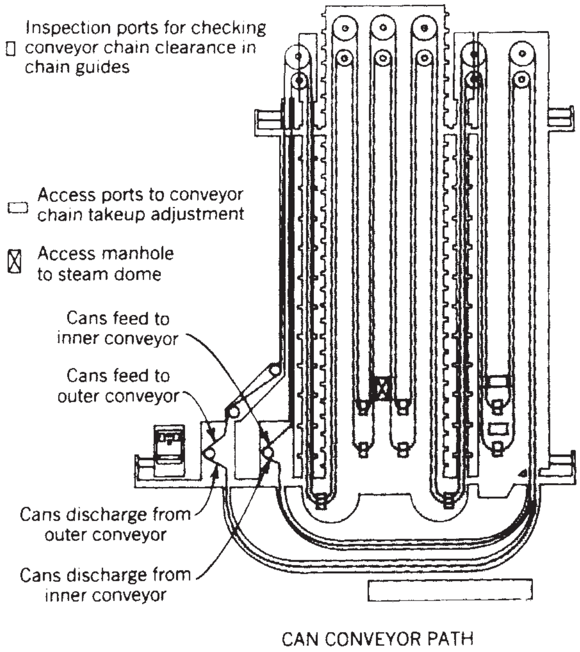

Figure 4. Flow diagram of a hydrostatic sterilizer for canned foods. (Courtesy of FMC Coporation, Food Processing Machinery Division.)

The heating time necessary to ensure that the coldest spot in the container receives the proper lethality depends somewhat on the consistency of the product. For viscous products such as canned pumpkin and baked beans, the primary heat-transfer mechanism is conduction. Products that have a thin consistency or are packed with brine (canned peas) are heated by convection. The transfer of heat to the center of the container can be greatly facilitated if internal mixing occurs in the can during retorting. This results in a shorter processing time and higher quality product.

Retorts that are designed to increase convection heating by container motion during processing are termed agitating retorts. Both end-over-end and axial rotation are used, but the latter predominates. Glass, semirigid, and flexible containers are not agitated because of fragility. Agitating retorts may be either batch or continuous types. Continuous retorts predominate because they have

greater efficiency and throughout but are less easily adapted to changes in container size.

The continuous rotary cooker–cooler (see Figure 5) has become widely used for large-volume operations in which convection-heated products such as vegetables in brine are packed in metal cans. This system feeds individual cans into and out of the pressurized vessels by means of rotary pressure lock valves. Cans are rotated around the inside of the vessel's shell by means of an inner rotating reel and a series of spiral channel guides attached to the shell (Figure 5). This system provides for intermittent agitation of the cans by providing rotation about the can axis during a portion of the reel's rotation inside the vessel. This system has the disadvantage that container size cannot be easily changed.

Regardless of retort design, consideration must be given to cooling containers after processing. For glass, flexible, and semirigid containers, cooling with overpressure is necessary. These containers would fail because of the internal pressure developed during heating should the external pressure drop. Even metal cans may buckle and panel if brought to atmospheric pressure while the contents are at 250°F (121°C). In batch-type still retorts, overriding air pressure with water cooling is used. Hydrostatic retorts (continuous still retorts) cool containers by removing heat from the water in the discharge leg. If more cooling is necessary, an additional cooling section is added and cool water is cascaded over the containers. Continuous agitating (rotary) systems cool under pressure by transferring containers to pressurized cooling vessels by means of rotating transfer valves (Figure 6). The second-stage vessels are maintained at elevated air pressures while the containers are cooled with water. A third-stage atmospheric cooler may also be incorporated.

In addition to the pressurized heating and cooling vessels, all retort systems require a set of precise instruments and controls. Regulations require a direct reading mercury-in-glass thermometer as well as temperature recording devices. A continuous temperature controller must be installed. For retorts that use pure steam, this may be a pressure controller; processing with overpressure requires a direct temperature controller. Retorts require reliable sources of steam, air, and water. A pressure reading device is required as well as an accurate recording timing device so that the scheduled process can be insured and the proper records maintained. All instruments must undergo periodic calibration.

REGULATION

The canning of foods is carefully regulated by the FDA, or in the case of canned meats and poultry, the United States Department of Agriculture (USDA). These agencies recognize the serious public health implications of improperly processed foods. The FDA has developed a complete set of regulations commonly referred to as the Good Manufacturing Practices (GMPs) for canning foods. These regulations govern the type of equipment used to can foods and the procedures, the frequency of inspection of containers and equipment, and the records that must be kept, and they provide for the filing of individual processes prior to production. The regulations pertaining to food canning are contained in Title 21 of the Code of Federal Regulations (CFR) under the following sections: (a) 21 CFR Part 108, "Emergency Permit Control"; (b) 21 CFR Part 113, "Thermally Processed Low-acid Foods Packaged in Hermetically Sealed Containers"; and (c) 21 CFR Part 114, "Acidified Foods."

Part 108 stipulates that food-canning plants must register their establishments and specific processes with the FDA. This section also contains provisions for issuing emergency permits to firms that the FDA believes do not fully meet the regulations. Part 113 is the most extensive section and details the equipment, procedures, process controls, establishment of correct process, critical factors, and necessary records for canning low-acid foods. This section also details the procedures to be used in evaluating the integrity of the double seams. Part 114 describes the GMP requirements for packaging high acid foods ($pH \leq 4.6$). This section includes general provisions as well as specific requirements for production and process control.

The USDA's Food Safety and Inspection Service (FSIS) has regulatory authority over canning poultry and meat products and has promulgated a series of regulations under Title 9 of the CFR. Current FSIS regulations are considerably more general than FDA regulations and have not kept pace with changes in canning technology. Meat and poultry canning operations are subject to continuous inspection in a manner similar to other FSIS-regulated plants. These regulations are contained in sections 318.11 and 381.49, which deal with the cleaning of empty containers, inspection of filled containers, coding, use of heat-sensitive indicators (see Indicating devices), and incubation of processed products. In 1984, FSIS proposed a more detailed set of regulations similar to those promulgated by the FDA for canning low-acid foods. The sections of the CFR that deal, in part, with meat and poultry canning, and related requirements will be 9 CFR 308, 318, 320, and 381.

TRENDS

The food-canning industry has undergone substantial changes, most notably in the area of containers (12). Changes are ongoing in the retort systems. Rotation, oscillation, gentle motion, and shaka are the various terms used by vendors to promote their particular system. The major trends are in the uses of semirigid and flexible pouches.

The industry is increaingly using the flexible pouch and semirigid containers, taking advantage of the thinner profile of these containers that can result in faster heating and higher quality food. Also the shipping cost of the empty can and glass jars to the retort facility is becoming more of an issue.

Metal as well as glass cans will have increasing competition from plastics and composite materials (14).

Development of thermal processes in which the food is commercially sterilized before packaging is ongoing. This allows food to be thermally processed in continuous-flow, heat-exchange systems that can result in higher quality products and allow the use of less expensive containers based on paperboard or thin plastics. This technology is used for juices, drinks, and milk. Recent products include soups, stews, and vegetables (8).

INTRODUCTION

Over 98% of all aluminum cans are drawn-and-ironed (D & I) cans used for beer and soft drinks (see Cans, fabrication; Carbonated-beverage packaging). The other 1–2% is accounted for by small shallow-draw food cans. In the United States, production of aluminum beverage cans has reached about 100 billion/yr (1). Virtually all beer cans are aluminum, and 100% of all soft-drink cans are aluminum. Until 1965, the three-piece soldered can was the only can used for beer and beverages (see Cans, fabrication; Cans, steel). It was generally made of 75-lb per base box (16.8 kg/m^2) tinplate (see Tin-mill products). Aluminum does not have the strength of steel per unit weight and cannot be soldered. Therefore, early in the development of the aluminum can, attention was focused on improving the properties of aluminum and perfecting two-piece D & I technology. More recently, the emphasis has been on saving metal, because the cost of metal is the single largest component of final product cost. One of the chief reasons for the success of aluminum cans has been their scrap value for recycling (see Energy utilization; Recycling). This article pertains to the technical developments that have led to today's aluminum beverage can.

HISTORICAL DEVELOPMENT

The significant developments took place in the late 1960s. Earlier, in 1958, Kaiser Aluminum attempted to make a 7-oz (207-mL) aluminum can using a 3003 soft-temper aluminum of the type used for aluminum-foil production, but the effort was not a commercial success. In the universe of aluminum alloys, the 3-series alloys contain a small percentage of manganese as the principal alloying element. The success of the aluminum can depended on the development of the 3004 alloy for the can body, which contains manganese along with a slightly lower amount of magnesium. (The softer 5182 alloy for can ends contains a higher amount of magnesium.) Reynolds Metals Co. began making production quantities of 12-oz (355-mL) seamless D & I cans in 1964 using a 3004 alloy. The walls of these first cans were straight, with a top diameter of "211": $2\frac{11}{16}$ in. (68.26 mm). The starting gauge was 0.0195 in. (0.495 mm); can weight was 41.5 lb/1000 (18.8 kg/1000).

Reynolds introduced the first necked-in cans (see Figure 1) in 1966, reducing the top diameter from 211 to 209, that is, $2\frac{9}{16}$ in. (65.09 mm). This represented a breakthrough in technology and container performance, particularly as it is related to cracked flanges. Cracked flanges were a serious problem in both double-reduced tinplate and straight-walled aluminum cans. The introduction of carbide knives at the slitter essentially eliminated cracked flanges on tinplate cans. Eliminating them on aluminum cans required a change from die flanging to spin flanging, and necking-in before flanging, which does not stretch the metal beyond its elastic limits.

In 1968, a new harder-temper (H19) 3004 alloy was introduced for aluminum cans. Although the 3004–H19 combination had been available since the 1950s for other purposes, it was not until 1968, when Alcoa and Reynolds were in commercial production with full-hard-temper can sheet, that it could be used to effect significant weight reductions. Weight/1000 cans decreased from 41.5 lb (18.8 kg) in the mid-1960s to 34 lb (15.4 kg) in the mid-1970s and to less than 30 lb (13.6 kg) in the mid-1980s. Both 3004–H19 and 3014-H19 are used today.

Gauge reductions have increased the point where design techniques have become critical to sustaining the can's ability to hold the product. With few exceptions, U.S. brewers pasteurize beer in the can. This generates high internal pressures, and most cans used for beer must be designed so that they have a minimum bottom buckle

Figure 1. A necked-in can.

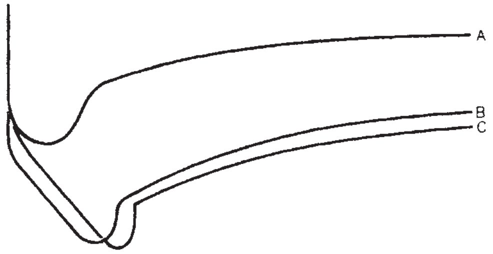

Figure 2. Can-bottom profiles: A, original bottom profile; B, Alcoa B-53, V-bottom profile; C, Alcoa B-80. (Courtesy of Alcoa.)

strength of 85–90 psi (586–620 kPa), depending on the carbonation level. Brewers were asking for cans with minimum column strength (i.e., vertical crush) of 300 lbf (1330 N).

A revolution has taken place in bottom profiles (see Figure 2). The original D & I bottom had a rather generous bottom-heel radius. In order to meet the 90-psi (620 kPa) minimum bottom buckle-strength requirement, a 211 can with this configuration would have to be made with a starting gauge of 0.016–0.0165 in. (406–419 µm). The next profile development, basically the Alcoa B-53 design, is widely used throughout the beer industry today because it allows the starting gauge to go as low as 0.013 in. (330 µm), in most cases without sacrificing the 90-psi (620-kPa) minimum bottom buckle strength. The Alcoa B-80 profile allows starting-gauge reduction to ~0.0126 in. (~320 µm).

An "expandable bottom" design might permit use of a 0.010-in. (254 µm) starting gauge for pasteurized product. In contrast to the current dome profiles, an expandable bottom is essentially a flat bottom with small pods located near the perimeter to provide stability to the pressurized can, reduce drag, and increase mobility. A totally flat bottom would drag too much on the filling line. The "expandable" bottom is designed to flex outward during pasteurization, relieving some of the generated pressure.

Sidewalls are still being redesigned (see Figure 3). In the 1970s, the so-called nominal thinwall (i.e., the area of the can that has been thinned most) generally ranged from 0.0052 to 0.0053 in. (132–135 µm). More recent versions of the D & I can have reduced the nominal sidewall to 0.0045 in. (114 µm). A reduction of this magnitude represents substantial cost reduction. It also means a corresponding reduction in the overall column strength (vertical crush) of the can, not below the minimum 300 lbf (1330 N) but in terms of overall operating average. Column strength is very critical to the brewers, who ship long distances by truck and rail. Extensive testing by the can companies and the beer and beverage industry in general has shown that the 300-lbf (1330-N) minimum is satisfactory. Because of the reduction in body-wall thickness, dents that were acceptable before have now become critical owing to their influence on reducing the can's column strength. Can makers and brewers are monitoring their handling systems for empty and full cans to minimize denting wherever possible.

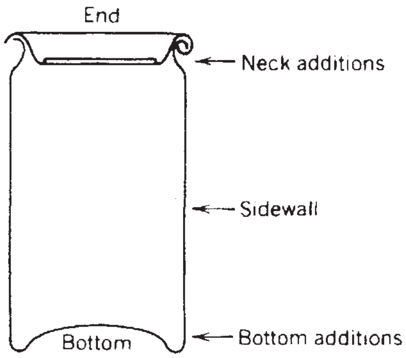

Figure 3. Design elements.

Figure 4. Double-, triple-, quadruple-, and spin-neck can.

In the 1980s, can suppliers reduced costs further by double "necking-in" (see Figure 4). These configurations reduced costs primarily because of the diameter reduction of the lid. In 1984, further activity with respect to necking-in began to occur. Cans with three or four die necks are now being run commercially (see Figure 4). In Japan, a can with eight necks was tested. Metal Box (UK) introduced a spin-neck can (see Figure 4), which essentially produced the same 206 top diameter as the triple- or quadruple-neck can, that is $2\frac{6}{16}$ in. (60.33 mm).

Another advantage of aluminum is the "split gauge." The industry used to sell coils in 0.0005-in. (12.7-µm) increments, for example, 0.0130 in. (330 µm), 0.0135 in. (343 µm), etc. A new pricing structure introduced in 1983 allows can-stock buyers to order gauge stock in 0.0001-in. (2.54-µm) increments. A can manufacturer can reduce costs by taking advantage of these slight gauge reductions. In addition, there has been a change in the gauge tolerance as rolled by the aluminum mills. In the 1970s, the order gauge was subject to a ±0.0005-in. (12.7 µm) tolerance; today, it has been reduced to 0.0002 in. (5.1 µm). This permits further gauge reduction because it allows the can manufacturer to reduce the order gauge without changing the minimum bottom buckle strength.

CURRENT DEVELOPMENT

Today 100% of all U.S. soft-drink cans and 95% of all beer cans are fabricated from aluminum (1). The industry has moved from 206-diameter necks on 211-diameter bodies to

204- and 202-diameter necks. These diameter changes have reduced the metal gauge and net weight from 0.0108 in. and 7.3 lb/1000 for 206 ends to 0.0088 in. and 5.3 lb/1000 for 202 ends. The primary development is with the 202 can ends, 200 is also being developed. Wide mouth cans openings are now being marketed that lower metal use by 10% (1). Resealable cans are being marketed in France. A small amount of plastic will be used at the opening and will not affect recycling (2).

Net can weights have also been reduced from approximately 30 lb/M at 0.0125 in. to 23 lb/M at 0.0108 in. This has been accomplished primarily by creating new stronger dome geometry, along with dome postreforming technology to improve performance criteria, such as dome buckle, drop resistance, and dome growth. These new dome designs are more difficult to manufacture, but provide improved performance and stacking at reduced gauges. Alcoa is lightweighting by using the thinnest aluminum possible. Finite element modeling helps with design prototypes (3). Can body gauging down has resulted in a 25–30% reduction in metal use (4).

Can sidewalls have been further reduced from 0.0045 in. down to 0.0038 in. nominal, and the number of die necks utilized to produce finished necks has increased to as many as 14 for the 202 diameter (4). Multidie necks combined with spin necking are still popular for all three neck diameters, and several canmakers are using multidie necking with spin flow necking.

CANS, COMPOSITE

M. B. Eubanks
Sonoco Products Company
Updated by Staff

INTRODUCTION

The "composite can" is broadly defined as a can or container with body and ends made of dissimilar materials. In commercial practice the composite can has several more focused descriptions: cylindrical or rectangular shape; rigid paperboard (or plastic) body construction; steel, aluminum, or plastic end closures; generally employing inside liners and outside labels; and generally delivered with one end attached and one end shipped separately to be attached by the user. Today the most common form is the cylindrical paperboard can with a liner, a label, and two metal ends. There are other packaging forms similar to traditional composite cans that are sometimes called *composites*, but which are more closely related to folding cartons. These are single-wrap fiber cans made from blanks and mainly designed for the users' in-plant production (see Cans, Composite, Self-Manufactured).

The composite can is not a new package. Early applications included refrigerated dough and cleansers. As technology improved, motor oil and frozen juice concentrates were converted to composites. In the last decade, snack foods, tobacco, edible oils, shortening, powdered beverages, pet foods, and many other items have been added to the list. Figure 1 illustrates some of the products currently available in composite cans.

Since their introduction, composite cans have generally been marketed and used as a lower-cost packaging form relative to metal, plastic, and glass. This emphasis has overshadowed other positive attributes such as the frequent use of recycled materials, weight advantages, noise reduction, improved graphics, and design flexibility. Because of its early applications in cleansers and oatmeal, the composite can once suffered from a low performance image associated with the term "cardboard can." This term cannot begin to describe the current and potential properties of the paperboard and other materials that go into today's composite cans.

By utilizing the best combination of materials, composite-can construction ensures optimum presentation and mechanical strength as well as hermetic protection. The choice of materials and production techniques for can components offers packaging solutions that are flexible and cost effective for mass consumption and luxury products as well as for numerous industrial applications.

Composite cans are normally available in diameters of 1–7 in. (3–18 cm) and heights of 1–13 in. (3–33 cm). Dimensional nomenclature for composites has been adapted from

Figure 1. Examples of composite cans in commercial use.

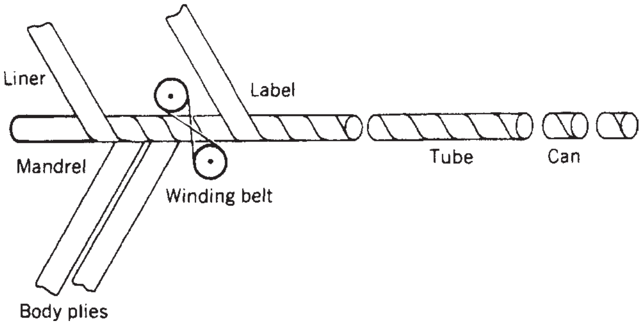

Figure 2. Spiral-wound composite-can fabrication.

metal cans, and nominal dimensions are expressed in inches and sixteenths of an inch (see Cans, Steel). Hence, a 404 diameter can has a nominal diameter of $4\,{}^4\!/_{16}$ in. (10.8 cm). Likewise, a height of $6\,{}^{10}\!/_{16}$ in. (16.8 cm) is expressed as 610, and so on.

MANUFACTURING METHODS

Composite-can bodies are produced by two basic methods: spiral winding and convolute winding. Figure 2 shows a schematic drawing of the spiral process. Multiple webs including a liner, body plies, and label are treated with adhesive and wound continuously on a reciprocating mandrel. The resulting tube is trimmed and the can bodies are passed on to flanging and seaming stations. Figure 3 depicts the convolute process, wherein a pattern is coated with adhesive and entered onto a turning mandrel in a discontinuous process. Trimming and finishing operations for the convolute and spiral systems are virtually the same. Most composite-can manufacturers favor the spiral process in situations where long production runs and few line changeovers are involved.

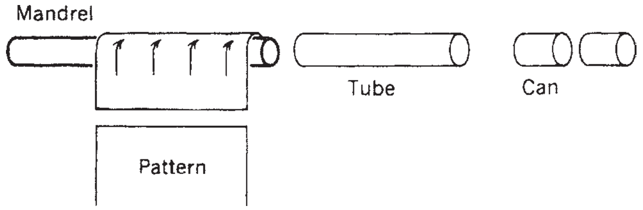

Figure 3. Convolute composite-can fabrication.

BODY CONSTRUCTION

Paperboard

The primary strength of the composite can is derived from its body construction, which is usually paperboard (see Paperboard). Body strength in composite cans is an attribute that has improved over the years and can be varied to meet many application demands.

In the early years of composite can development, it was common for can manufacturers to start with a readily available body stock such as kraft linerboard or tube-grade chip. These boards are adequate for most applications, but new boards with special qualities have also been developed for more demanding end-use requirements.

Research and development efforts in the combination paperboard field encompass a number of areas of expertise. Examples are (a) engineering mechanics concepts used to develop structural criteria and to develop tests to ensure that the paperboards possess the necessary resistance to bending, buckling, and creep; (b) surface chemistry used to predict the resistance of the board to penetration of adhesives, coatings, and inks and, similarly, protection from environmental conditions such as rain, high humidity, and freezing temperatures; and (c) process engineering used to optimize paperboard manufacturing and converting and to assist in quality assurance programs (see Specifications and Quality Assurance).

The scientific and engineering efforts have, in many instances, supplemented the artisan-like judgment of yesterday's papermaker. However, in many cases the new technological approaches have been blended with the papermaker's art to achieve the best of both worlds. As a result, the following advances have taken place: super-high-strength board that can be converted into composite cans with reasonable wall thicknesses that can resist implosion when subjected to near-perfect vacuum; resin-treated paperboards that retain their structural integrity when thoroughly wet; chemically treated paper that resists penetration by water over long time intervals; and paperboards that can be distorted, rolled, and formed in high-speed converting equipment without "creeping" back to their original shape.

Adhesives

The adhesives (see Adhesives) and coatings used in the manufacture of composite cans have also been improved to provide better heat and water resistance plus increased

Table 1. Adhesives Used in Composite-Can Manufacture

Adhesives	Properties
Poly(vinyl alcohol–acetate) blends	Good initial tack, good runnability, moderate to good water resistance
Dextrin	Fast tack, poor water resistance
Animal glue	Good tack, vulnerable to insect attack
Polyethylene	Requires heat, good dry bond, moderate water resistance
Hot melts	Require heat, difficult to handle, good water resistance, good water bond

operating efficiency. Most product applications require precision gluing equipment to control the amount and position of the adhesive on each web. The most commonly used adhesives in today's composite can production are listed in Table 1.

Liners

Like all successful packages, the composite can must contain and protect the products. For that reason, continuous improvement is sought in liner materials. By combining materials such as LDPE (see Polyethylene, Low-Density), HDPE (see Film, High-Density Polyethylene; Polyethylene, High-Density), PP (see Film, Nonoriented Polypropylene; Film, Oriented Polypropylene; Polypropylene), ionomer (see Ionomers), PVDC (see Vinylidene Chloride Copolymers), metalized PET, and PE (see Film, oriented Polyester; Polyesters, Thermoplastic) with aluminum foil (see Foil, Aluminum) or kraft (Paper; Paperboard), the barrier properties of composites can be matched with a broad range of product requirements (see Laminating, Multilayer Flexible Packaging). The polymers may be included as film or coatings, or both. Tables 2, 3 illustrate the physical properties of some of the more common liner films and complete liner constructions.

The laminates shown in Table 3 vary significantly in cost. Depending on can size, the difference in cost per thousand units can be substantial. The foil-based laminates, which provide virtually 100% water and gas barrier, are becoming quite expensive. If less than total impermeability is acceptable, it pays to investigate coated- or plain-film alternatives. For example, packers of frozen juice concentrates have gradually moved away from foil liners to laminations of PE or ionomer/PE and kraft.

End Closures

In addition to strength and versatility, the composite canister is also known for its numerous opening and closing systems. Consumers prefer easy-opening and dispensing features that provide resealability to maximize freshness. Paper, aluminum, steel, or plastic membrane closures are fitted on cans by single or double seaming, gluing, pressure inserting, or heat sealing.

A critical process in the manufacture of a composite can is double seaming the metal end (see Can Seamers). Since a composite can body is typically thicker than a metal can for any given package size, metal-can specifications for finished seam dimensions cannot be followed. Figure 4 shows composite double-seam profiles that are correctly and incorrectly made. Careful attention should be given to compound placement, selection of first- and second-stage seamer rolls, seamer setup, chuck fit, and base plate pressure if a satisfactory double seam is to be achieved.

Closures depend on the product to be packaged as well as the ease of use, protection needed, dispensing requirements, the opening and reopening ability, and necessary hermetic properties (1). Bottom end clsoures are primarily coated with steel although plastic, paper, and aluminum are sometimes used. The strength of the steel end is generally correlated with basis weight and temper. Coatings may also be applied to the end clsoure. Examples of coatings include tinplate, vinyl, epoxy, or phenolics. If maximum protection is needed, a sealing compound is applied to the end.

A variety of steel and aluminum ends with solid panel, removable tape, or other easy-opening features are available, as well as plastic-end closures with easy-opening and sifter tops. In composites, the most expensive components are usually the metal ends. With this in mind, gastight, puncture-resistant membrane closures for composite have been test marketed and evaluated by several companies (see Figure 5). They are considerably less expensive than aluminum full-panel removable ends, and they eliminate the cut-finger hazard posed by both the center panel and score residual on rigid ends. In addition, the membrane end eliminates the metal fines that can be produced by can openers.

Labels

The outer label on a composite can supplies additional package protection and, more importantly, enhances the can's aesthetic appeal and provides required consumer educational–instructional information. Composite labels include coated papers, foil/kraft laminates, and film constructions based on polyethylene or polypropylene. Flexographic, rotogravure, or offset printing (see Printing) are used, depending on cost and quality requirements.

Nitrogen Flushing

The materials and methods of constructing a composite can depend on its end use and desired performance characteristics. When composite cans were being developed for the snack industry, the concept involved creating a hermetically sealed containers that could replace the vacuum-packed steel can. Nitrogen flushing was developed to accomplish the removeal of oxygen from the container. It is based on the principle of flooding the container with a nonreactive gas just before it is filled. Powders have a tendency to stick together so several stages of purge are necessary. First the container is purged prior to filling, to purge the product in the filler, and finally to purge after filling. prior to seaming. For

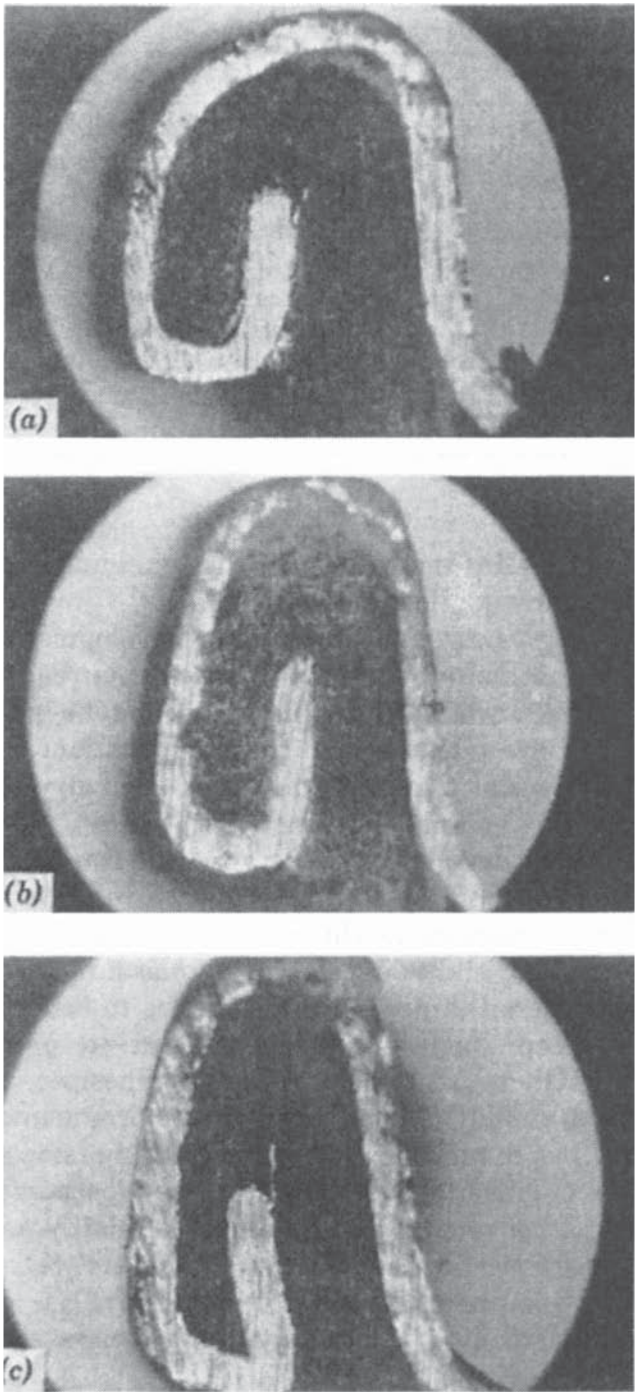

Figure 4. Composite-can double seams. (**a**) Loose, (**b**) correct, and (**c**) tight.

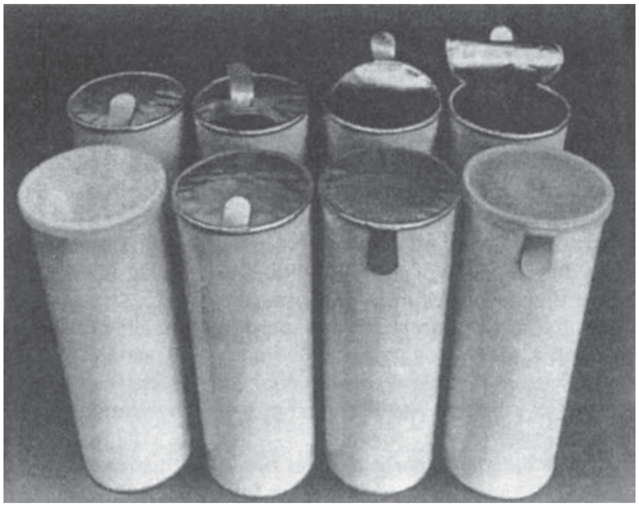

Figure 5. Composite with peelable membrane closure.

snacks, it may be necessary only to flush the filled can prior to seaming (1).

RECYCLING

The package's body plies are made from recovered and recycled fiber and can have a post-consumer waste ccntent of over 50%. In many communities, this qualifies the composite can for placement in the material flow stream of curbside recycling programs. In addition to the body, the metal lids are recyclable. An introduction of a paper bottom end can increase the amount of recycled post consumer content up to 70% and enhances the can's ability to be recycled (1).

NEW DEVELOPMENTS

While dry-food packaging is the most common application for today's composite cans, more and more retailers are seeing its value as a customizable option for vendable and nonfood products. Packaging engineers are focusing on ways to increase performance and convenience by enhancing existing features and materials, reducing costs, and redesigning of closure systems. Another way of using sorbents is being researched. Sorbents provide high moisture and odor absorbing capability. Generally, sorbents are included in the products as a nonedible packet consisiting of silica gel or clay. Research is focused on ways to build the sorbent into the liner structure. By continung to absorb oxygen, the product inside the can will remain fresher before and after opening (1).

Valved membrane ends are also being studied. These are designed for coffee. The one-way release valve allows for packing and sealing immediately after roasting. This eliminates the need for extended hold times for degassing and at the same time maximizes flavor and aroma. A vacuum is no longer necessary. Because the end is peelable, a can opener is not needed.

The resealable plastic overcap offers great promise for providing increased shelf life after opening. Redesign of the overcap will feature the addition of a gasket that will snap to the opening of the composite can.

CANS, CORROSION

David Reznik
Raztek Corporation, Sunnyvale,
California

Corrosion in food cans, manifested in failure phenomena such as detinning, hydrogen swell, and enamel delamination, has troubled the food industry ever since canning was practiced. Much research work has been invested in this subject, but problems still exist with only little relief. The major reason for this fact is that the mechanisms involved in the corrosion phenomena are not well known. Molecular hydrogen is well known as a product of the corrosion process, but its origins and its role along the corrosion process in atomic form is not well established or even considered (1, 2).

The existing theory cannot explain various corrosion phenomena, and therefore it cannot provide solutions to corrosion problems. There are many indications that all corrosion phenomena involve hydrogen activity. The source of the hydrogen is from water HOH, in which the radicals H and OH are interdependent, similar to the ions H^+ and OH^-. All the four species are involved in the oxidation and reduction reactions in nature. The state-of-the-art corrosion theories consider mainly the activity of the ions H^+ and OH^-, but ignore the major role of the radicals H and OH. The glass electrode that measures the pH defining the H^+ and OH^- activity is very common, but the redox potential defining the ratio of H and H^+ activities is rarely measured and considered. The pH indicates the degree of acidity or alkalinity of the liquid. The redox indicates to what degree the liquid is oxidizing or reducing.

Both H and H^+, and perhaps OH and OH^-, have some qualitative dimension, as expressed, for example, by the NMR (nuclear magnetic resonance) of the hydrogen. This energetic property differentiates hydrogen atoms based on its source. Hydrogen atoms and ions from different sources may have a different effect on corrosion and many other phenomena. This may be why different acids have a different corrosive effect, and the pH alone is far from providing an explanation to corrosion failures.

The source of corrosion is water, which contains the four species participating in the corrosion process. These are H and OH radicals as well as the well-known H^+ and OH^- ions. Corrosive materials affect some qualitative dimension of the hydrogen atoms of the water. This is why extremely small quantities of some material added to the water may have a dramatic effect on corrosion, as well as on many biological reactions. A simple known example for such an additive is sulfur dioxide, which in trace concentration may lead to detinning of fruit cans in a matter of days or even hours. The effect of such traces on pH are negligible.

These observations led to the conclusion that water is not just a solvent or carrier. It is the corrosive agent itself but is affected, however, by materials dissolved in the water and even by materials that the water was in contact with.

The major tool used for corrosion studies in the food packaging industry is still the test pack, by which a product or medium is packed, stored, and evaluated. This method should have been used to verify a mechanism, rather than as the research tool. In fact, very little was learned from test packs to ameliorate the theories of corrosion mechanisms. In many cases the conclusions from test packs were inconclusive and misleading.

Many analytical methods in corrosion studies (3) are actually based on oxidation–reduction reactions where specific hydrogen is involved (4). Hydrogen in molecular form was detected on the external wall of cans during storage (1, 5), but its origin and permeability (6, 7), as well as its reactions in the bulk of the metal (8, 9) have not been considered in can corrosion studies.

Enamel adhesion is based on hydrogen bonds (10), and reactions affecting the hydrogen bonding (11) affect the performance and the shelf life of enameled cans.

The corrosion mechanism involves oxidation–reduction reactions (12). In the case of detinning in plain cans (13), where the food is in contact with the tin-coated steel, the tin and some iron are oxidized. This is the tangible bottom-line result, but it can be shown that the active element leading to this result is the atomic hydrogen from water. The oxidation of the food product in enameled cans, manifested in color and flavor changes, can be explained by hydrogen loss (12).

Oxidation of organic matter is caused by loss of hydrogen atoms. Organic matter that gains hydrogen atoms is reduced. Oxidation of metals is usually defined as loss of electrons. Metallic ions can gain electrons and deposit as metals. It can be shown that the hydrogen atom, in water or in the food compounds, is the element that is transferred or gives and takes electrons, and in its absence there will be no changes in organic and inorganic matter.

THE CORROSION MECHANISM

The basic reaction of oxidation reduction is

$$H \leftrightarrow H^+ + e^-$$

The reaction to the right expresses the oxidation of the hydrogen atom to H^+ (15). The reversible reaction to the left is the reduction of the hydrogen ion H^+ to H atom. The Nernst equation derived from this equation is

$$E = E^0 + \frac{RT}{F} \ln \frac{[H^+]}{[H]}$$

where E is the electrochemical potential of the hydrogen electrode, E^0 is the standard hydrogen potential, R and F are constants, and T is the temperature. The expression $[H^+]$ is the activity of H^+, and [H] is the activity of atomic hydrogen. The means to measure this potential is basically a platinum surface, to which the atomic hydrogen is absorbed, and a reference electrode, such as a calomel half-cell.

Replacing platinum with tin, the reading will be different, because of the very different activity of hydrogen on tin. In conclusion, the redox potential measurement indicates the potential of hydrogen on the electrode at the conditions of the measurement. The galvanic cell, therefore, expresses the difference of hydrogen activity on the two metals.

The reaction on the cathode in a galvanic cell is known to be $H^+ + e^- \rightarrow H$, but it is not common consideration that the opposite reaction takes place on the anode, where H from the solution, gives its electron to the anode and turns into H^+. The latter may take an electron from the metal and turn back into H, and the metal will dissolve as positively charged ions. If the anode cannot lose electrons, the solution will be oxidized, because it lost hydrogen that turned into H^+. The net result is hydrogen formation on the cathode and H^+ or metal ions formation at the anode. According to the above, the hydrogen in its different forms is the major player in transferring electrons, or in oxidation reduction reactions.

In a corrosion process in plain tinplate cans, the metal is usually oxidized, and the product is reduced. In the case where hydrogen is formed on the cathode and there is no metal dissolution from the anode, the product itself is oxidized, because it lost atomic hydrogen.

$$\begin{aligned} \text{On the cathode :} \quad & 2H^+ + 2e \rightarrow H_2 \\ \text{On the anode :} \quad & 2H \rightarrow 2H^+ + 2e \\ & Sn + 2H^+ \rightarrow Sn^{2+} + H_2 \end{aligned}$$

The oxidation, therefore, can affect the solution as well as the metal. Loss of H from water creates excess OH radicals that may oxidize the product. Pears packed in plain cans will be slightly bleached, and some tin will dissolve. The product is reduced, and the tin is oxidized. In enameled cans, pears will darken because there is no metal dissolution.

Water is the source of H, which is in equilibrium with H^+ and the respective counter groups OH and OH^-. H is therefore the major parameter in the corrosion mechanism. Any additive to water will somehow affect the activity of the above four species, thus indirectly contributing to the corrosion process, through the effect of the additives on the water.

Radical and Ionic Reactions

Electrons can also be given to the anode by negative ions, such as chloride and hydroxyl ions. The chloride at the anode gives an electron to the anode and turns into chlorine radical, which attacks the water and forms HCl and OH radicals. The OH radicals may attack the metal, take electrons, and turn into hydroxyl ions OH^-.

$$Cl^- \rightarrow Cl + e^-$$

$$Cl + HOH \rightarrow H^+Cl^- + OH$$

$$Me + OH \rightarrow Me^+OH^-$$

or

$$H + OH \rightarrow HOH$$

The reaction of chlorine with water is not an ionic reaction; it is a radical reaction, similar to the attack of OH on the metal. Indeed, dry chlorine can attack metals directly in absence of water, but such reactions are out of the scope of the common corrosion in food cans.

The common approach in corrosion research is that the mechanism is ionic only and that the water is just the solvent and the carrier. This approach is incorrect and misleading. In fact, corrosion of metals in distilled water may be more severe than in tap water. The biochemical and pharmaceutical industries realize severe corrosion of stainless steel piping in distilled water.

The Electrochemical Potential

The galvanic corrosion has been explained on the basis of potential difference between two dissimilar metals. This is the driving force of the electrical current and therefore of the corrosion process. The electrochemical potential of a metal has been defined in textbooks as the tendency of the metal to dissolve, or to give electrons. Actually, the potential is not of the metal, but of the hydrogen on the metal. The potential difference of the galvanic cell or the bi-metal is therefore the difference of the hydrogen potential on the two metals. The potential of hydrogen depends on the solid to which it is adsorbed and the solution in which the solid is immersed. Also, the pressure above the solution has an effect on the potential (15). This is another indication that the potential of a metal has to do with hydrogen activity. The reactivity of the hydrogen with the metal will determine the type and extent of the corrosion. If the two metals are noble, the solution will be oxidized near the anode, where hydrogen gives its electron.

Potential difference does not require two different metals. Nonuniform mechanical and chemical composition leads to nonuniform absorption of hydrogen atoms to the metal and thus to potential differences. The potential of hydrogen on a stressed site on the metal is different than on a nonstressed area. The stressed metal site will usually serve as the anode, by accumulating hydrogen atoms that turn into ions by donating their electrons to the cathodic sites. The next step, as explained above, is the loss of electrons from the metal to the hydrogen ions. As a result, the metal dissolves as ions and the hydrogen atoms are reformed. Trapped hydrogen atoms in the bulk of the metal may lead to corrosion at the traps. It is well known that stresses in steel lead to trapping of hydrogen and that stressed areas tend to corrode. The type and rate of the corrosion will also depend on the metal composition and the distribution of the impurities on the surface and in the bulk of the metal.

A good indication that the electrochemical potential of metals is actually the potential of hydrogen on the metal is that an enameled metal surface has a potential very close in value to that of the uncoated metal. Coated tinplate has a different potential than coated TFS (tin-free steel). This means that hydrogen and protons, which can migrate through organic coatings, may reach the metal, where also electrons may flow. The fact that metal does not dissolve into the food does not mean that oxidation reduction reactions do not occur. A possible result of such potential difference is hydrogen swell and food discoloration.

Polarization

The activity of the hydrogen species in the solution is changing in the course of the corrosion process. Near the anode there is a depletion of H atoms, and near the cathode there is a depletion of H^+ and formation of H atoms. This leads to a decrease of the anode potential and increase of the cathode potential, which means a decrease in the potential difference and the driving force for electrons flow. This phenomenon is termed *polarization*. Oxidizing materials, which tend to combine with hydrogen atoms, will counteract polarization on the cathode. Reducing materials, which provide H atoms, will counteract the anodic polarization. Materials that counteract polarization are called *depolarizers*.

The Role of Oxygen

The term *oxidation* is perhaps the most misleading term in science. It has misled everyone, including scientists to relate oxidation to oxygen. While the combination of matter with oxygen is an oxidation process, most oxidation processes do not involve molecular oxygen. Oxygen is perhaps the mildest oxidizer in nature; however, its combination with hydrogen is forming the OH radical, which is the oxidizer in nature.

It can be shown that rust formation requires water or moisture and not oxygen, as it is commonly thought. Steel will rust under vacuum and high moisture, but it will not rust in dry air. Oxygen can enhance rust formation, by combining with hydrogen atoms adsorbed to the metal surface, and form OH radicals. Hot steel surface, charged with hydrogen under vacuum, will immediately form a layer of rust on exposure to air.

Oxygen is a mild cathode depolarizer, but in the presence of atomic hydrogen and a suitable catalyst, oxygen can form OH radicals that are strong oxidizers, because these tend to combine with hydrogen atoms to form water. Four hydrogen atoms are oxidized to water by one molecule of oxygen. Such activity, however, depends on the ability of the metal to catalyze the combination of molecular oxygen with atomic hydrogen. A good illustration of the mild oxidizing nature of oxygen can be demonstrated by the fact that bubbling air into orange juice for a few hours does not lead to discoloration. On the other hand, orange juice discolors in enameled cans sealed under vacuum. A food product that has lost hydrogen is oxidized. The hydrogen can be lost to solids, such as coated tinplate, that absorb hydrogen atoms. The oxygen may combine with these absorbed hydrogen atoms to form OH radicals that will directly oxidize the product. Oxidation of metals is defined as loss of electrons. It is quite well established that the electrons are lost in the corrosion process to H^+ or to OH radicals, rather than oxygen.

On the basis of these observations, the oxygen is a secondary player, which enters into the game at a later phase in the corrosion mechanism, when the depolarization is the governing mechanism. The combination of molecular oxygen and hydrogen requires a suitable catalyst. Steel seems to be a good catalyst for such a reaction, but it also is a strong absorber of hydrogen atoms.

Hydrogen Activity in Metals

Hydrogen embrittlement and stress corrosion are formed by absorption of hydrogen into the metal. Hydrogen trapped in steel can form extremely high pressures in the metal, leading to cracking, blistering, and pitting. The hydrogen trapped in the steel can react with many of the noniron elements, such as carbon, sulfur, and phosphor. The result is pitting corrosion, decarbonization, and loss of strength.

Redox Potential of Water and Aqueous Solutions

The quality parameters of water in contact with the metal should include its redox potential that takes into consideration not only the pH, but also the hydrogen activity. Water is composed from H and OH radicals. The multiplication of the activities of the H and OH radicals is constant, similar to the relationship of H^+ and OH^- from which the pH values are derived. When the H activity is higher than the OH activity, the water is reducing, and when the activity of OH is higher, the water is oxidizing. In neutral water the activity of the H and the OH is the same. Neutral water with respect of redox is not the same as neutral water at pH 7, and vice versa. Water at pH 7 can be very oxidizing and can be made very reducing by bubbling hydrogen in the water. Orange juice, for example, is acidic and reducing. Tap water may be at pH 7 and very oxidizing. The redox potential, as defined by the Nernst equation given above, includes the effect of the pH, but the pH does not include the redox. Many materials added to the water may affect the redox but not the pH. A good example is the addition of ozone and hydrogen peroxide to water, which will affect the redox but not the pH. The corrosivity of the water may sharply change by such additives. It is very important to consider the redox potential as well as the pH of the water used for the product and the process, in order to minimize internal corrosion, and that of the cooling water to avoid external corrosion.

THE SPECIFICITY OF HYDROGEN

The empirical corrosion research clearly indicates that the pH alone can neither explain nor predict corrosion phenomena. The corrosivity of various food products having the same pH may be very different. Acetic acid, for example, is much more corrosive than citric acid in contact with steel, but the opposite is true for tin that is not attacked by acetic acid. In lack of a scientific explanation to these facts, this phenomenon is explained by the term “affinity.” Even the consideration of the redox potential does not enable prediction of corrosion. Two solutions at the same pH and the same redox may exhibit different corrosion effects on the same type of can.

Haggman (2) showed that steel with high sulfur content is attacked by foods containing sulfates. Similarly, foods containing phosphates are corrosive to steel containing high phosphor levels. All of these confusing facts, which cannot be explained by the common theories of corrosion mechanisms, are indicative that some parameter, having a major effect on corrosion, is not known and therefore not considered.

Researching the mechanism of biological oxidation reduction provides a clue that might point out a possible direction for explaining the puzzling phenomena described above.

The specificity of enzymes is well known. Enzymes are responsible for the oxidation reduction reactions in biological systems. Each biological reaction requires a specific enzyme. The catalyst for the reduction of carbon dioxide into sugar in the photosynthesis reaction is the chlorophyll. No other catalyst in nature will do it. This reaction also requires very specific light energy, at a very specific narrow range of wavelength or frequency. The physicist relates to energy also through its qualitative properties, while others usually consider energy quantitatively only. Energy has a dimension of intensity, but also a qualitative dimension expressed in wavelength or frequency.

Antioxidants donate hydrogen atoms, thereby serving as reducers. However, such reducing activity is quite specific. Vitamins C and E are antioxidants, but each one is responsible for the reduction of specific systems. This means that the hydrogen donated by vitamin E is qualitatively different from that of vitamin C, or other antioxidants. In other words, if antioxidants had not have this specificity, there would have been only one antioxidant in nature.

The summary of all these facts leads to the conclusion that hydrogen atoms and ions differ in their qualitative energetic properties. This is the source of the multiple forms of corrosion, and this must be the explanation for the lack of understanding and control of some corrosion phenomena.

Nuclear magnetic resonance (NMR) spectroscopy is based on the theory that the active hydrogen atom in an organic molecule has a specific energetic property. This property is specific to every material and therefore can be used for the purpose of identification of materials. This knowledge is applied in medicine to identify, for example, cancerous cells in biological tissues. Applying NMR spectroscopy to corrosion research may lead to explanations as to why atomic and ionic hydrogen from different sources have a different corrosion effect on a certain metal.

COMMON CORROSION PROBLEMS

The mechanisms explained above can be used to enlighten some of the common corrosion failures.

Pitting Corrosion

Microscopic examination of the metal in cans exhibiting "hydrogen swell" and sulfide black reveals pits in the steel. This type of corrosion is common in cans with foods containing sulfur. It has been realized that the pits occur more on stressed areas, in steels containing sulfur.

Hydrogen atoms that had been in contact with a sulfur-bearing compound permeate into steels and are trapped at preferred specific points. Such points contain extra amounts of sulfur, which is irregularly distributed in the steel. The permeation and trapping of hydrogen in such sites is enhanced, if the sites are mechanically stressed. The hydrogen trapped in the steel develops very high local pressures in the steel. The trapped hydrogen reacts with the nonmetallic components of the steel, and it also recombines to form molecular hydrogen gas. Such activity in the steel occurs mainly in enameled cans. This process requires permeation of hydrogen into the steel, and it is therefore more common in enameled tin-free steel and low-tin-coated tinplate. The permeating hydrogen may leave to the atmosphere, unless trapped by nonuniform distribution of impurities and mechanical stresses.

Sulfide Black

The trapping of hydrogen in the steel depends on the steel and the food composition. The gas emanating from the pits may be only hydrogen, but usually, in case of pit formation, it is composed of a mixture of compounds containing iron, sulfur, and other elements from the steel. These erupting compounds appear as black spongy lumps, termed by canners as "sulfide black." This phenomenon occurs mainly in enameled cans, and the sulfide black appears mainly on the coated side seam and along beads and scratches, where irregular stresses are formed. The food product triggers the formation of the sulfide black, but the steel composition and mechanical stresses are the controlling factors in the mechanism of sulfide-black formation.

Enamel Peeling and Under Film Corrosion

The bonding between the enamel and the metal is based on hydrogen bonds. These bonds are formed by hydrogen atoms shared by the metal and the coating. The H atom, coming usually from the organic coating, shares its electron with the metal and the coating. For example, the hydrogen atom of an OH group in the coating may share its electron with an oxygen atom on the metal surface. The hydrogen bond can be described as

$$\text{Metal}-\text{O}\cdots\text{H}\cdots\text{O}-\text{polymer}$$

Such bonds can be destroyed by addition of a hydrogen atom to the bond. By that, two OH groups that repel each other will be formed, and the metal will repel the polymer. This means that the delamination is caused by a reduction mechanism. A complete delamination, with or without any corrosive attack on the metal, can occur when the food product is very reducing, the polymer is very permeable to hydrogen atoms, and the metal surface is extremely impermeable to the hydrogen. This excess of atomic hydrogen will be formed between the tin and the polymer, leading to reduction of the metal and the loss of the hydrogen bond. Such complete delamination was frequent when heavy hot-dipped tin coatings were coated with phenolic and other types of polymer. Partial delamination, followed by corrosion under the enamel in tomato cans, is still a common phenomenon. It appears usually near scratches and on stressed areas, such as beads and side seams.

The hydrogen bond can also be destroyed by oxidation—that is, by removing the hydrogen atom that is forming the bond. Pulling the hydrogen out chemically or electrochemically may lead to loss of the bonding hydrogen from the polymer. The loss of adhesion in such cases is expressed in small blisters to the enamel, pit formation, and some metal dissolution, and it is frequently indicated by formation of hydrogen gas in the container. The latter leads to vacuum loss and even hydrogen swell.

Hydrogen Swell

The formation of hydrogen gas and severe tin dissolution in plain cans is well known. This is usually explained as the attack of H^+ on the tin. The mechanism is much more complicated, and it involves the redox potential of the food and the specificity of the hydrogen in relationship to the tin and steel composition. The pH alone is far from explaining why a few parts per million (ppm) of sulfite, which have no significant effect on the pH, will lead to very rapid detinning. The tin is attacked by H^+, which, as mentioned above, has also a qualitative dimension besides its concentration in the food. The H^+ could also be formed from atomic hydrogen that entered the bulk of the tin. The fact that large quantities of hydrogen gas are formed may indicate that the atomic hydrogen in the tin delivers the electrons to cathodic sites in the steel. Analysis of cases of such failure supports the conclusion that the interaction of the tin with specific hydrogen is the controlling factor in rapid detinning. The redox potential of the product and the specificity of the hydrogen of the product, as well as depolarization agents in the product, are the important parameters to be considered in such failure studies.

Hydrogen swell occurs also in enameled cans. The mechanism is commonly attributed to the porosity of the enamel. The enamel coverage and its thickness affect the resistance to hydrogen permeation into and out of the enamel. The resistance is only one of the factors affecting hydrogen permeability. At zero driving force, the resistance is meaningless. The formation of the hydrogen pressure and its permeability depend mostly on the characteristics of the metal and the food product. There is a certain optimal enamel coating that should be applied.

This optimum depends on a few factors related mainly to the metal and the product but not related to the enamel. Hydrogen atoms can diffuse through the enamel and dissolve and accumulate in the metal, but they can also migrate to the external wall. They can then react with the impurities in the steel, form pits, recombine to form molecular hydrogen, and diffuse through the enamel. It is possible to have hydrogen swell without significant or equivalent metal dissolution.

Darkening of Light-Colored Fruit

Corrosion in cans refers to the oxidation of the metal. The role of hydrogen in its atomic and ionic form in this corrosion process was explained above. Oxidation of the food product may be regarded as the corrosion of the product, and it is explained as loss of atomic hydrogen. In many cases the hydrogen that was lost from the food is the hydrogen that has led to the corrosion. In other words, the metal can, enameled or plain, can lead to oxidation of the food product by absorbing atomic hydrogen from the product.

Darkening of the food is the result of oxidation of some compounds in the food. The oxidation is due not to addition of oxygen, but rather to hydrogen loss. The composition and the physiochemical properties of the food, the organic coating, and the metal, with respect to hydrogen activity, are the factors involved in the mechanism of the oxidation of both the metal and the food.

CONCLUSION

Hydrogen in its atomic, ionic, and molecular form participates in any corrosion process. There is no corrosion without hydrogen. The electrochemical potential of the metal is the potential of hydrogen. The redox potential of the food defines the hydrogen activity of the food and its tendency to lose or gain hydrogen atoms.

The specific energetic properties of the active hydrogen will determine the rate of corrosion. The hydrogen activity and its effects have to do with the composition of the materials involved. The interaction of the materials with hydrogen determines the type and rate of corrosion. The properties of materials, such as hydrogen permeability through the polymers and the metals, should be studied and correlated with performance.

The source of hydrogen is water that acts through its H and OH radicals. The redox potential of water, together with the pH and the specificity of the hydrogen, have to be considered in order to understand and control corrosion. The water used for processing and the product water should be considered along the above parameters.

The food product composition and any additive will have an effect on the corrosivity of the product. The packaging materials should be studied in view of their interactions with hydrogen, taking into account the specific properties of the hydrogen atoms in the product and the affinity of the specific hydrogen with the specific packaging materials.

This article is a summary of the author's research through a new approach to corrosion studies. The research is based on the well-verified assumption that hydrogen activity is the major parameter controlling corrosion. The research is far from being complete and may not offer immediate solutions to all corrosion phenomena and failures. It may serve as a new direction for researchers in this field who seek better understanding of the corrosion mechanisms and means to avoid failures.

Corrosion failure analysis through the presented theory can spread light on many unexplained corrosion phenomena, such as detinning, enamel peeling, and underfilm corrosion, as well as sulfide black and pitting corrosion. The key to understanding and solving corrosion problems is *thinking hydrogen*.

CANS, PLASTIC

Updated by Staff

INTRODUCTION

Cans are defined here as open-mouthed cylindrical containers, usually made of aluminum (see Cans, aluminum) or tinplated steel (see Cans, steel). This form can also be made of plastics, by injection molding (see Injection molding), blow molding (see Blow Molding), or forming from sheet (see Thermoforming). Such cans have been made for many years and have taken small shares of some markets, but are not dominant in any. Plastics are much less rigid than metals, thicker walls are needed for equivalent performance, and container weight and cost can become excessive. For carbonated beverages (see Carbonated beverage packaging), cans are rigidified by internal pressure, but other properties such as burst strength, creep, and gas barrier become more critical.

Tensile strength is needed, especially in beverage cans, and can be achieved through selection of appropriate plastics plus orientation (stretching). Orientation in the circumferential (hoop) direction is hardest to do, and this explains why blow molding from a narrow parison may give better performance than thermoforming or direct injection to size. Heat resistance may be needed: either around 122°F (50 °C) to resist extreme warehousing conditions; or 140°F (60 °C) for 30 min (pasteurization); or 185–212°F (85–100 °C) for a few seconds (hot filling); or 257°F (125 °C) for 20–40 min (retort sterilization cycle). A can for processed foods must withstand the internal pressure generated when a closed can is heated. In a sterilizing retort, compensating overpressure may be needed outside the can to prevent failure. Not all retorts are capable of such overpressure (see Canning, food). Gas and/or moisture barrier and chemical resistance are needed for most packages. The can shape is advantageous for barrier, because it offers a low surface-to-content ratio, but it also introduces the possibility of failure from chemical attack in some places, particularly the stressed flange area and the bottom edge.

Product-design centers on these two features: the flange and the base. A precise flange is needed to guarantee a perfect seal, which is absolutely critical for sterilized cans and is certainly desirable for contained liquids, especially under pressure. If a plastic end is used, heat-sealing is possible, but the plastic end will be less rigid and may require a heavier flange. Common metal ends may be used, but flanges must be very flat. Also, no matter what end is used, stresses and later stress cracking in that region must be anticipated and avoided.

Vertical sidewalls are desired for easy transport in filling lines. Tapered walls do allow nesting, which has storage advantages, but for mass applications the filling speed is more important. Another design concern is the necked-in end now customary for beverage cans, which allows tighter six-packing and cheaper ends. This can be done with plastics, but mold design is more complicated to permit the undercut needed.

APPLICATIONS

Thermofolded 250-mL PET cans have been used in Great Britain (Plastona), but they are nonvertical (they nest), and they are not coated to enhance barrier properties. In the United States, Coca-Cola was working with "Petainers," which are cans drawn in solid phase from molded PET cups developed in Europe by Metal Box and PLM A.B. The term Petainers now refers to bottles. In Italy, some beverage cans are made by thermoforming, whereas some are made by blowing bottles and cutting/flanging the tops. The latter should give the best properties for given weight because of more orientation.

For heat-processed foods, polypropylene is the preferred material because it has the highest heat resistance of the commodity thermoplastics. Polycarbonate (see Polycarbonate) and other engineering plastics have been suggested, but are much more costly. Both PP and PC are poor oxygen barriers, however, and would need a barrier layer for many foods. Metal Box also worked with extruded tubes with top and bottom flanged ends, and resin suppliers have made cans on pilot lines, but there is still no large-scale commercial use. One of the problems is that other forms of plastic (e.g., trays, bottles, pouches and bowl shapes) are competing for the same markets. For frozen juice, composite cans have most of the market (see Cans, composite), although Tropicana has injection molds its own polystyrene cans, and some injection-molded HDPE cans appeared in the market as well. Injection-molded HDPE cans are used for cake frostings, and dry beverages are sometimes seen in plastic cans, notably the heavy injected PP cans used in Italy for coffee.

The Plastic Can Company (PCC) has patented a two-stage PET paint container. The technology that has been used for bottles is now available for cans. The technology allows preforms and lids to be manufactured centrally and economically shipped and stored at the paint filling plant before being blow molded into finished cans on site. The plastic can replaces the traditional metal lever lid containers used for paints and dry goods with a single plastic molding. Its benefits include: use of environmentally friendly plastics such as PET to be used for the first time for oil and solvent-based paints and for water-based paint; transparent cans allowing consumer to see color of paint; air tight on resealing; rustproof. Also, PET is cheaper and lighter than steel. PCC is now developing cans intended for kitchen/home use with hand-openable and resealable air-tight lids for dried and preserved foods (1).

CANS, STEEL

Fred J. Kraus
George J. Tarulis
Crown Cork & Seal Company, Inc., Alsep, Illinois

In 1975, France not only was involved in a revolution but also was at war with several hostile European nations.

The French people as well as the armed forces were suffering from hunger and dietary diseases. Consequently, a prize of 12,000 francs was offered by the government to any person who developed a new means for the successful preservation of foods. Napoleon awarded this prize to Nicholas Appert in 1809. Mr. Appert's discovery was particularly noteworthy because the true cause of food spoilage was not discovered until some 50 years later by Louis Pasteur. Appert had nevertheless recognized the need for utter cleanliness and sanitation in his operations. He also knew or learned the part that heat played in preserving the food, and finally, he understood the need for sealed containers to prevent the food from spoiling. The containers he used were wide-mouthed glass bottles that were carefully cooked in boiling water (1, 2).

A year after the recognition of Appert's "canning process," in 1810, Peter Durand, an Englishman, conceived and patented the idea of using "vessels of glass, pottery, tin (tinplate), or other metals as fit materials." Thus, the forerunners of modern food packages were created. The original steel cans had a hole in the top end through which the food was packed. A disk was then soldered on to the top end. The disk had a small hole in it to act as a vent while the can was cooked. The vent hole was soldered and closed immediately after cooking (2).

Durand's tinplate containers were put together and sealed by soldering all the seams. The techniques were crude but nevertheless, with good workmanship, afforded a hermetic seal. A *hermetically sealed container* is defined as a container that is designed to be secure against the entry of micro-organisms and to maintain the commercial sterility of its contents after processing. Commercial sterility is the inactivation of all pathogenic organisms and those spoilage organisms that grow in normal ambient distribution and home-storage temperatures. No technological advance has exerted greater influence on the food habits of the civilized world than the development of heat treatment and the use of hermetically sealed containers for the preservation of foods (1, 3).

Foods canned commercially by modern methods retain nearly all the nutrients characteristic of the original raw foods. Several investigations showed that good canning practices as well as proper storage and consumer preparation improve the retention of the nutritive value of canned foods (4–6).

The steel container provided a reliable lightweight package that could sustain the levels of abuse that were common in packing, distributing, and selling of products. It has also been necessary to improve and develop new concepts to keep up with the advances in packing procedures, materials handling, and economic pressures.

EVOLUTION OF THE CAN

A four-track evolutionary road developed. One uses solder to seal all the can seams. This process evolved from the hole-in cap container to one that holds evaporated or condensed milk. These "snap-end cans" retain the vent hole in the top that permits filling the can with a liquid. They are then sealed with a drop of solder or solder tipping. The second track combines the soldering of the side seam with the mechanical roll crimping the ends onto the body. The attachment procedure known as *double seaming* was patented in 1904 by the Sanitary Can Company. This invention significantly improved opportunities to increase the speeds of can manufacture and packing operations. Today, double seamers or closing machines seal cans in excess of 2000 cans per minute with filling equipment that can match this task. The third track uses a press operation that stamps out cuplike structures with an integrated body and bottom, with the lid or top attached by double seaming. These began as shallow containers like sardine cans. These drawn or two-piece cans evolved into taller cylindrical cans that are popular for many food products and carbonated beverages. The primitive shallow cans are fabricated on simple presses. The taller two-piece cans go through multiple press operations like the draw–redraw technique or through a drawn press and wall iron operation. The fourth track is the incorporation of a welded side seam for three-piece cans, which provided greater body strength and more double seaming latitude in comparison to the soldered side seam.

The growth of the steel can caused the manufacturing function to change. At first, the packers manufactured their own cans. This was understandable, because the same craftspersons and equipment were necessary to seal the can as well as to make them. When the double-seamed can or "sanitary can" was accepted, the can manufacturing function coalesced into large manufacturing organizations. This came about because the double-seamed can lent itself to mechanized production whereas the all-soldered can remained a manual operation. Hence, it was economically attractive to invest large sums of money for improving the sanitary can. A few large packers could afford to be self-manufacturers, and they invested large sums to keep up with the developing technology. However, their attempts to produce cans was often short lived because of economic changes that forced them to become dependent on the can companies for their container needs.

Today some packaging companies still make their own containers.

SHAPES AND SIZES

A wide variety of styles and sizes have grown out of the tremendous usage of steel containers (see Tables 1 and 2). The first figures of the container dimension represent the diameter of the container measured overall across the double seam; the second figure is the height, which is the vertical overall height measured perpendicular to the ends of the can. The first digit in each number represents inches; the second two digits represent sixteenths of an inch. Thus, a 307 × 113 can is 3 7/16 in. in diameter and 1 13/16 in. high. For rectangular cans, the first two sets of digits refer to base dimensions; the third set refers to can height.

Some can sizes are given various "names" by which the can is known. Some of these names that are identified in Table 2 are very old, dating back to the early history of

Table 1. Steel Can Styles and Sizes

Style	Dimensions in. (cm)	Capacity	Some Uses	Convenience Features
Aerosol cans (*1*)	202 × 214–300 × 709 (5.4 × 7.3–7.6 × 19.2)	3–24 oz (85–680 g)	Foods, nonfoods	Designed for fit of standard valve cap
Beer-beverage cans (*2*)	209.211 × 413 (6.5/6.8 × 12.2) 209.211 × 604 (6.5/6.8 × 15.9) 207.5/209 × 504 (6.3/6.5 × 13.3)	12 or 16 fl oz (355 or 473 cm^3)	Soft drinks, beer	Easy-open tab top, unit-of-use capacities
Crown-cap, cone-top can	200 × 214–309 × 605 (5 × 7.3–9 × 16)	4–32 oz (113–907 g)	Chemical additives	Tamperproof closure, easy pouring
Easy-open oblong can	405 × 301 (11 × 7.8) #1/4 oblong	4 oz (113 g)	Sardines	Full-paneled easy-open top
Flat, hinged-lid tins (*3*)	112 × 104.5 × 004–212 × 205 × 003.75 (4.4 × 104.5 × 0.64–7 × 5.9 × 0.6)	12–30 tablets	Aspirin	Easy opening and reclosure
Flat, round cans	213 × 013 (7.1 × 2.1)	1 1/2 oz (43 g)	Shoe polish	Friction closure
Flat-top cylinders (*4*)	401 × 509–610 × 908 (10.3 × 14.1–16.8 × 24)	1–5 qt (946–4730 cm^3)	Oil, antifreeze	Unit-of-use capacities; tamperproof since it cannot be reclosed
	211 × 306 (6.8 × 8.6)	8 fl oz (237 cm^3)	Malt liquor	
	211 × 300 (6.8 × 7.6)	8 oz (227 g)	Cat food	
	300 × 407 (7.6 × 11.3)	15 oz (425 g)	Dog food	
Hinged-lid, pocket-type can			Tobacco, strip bandages	Firm reclosure
Key-opening, nonreclosure can (*5*)			Sardines, large hams, poultry, processed meats	Contents can be removed without marring product
Key-opening, reclosure cans (*6*)	307 × 302–502 × 608 (8.7 × 7.9–13 × 16.5)	1/2–2 lb (0.2–0.9 kg)	Nuts, candy, coffee	Lugged cover reclosure
	401 × 307.5–603 × 712.5 (10.3 × 8.8–15.7 × 19.8)	1–6 lb (0.45–2.7 kg)	Shortening	Lid is hinged
	211 × 301–603 × 812 (6.8 × 7.8–15.7 × 22.2)	1/4–5 lb (0.11–2.2 kg)	Dried milk	Good reclosure
Oblong F-style cans (*7*)	214 × 107 × 406–610 × 402 × 907 (7.3 × 3.7 × 11.1–16.8 × 10.5 × 24)	1/16–1 gal (237–3785 cm^3)	Varnish, waxes, insecticides, antifreeze	Pour spout and screw-cap closure
Oblong key opening can (*8*)	314 × 202 × 201–610 × 402 × 2400 (9.8 × 5.4 × 5.2–16.8 × 10.5 × 61)	7 oz–23.5 lb (0.2–10.7 kg)	Hams, luncheon meat	Wide range of sizes, meat-release coating available
Oval and oblong with long spout (*9*)	203 × 014 × 112–203 × 014 × 503 (5.6 × 2.2 × 4.4–5.6 × 2.2 × 13.2)	1–4 fl oz (30–118 cm^3)	Household oil, lighter fluid	Small opening for easy flow control
Pear-shaped key-opening can (*10*)	512 × 400 × 115–1011 × 709 × 604 (14.6 × 10.2 × 4.9–27.1 × 19.2 × 15.9)	1–13 lb (0.45–5.9 kg)	Hams	Easy access through key-opening feature, meat-release coating available
Round truncated			Waxes	Screw-cap simple reclosure
Round, multiple-friction cans (*11*)	208 × 203–610 × 711 (6.4 × 5.6–16.8 × 19.5)	1/32–1 gal (118–3785 cm^3)	Paint and related products	Large opening, firm reclosure, ears and bails for easy carrying of large sizes
Round, single-friction cans	213 × 300–702 × 814 (7.1 × 7.6–18.1 × 22.5)	≤ 10 lb (4.54 kg)	Paste wax, powders, grease	Good reclosure
Sanitary or open-top can (three-piece) (*12*)	202 × 214–603 × 812 (5.4 × 7.3–15.7 × 22.2)	4 fl oz–1 gal (118–3785 cm^3)	Fruits, vegetables, meat products, coffee, shortening	Tamperproof, ease of handling, large opening
Slip-cover cans			Lard, frozen fruit, eggs	Simple reclosure

Table 1. Continued

Style	Dimensions in. (cm)	Capacity	Some Uses	Convenience Features
Spice can, oblong (*13*)	Wide range	1–16 oz (28.4–454 g)	Seasonings	Dredge top, various dispenser openings
Square, oval, and round-breasted containers (*14*)			Powders	Perforations for dispensing, reclosure feature
Two-piece drawn redrawn sanitary can	208 × 207/108 (6.4 × 6.2/3.8)	3–5 1/2 oz (85–156 g)	Food	Improved can integrity, stackability
	307 × 111 (8.7 × 4.3)	6 3/4 oz (191 g)		
	211 × 214 (6.8 × 7.3)	7 1/2 oz (213 g)		
	404 × 307 (10.8 × 8.7)	1 1/2 lb (680 g)		

canmaking. Today most cans are identified by their dimensions and not by name. Some of those names and can sizes listed are no longer applicable.

International standards for can sizes have been developed under auspices of the International Standards Organization (ISO), and cans are named in many countries on the basis of ISO standards. The specifications, measurements, and nomenclatures in ISO standards are used to describe cans in several countries. As can sizes listed in the ISO standards are the least likely to be restricted in international trade, it would be advisable when developing a new product line or changing package sizes to consider can sizes from the ISO standards. To comply with the ISO standards, the Can Manufacturers Institute has now recommended that U.S. can sizes be identified in metric measurements according to their body plug diameter rounded to the nearest whole number of millimeters, and their height must be rounded to the nearest whole number of millimeters as shipped from the can factory. For example, the 307 × 113 is identified as 83 × 46 mm.

Normally, during the selection of a container size for a specific item the concerns are not with providing a can with minimum surface area, but rather to minimize package metal weight (i.e., cost) within practical limitations. As an example, the filling, processing, and end attachment operations demand that the circular ends be made of thicker metal than the cylindrical body. The cost impact tends to reduce end diameter while increasing body height compared with the theoretical dimensions for minimum surface area. Furthermore the ends are attached to the body with mechanically overlapped metal formed into the body and ends. Again, the requirement for thicker metal for the ends would favor smaller diameter.

Similarly, the body beads (for strength against can collapse) and end beads (for rigidity) increase the effective surface area. This again favors a smaller diameter to minimize metal weight. In addition, the ends are punched out of a rectangular sheet of metal in the manufacturing process. Not only must the weight of metal used in the ends be minimized, but also the scrap produced from manufacturing round ends from square sheets has to be held to a minimal level.

Other limitations must also be considered. For example, the can manufacturer provides to the customer a can with one end attached (factory-finished can). The customer, in turn, fills the empty can and conveys it to another machine, where the top end (customer/packers end) is attached. To avoid spilling product until the top end can be attached, the can is not fully filled but a small “headspace” remains. Besides preventing product loss, this void provides for product expansion during processing and allows the consumer to open the can without splashing. This need for a headspace requires the can to be slightly taller than the theoretical height. In conveying, the laws of physics (inertia) state that the liquid juice will try to remain in place while the can begins moving. Without adequate headspace, juice would flow out of the open can. At a given conveying speed, less headspace is required for a smaller-diameter can than for a larger one. Therefore, it would be required to either increase can height for a

Table 2. Popular Can Sizes

Dimensions	Popular name	Inches	(mm)	Capacity[a] (oz)	(cm^3)
202 × 214		2.13 × 2.88	(54 × 73)	4.60	(137)
211 × 413	12 oz	2.69 × 4.81	(68 × 122)	12.85	(380)
300 × 407	#300	3.00 × 4.44	(76 × 113)	14.60	(432)
303 × 407	#307	3.19 × 4.38	(81 × 111)	16.20	(479)
307 × 409	#2	3.44 × 4.56	(87 × 116)	19.70	(583)
401 × 411	#2 1/2	4.06 × 4.69	(103 × 119)	28.60	(846)
404 × 700	40 oz	4.25 × 7.00	(108 × 178)	49.55	(1465)
603 × 700	#10	6.19 × 7.00	(157 × 178)	105.10	(3108)

[a] Completely filled.

larger diameter can, or customers would have to slow their lines to avoid spilling product. Increasing the can height would make air removal more difficult. Increased air (actually the oxygen in the air) content would have a somewhat negative effect on product quality.

CAN PERFORMANCE

No other container has all the attributes of the can: economy, strength, durability, absence of flavor or odor, ease in mass handling without breakage, compactness, lightness, and no light damage to product; the can also provides a hermetic seal and can be produced at exceptionally high speeds and be lithographed.

Food cans are expected to have tightly drawn-in ends. A can with swelled ends or with metal feeling springy or loose is not merchantable. Consumers associate such appearances with spoiled contents. Gases produced by microbial action can, indeed, cause such appearances. It is also important to remove air from food cans to retard adverse internal chemical reactions. Therefore, end units must be properly engineered to cope with their many environments. They must act as diaphragms that expand during thermal processing and return to their tight drawn-in appearance when a vacuum develops during cooling. The necessary strength is built into the end units by the use of adequate plate materials and design of end profile (see Figure 1).

Food ends are either profiled structures requiring a mechanical means for opening or designed with scores for easy opening. Since the introduction of the easy-opening/convenience end in the mid-1960s, a broad variety of products have been packaged in cans with this feature. These easily removed ends are available in various diameters, metals, coatings, and configurations to meet product needs. Units can be removed as a whole with separation occurring around the perimeter of the end or only a portion of the top can be removed. For those products where consumer protection is desired, easy opening ends can be provided with safety features.

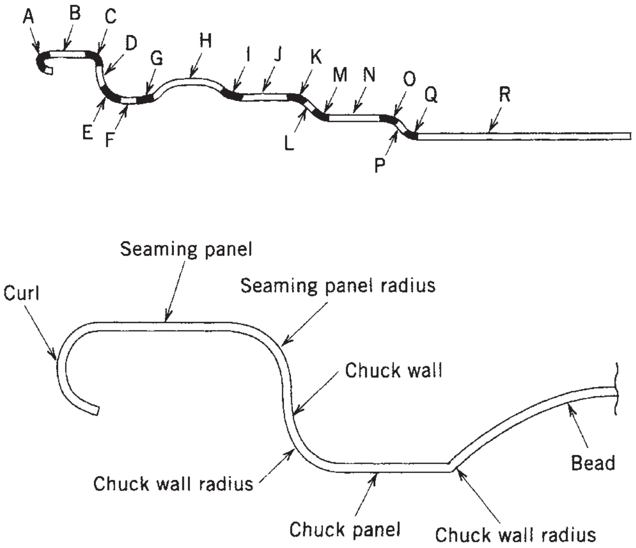

Figure 1. End profiles (A—curl, B—seaming panel, C—steaming panel radius, D—chuck wall, E—chuck wall radius, F—chuck panel, G—chuck panel radius, H—bead, I—bead-edge radius, J—first expansion panel, K—first expansion panel radius, L—first expansion panel step, M—first expansion panel step radius, N—second expansion panel, O—second expansion panel radius, P—second expansion panel step, Q—second expansion panel step radius, R—center expansion panel).

Ends used for carbonated beverages and aerosol products and those used for noncarbonated beverages packed using liquid-nitrogen pressurization, need little or no vacuum accommodation but rather resistance to high internal pressure. An end unit will permanently distort or buckle when the internal pressure exceeds its capability. This also renders the can unmerchantable because the distortion could affect the double-seam integrity.

Cans with inadequate body strength will panel because of internal vacuum or collapse under axial load conditions. A panel is the inward collapse of the body wall because of pressure differential. The condition may appear as a single segment, many flat segments, or panels that develop around the circumference of the cylindrical can body. Axial load is the vertical pressure that a packed container will be subject to during warehousing and shipping. The axial load capacity of a can is greatest when the cylinder wall is in no way deformed. A casual dent or designed structure that breaks the integrity of the straight cylinder will, in most cases, reduce the axial load capability of the container. Panel resistance and axial load capability are direct functions of the metal specification.

Panel resistance can be enhanced by the fabrication of beads in the body wall. This, in effect, produces shorter can segments that are more resistant to paneling. However, such beads predispose the container to early axial load failure. The deeper the bead is, the greater the paneling resistance but the greater the reduction in axial load capability. Many shallow beads can provide additional paneling resistance with less reduction in axial load capability, but labeling problems are often associated with cans with such bead configurations. Consequently, there are many bead designs and arrangements, all of which are attempts to meet certain performance criteria (7).

The steel container with proper material and structural specifications possesses, within limits, good abuse resistance. Excess abuse causes obvious damage, and severely dented cans are unacceptable in the marketing of canned products. Insidious events run parallel with excessive abuse. The double seams may flex momentarily, permitting an equally short-term interruption of the hermetic seal. Under some unsatisfactory conditions, this lapse can permit the entrance of micro-organisms that cause spoilage. This leakage can also admit air that accelerates adverse chemical reactions within the container. Many cans that show some level of damage are in the food distribution chain, and the safety of using such products is frequently questioned. To prohibit the sale of all containers that have insignificant amounts of damage would be a waste of large amounts of acceptable food (8).

CAN CORROSION

The steel container is not chemically inert and, therefore, can react with its environment and its contents. Steel's major ingredient, iron, is a chemically active metal that readily takes a part in reactions that involve water, oxygen, acids, and a host of other elements and compounds that can participate in oxidation reduction reactions (see the Cans, corrosion article).

The application of tin to the surface of sheet significantly increases the corrosion resistance of steel. Nevertheless, the potential for corrosion attack persists. Although numerous modifying factors produce varied patterns of attack, the chemical fundamentals for oxidative corrosion are the same. The basic requirements are always (a) differences in potential between adjacent areas on an exposed metallic surface to provide anodes and cathodes, (b) moisture to provide an electrolyte, (c) a corroding agent to be reduced at the cathode, and (d) an electrical path in the metal for electron flow from anodes to cathodes.

Under normal conditions, tin forms the anode of the couple, going into solution at an extremely slow rate and thus providing protection to the canned food. Under some conditions, iron forms the anode with resultant failure because of perforations or the development of hydrogen and subsequent swelled cans (hydrogen springers). Under other conditions, as when depolarizing or oxidizing agents (i.e., nitrates) are present, the removal of tin will be greatly accelerated with a consequent significant reduction in shelf life. Hydrogen is formed by the following two distinct processes: (a) at exposed steel areas that are protected cathodically by the tin–steel couple current and (b) as the steel corrodes, either because it is not completely protected by the tin or after the tin has been consumed. When perforations occur, they are usually the result of the same process in which hydrogen is developed except the steel is consumed in a localized area (9–11).

PRODUCT COMPATIBILITY

Products can be loosely categorized in terms of their susceptibility to chemical reaction with the can. Oils and fatty products seldom react with the metal surface of can interiors. However, when small quantities of moisture are present, either by design or accident, adverse reactions can develop. Highly alkaline products, usually nonfoods, will rapidly strip off tin or organic coatings but will not corrode the base steel. Acid products are corrosive, and highly colored acid foods and beverages are also susceptible to color reduction or bleaching, because of the reaction of the product with tin.

In this regard, when tin is exposed to some food products, a bleaching action occurs. Although this is objectionable with many products, such as the red fruits, and is avoided by the use of a suitable can lining, this bleaching action is desirable in certain instances. This is particularly true with the lighter-colored products such as grapefruit juice and grapefruit segments and sauerkraut. A slight bleaching action keeps the color light and compensates for the normal darkening effect, which may result from the processing or sterilization. Peaches and pears packed in cans completely enameled inside will be somewhat darker in color and slightly different in flavor than if packed in nonenameled plain tin cans. Although some individuals may prefer peaches packed in all enameled cans, it is doubtful that such cans will be produced under current conditions because the presence of an appreciable area of plain tin greatly increases the shelf life of this canned product.

Foods with $\mathrm{pH} > 4.6$ often have sulfur-bearing constituents (e.g., protein) and react with both tin and iron. This has been recognized as a problem for as long as such products have been canned, and the cause has been sought by many investigators. These low-acid foods form a dark staining of the tin surface and react with the iron to form a black deposit that adheres to both the can interior and the food product or can cause a general graying of the food product and liquor. This is often referred to as *black sulfide discoloration* or *sulfide black*. It can be unsightly but is harmless. Although sometimes exclusively a can headspace phenomenon, any interior container surface can be affected. Also, the black sulfide discoloration condition generally occurs during or immediately following heat processing, but occasionally it develops during storage. It is believed to be an interaction of the volatile constituents from the food product and/or oxidation–reduction agents in the food product with an oxidized form of iron from the tinplate. The staining of the tinplate is not part of this reaction (13, 14).

Although tin sulfide staining and black sulfide discoloration is harmless from a product standpoint and has no detrimental effect on container or product shelf life, it has been found to be objectionable from an aesthetic standpoint.

In addition to container and product appearances, some food products and beverages are highly sensitive to off-flavors caused by exposure to can metals (12).

CAN METAL

The term "tin can" is somewhat of a misnomer, because tin cans are made of steel sheets that have either no tin or coated with a thin film of tin. The steel products commonly produced for container components have a theoretical thickness ranging from 0.0050 to 0.0149 in. (0.127 to 0.378 mm) expressed as weights per base box* of 45–135 lb. Depending on end use, the plate (blackplate) can be processed by the electrolytic deposition of metallic chromium and chromium oxides and coated with a lubricating film (tin-free steel) or coated with tin by electrodeposition. Improvements in electrolytic tinplate, since its commercial introduction in 1937, have increased both its

---

* *Base weight*—approximate thickness in pounds per base box: (base weight $\times$ 0.00011 = theoretical thickness). *Base box*—unit of area: 112 sheets, 14 in. $\times$ 20 in. = 31,360 in.^{2} (217.78 ft^2); dimensions in increments of 1/16 in.

Package: 112 sheets of any dimensions. *Number of base boxes in a package:* use ratio tables (ASTM A623) or L(in.) $\times$ W(in.) $\times$ 112 = 31,360. Number of base boxes in a coil: L(in.) $\times$ W(in.) = 31,360.

versatility and uniformity of performance. Electrolytic plate has entirely replaced hot-dipped plate in present-day cans. The result of these changes/improvements has allowed for reductions in tin coating weights. Tin plate carries a coating of tin that may vary from 0.000015 to 0.000100 in. in thickness, depending on the grade. Differential coated electrolytic tinplate, with different coating weights of tin on each side of the steel baseplate, has been used commercially since 1951. Containers made of differential coated tinplate have an inside tin coating of sufficient thickness to withstand the corrosive attack of processed foods and an outside coating adequate to withstand the rigors of processing and atmospheric conditions. The thickness of tin coating is designated by the total amount of tin used on coating one base box of plate. For example, #25 plate is electrolytic tinplate on which 0.25 lb of tin was electroplated on one base box, covering both sides of the sheet. Thus, the coating on one side of the sheet is one half that amount of tin, or 0.125 lb.

For structural integrity, base weight or gauge thickness is a prime consideration, but any increment of base weight is an increment in container cost. Often, the temper or design of can components can provide added strength without the need to add base weight. The chemistry and general metallurgy of the steel plate has considerable influence on the performance of steel containers. Before the advent of continuously annealed and cold-rolled double-reduced steel plate, which influence plate stiffness or temper, it was necessary to add ingredients to the steel to produce high tempers. Temper as applied to tin-mill products is the summation of inter-related mechanical properties such as elasticity, stiffness, springiness, and fluting tendency. During the development of the use of cold-reduced steel for mill products, the fabricators determined that various steel compositions and degrees of hardness in the base metal would permit the production of containers for a wider variety of products. Although there are certain limitations to the Rockwell hardness test,[†] it has been adopted as an industry standard because of its simplicity and overall good correlation with fabrication requirements. As a result, ranges of Rockwell hardness were developed to guide the steel manufacturers, and these Rockwell hardness ranges have become accepted as temper ranges.

Rephosphorized steel was necessary to fabricate beer can ends with sufficient buckling resistance. When the market opened for canned carbonated soft drinks, rephosphorized steel was not acceptable because of the corrosive nature of soft drinks and the high susceptibility of this plate to corrosion. Test pack experience indicated that some could perforate the endplate in 4–6 weeks. The availability of continuously annealed plate without the corrosion sensitivity properties of rephosphorized steel permitted the canning of soft drinks. It was still necessary to use heavier base weight material for the high-carbonation drinks. The added stiffness afforded by cold-rolled double reduced plate permitted the canning of all soft drinks with carbonation ranging from 1.0 to 4.5 volumes in cans with the same basis-weight ends. These same economies have been applied to other products where container fabrication could be adapted to the degree of stiffness characteristic of this plate (14).

CAN FABRICATION

One who is not associated with the container industry seldom realizes that the manufacture of cans is classed as one of the most mechanized industries, and in addition to the large amount of automatic equipment used, the speed at which cans are made no doubt rates among the faster automatic operations (see the Metals Cans, Fabrication article).

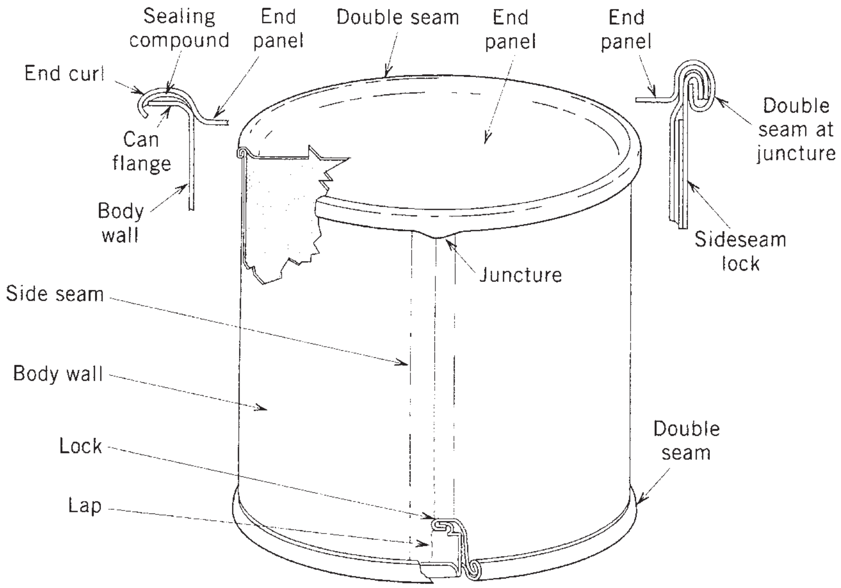
The most common type of steel can produced today are three-piece cans that consist of a body with a welded or soldered side seam in conjunction with two end components (see Figure 2). Another popular structure is the two-piece can, which is produced by either a single-draw, draw-redraw (DRD), or drawn-and-iron (D & I) process. Some limited quantities of cemented side-seam cans are produced for dry and nonthermal processed type products.

Most three-piece tinplate cans currently made have wire-welded side seams. The traditional soldered can is now in the minority and only is used for irregular-type meat cans and specialty cans. The solder used in canmaking is now generally composed of tin and silver. In July 1995 the U.S. Food and Drug Administration (FDA) has issued a final rule prohibiting the use of lead solder in the manufacturing of food cans, including imported products. The tin/silver solder is categorized as a soft solder and has a relatively low melting point, usually below 450°F, (232°C). Tinplate cans are easily soldered because the tin solder alloy readily fuses with the tin on the surface of the steel. In addition to providing a hermetic seal, solder also contributes to the mechanical strength of the seam by forming a metallurgical bond with the tin plate. Solder also has a certain amount of ductility and can be plastically deformed within certain limits. This characteristic permits the soldered laps of the body to be flanged and then incorporated into the double-seaming process. The speed of the can manufacturing line, the temperature of the molten solder, and the length of cooling all play an important role in good soldering operations. The soldered side seam can has been replaced for many can structures with an electrical resistance—welded seam. Benefits include a clean compact process and a much narrower weld area, which allows virtually wrap-around decoration and greater integrity, particularly for seaming-on of ends, because there is much less metal overlap thickness at the weld compared with the soldered lock and lap seam employed on soldered cans. The welding unit is easily integrated and ancillary equipment used on solder bodymaker lines.

Two reliable welding systems were developed and used commercially: The forge–wheel welding system developed

---

[†] A device used to measure the surface hardness of canmaking plate. A 1/16-in.-diameter ball penetrator is impressed into the plate surface with a 30-kg load. The measurement expressed as a Rockwell 30T reading, is inversely proportional to the penetration. An arbitrary scale is used to convert Rockwell readings into plate temper values. The stiffness increases from T-1 to T-6.



Material	Application	Method
Metal plate	Can units (bodies and ends)	Bodymaker; end press
Solder	Side seam sealling and bonding	Side seamer
Flux	Soldering aid	Bodymaker and/or side seamer
Sealing compound	To can ends for double-seam sealing	Comound liner
Protective coating	Metal plate protection	Roll coater or spray
Body and ends	Affix ends to body	Double-seamer

Figure 2. Double-seam three-piece can.

by Continental Can Company, and the wire weld system was developed by Soudronic AG (15, 16). Both are resistance-welding systems and variations of a forge weld (see Figure 3). The materials to be welded together are heated by an electric current passing through the materials. The resistance of the overlapped side seam produces the required welding heat. To obtain a weld, the heated material must be pressed together or clamped. This clamping capability is provided by wheels in the welding process. Because welded seams are basically lap seams, a raw edge exists, which generally requires a side-seam stripe coating application to minimize metal exposure.

For economic reasons, the forge-wheel welding process is no longer a viable commercial operation. Such forge-welded cans used tin-free steel (TFS) plate and started with the grinding of the body blank edges to remove oxide and chromium to ensure acceptable welds. After blanks are formed into cylinders, the edges are tack welded together to produce an overlap, and the seam is made by rolling electrodes that weld the interior and exterior of the lap simultaneously.

In the wire welded operation that is used extensively today, the welding process consists of passing the seam with a small overlap between two electrode wheels over which runs a copper wire. The use of copper wire as an intermediate electrode is necessary to remove the small amount of tin picked up from the tinplate during the welding process, which would otherwise reduce the welding efficiency. A constantly renewable copper surface is presented to the weld area. To obtain a weld, the heated material is pressed together or clamped by wheels in the welding process (see Figure 3).

Another innovation has been the introduction in the early 1960s of the seamless two-piece can (integral base and body, with one customer end). Metal forming technology has been used to produce these cans from a flat sheet. Drawn and ironed cans employ tinplate and are manufactured by first drawing a shallow cup and then extending the sidewalls by thinning the metal between two concentric annular dies in an "ironing" process. This results in a can with a normal base thickness and thinner walls, and it is economical in materials usage. The capital cost of D&I canmaking plants is high, but unit costs are the lowest of all container types if the throughput is sufficiently great. Because of the thin walls, body beading is essential to maintain rigidity for vacuum-packed food cans. The other two-piece can achieves final can dimensions through a series of consecutive drawing operations. In these DRD cans, the thickness of the bottom end and the side walls is largely the same and there is not the same opportunity for saving on metal. Unlike the D&I can,

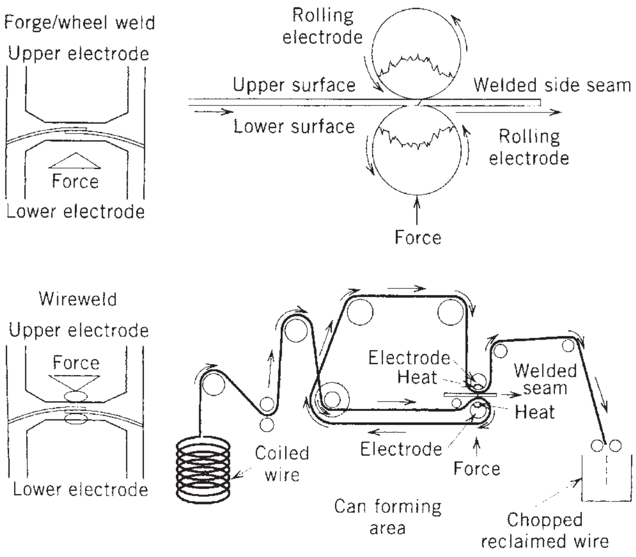


Figure 3. Welding process.

which uses tinplate and inside spray coatings, the DRD can uses TFS-precoated sheet or coil plate.

Organic sealing materials have been used as side-seam sealants mostly before the advent of the welded can. They have been used in situations where soldered structures were not compatible with the product, when special wraparound lithography is desired, and when tin-free steel is used. For the most part, polyamides and organosols are used as the basic resin of organic sealing materials. They are normally used for a variety of can sizes, shapes, and styles that are used for dry and nonfood products. However, a polyamide hot-melt adhesive has been successfully used in oblong meat cans that are subjected to a high-temperature thermal process.

Much consideration has been given to cost reductions of the metal can. In conjunction with thinner gauge and higher temper plates, the reduction of the can diameter of the two-piece beverage cans in the area of the end unit has reduced the cost of metal cans significantly. This body diameter reduction is usually accomplished by a die necking-in process, which is performed prior to flanging. The necking-in process tends to alter the can height, so careful body cut edge and/or can trim diameter must be calculated to afford these accommodations. With three-piece cans, this necked-in structure can be fabricated on both ends; however, it is done on only one end of two-piece cans used for liquid-type products.

The popularity of steel cans has been in large measure caused by the double seam's ease of fabrication and robust resistance to physical abuse. This seam structure is the portion of a can that is formed by rolling the curled edge of the end and the body together to produce a strong leak-proof structure. This seam is normally formed by a set of first and second operation seaming rolls while the end and the can body are held together by a seaming chuck. The first operation seaming roll forms the seam by interlocking the curled edge of the end with the flange of the can body. The second-operation seaming roll compresses the formed seam to make a hermetic seal (Figures 4–6).

Because metal-to-metal contact does not produce good sealing capability, a rubber-like material known as *sealing compound* is applied to the loose end-unit seaming panel that becomes engaged to the body flange to form the double seam. This material acts like a sealing gasket. Compound placement and compatibility with the product are important in providing for a hermetic seal. End-sealing compounds are generally one of two types: (a) water base—rubber/water dispersions and (b) solvent base—rubber/solvent dispersions.

COATINGS

Organic protective coatings are used as can linings to provide the additional protection above that provided by the metal substrate. These organic materials are applied to a flat plate or a coil-coated plate and are cured by means of continuous ovens. Spraying after complete or partial fabrication is also done when low-metal-exposure cans are required for aggressive-type products. It is desirable to use can linings that possess a reasonable degree of latitude in film weight and bake. The roller coating machines and the spraying machines used to apply linings provide means for close control of film weight. The films, of course, are relatively thin, about 0.0001–0.0005 in. thick or with a weight of 2–6 mg/in.^{2} Control limits generally allow for variation of ± 0.5 mg/in.^{2}

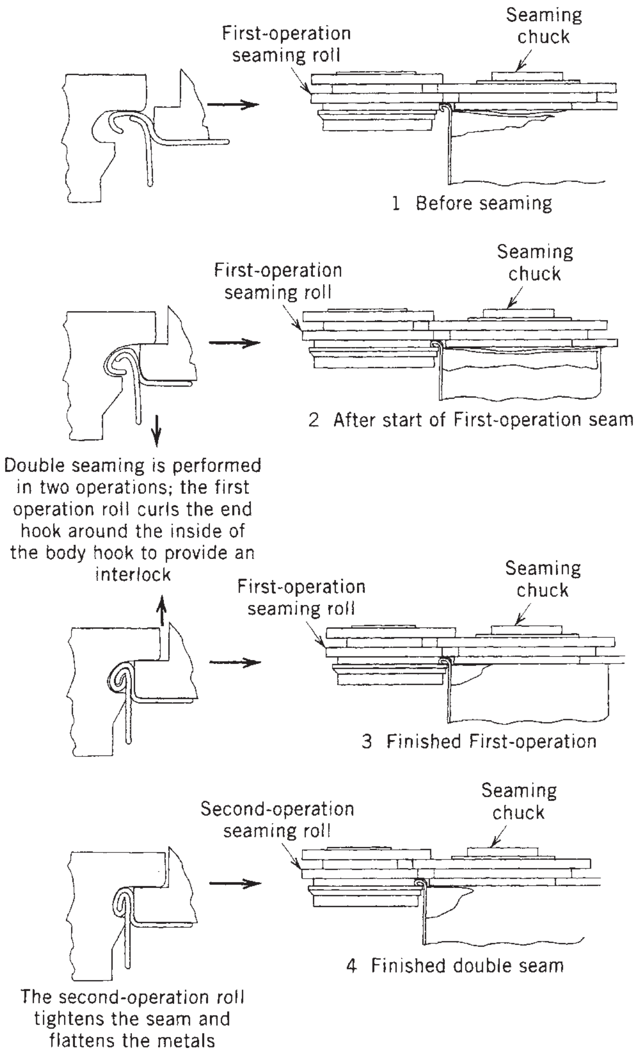

Figure 4. Sequence of operations in seaming a can end onto a can body.

Can linings must be nontoxic, meet government standards, be free from odors and flavors, and be readily applied and cured. They also must withstand the mechanical operation of canmaking, must provide the required barrier between canned product and metal, and finally must be economical. Accelerated tests are used as screening or control tests, and evaluations under commercial conditions are normally required before final approval of a can lining is standardized. When required, product test packs will be made and monitored over a period of time to confirm that the coating material is compatible with the intended product and/or container components.

Coatings accomplish several purposes. They make possible the use of less costly steels that permit the use of

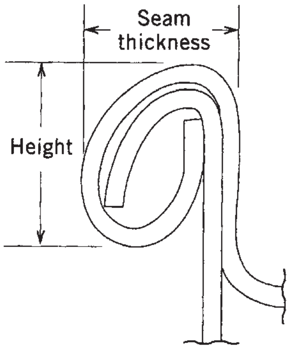

Figure 5. First operation.

different types of tin-mill products in the can body and ends. They protect the steel against corrosion and the product from the steel and on the can exterior, minimize rusting, and serve as a background to or improve adhesion for lithography. Inorganic protective coatings that often contain phosphates, chromates, or both are usually applied to tin-free steel at the tin mill to prevent rust and provide a good surface for organic materials. If tin or iron is detrimental to a product, then a suitable protective coating can be applied. These coatings can prevent bleaching discoloration by tin to dark pigments of foods such as strawberries, blueberries, blackberries, and cherries. Also, protective coatings can reduce the metal exposure for metalsensitive products such as beer and certain soft drinks. Other products would react with the unprotected can interior to cause corrosion or cause discoloration of both container and product. Finally, a protective coating can mask unsightly discoloration of the can interior.

Currently, the major trend in coating technology is toward waterborne coatings to replace conventional organic coatings. Typical organic coatings contain as much as 70% solvents and are subject to stringent environmental restrictions. One answer is the aqueous coating, which contains only a small amount of organic solvents and can use the same coating and curing equipment. These aqueous coatings, which were commercialized for food cans in the early 1990s, exhibit the same good flow and leveling characteristics as found with solvent-base coatings.

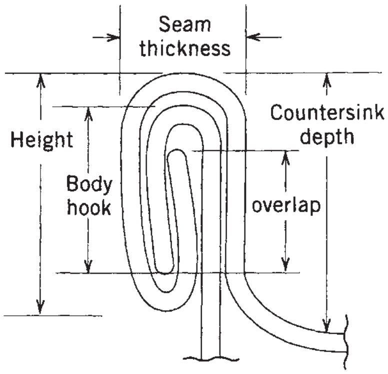

Figure 6. Second operation.

Metal exposure in the side seam area is a common occurrence with all three-piece can structures, and a special protective coating material (a “side stripe”) is sometimes applied to the inside and outside side seam area by spray or roller, online, followed by curing. Most stripes used are organic liquid materials, which provide only minimal coverage. Polyester powder (thermoplastic) electrostatic spray stripes give superior performance. These types of stripe coating provide 100% side-seam coverage, but they are more costly than liquid stripes. However, powder stripes have poor heat resistance and are not recommended for use in cans that will be subjected to aseptic process conditions that employ super-heated steam.

Organic protective coatings were first applied to can interiors to protect the red fruit colors. Coatings used to combat this problem were often called “regular” or “R-enamels.” Now they are generally identified by a number, letters, or a combination of numbers and letters.

If ordinary oleoresinous can linings are used for foods containing appreciable quantities of protein such as corn, peas, and fish, then a black tin sulfide stain will form under the enamel; under certain conditions, black sulfide discoloration will form at iron-exposed small scratches and fractures. To minimize black sulfide discoloration, oleoresinous enamels used for such products contain about 6% of a fine-particle-size zinc oxide, which is added for its chemical reactivity and not as a pigment. The sulfides that form during the processing or heat sterilization of the protein-containing foods react with the zinc oxide, which “de-zincs” and allows the formation of zinc sulfide. Zinc sulfide is white and generally goes unnoticed. Can linings containing zinc oxide were first developed for corn cans and were called “corn enamels”; their use was soon extended to other products, and they were then called “C-enamels.”

Sulfide staining appears as a brown or brownish blue stain on the surface of the tin coating and cannot be removed by rubbing. Sulfide staining occurs not only on exposed tin surfaces but also in tin surfaces protected by many of the enamels because the volatile sulfur compounds involved can permeate certain types of enamel coating. To prevent underfilm sulfide staining, enamels impervious to volatile sulfur compounds are used where possible. However, such enamels are not always compatible with the product being packed, in which case it is necessary to use a pigmented enamel that will either inhibit or mask the sulfide staining. These methods of inhibiting or masking sulfide staining are limited to their application, because not all enamels combine satisfactorily with a given pigment or additive.

Many coatings are now in use and being developed for steel cans used for a variety of food and nonfood products. Some of those materials, which are supplied by coating suppliers to the application facility and are now being used, include acrylic, alkyd, epoxy amine, epoxyphenolic, oleoresinous, oleoresinous w/zinc oxide, phenolic, polybutadiene, vinyl, and vinyl organosol. Each material has its own unique performance characteristics with regard to its application, fabrication, product compatibility, flavor and odor, process resistance, and so on.

It has been apparent since the early days of canning green vegetables that the bright green darkens as a result of the required thermal process, that is, the bright green chlorophyll undergoes a chemical change to an olive green pheophytin. There have been several studies conducted to inhibit this chemical change. They all demonstrate an inhibition capability by using additives containing magnesium ions and careful control of pH by the addition of hydroxyl ions. All of these procedures cause some toughening of the product, which probably discourages any commercial pursuits. The Crown Cork and Seal Company, Inc. has a patented process called "Veri-green," which incorporates additives to the product as well as the protective coating. The materials added are specific for particular products, and pretesting is necessary (17–21).

DECORATION

Decorative lithographic designs afford an external protective coating. The process of application is known as *offset lithography*. Lithography is a printing process based on the fact that oil and water do not mix. The decorative design to be printed on the tinplate is etched onto a plate known as a *master plate* in such a manner that the image area to be printed is ink receptive, whereas the portion to be blank is water receptive. A lithographic design is a system or a series of coatings and inks printed on plate in a particular sequence. The order of laydown is determined by the purpose of the coat, the kind of coating or ink, and the baking schedule for each coat or print. The print process is usually carried out with sheet stock prior to slitting into can body blanks or scroll shearing into the end stock. The sequence and type of equipment used depends on the design and the ultimate use of the can (see the Decorating article).

With the advent of two-piece cans, less elaborate designs are used on beer and soft-drink cans because it was necessary to use presses that print completely fabricated cans. The finishing varnishes are usually the external protective coatings. They not only protect against corrosion but also must be rugged enough to resist scuffing and abrasion.

For drawn-and-iron beaded food cans, the outside is coated with a water-based colorless wash coat material. After packing, the customer glues a paper label to the body wall, which identifies the contents.

TECHNOLOGICAL DEVELOPMENTS

The steel can has grown despite competitive pressures. During war years, tin and iron become controlled materials, and other more available packaging materials usually make inroads into the steel-can market. These same constricting conditions often give rise to the development of methods that reduce the consumption of the controlled materials. During World War II, the electrolytic deposition of tinplate was commercialized, which resulted in substantial reductions in tin consumption. Competition from aluminum in the beverage-can business gave impetus to pursue the use of tin-free steel to afford more favorable economics. Successful cost reductions with no reduction in performance, however, has been the cause for the continued growth of the steel can. The advent of cold-rolled, double-reduced plate permitted significant reductions in base weight. To accommodate the fabricating characteristics of this material, new approaches in end manufacture and double seaming had to be developed. Another direction to cost reduction was to reduce materials usage. This was accomplished by using smaller-diameter ends and necking-in the can bodies to accommodate the reduced-diameter ends. This saving can be directed to one or both ends on three-piece cans.

The use of convenience features has been an important stimulus to the growth of steel cans. Key-opening lids and rip strips have been part of fish and meat cans for generations. This style was also standard for coffee and shortening cans, but economic pressures caused a change to less expensive open-top food cans. Development of the integral rivet and scored end solved many can opening problems, particularly in the beverage and snack-food businesses.

There have been dramatic developments in the overall operation of can-making plants with increasing use of automated procedures and computerized control systems and techniques to optimize production processes. There has been a reduction in the number of operatives, but the working conditions of those remaining have been greatly improved. These new developments are ensuring that the can remains cost effective and reliable.

With thinner gauge plates and faster production speeds, can-making equipment has become increasingly precise in its operations. Reliability is all important, and quality-control measures have been put in place at every critical step to ensure container integrity. These include gauge measurements, weld monitors, and leak testing. Also there is more use of sophisticated statistical control charts, statistical analysis, and design of experiments to solve complex problems, particularly in manufacturing and technical areas.

There have been innovations in coatings technology such as the introduction of waterborne coatings, coil coating, powder coating in electrostatic spray systems, and organic resins that are deposited electrophoretically on the can components from an aqueous solution. Increasing use is being made of the new ultraviolet systems, which dry-sheet coatings and inks in seconds at ambient temperatures. Also, laminate polymer films have been introduced to compete with liquid organic coatings to metal substrates that are used for can components.

Early in the 1970s, health authorities and the FDA became concerned about the increment, if any, of lead and other heavy metals that are picked up by foods packed in soldered cans. The manufacturers of baby foods and baby-formula foods or ingredients, such as evaporated milk, were the first to be asked to reduce the level of lead in their canned products. Better care during soldering operations and ventilation resulted in major reductions but did not eliminate all lead in the respective foods. Currently all soldered cans being produced are using lead-free solders. Also, the introduction of the three-piece welded and two-piece cans have virtually eliminated the concern of lead contamination (22).

CAPPING MACHINERY

In categorizing capping machinery that applies closures to bottles and jars, the best place to start is with the closure itself (see Closures). The different types of machinery for applying these closures have features in common (e.g., straight-line vs. rotary). This article provides a basic description of machinery used for continuous-thread (CT) closures, vacuum closures, roll-on closures, and presson closures.

CAPPERS FOR CT CLOSURES

There are four basic types of capper for CT closures, which are as follows: hand cappers and cap tighteners; single-spindle (single-head), intermittent-motion cappers; straight-line, continuous-motion cappers; and rotary continuous-motion cappers.

Torque Control. All automatic cappers apply the closures mechanically, but they differ in their approaches to torque control. In general, torque control is achieved with chucks or spinning wheels (rollers). Straight-line, continuous-motion cappers generally control torque mechanically, but all other types use either pneumatic or mechanical means, or combinations thereof.

A pneumatic chuck contains a round flexible ring with a hole in the center (1). The cap enters the hole when the ring is in its relaxed state. When air pressure is applied, the ring compresses and grips and holds the cap while it is moved to the bottles and screwed on. The air pressure may be applied by the downward movement of an air piston, or it may be directed into the space between the ring and the wall of the chuck (see Figure 1).

The amount of torque is controlled by a pneumatic clutch operated by pressure from low-level pneumatic lines (see Figure 2). It contains two or more sets of disks that are pressed against each other when air is applied, which connects the chuck and drive shaft. When the cap is screwed on to the point that the torque being applied equals the force being applied to the disks by air pressure, the disks start to slip and the drive shaft is disconnected.

A typical mechanical chuck has jaws that close around the skirt of the cap to maintain a grip until the closure application is complete (see Figure 3). A mechanical chuck can be controlled by a pneumatic clutch, but it also can be controlled by a spring-loaded clutch or a barrel cam. The pneumatic clutch is similar to the clutch used for a pneumatic chuck. A spring-loaded clutch (see Figure 4) uses a spring to disconnect the chuck from the power source when the preset amount of torsion has been applied to the cap (1). Torque can be increased by compressing the spring by screwing down the collar on top of the spring; it can be decreased by moving the collar to loosen the spring. The chuck opens to release the bottle when the torsion on the cap matches the torsion on the spring.

On some capping machines, the heads are raised and lowered by a follower riding on a barrel cam (see Figure 5). Manufacturers of capping machinery have different approaches to torque control based on the principles or combinations thereof, described above.

Hand Cappers/Cap Tighteners. With operating speeds of up to 20 caps/min, hand cappers are used for low

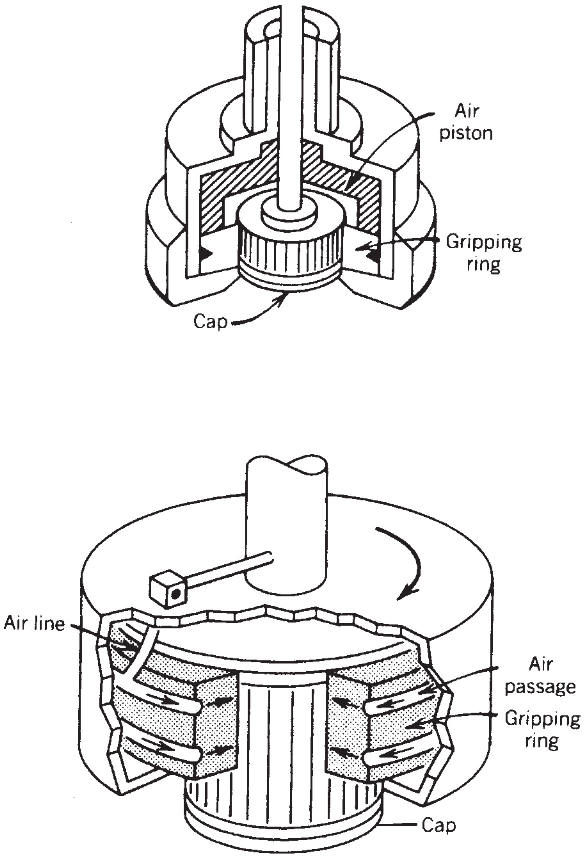

Figure 1. Pneumatic chuck (1).

production volumes or unusual caps. Hand cappers work with some kind of handheld chuck. Cap tighteners, a step up in automation, are useful for pump and trigger-cap applications, retorqueing after induction sealing, and short production runs in general.

Single-Spindle, Intermittent-Motion Cappers. Using either pneumatic or mechanical torque control, these cappers can theoretically apply up to 60 caps/min, and they are useful for relatively short production runs. Their versatility is limited by the intermittent motion that would tend to cause spillage from widemouth containers.

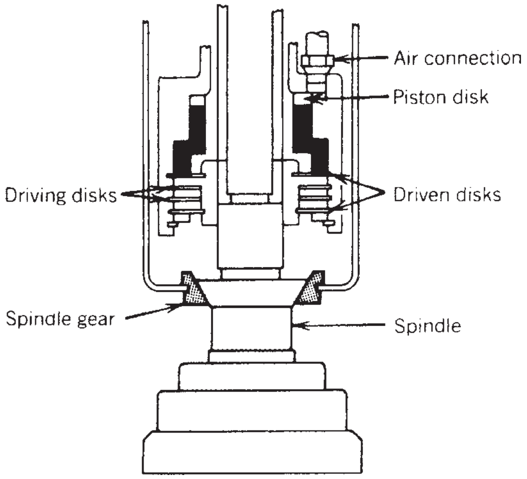

Figure 2. Pneumatic clutch (1).

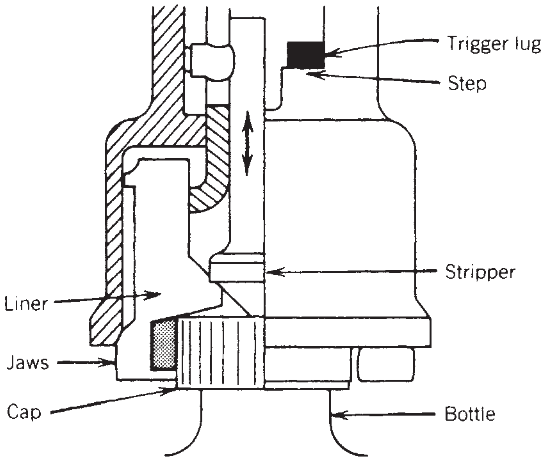

Figure 3. Mechanical chuck with jaws (1).

Straight-Line, Continuous-Motion Cappers. On these machines, torque-control clutches are built into multiple spindles that turn the rollers (disks) that apply the caps (see Figure 6). In contrast to the single-spindle cappers, the bottles never stop and the speed of capping is limited only by the speed of the conveyor. The capability of the machines has traditionally been quoted as 60–300 caps/min (in contrast to rotary machines that can be more than twice as fast), but by using multiple spindles, speeds can be increased greatly; for example, with eight spindles at four stations, production can be as high as 600/min or more, depending on the size of the cap and the container.

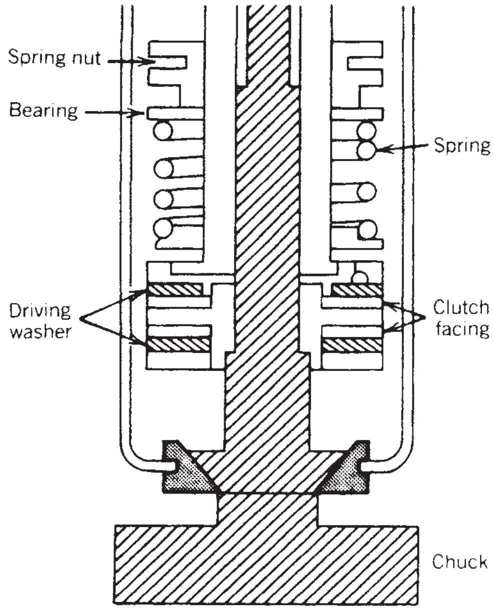

Figure 4. Spring-loaded clutch (1).

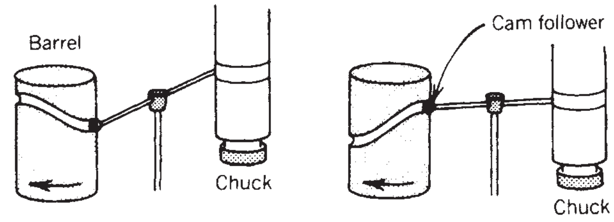

Figure 5. Barrel cam arrangement (1).

The major advantage of straight-line (vs. rotary) cappers is that they generally do not require change parts, and cap and container sizes can be changed with little downtime.

Rotary Continuous-Motion Cappers. Rotary cappers use many heads in combination in a rotary arrangement that permits high speeds: 40–700/min (see Figure 7). The speed of application of one cap by one head is limited, but rotary cappers can achieve 700/min through the use of 24 heads. (Production speeds are always related to the size of container and cap. Rotary machines are available with more than 24 heads, but 700/min is a rough upper limit.)

Extra Features. Most of the automatic machines can be supplied with optional equipment for flushing with inert gas. A time existed when application torque could be measured only by testing removal torque, but today's capping machinery is equipped with sensors that provide continuous measurement and constant readouts.

CAPPERS FOR VACUUM CLOSURES

Three basic types of vacuum closure exist and are as follows: pryoff side-seal; lug; and presson twistoff. The pryoff side-seal closure, the earliest type of vacuum closure, has a rubber gasket to maintain the vacuum in the container. This type of closure has been displaced in the United States by the other two types. The vacuum is generally achieved by a steam flush (2), which also softens the plastisol to facilitate sealing.

Lug Closures. Lug closures have 4–6 lugs that grip onto special threads in the bottle finish as well as a flowed-in plastisol liner (gasket). The lugs mate with the threads with a half turn. This process is almost always done by straight-line machinery that incorporates two belts moving at different speeds. Maximum production speed with this type of closure and machinery is about 700/min.

Press-On Twist-Off Closures. These closures are used primarily on baby-food jars, but they now are being used on other products as well. One of the reasons for their increasing popularity is the very high production speeds attainable. Like lug closures, they have a plastisol liner, but the liner is molded for high precision. Unlike lug closures, the skirt of the closure is straight. The seal is achieved when the plastisol softens and conforms to the bottle threads. Unlike threaded closures—which require multiple turns—and lug closures—which require a half-turn—presson twistoff closure require no turn at all. They are applied by a single belt that presses the closure onto the bottle at very high speed (e.g., over 1000/min on baby food jars). These closures are held on by vacuum, which is

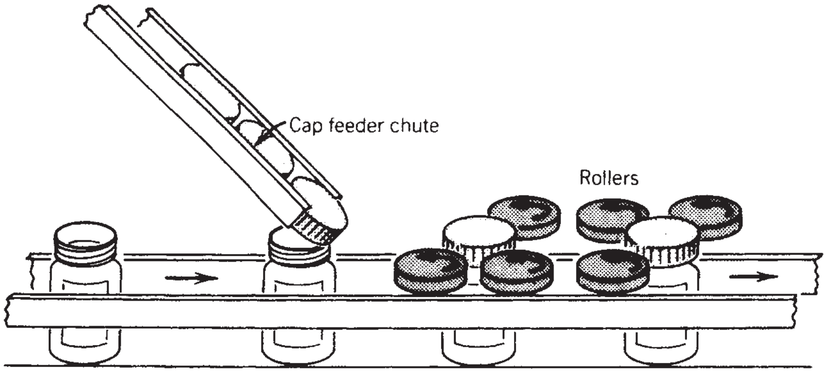

Figure 6. Roller screw capping (1).

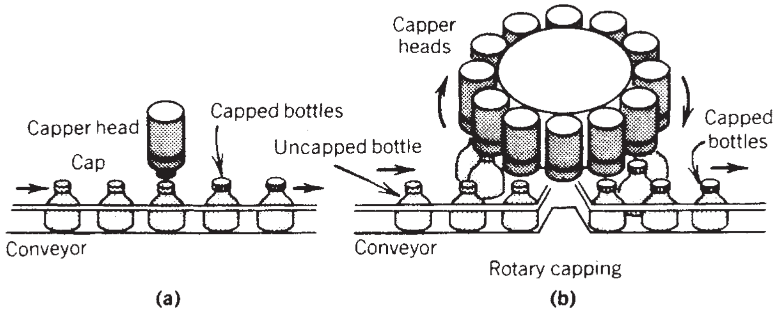

Figure 7. (a) Straight-line and (b) rotary capping (1).

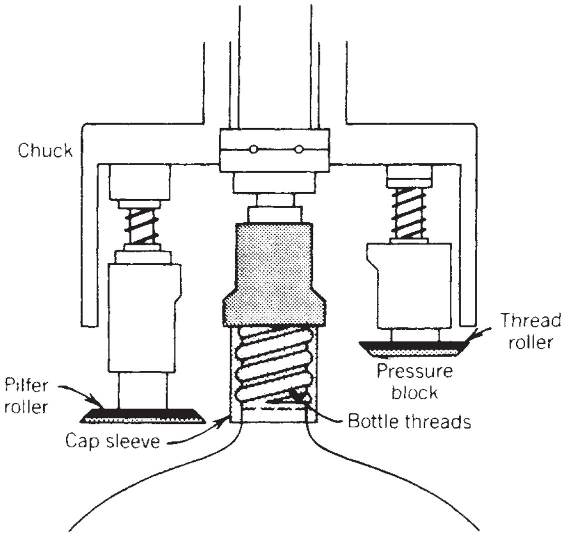

Figure 8. Applications of roll-on closures (1).

achieved by sweeping the headspace with steam. The use of these closures was limited at one time by a requirement of reduced pressure of at least 22 in. of mercury (74.5 kPa) to hold them on. Not all products benefit from that degree of vacuum. A recent development is the ability to use these closures with a much lesser degree of vacuum.

CAPPERS FOR ROLLON CLOSURES

A rollon closure has no threads before it is applied. An unthreaded (smooth) cap shell (sleeve) is placed over the top of the bottle, and rollers in a chuck (see Figure 8) form the threads to conform with the threads on the bottle finish. The chucks are raised and lowered by capper heads. These closures are available with and without a pilferproof band that is a perforated extension of the skirt. If such a band exists, it is rolled on by a special roller in the chuck. Operating speeds of the machines are in roughly the same range as rotary cappers for CT closures: up to 700/min.

CAPPERS FOR PRESSON CLOSURES

The familiar crown closure for carbonated beverage bottles is one type of presson closure. The cap is applied by rotary machines that can operate with production rates of over 1000/min (see Figure 9). Other types of presson closures are snap-fit caps, with or without a tamper-evident band; dispensing caps, which are often secondary closures; and overcaps.

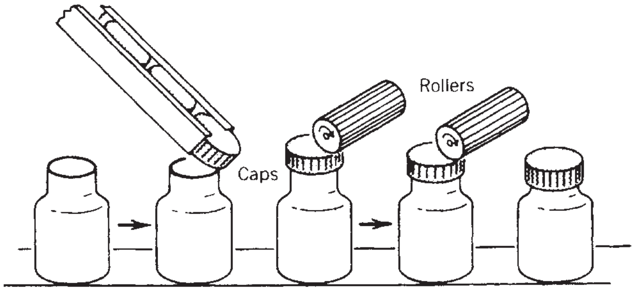

Figure 9. Roller application of presson closures (1).

Like screw caps, press-on caps can be applied by chucks or rollers, but the chucks and rollers do not need twisting action, nor clutches for torque control. Several approaches exist for controlling the amount of pressure applied by chuck-type cappers. The capper head can be spring operated, with tension controlled by a collar adjustment; or a pneumatic clutch can control it with air pressure; or a barrel cam can be used. On a roller-type presson capper, the cap passes under one (shallow cap) or more (deeper cap) rollers that press the cap on tight.

CARBONATED BEVERAGE PACKAGING

A. L. Griff
Edison Technical Services
Updated by Staff

INTRODUCTION

Carbonated beverages represent the biggest single packaging market, with over 100 billion (10^9) beer and soft-drink containers filled each year in the United States. According to beverage marketing, every person in the United States consumes about 192 gallons of liquid per year. This translates to 3.7 gallons per week or 2 liters/day. Nonalcoholic drinks comprise 87% of the total, and carbonated soft drinks account for 28% of the nonalcoholic types (1). The packages cost substantially more than the contents and are actually the beverage producer’s largest expense item. Performance requirements are quite severe: Because the contents are under pressure, they must hold their carbonation and must withstand summer storage and (for beer) pasteurization temperatures that may reach 55–60°C. Furthermore, the highly competitive nature of this business has brought container design and manufacturing to a highly refined level in order to keep cost to a minimum. Even $0.001 per container becomes big business when multiplied by the billions (10^9) of containers made and used.

PACKAGE TYPES

There are four major categories of carbonated beverage container: plastic bottles, nonreturnable glass, refillable glass, and metal cans.

Plastic Bottles

These are mainly 2-L soft-drink bottles, which first appeared in the mid-1970s and in just a few years took over around one-third of the soft-drink sales volume. The bottles are stretch-blowmolded (see Blow molding) from PET polyester (see Polyesters, thermoplastic). The stretching (orientation) is needed to get maximum tensile strength and gas barrier, which in turn enables bottle weight to be low enough to be economical. Because material cost is about two-thirds of total manufacturing cost, such weight savings are essential. Typical 2-L bottle weights are around 60 g PET, with some as low as 50 g, plus a high-density polyethylene base cup (18–24 g), a label (3 g), and a closure. One design uses no base cup; instead, the bottle itself forms five petal-like feet at the base. It uses slightly more PET (65–70 g), but total weight is less because of the absence of the base cup.

A 3-L PET bottle has been used, with weights around 80–85 g PET plus 22–28 g for the base cup, or around 90 g without the base cup. Although the 3-L may not be as popular as the 2-L bottle in terms of size (too large for most refrigerator-door shelves), it is more economical.

Half-liter PET has been offered since 1979 but has never caught on because it does not provide enough economic incentive to change; and in small sizes, the advantages of safety and light weight are not as significant. Instead of 0.5-L, 16-oz (473-mL), PET is now offered to compete more directly with 16-oz (473-mL) glass and to save a gram or two of bottle weight because of the smaller volume (6% less than the half-liter). Typical bottle weights for these small PET containers are 28–30 g plus a 5-g base cup. Some cupless designs have been developed but have only minor commercial use thus far.

In the deposit-law states, small plastic bottles are more successful because come consumers do not like the handling and return of glass and are unwilling to pay more for metal cans. In these 11 states, however, which represent over 20% of the population, the 2-L PET bottle has been the real winner, because many people prefer to pay one deposit instead of six (see Recycling).

It is believed that an improved plastic barrier to CO_2 loss (see Barrier polymers) would allow lighter (hence cheaper) bottles and thus spark the large-scale use of single-service sizes for soft drinks and also open up the beer market to plastic. Such containers are the object of much development, both in can and bottle forms (see Cans, plastic).

Plastic bottles of all sizes usually carry full wraparound labels, either a shrunk polyolefin sleeve or a glued polypropylene/paper laminate (see Labels and labeling). Some plastic bottles have foamed plastic labels, which have a desirable nonslip feel and offer a little thermal insulation. These used to be very large, extending down over the base cup for maximum advertising effect (Owens-Illinois Label-Lite) but lately have been in conventional wraparound form and size (Owens-Illinois Plasti-Grip).

Nonreturnable Glass

These are mainly 10- or 16-oz (296- or 473-mL) size, with a Plastishield (Owens-Illinois and licensees) foam-plastic protective label or a paper/polyolefin rollfed or an all-plastic shrink sleeve (see Bands, shrink). Typical bottle weights are around 130–140 g and 180–185 g, plus 3–4 g for the label. The glass industry has strongly promoted these containers in competition with metal cans, both in retail markets and in vending machines. Glass has an apparent cost advantage, which carries through to retail level and has managed to hold onto its market share in this size. However, the advantage in container cost is eroded by labels, closures, secondary packaging, filling speeds, and occupied space, plus the possibility of breakage and costs of clean-up. In all of these aspects, cans have an edge.

Prelabeling has become standard. The labels are preprinted and come to the bottler with no need for a further printing operation. Patch labels are cheaper and better for short runs, but are disliked by retailers because the bottles can be turned to obscure the labels.

The old crown closure that had to be pried off has all but disappeared for nonreturnables and is seen only on refillable glass to allow use of bottles with corresponding threadless necks (see Closures). The nonreturnables and even some refillables use roll-on aluminum screw caps on threaded necks, with a tamper-evident ring (see Tamper-evident packaging). The threaded screw-off crowns that are crimped over a fine-threaded neck remain, but in diminishing numbers despite low cost. They are harder to open and are thus used mainly for beer (stronger hands), and their lack of tamper protection has discouraged their use.

The use of plastic closures for both glass and plastic bottles increased in 1984 after a decade of trial use and design refinement. The two most popular designs use a separate liner, but there are linerless designs as well. These closures weigh around 3 g in standard 28-mm size and are slightly more expensive than competitive aluminum roll-ons. All unscrew and fit over the same threads as the roll-ons and have some visible indication of tampering. Initial successes have been with soft drinks; a few have been tried for beer, but they have not been accepted due to their inability to withstand pasteurization.

Refillable Glass

The refillable glass bottle is still used is some markets. O-I Global is the primary supplier of glass bottles to the beer industry and produces returnable beer bottles (3). The main sizes are 16-oz (473-mL) for soft drinks and 12-oz (355-mL) for beer, with some soft drinks also in sizes around a quart. It is usually the cheapest way to buy soft drinks on a unit price basis (except where 2-L bottles are being discounted), but most consumers prefer to pay a little more for convenience. In deposit states, refillables do better but remain a minor factor, after 2-L PET and metal cans. Typical bottle weight is around 300 g for the 16-oz

(473-mL) soft-drink bottle and is 250 g for a 12-oz (355-mL) beer bottle that is used in bars and hotels where economy is foremost and delivery/return is not a problem.

Labels on major-brand soft drink refillables may be permanently silk-screened. Paper/plastic patch labels are used on most refillable beer bottles. Full wraparound labels are seldom seen because the containers are usually sold in six-packs or cases that cover most of the label area.

The economics of refillables is very different from that of other containers, because the bottler must support a "float" of containers and cases (which may cost as much as the containers themselves), as well as a larger fleet of delivery trucks (less compact, must stop to pick up as well as deliver), and the appropriate cleaning and washing machinery. For this reason, soft-drink franchises have been a classic home for local investor/entrepreneurs, and this spirit persists in the soft-drink industry today despite the predominance of nonreturnable packaging.

Refillables are often promoted for their environmental benefits. The concept of refill/reuse may be laudable as it supports a resource conservation ethic, but the actual use of refillables brings its own environmental problems: water pollution from washing, air pollution from less efficient truck usage, and sanitation problems in both shops and homes.

Proponents of nonreturnables also point to the success of aluminum recycling. Opinions and emotions are very strong in these areas, but an impartial examination of the facts leads to no firm conclusion. In fact, much depends on locality—that is, the nature of the water supply, the extent of recycling possible, the degree of urbanization, and the number of trips made by each refillable. There is no easy answer to this question, and neither refillables nor nonreturnables offer a clear advantage on environmental grounds.

Metal Cans

The 12-oz (355-mL) aluminum can with easy-open end is the primary small carbonated-beverage package, despite apparently higher container costs and retail price compared to either glass or plastic (see Cans, aluminum). Container weight and design have been the subject of much development work, with the weight of a modern can now down to around 15 g including the end. There is at least one necked-in ridge at the seam to allow wall-to-wall contact, which helps on the filling lines, makes firm six-packs, and uses smaller, cheaper ends. Double- and triple-necked cans are sold to get even smaller ends, and a new spin-neck design has a conical top section which achieves the same effect.

Nondetachable ends with a ring-like tab to pull, but without the ring coming off to create litter and a safety hazard, have replaced the pull tab almost completely in the United States. Pull tabs are still common in China and the Middle East. Nondetachable rings are mandatory in certain states and are often used in other areas to avoid manufacture and stocking of both types and to present an environmentally supportive image. A reclosable end for a flat-topped can has been announced but is not yet on the open market. Another reclosable metal can had a special polypropylene bottle-sized closure. It was introduced in 1983, but later withdrawn.

Steel cans were much more common than aluminum before the early 1960s, but their use has declined, especially for beer, and the old three-piece can with soldered side seam and separate top and bottom ends is seldom seen any more in this market (see Cans, steel). There are some three-piece cans with welded side seams and even more two-piece steel cans, drawn from steel much as aluminum cans are made (see Cans, fabrication). These may weigh as little as 37 g (with 5 1/2 g aluminum end). Although the steel can is heavier, the material is cheaper and the steel industry had expected to keep more of the beverage market than it did with the two-piece cans. But fabrication is more expensive, coatings are more critical (to prevent rust), and aluminum did a fine job of selling its recyclability on a consumer level. (Steel can be recycled, too, of course, and is easy to separate from solid waste streams by magnets. However, the economics are not favorable, and it does not always pay to get the cans back into the new-material stream, which is what really counts.) Formerly, the need for short runs of preprinted cans for house brands and other low-volume products kept three-piece steel in the running, but the growth of cooperative large-volume canning, improved machinery to coat and print finished cans, and the disappearance of many smaller brands have all contributed to steel's decline.

Approximately 55% of drink cans made in Europe and Asia are steel. It still is the main can material for foods, juices, coffee, and many other products because the internal pressure of carbonated beverages stiffens the filled container and makes steel's great advantage in rigidity of little importance. For the other products, this advantage counts, and it makes aluminum more costly on an equal-performance basis.

Metal Bottles

Coca-Cola has announced that it will bottle some of its products in aluminum bottles in 2008. Coke joins Budweiser and Pepsico in this new cutting edge form of packaging. Aluminum bottles offer enhanced graphic capabiities and the ability to keep the beverage colder. These bottles cost three times more than the ones made of glass. Coke will scale back on the graphics on its bottles. Moutain Dew will present splashy designs created by contemporary artisits. Budweiser is credited for being the first company to offer aluminum bottles in 2005. The aluminum bottles keep the beer at 22°F Glass would expode at this temperature. Sales of beer in aluminum bottles rose 33% in 2007 (4).

BEER VERSUS SOFT DRINKS

Packaging beer into bottles and cans is an immensely expensive process. Packaging must be rapid, ~2000 units per minute, so that large volumes of beer can be broken down to consumer units in a reasonably short time. Second, oxygen must be rigorously excluded. The market for large-size containers such as the 2-L PET bottle is very small for beer, and it will remain so because beer quickly goes stale once the container is opened and exposed to the oxygen in the air. Thus, it must be consumed quickly and cannot be reclosed and finished later, and the large-size market is limited to parties where rapid consumption can be expected. But even at these occasions, there is some preference for cans and small bottles (what one does not drink now, one can drink later). On the other end, there is some competition from kegs and even a plastic sphere that is set in a waterproof carton surrounded with ice. These bulk packages are also used in bars.

Almost all soft-drink cans are actually 12 oz (355 mL) in capacity, as are most beer cans; but some beer is sold in 8-, 10-, and 16-oz (237-, 296-, and 473-mL) sizes, and even a 32-oz (946-mL) size has been used. The nonreturnable glass includes 12 oz (355 mL) and 32 oz (946-mL) for beer and includes 16 oz (473 mL) and 28–32 oz (829–946 mL) for soft drinks. Refillables are 12 oz (355 mL) for beer and are 16 and 32 oz (473- and 946-mL) for soft drinks.

Another addition to both beer and soft-drink marketing was the 12-pack of cans (and bottles), boxed in carry-home secondary packaging and offering an economical compromise between the six-pack and the 24-unit case (see Carriers, beverage). Secondary packaging is an important aspect of beverage packaging, with shrink-film, plastic can-holding rings, paperboard carriers, molded-plastic bottle carriers, and corrugated and molded-plastic cases all vying for their share and making their contribution to the total system price of the primary package.

Plastic containers have entered the huge single-service beer market. These bottles must be able to withstand pasteurization conditions, with a good-enough oxygen barrier to assure desired shelf-life under the most unfavorable storage conditions. The shelf-life problem is made worse by the presence of some oxygen in the beer as brewed and in the headspace of the container. In effect, any oxygen permeability at all puts pressure on the brewing operation to tighten their oxygen-excluding procedures even more. For a high barrier one-trip bottle, people are looking to multilayer or coated bottles to reduce oxygen permeability.

Despite these problems, many companies are working to develop a plastic beer container, because the sheer size of this market gives these efforts a huge potential.

Already 10% of the beer consumed in Europe is in PET bottles. In Korea, the Hite Brewery Company claims that 15% of all beer consumed in South Korea comes in 1.6-L multilayer PET bottles with a shelf life of 26 weeks. In the United States, first steps have been taken by Anheuser Busch and Coors in supplying their beers in 16-oz (453.3-g) multilayer bottles (2). Brewers in Denmark introduced their beer in returnable poly(ethylenea-naphthalene-2,6-dicarboxylate) (PEN) copolymers in 1999, and a 1.25-L beer bottle was offered for sale in Norway. In both countries, there is recycling and bottle return is widely practiced. Plastic beer cans have also been tested in Great Britain. Elsewhere in Europe, PVC bottles have been used at soccer games and institutions where breakage and cleanup are serious problems. In Japan, 2-L and 3-L elaborate beer bottles are made from PET, but they are virtually gift items and far too expensive for any mass market. The Japanese also have small (11.5-oz 340-mL) PET beer bottles on the market on a limited scale.

Beer and soft drinks differ in carbonation content, which affects pressure requirements and rate of CO_2 loss. Pressure is typically expressed in volumes or in g/L of carbon dioxide. One volume equals approximately 2 g/L. At room temperature, each volume produces about one atmosphere (0.1 MPa) of internal pressure, but this changes with temperature, so that a 4-volume beverage such as a cola rises to 7 atmospheres (0.7 MPa) pressure at 100°F (38°C) and to 10 atmospheres (1 MPa) at maximum storage/pasteurization temperatures. The carbonation levels of some common beverages are

	Volumes of CO_2	g/L
Club soda and ginger ale	5	10
Common cola drinks	4	8
Beer	3	6
Citrus and fruit soft drinks	1.5	3

The beer industry differs from the soft-drink industry in still another, very important way: There is no franchise system. In the franchise system, a parent company licenses a large number of local bottlers, who run independent businesses under the supervision of the parent and buy their flavor concentrate from that parent. In the beer industry, on the other hand, there is great concentration, with 90% of the beer made by the top 10 companies. Most of these have some captive container capacity, so that introducing a new container may mean idling of existing capacity and not just a simple cost comparison. The distribution systems also differ greatly. Soft drinks are much more local, and even the big franchises and cooperative canning plants are still regional. Brewers, however, distribute over wider areas, and some ship to more than half the country from a single location. Such distances make container compactness important, discourage breakable glass and less-than-perfect closures, and make refilling (but not recycling) less economical.

DEPOSIT LAWS

No discussion of carbonated beverage packaging would be complete without comment on the deposit laws which are in effect in 11 states and 12 Canadian provinces as of 2008. All beverage containers carry a deposit, typically 5¢ or 10¢. Despite many complaints, the industry and the public have learned to live with such laws, and they argue over the relative merits and troubles that they bring. It is fairly well agreed, however, that the cash value for discarded containers does keep most of them off the highways and gets more of them into the recycle streams. Seven states have reported a reduction of beverage bottle litter by 73–83%. The aluminum-can industry, which has a widely publicized recycle system in operation in both deposit and nondeposit states, now claims that more than 53% of all aluminum beverage cans are recovered in this way. There were some attempts to repeal the deposit laws in a few states, all unsuccessful (5).

On a national scale, in November 2007 Senator E. Markey of Massachusetts proposed a deposit law that would require a refund for certain beverage containers. This was proposed as an amendment to the Solid Waste Disposal Act as the Bottle Recycling Climate Protection Act. It is meant not only to reduce litter, but to protect natural resources through recycling and reduction of solid waste into landfills. This amendment would apply to all of the United States. States with high recycling rates would be exempt.

CAREER DEVELOPMENT, PACKAGING

Burton R. Lundquist
Armour Food Company,
Conagra (retired), Cave Creek,
Arizona

Career planning and development should be a lifetime occupation. Without a plan or specific development activities, one's career will tend to drift. There must be a conscious effort to set and achieve goals. Planning and implementation of your plan are probably the most important things you can do to maximize your capability and realize the success you desire. It should be noted that plans should be flexible and should be changed and refined to fit new goals.

One of the most important steps in career development is a career book to document the plan and keep a record of accomplishments. This book should be started as early in the career as possible in order to maintain a complete record of all important accomplishments. Most packaging professionals who have been active for 10 or 20 years have forgotten many of their most important accomplishments. They have no records to show how or what was accomplished. Even recent graduates cannot remember all their important activities. I personally believe that every packaging student should have a career book to keep copies of the results of important projects. There is also an opportunity for packaging directors to give each new employee a career book. I personally required each of my packaging engineers to maintain their book and keep it current. With each annual review they had to present their up-to-date book. There is great satisfaction for everyone in reviewing all that has been accomplished during the year. It should be noted that the career book is a great tool to present your credentials when interviewing for a new job or even for a new position with your current employer.

Your career will span many years and possibly many different jobs and companies. Therefore, you can expect to have more than one volume. Be sure to buy a high-quality book because it must last a lifetime. Have your name embossed in gold, and use plastic inserts to protect your documents and specimens. Some of the most important things to include in your book are your college degree; certificates from continuing education; Institute of Packaging Professionals Certification; copies of patents; awards, letters of recommendation, and congratulations; samples of packages that you developed or were involved with; ads and promotional material for new products with new packages; copies of papers that you presented, publications, proposals, and prototypes of new packages; photographs of projects, co-workers, employees, family members, and so on. Your book is a personal record, so the types of record put in the book may vary with different individuals. The important part is to maintain as complete a record as possible. In addition to the book, the documents may also be scanned and stored electronically in the computer.

BUILDING RELATIONSHIPS

The author has worked as a packaging professional for over 40 years and has learned that it is impossible to make any meaningful accomplishments by working alone. Real accomplishments are made by people working together, and working together builds relationships. Relationships should be built with all the people with whom you interact: your manager, employees, co-workers, suppliers, members of professional organizations, universities and educators, and packaging professionals in other companies, including your competitors. Use these relationships to make things happen. The success of most projects is dependent on using the right people. Use this resource to explore new ideas, help solve problems, identify new contacts and new relationships, organize new projects, implement new systems, and bring projects to a successful conclusion. Relationships are of tremendous value when you network to make a job change. The same networking can be used to identify candidates for a position you may wish to fill. It is the best way to identify speakers for professional seminars, authors to contribute to publications, and candidates for professional organizations. Relationships will bring richness to a career.

Active participation in professional organizations is one of the most important places to build relationships. Professional organizations provide an important opportunity for association with many people who share common interests and goals. Membership is not enough. The maximum benefit is obtained only with active participation. This may be at the national level or at the local chapter level. The Institute of Packaging Professionals (IOPP) is the primary organization for packaging professionals. There are 41 Chapters across the country and 10 Technical Committees. The Packaging Digest lists 138 packaging-related trade and professional organizations. This list includes The Institute of Food Technologists, which has a packaging committee. There are 49 international associations for professionals outside the United States. All of these professional organizations provide the packaging professional to interact and build relationships with other professionals and establish lifelong friendships.

CONTINUING EDUCATION

This is probably the most important part of career development. It is essential for continued growth and expansion of your knowledge base and overall capability. We all start with a base to build on, and how we build and expand on that base determines the extent of growth of our overall capability. Recognizing that packaging technology utilizes many different disciplines, there are many different resources we can use to expand our knowledge and also to learn how to develop new disciplines. Many universities provide continuing education. These may be in the form of night school courses or short courses. Other sources are seminars at Packaging Expositions, Institute of Food Technology and other professional meetings, regularly scheduled seminars by the Institute of Packaging Professionals and other professional organizations, and seminars by suppliers. The professional journals are a source of information on current developments.

Some other types of training that will support career development are public speaking, assertive training, report writing, writing patent disclosures, and learning management skills. An important skill to consider is to learn a second language. Next to English, Spanish is the most commonly used language in the United States. NAFTA will expand the need for people who can speak Spanish.

A development area few professionals have recognized is the need to learn to use the right side of the brain. Most of us primarily use the dominant left side of the brain. Dr. Betty Edwards, in her book *Drawing on the Right Side of the Brain*, states “The left side of the brain analyzes, abstracts, counts, marks time, plans step-by-step procedures, verbalizes, and makes rational statements based on logic. It is said to be more closely linked to thinking, reasoning, and the higher mental functions.” It is recognized that most of our training and education has been directed at the dominant left side. The right side is the creative side. “It uses imagination, the dreamer, the artificer, the artist. Using the right side, we dream and create new combinations of ideas.” Most of the training on the use of the right side of the brain appears to be directed at learning to draw. This does provide a means for self-expression. It is said that learning to use the right side of the brain will release you from stereotypic expression. This release in turn will open the way for you to express your individuality in all aspects of your career. Seek out art training that teaches how to draw using the right side of your brain. If you are lucky, you may find courses in imagination, visualization, perceptual or spatial skills, or inventiveness. The right and left sides of the brain do communicate. You can develop your capability to the maximum when both sides of your brain are working together. There are techniques, such as brainstorming and mindmapping, to stimulate creative thinking and generate ideas, Mind mapping software is also available commercially to create diagrams of relationships between ideas or other pieces of information.

SHARING KNOWLEDGE

Sharing knowledge with others is very important to career development. It provides a means for dialog with your peers about what you have learned, new research and development, unique ideas and patent disclosures, and areas you want to explore. Sharing leads to better organization and understanding of ideas. Sharing is also an important part of learning. If we don’t share with others, we do nothing to expand the information base. Take every opportunity to share through publications and presentations at professional meetings, by participating in IOPP and other groups such as the American Society of Testing and Methods (ASTM) and Technical Association of Pulp and Paper. You can be one of the continuing education resources for new professionals starting their career. This sharing will provide another opportunity to build relationships.

MANAGER’S RESPONSIBILITY

Managers and supervisors have a special responsibility to assist their staff in developing their career to the maximum of their capability. They need to be involved with career books, helping their staffs build professional relationships, and providing opportunities for continuing education and sharing. They should support programs that will help all aspects of career development. In many cases the supervisor is the key to the entire career development process.

CARRIERS, BEVERAGE

Octavio Orta
Coated Board Systems Group,
Riverwood International
Corporation,
Atlanta, Georgia
Updated by Staff

INTRODUCTION

Beverage carriers have traditionally been designed to group primary beverage containers into retail units of sale, as well as to protect the primary containers and merchandise or market the liquid contained.

The grouping function is important, because it must securely provide easy portability of a plurality of single cans, bottles, cups, tubs, or paperboard containers of beverages in units of sale that meet the needs of consumers. Typically, multiples of 4, 6, 8, 10, or 12 are commonly found; but larger multiples of 15, 18, 20, 24, 30, and even 36 have grown in popularity.

The protection function has developed to mean protection to the primary container against breakage, leakage, denting or disfigurement; protection to the beverage as in the case of providing a barrier against ultraviolet-ray degradation of beer; and protection to the consumer against personal injury from accidents while carrying or using the package.

The merchandising or marketing function has also evolved because of the development of brand proliferation and flavor segmentation in all beverages. The introduction of "new-age beverages," teas, microbrewed beers, and so on, established a need for the secondary package to establish brand identity, have on the shelf point-of-purchase appeal, establish differentiation among brands and flavors, and evoke media advertising.

The beverage carrier also provides a means of displaying retail unit Universal Product Codes (UPCs) reading through modern laser scan checkout machines while masking UPCs from the individual primary containers.

As beverages have been formulated to appeal to different tastes, primary containers have changed, and so have beverage carriers. The following have resulted in an evolution of the various types of carriers used as beverage secondary packages: metal cans with thinner wall thicknesses; glass bottles with thinner wall thicknesses; poly(ethylene terephthalate) (PET) and other plastic bottles in various sizes and shapes; plastic tubs, cups, and containers of various configurations; and paperboard "boxes" of various sizes and shapes.

CAN MULTIPACKS

Several different raw materials are used in the multiple packaging of cans. Since over 55% of beverages in the United States are sold in cans, these various multipacks are the most commonly purchased today.

Plastic Ring Carriers

The Hi-Cone (Illinois Tool Works) plastic ring carrier is still widely used to package beverage and food cans into 4 s, 6 s, 8 s, and other multiples. This carrier consists of a series of plastic rings that carry cans by the rim and grips them throughout the distribution and retail cycles. The rings are equipped with cutout "finger holes" for gripping and have tearout strips in order to access the cans themselves. These rings are applied by a machine furnished by Illinois Tool Works and applied in line at the canning line between the filler and the palletizers (see Figure 1).

Paperboard Carriers

Paperboard carriers for cans are used in two different varieties, the wraps and the fully enclosed sleeves. In the United States, fully enclosed sleeves are used for the majority of the can multipacks. Sold in 12, 15, 18, 24, 30, and even 36 multipacks, the popularity of these has grown significantly. Originally sold in 3×4 up to 4×6 can configurations, these carriers have recently developed to be double layered stacks of cans with an interstitial pad between the cans. Thus, multiples of $2 \times 3 \times 4$, $2 \times 3 \times 5$, and $2 \times 3 \times 6$ have been growing as a percent of the total retailed cans (see Figure 2).

Typically, these fully enclosed sleeve packs are formed from a preglued sleeve of paperboard that is then removed from a magazine in a packaging machine, and collated single or double layers of cans are packed inside these sleeves in a parallel and continuous motion at speeds of

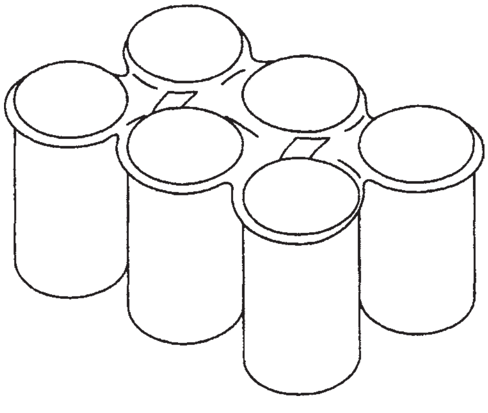

Figure 1. Plastic ring carriers.

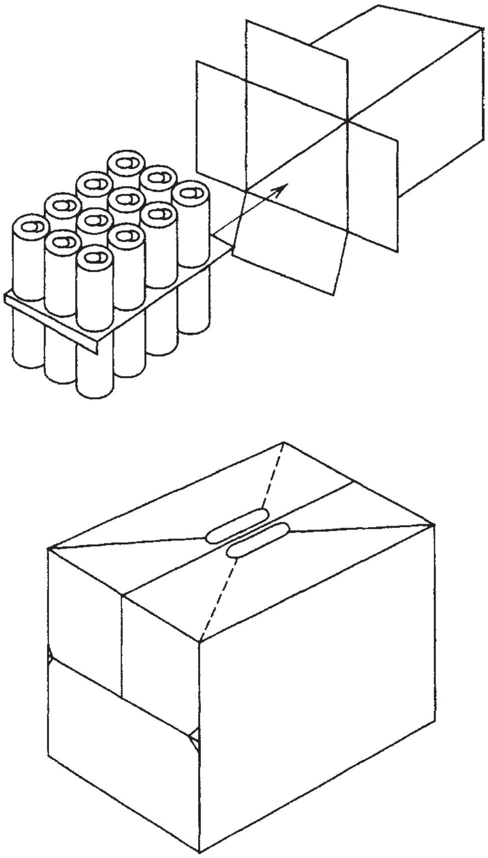

Figure 2. Paperboard carriers.

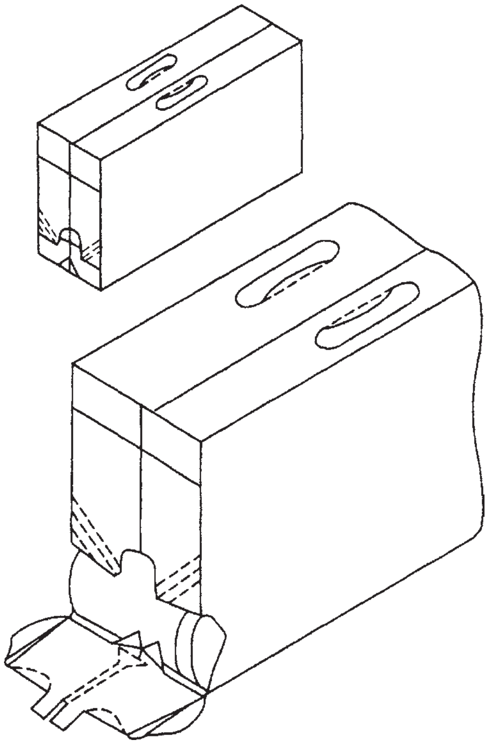

Figure 3. Fully enclosed sleeve packs.

≤3000 cans per minute. The ends of the sleeves are then folded and glued or locked in place (see Figure 3).

While the fully enclosed sleeves are the most popular form of secondary packaging for beverage cans in the United States, can wraps continue to be popular in Europe, Asia, and other parts of the world. Paperboard can wraps are printed and die-cut blanks of paperboard, which are removed from a magazine in a packaging machine, brought over the cans in line and in continuous motion; then the side wing panels are folded down, the bottom flaps are folded in, and the cartons are locked or glued in line (see Figure 4)(1).

Both the fully enclosed sleeves and the can wraps are formed principally from paperboard formulated with 70–80% virgin fiber and 20–30% recycled fiber and containing high resistance against wet tear.

The most common machinery used for forming fully enclosed sleeves is supplied by Riverwood International, The Mead Westvaco Corporation, and R. A. Jones Company, while the majority of the wet-strength carrierboard used in manufacturing these packages is supplied by Riverwood International and/or The Mead Westvaco Corporation.

Other forms of can multipackaging are (a) paperboard "clips," which grip the rims of cans, holding them by this rim through distribution and retail, and (b) shrink film, utilizing thermoplastic films that shrink around the cans with the application of heat. Both of these forms of can multipackaging have been tried in applications in the United States, but have not been able to sustain measurable shares of the total can packaging market segment (see Figure 5).

BOTTLE MULTIPLE PACKAGING

Basket-style carriers are a popular form of multipackaging nonreturnable or one-way glass bottles (and for some returnables), especially in smaller multiples such as 4, 6, or 8 packs, and particularly in premium brands. Basket-style carriers have also been chosen by the Coca-Cola Company to package their proprietary PET contour-shaped bottle with special die-cut designs registered to make their design proprietary to the Coca Cola Company. Thus, the popularity of basket-style carriers continues regardless of whether they are used to package returnable or nonreturnable glass bottles or to package plastic bottles (see Figure 6).

Basket-style carriers traditionally are die-cut and preglued from virgin or recycled paperboard, and all provide cells for each bottle, sides and ends that are attractively printed for merchandising and brand identification, and a central handle panel that rises above the necks of the bottles and provides for convenient and easy portability. Riverwood International, Mead Westvaco Packaging, International Paper, and Zumbiel are the primary suppliers of these carriers.

Outside the United States, nonreturnable bottles are more commonly multipacked in paperboard wraparound carriers, which, similar to can wraps, are formed, wrapped,

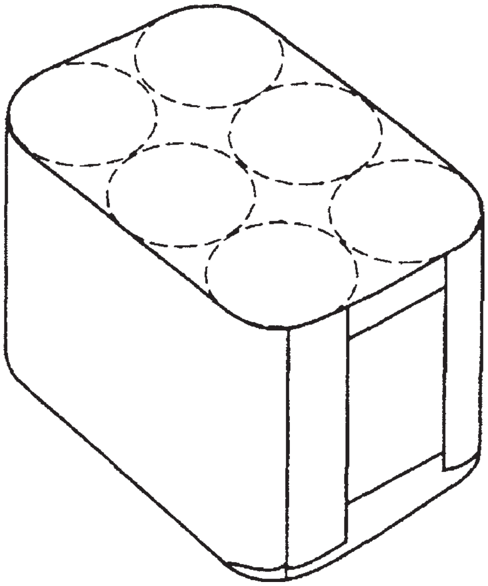

Figure 4. Can wrap.

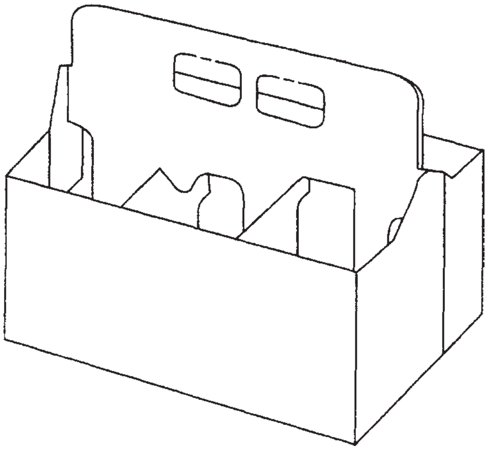

Figure 6. Bottle basket.

and glued or locked in place by in-line wrap machines. These wraps, most commonly used to form 4-, 6-, and 8-packs, are applied by in-line machines supplied by various companies such as Riverwood International, The Mead Corporation, and Certipak, a division of Kliklok.

Plastic bottles are also multipacked in plastic rings supplied by Illinois Tool Works. In the case of bottles, the rings fit snugly around the middle portion of the bottles and provide a handle protruding from one side in order to carry the bottles. These rings commonly form 6 or 8 packs of bottles.

Other forms of multipackaging nonreturnable bottles appear in the form of clips that grip the bottles by the neck or under the crowns and provide a handle with which to carry the bottles (see Figure 7).

These clips are commonly used in countries of the European Union (EU), where the concern for environmental wastes has driven retailers and consumers alike to seek minimal packaging while offering portability and some merchandising possibilities. Clips can be formed from virgin paperboard and are also available in plastic.

Finally, for larger multiples of glass bottles, the fully enclosed paperboard sleeve is still the most widely utilized multipack, particularly in the brewing industry. In this package, the preglued sleeve, die-cut from wet-tear-strength board, is applied in-line and in a continuous motion by a packaging machine in an operation similar to the can fully enclosed package machines previously described. Operating at speeds of up to 1800 bottles per minute, these machines can operate with or without inserts that provide separations between the bottles.

These fully enclosed packs are commonly used for premium brand product and serve as an ultraviolet-ray

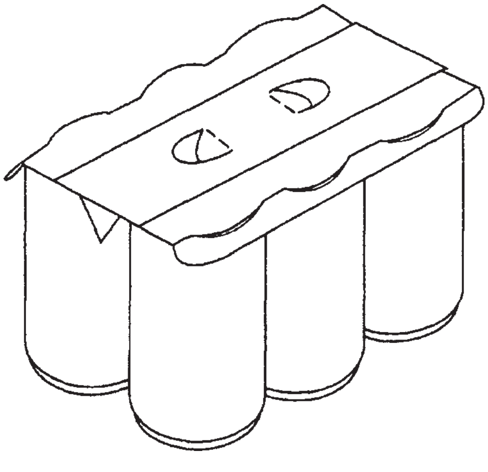

Figure 5. Paperboard clips.

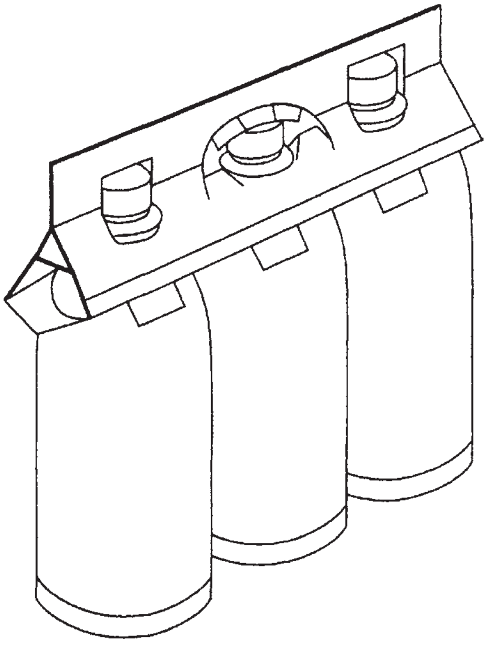

Figure 7. Bottle grips.

barrier to the product as well as a merchandiser on the retail shelf.

New Designs

All of the manufacturers of beverage carriers claim that they can make custom carriers for their clients. Award-winning designs have recently come from the Mead Westvaco Packaging. The “IcePak” is a carrier that holds ice and melted ice in the form of an end load sleeve so that it could be loaded with automated equipment. The bottom flap is interconnected to the side and bottom flap to form a water seal. Top flaps and gusset form a chimney. Cooled natural Kraft provides wet strength without additional coating. The “Bottle Master” is a three-bottle carrier with unique positioning so no glass to glass contact occurs. The bottle package was designed to run on existing gluers with minimal make ready. It ships flat and easily pops open, locks open, and loads bottles. The “Bottle Master with Crown Design” is a regular carrier with a cut-out crown image. It was designed for Anheuser-Busch and ensures zero impact on operations and runs on exisitng equipment. The “Fridgemaster has duo strap handles added to the standard 12-can refrigerator pack (2).

CARTONING MACHINERY, TOP-LOAD

C. R. Kuhr
Kliklok Corporation
Decatur, Georgia

Top-load cartoning employs flat paperboard blanks that have been die cut by a carton manufacturer [see Figure 1(**a,b**)] to produce specific shapes and sizes when formed or folded into finished trays or hinge-cover packages. This style generally includes no pregluing by the carton converter, so flat blanks can be stacked directly on a pallet and shipped without secondary shipping cases. Hence, top-load cartons are economical. They also allow product placement through an opening on the largest panel of the carton, which can greatly simplify the loading operation (see the Machinery, cartoning, end-load; Cartons, folding articles).

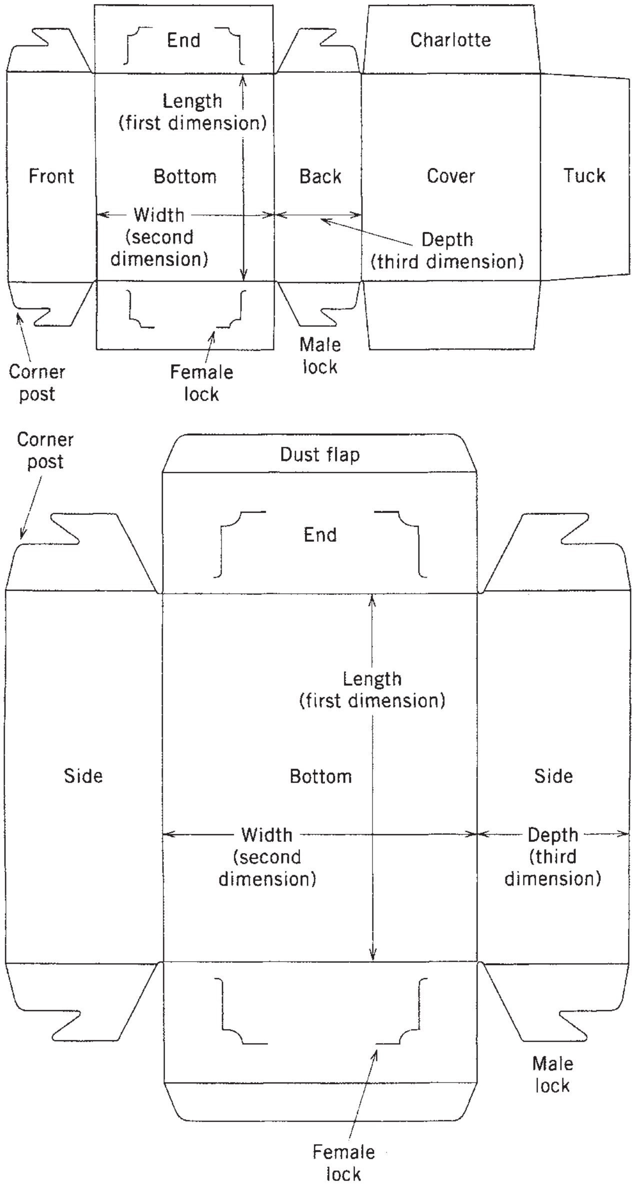

Figure 1. Diagrams of typical (**a**) hinge-cover carton and components and (**b**) dust-flap-style paperboard tray.

CARTON FORMING

The heart of any top-load packaging operation is the carton-forming machine [see Figure 2(**a,b**)]. Although various configurations exist, the most common is a vertical system that provides overhanging delivery to outfeed conveyors or packing conveyors. Generally, these forming systems incorporate an inclined, gravity-advance magazine or powered horizontal hopper from which individual die-cut blanks are fed. Carton blanks are retained by small projections or tabs that extend slightly from the sides of a gate frame at the front of the magazine. Vacuum cups, mounted on a reciprocating feed bar, pull the individual carton blanks from the magazine and transport them in a downward arc. As vacuum is released, they are deposited in a registered position on top of a forming

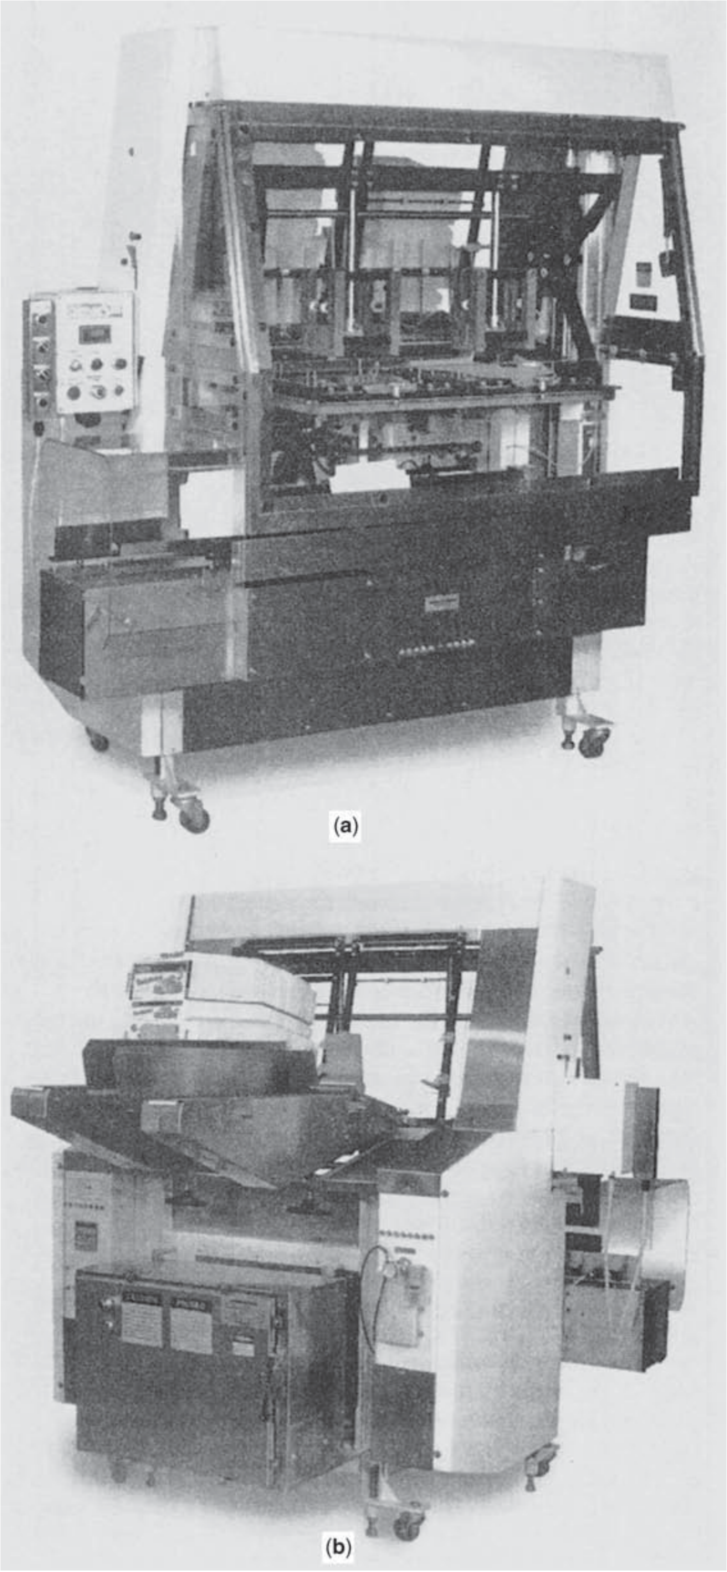

Figure 2. (**a**) Top-load carton forming machine with double-forming head; (**b**) rear of carton forming machine with powered carton hopper.

cavity. The carton blank is rotated from vertical to a horizontal plane during this feed cycle, with the vacuum cups contacting its inside surface. As the feed bar moves upward to feed the next blank, a plunger or mandrel moves downward to force the blank through the forming cavity (see Figure 3). The plunger is designed so that the carton body conforms to its shape. The carton is folded, guided, and manipulated by a series of metal or composite plastic fingers and plows installed within the forming cavity. As the plunger completes each forming stroke

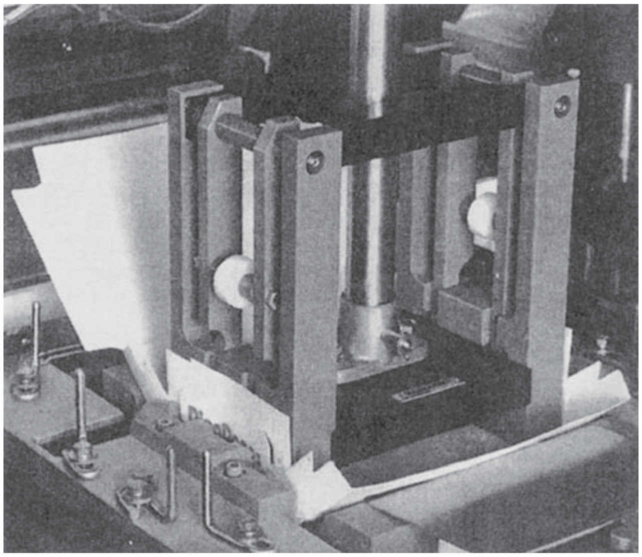

Figure 3. Lock-style carton forming head.

and begins moving upward, spring-loaded mechanical traps retain the carton and strip it or remove it from the plunger. In some cases, special carton coatings, shapes, or speeds dictate the use of a timed air blast system to positively eject the carton onto takeaway conveyors.

A wide range of carton sizes can be accommodated in styles ranging from simple rectangular corner-lock trays to a myriad of special shapes such as triangles, hexagons, octagons, and complex hollow-wall or shadow-box structures. The key to top-load carton forming lies in the special tooling that is designed and manufactured for each carton size and style. This removable tooling is commonly referred to as *a forming head*. It can be a relatively simple device or a complicated unit requiring various cams and actuation for flap folding and manipulation of the paperboard panels. The forming head consists of (a) the forming cavity, (b) a plunger or mandrel, and (c) various components for the hopper or magazine. By interchanging this tooling on any given forming machine, it can erect different carton styles, shapes, and sizes within a specified size range. For standard designs such as simple trays or hinge-cover cartons, the tooling can generally be changed in 10–15 min. In many cases, a multiple-head configuration is employed to erect several cartons with each forming stroke and increase the output of cartons per minute. Depending on the size of the package to be formed, machines may accommodate double, triple, or even quadruple forming heads. The carton body can be formed using locks, adhesive, or heat sealing.

LOCK FORMING

Dozens of different lock designs are available for forming trays and cartons to meet various packaging requirements. Most often, the lock design consists of a vertical and/or horizontal slit in the upright panels or walls of the carton body through which a specially shaped corner post or tab is inserted during the forming operation (see Figure 4). The opening of the die-cut slits in the vertical walls and folding and insertion of the locking tabs are accomplished using specially designed and fabricated fingers or guides that are an integral part of the forming cavity. Normally, a mechanical actuation is also incorporated in the plunger to pull in the locking limb and ensure positive engagement.

GLUE FORMING

Glue forming of flat die-cut paperboard blanks can be accomplished using either hot-melt or cold-vinyl adhesives (see the Adhesives article). Hot-melt adhesive is generally applied in one of two ways. The simplest method employs open heated reservoirs mounted in the machine directly below the forming cavity to melt and contain the adhesive. This is commonly referred to as an “open pot” system. Applicator blades are mounted on a shaft that runs across the top of each reservoir. As the carton blank is placed on top of the forming cavity, the shaft is mechanically actuated and the blades rise upward from within the adhesive. They apply a series of dots or lines of adhesive to the underside of a flap or corner post located in each corner of the carton blank. As the carton is plunged through the forming cavity, these flaps are folded inside the vertical walls of the carton. Spring-loaded rollers in the cavity

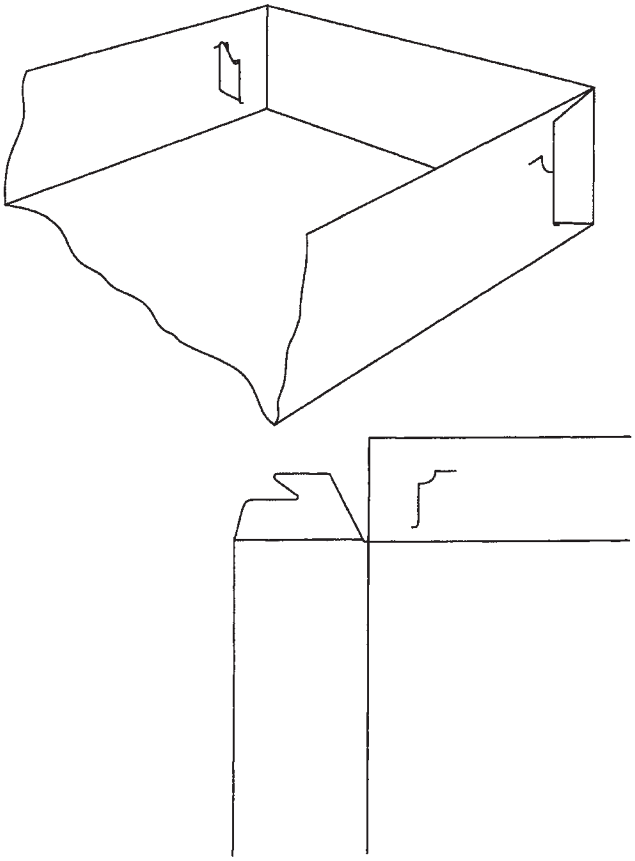

Figure 4. Common stripper-lock design: (**a**) assembled; (**b**) unfolded.

provide compression using the plunger inside the carton for backup. This technique compresses the adhesive and dissipates heat to allow quick bonding for reasonably high forming speeds.

The other commonly used method of hot-melt glue forming employs an enclosed, pressurized system where adhesive is supplied through heated hoses to guns or nozzles that spray a pattern on the inside of the carton's vertical body panels. Depending on the size of the carton and the pattern desired, this may be performed by first feeding cartons onto a short section of horizontal conveyor and applying adhesive as they are shuttled into position on top of the forming cavity. This avoids the need to mount necessary feed hoses and nozzles within the constraints of the forming cavity. It also allows greater pattern flexibility, and fewer nozzles can be used to apply glue to opposing corners of the carton as it travels beneath them. In other cases, where only simple glue patterns are required, applicator nozzles may be permanently fixed at each corner of the carton above the cavity. After adhesive is applied, the blanks are plunged vertically through the cavity and compressed in the manner described above.

Cold-vinyl carton forming was virtually eliminated with the advent of hot-melt adhesives because of the extended compression times required for setup. Carton styles were generally limited to specific compatible designs, such as outward tapered trays, which could be nested for extended compression times after the package was discharged from the forming machine. However, recent developments in applicator technology and new end-use markets have created a renewed interest in this forming method. Today, it is frequently used to produce paperboard scoops, boats, and clamshells for the fast-food and food-service industries, as it suits their requirement for economical, preformed packages with a bonding medium that is not sensitive to heat. This heat resistance has also led to applications in connection with "ovenable" cartons. In the forming operation, a carton blank is fed from the magazine and deposited on top of a forming cavity. Specially designed adhesive application nozzles are mounted on the forming cavity and are then mechanically actuated to deposit small dots of cold-vinyl adhesive on the inside of the carton blank. Adhesive is supplied under pressure from a single remote tank. A plunger forces the blank through the forming cavity and, in this case, deposits the formed trays into a nest or stack to keep them under pressure until the adhesive has set. This method allows forming at speeds of up to ~80 strokes per minute or more than 300 cartons per minute with multiple heads to satisfy the substantial production volumes required by the fast-food industry.

HEAT-SEAL FORMING

Heat-seal forming uses special coatings or preapplied hot-melt adhesives on the paperboard as a bonding medium in the carton-forming operation. Overall board coatings that can be heat-seal formed include single-side polyethylene, double-side polyethylene, polyester, and polypropylene. Special pattern-applied hot-melt adhesive coatings, placed only in the area to be bonded, can also be used. The heat-seal system is designed to force air through electrically heated quartz elements into specially designed nozzles on the forming cavity. Depending on the carton coating, air temperatures that range from 400 to 800°F (200–425°C) are directed over specific areas of the carton blank, where the coating on the paperboard stock is melted or activated. The carton blank is plunged through the forming cavity, and the board coating serves to bond the appropriate carton flaps. High speeds—up to a maximum of ~90 strokes per minute—can be achieved, depending on variables such as coating thickness, carton size, and carton style. Heat-seal forming operations require some degree of cooling to prevent heat buildup in various parts of the forming head and to accelerate carton compression times. Water or special refrigerants are plumbed to various components within the forming cavity and plunger. The extent of cooling generally depends on the bonding medium used, but it becomes most extensive when double-polyethylene coatings are involved. Heat-seal forming is employed most often in the frozen-food industry, where thermoplastic coatings are otherwise included for moisture-barrier protection, graphic enhancement, or a degree of leak resistance necessitated by wet products.

TOP-LOAD FORMING CAPABILITIES

Various carton forming machine models are produced, each designed for a given size range and speed rating. The same basic machine chassis can usually be modified with special attachments and equipped as a dedicated lock, glue, or heat-seal system. As indicated, machines can be equipped with double, triple, or quadruple heads to feed and form multiple carton blanks simultaneously. Forming speeds generally range from 20 to 120 strokes per minute, and with multiple forming heads, a single machine can produce more than 300 cartons per minute.

CARTON CONVEYING

After forming, the top-load carton is typically carried on a conveyor for loading either manually or automatically. For slow- to moderate-speed hand packing, simple flat-belt or plastic tabletop chain conveyors are frequently employed and offer the most economical approach. One end of the conveyor is generally placed below the forming cavity and is independently driven with no electrical or mechanical connection between the conveyor and the forming machine. After forming, trays or cartons drop onto the conveyor and are carried downstream for product loading. The alternative to this method is a conveyor with chain flights or lugs (see Figure 5). Generally, flighted conveyors are either attached to and mechanically driven by the forming machine or electronically synchronized through the use of intelligently controlled independent drive motors. Flighted conveyors offer the advantage of packing the operators, because they cannot individually retard cartons for loading as they can on a flat belt. Flighted systems are required to achieve adequate carton control in any

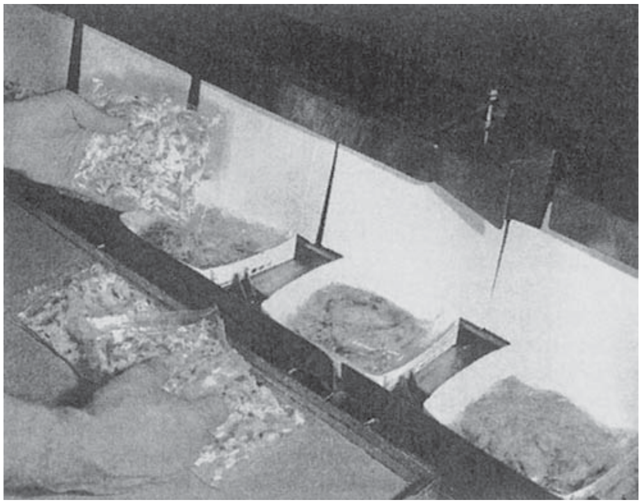

Figure 5. Flighted carton packing conveyor, hand packing.

high-speed operation. They also allow the carton cover to be controlled during the packing operation by either maintaining a vertical position or folding it back almost 180° to permit loading from either side of the conveyor. Packing conveyors should be designed so that the bottom of the carton is approximately 30–34 in. (76–86 cm) from the floor. This helps optimize the efficiency of operators who are placing product into the cartons by hand.

MANUAL PRODUCT LOADING

For hand-pack operations, product can be presented to the operator in many different ways. These range from tote bins to product conveyors running up to the carton conveyor. The most efficient method involves bringing the product in on a flat belt or tabletop chain that runs parallel and adjacent to carton flow. The bottom of the product should be elevated just slightly above the top of the carton to allow for simple sweep loading into the largest opening of the carton. This is the most efficient and reliable method of hand packing.

AUTOMATIC PRODUCT LOADING

The automatic loading of products into top-load cartons can be accomplished using many different standard and or highly customized systems. Free-flowing products, such as individually quick-frozen vegetables, are often filled automatically using a volumetric system that is integrated mechanically or electronically with the carton conveying system. Where netweight filling is desirable, a variety of different systems can be employed. These are normally interlocked electrically with the carton forming and conveying system to sense the presence of a formed carton and to signal the scales to dump. For net weighing or automatic loading of some products into top-load cartons, the carton conveyor must sometimes operate on an intermittent-motion basis. This allows the carton to stop or dwell momentarily beneath a filling device, providing sufficient time to completely load the product charge. Alternatively, special traveling or reciprocating-funnel systems can be incorporated at the point of product loading to allow continuous motion. The top or throat of the funnel is designed to provide a continuous open target beneath the filler discharge while the bottom aligns and travels in synchronization with the carton on the conveyor.

Many products are loaded into top-load cartons by count, in a specific pattern. These range from things such as spark plugs or hardware items to bare frozen hamburger or potato patties. Many other products such as wrapped candy, pouched mixes, boil-in-bag items, overwrapped baked goods, healthcare and pharmaceutical items, office supplies, tobacco products, and all types of frozen foods have been automatically loaded into top-load cartons. The loading technique depends on the product and can vary from a simple mechanical shuttle to advanced units that automatically align, accumulate, group, and transfer product into the carton. Characteristics and consistency in the product's weight, size, shape, texture, temperature, and surface traits all have significant influence on the method of automatic loading. The transfer of such products is most frequently accomplished using a high-volume, low-pressure vacuum pickup system (see Figure 6). A reciprocating-vacuum manifold transports items into the carton after they have been previously organized into required patterns. In some instances, advanced robotics, incorporating sophisticated vision

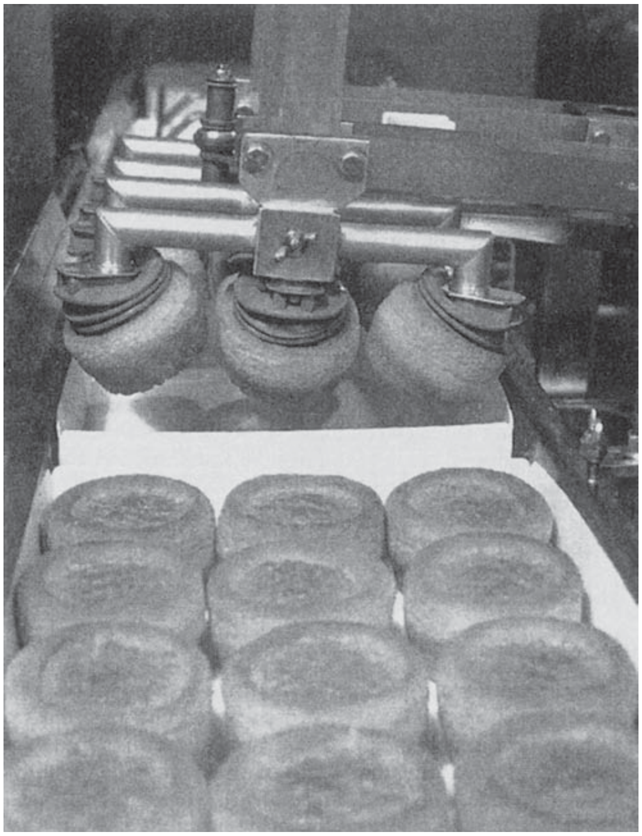

Figure 6. Automatic product loading, vacuum transfer.

systems, are used to locate product from a randomly positioned supply and automatically transfer it into cartons.

CARTON CLOSING

When hinge-cover or self-cover designs are used in any topload cartoning application, the method of carton closing becomes a final major consideration. General categories of carton closers include flighted or lugless models. On flighted systems, actuation and sealing functions are timed according to predefined spacing between conveyor flights. On lugless systems, intelligently controlled motors and other functions react to the presence and position of a carton as it is photosensed on conveyor belts. In broad terms, flighted systems generally provide a higher degree of carton control, whereas lugless systems offer greater speed, flexibility, and ease of maintenance. For slow to moderately high-speed flighted operations, the closing machine is usually an independent unit with its own drive motor. It is equipped with a special infeed assembly that accepts cartons at random from an upstream packing conveyor and automatically times them into the flights of the closing machine. When flighted systems are required to operate at high speeds (>200 cartons per minute), it is desirable to eliminate the infeed section and drive the entire packaging line from the carton forming machine. This "line-driven" method requires the use of flighted packing conveyor and ensures that positive carton control is maintained throughout. The need to retime cartons into the closer at high speeds is eliminated.

Lugless systems are, inherently, independent as opposed to line-driven. Cartons are received at random and conveyed with sequential belts that have special surface traction characteristics. Both overhead and underlying conveyor belts may be employed to maximize control. Each sequence of the operation is powered by its own individual, intelligently controlled drive motor, so speeds and relationships between various machine functions can be readily adjusted through program controls. This allows a much greater degree of flexibility and finetuning without the need for physical changeover and tool adjustments.

DUST-FLAP-STYLE CLOSURE

Dust-flap-style cartons require closure of only a single tuck panel. As such, they can be closed on a straight-line operation where it is unnecessary to turn or rotate the carton. A static plow folds down the leading dust flap while a rotating paddle or wheel assembly, timed to the carton-conveying chain, serves to "kick" the trailing dust flap forward. After this has taken place, the cover is plowed down using guide rods, belts, or rollers. As the cover is plowed down, the front tuck score is prebroken in preparation for final closure. Dust-flap-style cartons can be closed either by inserting and locking the front tuck inside the body of the carton, or, by applying hot-melt adhesive to the inner surface of the tuck and adhering it to the outside of the carton's front panel.

TRIPLE-SEAL-STYLE CLOSURE

The hinge-cover carton design most frequently used is the triple-seal ("tri-seal") style, which is also called the "three-flap" or "charlotte" style. For this carton style, three primary closer designs are available: vertical, right angle, and straight line. For slow-to-moderate-speed operations, where space is a limiting factor, a compact machine design consists of an intermittent motion unit with vertical carton compression. Cartons are indexed by shuttling them at a right angle into a single hot-melt adhesive application station. Adhesive is applied to all three carton cover flaps simultaneously.

This type of closer generally uses an open-reservoir style of application system, with blades rising from within the adhesive to apply solid lines or dots of adhesive as required. It can also be equipped with gun- or nozzle-style applicators that spray adhesive onto the carton flaps. After adhesive application, the entire carton is elevated vertically through a compression tunnel that folds down all three flaps and discharges finished cartons at the top of the machine.

For most applications, tri-seal cartons are closed using either right-angle or straight-line machine configurations. In the right-angle operation (see Figure 7), the carton is indexed into the closer, the front tuck is sealed to the carton body, and the carton is shuttled through a 90° change of direction for sealing the charlottes or end flaps. With the straight-line closer design (see Figure 8), the carton body is rotated or turned 90° after closure of the front tuck, as it continues to travel in a straight line. This positions the charlottes parallel to the line of travel to facilitate application of adhesive or hot-air sealing and subsequent compression. To achieve proper registration between the cover and the carton body, it is best to fold down and trap the trailing charlotte before front-tuck closure. This is generally executed with an overhead, rotating tucker paddle. This paddle is positioned above a chain transfer area, where a new set of lugs then traps the trailing charlotte against the rear of the carton and holds

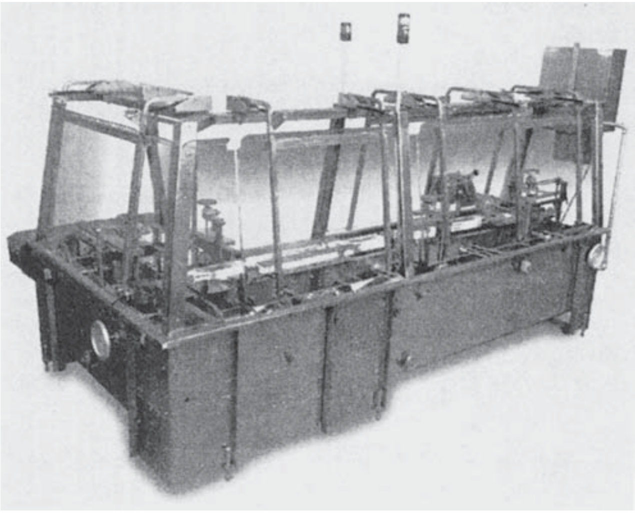

Figure 7. Right-angle top-load carton closer.

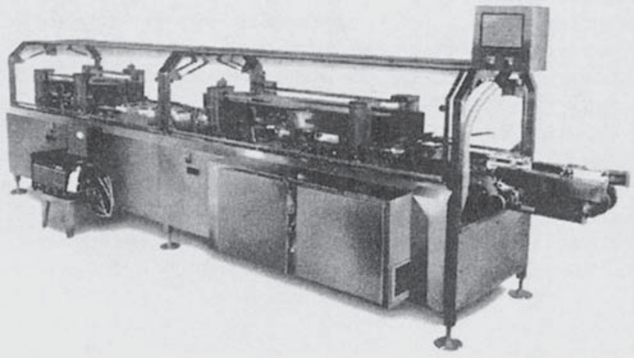

Figure 8. Straight-line lugless top-load carton closer.

it in position through the front-tuck closing section. On lugless systems, the speed of overhead belts can simply be adjusted in relation to the carton-carrying belts in order to precisely position the cover.

LOCK CLOSURE

Closure of tri-seal cartons can be accomplished using locks, adhesive, or heat sealing. Lock closure is effected by using specially designed plows, guides, and tucking fingers and is employed most often in the frozen-vegetable industry for plain-paperboard shells that are later overwrapped with printed paper.

ADHESIVE CLOSURE

Adhesive closure can be accomplished with either hotmelt or cold-vinyl adhesives. Hot melt is most frequently employed, and the adhesive is commonly applied using either open-pot or enclosed, pressurized nozzle systems. Depending on the glue pattern required, a thin wheel or cluster of wheels can be used to apply adhesive from an open reservoir to the carton flaps. When special patterns are desired, intaglio-wheels or nozzle-type applicators supplied by a remote tank generally offer greater flexibility.

Historically, cold-vinyl adhesive found little application in on-line closing operations because of extended compression times required for setup. Recently, however, interest has been prompted by the requirement for ovenable paperboard packaging, where most hot-melts are unsuitable because they tend to soften and release during cooking. As a result, systems have been developed for polyester-coated ovenable board stocks. These systems apply a finely atomized spray of cold-vinyl adhesive, which is followed by the application of electrically generated hot air in a manner similar to that used for heat sealing. The hot air accelerates the water evaporation process and allows use of carton compression sections that are comparable in length to those of hot-melt systems. Sufficiently high production speeds (~150 cartons per minute) are achieved. This system has been used with polyester-coated paperboards for dual-oven applications, where the product is intended for preparation in either microwave or conventional ovens. Among the various thermoplastic polymers used for carton coatings, polyester is generally the only one considered suitable for dual-oven use because of its high-temperature compatibility and limited heat solubility. By the same token, these characteristics necessitate high temperatures and extreme compression when the coating is used as a heat-sealing medium to bond the carton. Although the coating can be used for carton forming, where a plunger inside the carton provides necessary backup for compression, it is not practical for conventional heat-seal closure because only limited compression can be applied against the hollow package.

HEAT-SEAL CLOSURE

Heat-seal closure can be used for cartons that include thermoplastic coatings, heat-sealable wax coatings (see the Waxes article), or preapplied hot-melt adhesives. Here again, the board coating or sealing medium is activated using electrically generated hot air at high temperatures. The package then proceeds through compression to bond the flaps as the coating solidifies. For wax-coated cartons, the compression section must consist of refrigerated bars to prevent smearing of the wax. This method also results in quick bonding of the paperboard flaps, within a relatively short compression section.

OPTIONAL FUNCTIONS

Top-load cartoning systems can be equipped with a wide variety of options, including many types of coding devices, leaflet feeders, labelers, sensors, and computers to facilitate effective control and management of the entire packaging system.

CARTONS, FOLDING

Paul Obolewicz
Rand Whitney Packaging,

INTRODUCTION

Folding cartons are containers made from sheets of paperboard (see Paperboard) that have been cut and creased for forming into a designed shape. They comprise a significant proportion of the packaging found in the retail sector. Cartons meet packaging needs cost-effectively by providing product protection and information, visual impact, and convenience appropriate for the product concerned and its method of distrbution and consumer use (1).

There is evidence that paper was used by Egyptian merchants to wrap goods for their customers as early as

1035 A.D. The modern-day folding-carton industry began in 1839 when Colonel Andrew Dennison began producing commercial folding cartons to complement and protect jewelry sold in his retail store. By the mid-1890s, automatic machines were in widespread use for the production of cartons (2).

Merchandise displays at supermarkets and drug, hardware, automotive, and department stores demonstrate the extent to which folding cartons are used today. Cereal, crackers, facial tissue, detergent, dry mixes, frozen food, ice cream, butter, bacon, bar soap, candy, cosmetics, toys, cigarettes, canned beverages, carryout foods, and pharmaceuticals represent the broad range of products for which folding cartons are commonly utilized. The use of folding cartons is widespread because of the ability of this packaging format to satisfy the functions of protection, utility, and motivation. Protection from crushing, bending, contamination, sifting, grease, moisture, and tampering can all be built into folding cartons. For the producer, utility is achieved through high-speed automatic packing (see Cartoning machinery). For the end-user or consumer, utility is provided by opening, reclosing, and dispensing features. In some cases, the carton even serves as the cooking utensil. High-quality graphic reproduction, excellent billboard presentation of the graphics design, and the ability to take on unique and varied shapes provide the carton user with the means to motivate the consumer to purchase products packaged in folding cartons.

PAPERBOARD SELECTION

Successfully meeting the needs of a folding-carton user begins with choosing the paperboard best suited for the job. In general, this means selecting the grade with the lowest cost per unit area that is capable of satisfying the performance requirements of the specific application. Economics and performance dictate careful selection of paperboard grades for each use.

Selection Criteria

A variety of criteria are commonly used in the selection of paperboard grades. The Technical Association of the Pulp and Paper Industry (TAPPI) has published standardized test methods for many of these criteria (3) (see Testing, packaging materials). TAPPI Standard Methods are widely used and accepted by the industry. The most important and widely used criteria are shown below.

FDA/USDA Compliance. This is a nondiscretionary criterion for food products and is dependent on the type of food and the type of contact anticipated between the food and the paperboard or coatings on the paperboard.

Color. Color is typically chosen for marketing reasons. The side of the paperboard that becomes the outside of the carton is generally white, but the degree of whiteness varies among grades. Depending on the materials-selection and processing strategies of suppliers, outside board color can be blue-white or cream-white. These shades are noticeably different and can limit substitution of grades. Board color on the inside of cartons varies from white to gray to brown.

Physical Characteristics. It is possible to establish minimum levels for each carton application that allow the package to satisfactorily withstand the rigors of packaging machinery, shipping, distribution, and use by the consumer. Physical properties commonly used to predict suitability of board for a given use include stiffness, tear strength, compressive strength, plybond strength, burst strength, tensile strength, elongation, and tensile energy absorption. Physical criteria normally define the basis weight and thickness of paperboard that is used to produce a carton.

Printing Characteristics. Following the selection of a specific graphic design and printing method for the carton, a paperboard is selected based on these criteria: smoothness; coating strength; ink and varnish gloss; mottle resistance; and ink receptivity. Not all criteria are important for every printing technique.

Barrier. The most common barrier requirements are for cartons to provide protection against moisture and grease. The choice of a barrier material and application method influences board choice. For example, if polyethylene (PE) is to be applied to the carton, a board with a treatment that holds the PE on the board surface can have economic and processing advantages over an untreated board. Materials and application methods are described below.

Paperboard Types

In the United States, the three most widely used types of paperboard are identified as follows:

Coated Solid Bleached Sulfate (*SBS*). 100% virgin, bleached, chemical furnish, clay-coated for printability.

Coated Solid Unbleached Sulfate (*SUS*). 100% virgin, unbleached, chemical furnish, clay-coated for printability.

Coated Recycled. Multiple layers of recycled fibers from a variety of sources, clay-coated for printability.

Coated recycled boards are the most widely used. Other types include folding box board (FBB) and white lined chipboard (WCC).

Overall treatments or coatings are applied to webs of paperboard to provide specific functions. Clay-based coatings to provide high-quality printing surfaces are the most common treatment applied on the paperboard machine. Grease-resistant fluorochemicals are applied on board machines as well, either as furnish additives, surface treatments, additives to clay coatings, or in combination. Mold-inhibiting chemicals are also applied to boards designed for bar-soap packaging, to prevent moisture in the product from initiating mold growth. Surface treatments applied on other-than-board production equipment are discussed below under Carton Manufacturing Processes.

Paperboard is the overwhelming choice as the substrate for folding cartons. However, a segment has developed that utilizes plastic sheet as a substrate. These cartons are normally produced from clear, impact grades of PVC sheet (see Film, rigid PVC) using specialized heated-scoring techniques to achieve acceptable folding characteristics. Unique product visibility is the primary reason for the use of this more costly substrate for specialty folding-carton applications, such as cosmetics and soft goods (see Boxes, rigid plastic).

Another segment making an impact on the folding carton market is E-flute, and the newer F-flute is corrugated. E-flute is a transitional medium between corrugated and folding cartons. While E-flute height, depending on the profile of the manufacturing ranges within 43/1000 and 5/1000 in. F-flute, is typically ~30/1000 in. The fluted material has positive attributes for its stacking strength, low weight, and stiffness, as well as for its insulating and shock-absorbing properties. It is used typically in cartons for products such as perfumes, glassware, household products, candies, fast foods, and countertop displays.

CARTON STYLES

As the demand for cartons grew, so did demands for additional features. These demands catalyzed the development of new and unique ways to cut and fold sheets of paperboard to produce cartons. The records of the U.S. Patent and Trademark Office contain many thousands of patents granted to protect folding-carton structures.

Three broad classifications are commonly used to categorize folding-carton styles: tube (end load); tray (top load); and special construction. Figure 1 describes accepted terminology for the various parts of tube (**a**) and tray (**b**) cartons (4), as well as the order in which dimensions are listed in carton specifications. Compliance with these standards prevents confusion.

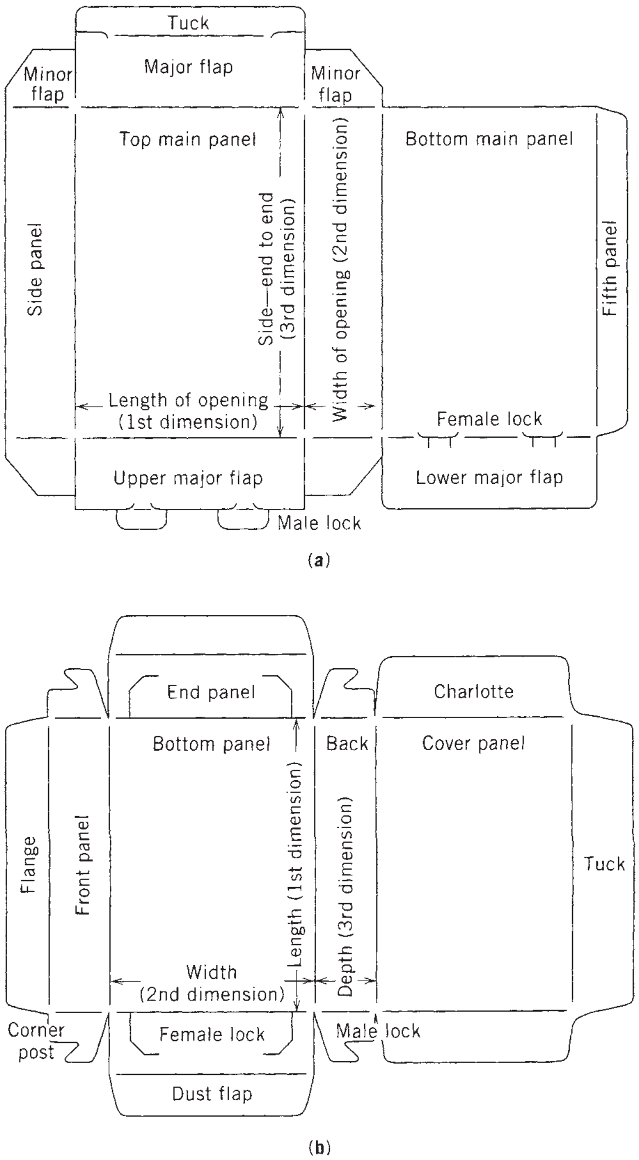

Figure 1. Terminology.

Tube Style

Tube (shell) constructions are the most common style in use today. Figure 2 shows a typical sealed-end carton in various stages of production and filling. These cartons are characterized by a fifth panel glue seam in the depth direction, yielding a side-seamed shell that folds flat for transportation. The cross section of the carton opening is normally rectangular, and product may be loaded either horizontally or vertically (see Cartoning machinery). Tube-style cartons are well-suited for very high speed automated filling lines, but they are also used for manual filling applications.

Figure 3 shows the treatment of end flaps on a tuck-end carton. Other end treatments are in common use, including zippers and similar opening features for sealed-end cartons. Internal shelves and panels are often included to secure and protect the product. This is particularly done when the product is irregular in shape or the carton is much larger than the product for improved graphic presentation or shoplifting deterrence. When heavy granular products are packaged, bulging of main panels can be a problem. The use of bridges connecting the two main panels increases the carton's integrity required to resist bulbing. These bridges can be made from paperboard and attached during the gluing operation.

Tube-style cartons are commonly used for granular or pourable solid products such as detergent, cereal, and dry mixes. Dispensing features are often designed by special cuts and creases in the paperboard. End opening is preferred when inner bags are employed (see Bag-in-box, dry product). Large products packed one to a carton, such as pizzas, frozen dinners, pot pies, cosmetics, and pharmaceuticals, are packed in end-opening tube-style cartons. End-loaded cartons are also designed for opening and product removal through the main panel; a cream cheese carton is a good example of this approach. Gabletop milk cartons also fall into the tube or shell category (see Cartons, gabletop). They incorporate liquid-tight sealing

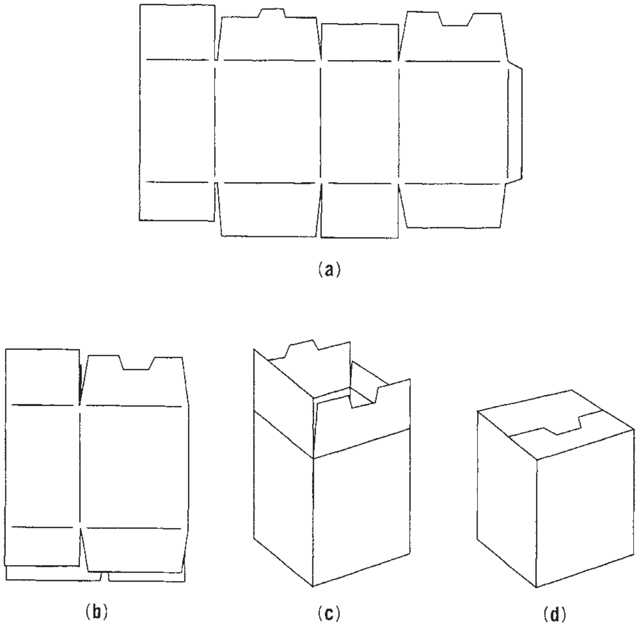

Figure 2. Sealed-end carton: (**a**) blank; (**b**) side-seamed shell; (**c**) carton erected for loading; (**d**) filled and sealed carton.

and a reclosable pour spout. From ice cream to lipstick, tube-style cartons satisfy many diverse packaging needs.

Tray Style

Tray or top-load cartons are characterized by a solid bottom panel opposite the product-loading opening. As shown in Figure 1**b**, panels are connected to each edge of that bottom panel. Tray cartons are especially useful for manual or automatic loading of multiple products. Figure 4 contains schematic drawings of a tray carton blank, the carton setup for loading, and the completely closed and sealed carton. In this example, the front and back panels are connected to the end panels using mechanical locks. Panels are also commonly connected using adhesives or heat sealing (see Adhesives; Sealing, heat).

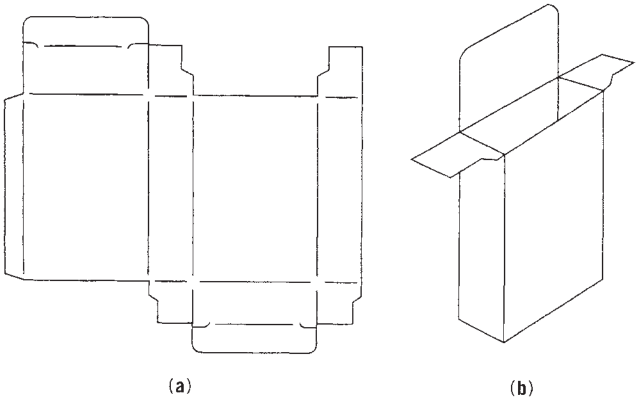

Figure 3. Tuck-end carton: (**a**) blank; (**b**) erected carton for loading.

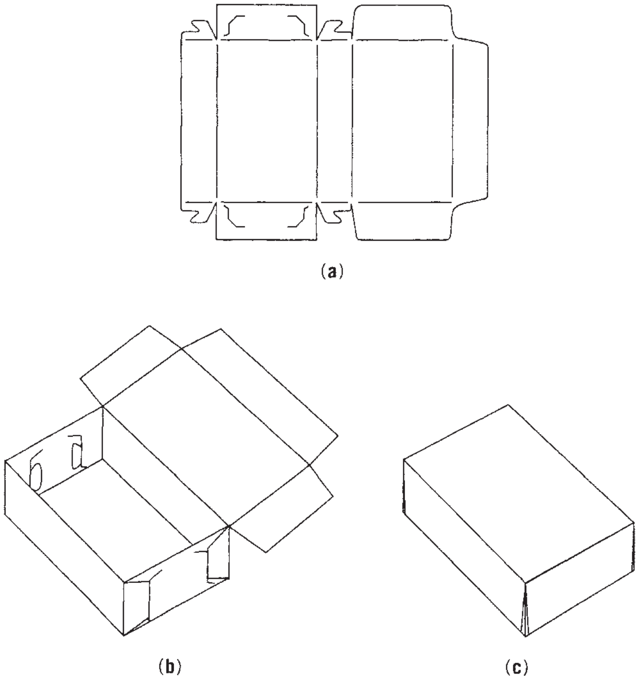

Figure 4. Locked corner hinge cover carton: (**a**) blank; (**b**) carton; (**c**) tuck-end carton.

Where additional resistance to leakage is desired, web corners are employed. Figure 5 shows a web-corner tray with folded double sidewalls that provide finished sidewall edges. A similar, slightly larger tray could be used to cover the tray following product loading, yielding an extremely crush-resistant package. Figure 6 shows a six-corner

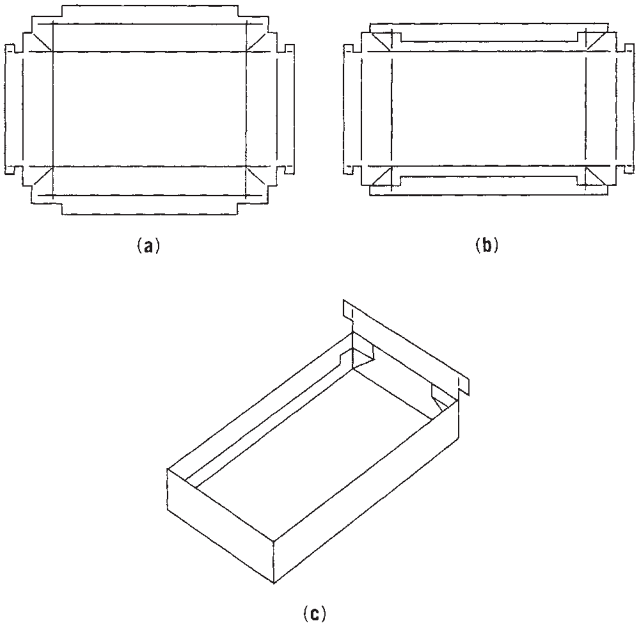

Figure 5. Web-corner tray: (**a**) blank; (**b**) sidewalls glued; (**c**) final panel folding.

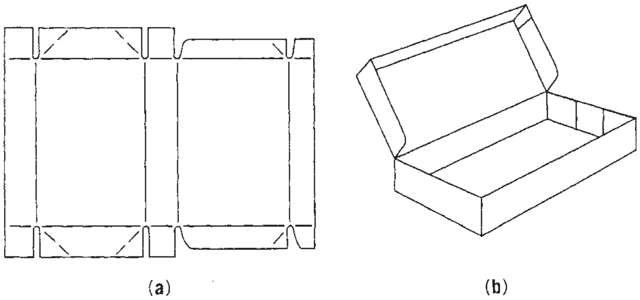

Figure 6. Six-corner carton: (**a**) blank; (**b**) carton erected for loading.

carton that can easily be set up by hand. Diagonal scores permit the tray to be glued and delivered in a collapsed form. Web corners could be incorporated with additional modifications.

Tray cartons that require no gluing at the point of use (e.g., the six-corner carton of Figure 6) are used extensively for manual loading. The cake, pie, or pastry carton employed by the local bakery is the best example of the utility of these designs. Garments and other dry goods are often packed, especially when purchased as gifts, using two-piece cartons that comprise two collapsible glued trays. Tray cartons are also widely used for products that can be automatically packaged. Doughnuts and fish sticks are examples of products commonly packaged in tray-style cartons with attached covers. Cartons similar to that shown in Figure 4 are used for products of this type. Most display cartons for smaller candy packages also fall into the tray category.

Special Construction

Special construction is a classification employed for cartons that do not fit tray or tube descriptions, or that represent sufficient departures from normal tray or tube practice. A blister package that employs a combination of heat-seal-coated paperboard and a clear thermoformed plastic blister is a good example of a special construction (see Carded packaging). The automatic-bottom carton shown in Figure 7 combines elements of a side-seamed tube carton with those of a top-load carton and requires no manipulation to form the carton bottom. When the collapsed shell is opened, the bottom panels lock into place. This carton is used extensively for fastfood carryout packaging. It is also popular for hardware items.

The bottle-wrap carton in Figure 8 is an example of the many wraparound carrier cartons used for multipacks of bottles, cans, or plastic tubs (see Carriers, beverage). These cartons are either locked or glued after being wrapped around the primary packages.

The tube, tray, and special carton styles depicted and described here are broadly representative of the great variety in shapes and sizes produced by the folding-carton industry. Customization of design for function or appearance is a significant advantage of folding cartons.

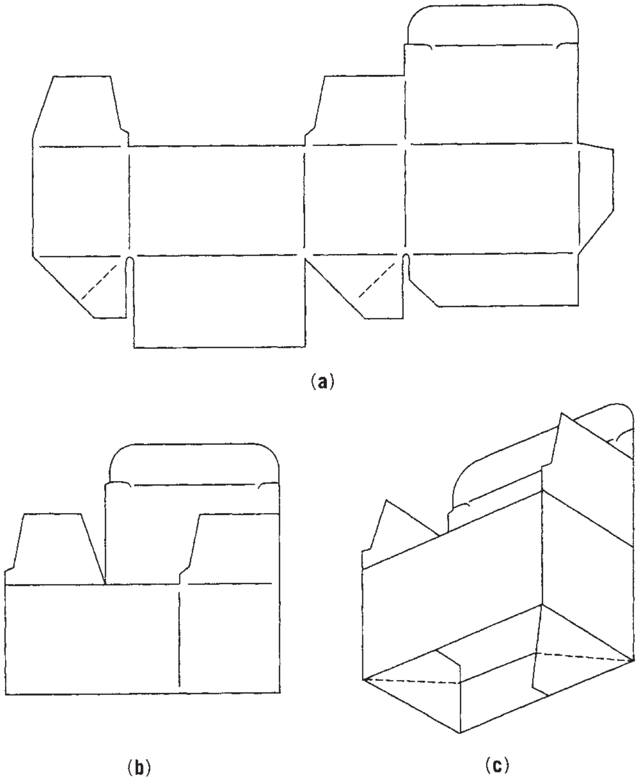

Figure 7. Automatic-bottom carton: (**a**) blank; (**b**) carton glued for shipping; (**c**) bottom view of erected carton.

CARTON MANUFACTURING PROCESSES

After a paperboard grade has been selected for a specific carton style and use, a variety of manufacturing options are available for converting that board into cartons. Although it is a highly unusual carton that requires each one of the steps or stages described below, all are commonly employed to produce folding cartons in today's market.

Extrusion Coating

This technique involves the coating of one or both sides of the paperboard web with a relatively thin (generally less than 0.001-in. (25.4-μm)) layer of a thermoplastic polymer (see Extrusion coating). Low-density polyethylene (LDPE) is the most commonly used extrusion coating for folding cartons and provides a cost-effective means of obtaining excellent protection against water resistance as well as a fairly good water-vapor barrier. LDPE is also used as a heat sealant (see Sealing, heat), particularly when two-side coatings are employed. When the use temperature of the package exceeds 150°F (65°C), HDPE or PP can be used to raise the acceptable use temperature to 250°F (121°C). These two polymers also provide improved grease resistance. Coating board with PET can raise the use temperature to over 400°F (204°C), suitable for most "dual-ovenable" applications. Coextrusion, in which back-to-back layers of two plastics are laid onto paperboard,

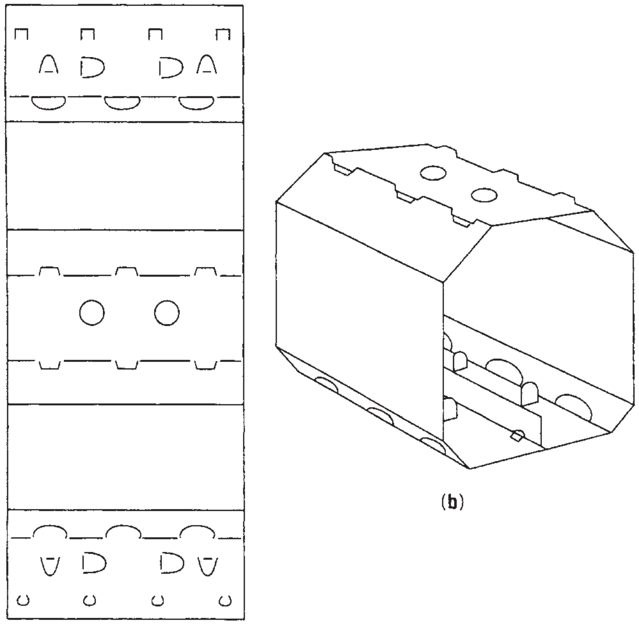

Figure 8. Bottle wrap carton: (**a**) blank; (**b**) erected carton. (Bottles omitted for clarity.)

makes it possible to take advantage of the special properties of some exotic plastics, such as nylon, that by themselves will not adhere to paperboard.

Laminating

The earliest means of significantly enhancing the properties of paperboard was the combination with other materials through lamination (see Laminating). The most commonly used laminating adhesives are water-based glues (see Adhesives), or thermoplastic polymers. Materials laminated to paperboard include high-quality printing paper for enhanced graphics capabilities (see Paper), grease- or water-resistant paper for improved barrier, aluminum foil for barrier or aesthetics (see Foil, aluminum), and film (sometimes metallized) for barrier or aesthetics (see Metallizing).

Printing

Prior to the printing operation, paperboard is handled in web form. A decision must be made to continue in web form or convert the web to sheets before printing and die cutting. This choice is primarily dictated by the printing technique chosen (see Printing). Sheeting is most often done at the carton-producer's facility. A small segment of the industry purchases board sheeted at the paperboard mill.

The main processes for carton printing today are offset lithography, flexography, and gravure. Letterpress and silk screen are used to a limited extent. The most recently introduced process, digital printing, can be used for short print runs and for customizing packaging in already premade bulk. Printing involves solid print, text, illustrations, and diagrammatic representatios. Brand positioning can have a major influence on the printing design. Functional needs have to be taken in to account. Products that retain ink odors require special attention in choice of inks and printing methods. Products that are packed hot may need rub-resistant print surfaces (1).

With respect to quality of reproduction, there is overlap in what can be achieved today with the various printing processes. Gravure was considered best for solids, whereas offset lithio was considered best for halftones. Today, offset gravure and conventional gravure with eletrostatic assist may improve gravue halftone reproduction. In the past, offset lithio would be used to print a design on a box of chocolates and the rest of the printing would be done by sheet-fed gravure. This was necessary to prevent the occurrence of residual odors that would be retained from the lithio ink and would be a hazard to chocolate. Today, there is a wide choice of offset lithio ink and drying systems that assist drying. Today, presses are fitted with coating units that can apply UV-cured varnishes that are water clear, have high gloss, and are rub-resistant.

It is still true that cylinders are relatively more expensive for gravure than plates for lithio and flexo, but they are longer-lasting and therefore competitive when longer runs are required.

Silk screen printing has always been known for its ability to print thick films of ink. UV systems can be used in silk screening, and this has the advantage of rapid ink drying. A range of special effects is possible and incliude raised images, such as Braille, warning symbols, highly opaque prints, and high-luster varnish and textured finishes (5).

Cutting and Creasing

Following the printing operation, individual cartons are cut from webs or large sheets and creased or scored along desired folding lines. Reciprocating flat-bed or platen cutting is almost invariably used to cut and crease sheets printed by offset lithography. In this technique, an accurately positioned array of steel cutting knives and scoring rules (see Figure 9) is pressed against a printed sheet of paperboard. The knives penetrate through the paperboard to cut out the pattern of the carton. Rules force the board to deform into channels in the counter plate, producing controlled lines of weakness (scores) along which the board will later predictably bend or fold. Alternatively, scores can be produced by cutting partially through the paperboard or by alternating uncut segments with completely cut-through segments.

In years past, knives and rules were separated and held in place by hand-cut blocks of dimensionally stable hardwood plywood. Hundreds of individual blocks were required for dies incorporating 10 or more carton positions. Greater accuracy and consistency as well as substantially reduced die preparation time is being used today through the use of computer-controlled laser die cutters. The laser beam is used to cut slots in large sheets of the same special plywood. Knives and rules are cut and bent automatically or manually and placed by hand into the slots. Crease or score quality has been improved

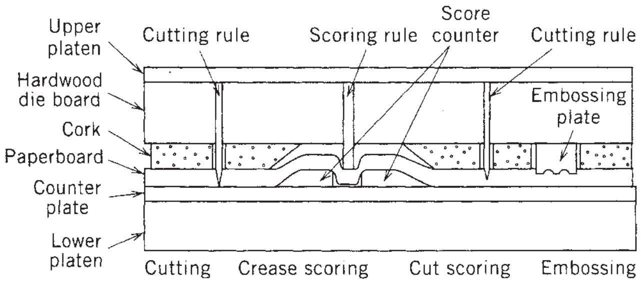

Figure 9. Flat-bed cutting-die schematic.

through the use of computer-controlled counter-plate machining and accurate pin-registration systems.

Transport of printed sheets in a sheet-fed platen cutter is accomplished with mechanical grippers that hold the leading edge of the sheet. Small nicks in the cutting knives result in uncut areas that keep the full sheets intact and permit transport from the cutting and creasing station to the stacking station. Large stacks are then removed from the machine; and unwanted pieces of board, called broke, are stripped from the cut edges of the cartons, yielding stacks of printed carton blanks. Newer sheet-fed platen cutters incorporate automatic stripping of broke between the cutting and stacking stations. Platen cutters are also employed to cut and crease paperboard printed in web form. In the past, these cutters were often placed out of line from normally faster-running presses. Speed increases permit economical in-line placement, which is common today.

Rotary cutting and creasing offers the advantage of higher speeds than reciprocating platen cutting, but at greater cutting die cost. Matched machined cylinders used for fixed carton sizes are most often placed in-line with printing operations. Both electrical discharge and mechanical machining are used to produce the knives, rules, and score channels in these matched cylinders.

Rotary cutting dies have also been developed for sheet and web cutting and creasing that are produced by pattern chemical etching of thin metal plates. Cutting and creasing patterns are coated with chemical-resistant materials, and chemicals are used to reduce the thickness of the plate in the unprotected areas, resulting in raised rules. Creases are formed by pushing the paperboard with the rule of one plate into a channel formed between two rules of the second plate, a configuration quite analogous to that of platen creasing. Cutting, however, is quite different; cutting rules on opposing plates are offset slightly from each other. As these rules rotate, approaching each other closely but not touching, they compress the board. Compressive forces within the board cause it to rupture, yielding cut edges. For sheet-fed cutting, these etched flexible dies are mounted on large cylinders which, like sheet-fed offset plate cylinders, leave a gap between leading and trailing edges. This gap accommodates sheet feedup and variable repeats. For web cutting, however, leading and trailing edges must be butted to correspond to the continuously printed webs. Die mounting techniques as well as carton layout on the web are the keys to the successful operation of this approach.

Two additional specialty converting steps are accomplished on cutting and creasing equipment: foil stamping and embossing. Foil stamping involves the use of heat and pressure to transfer a thin metallic or pigmented coating from a carrier film to the carton surface to obtain patterned decorative effects. When this is done in combination with embossing, reflectance and gloss are combined with raised image effects for enhanced graphic presentation. Embossing alone can generally be accomplished on standard die-cutting equipment. Foil stamping and detailed, deep embossing requires the ability to heat the stamping and embossing plates. This is most commonly accomplished on a second pass through specialized equipment.

HOT-MELT APPLICATION

Hot melts (see Adhesives) can be preapplied at this or a later production point using knurled wheels or timed guns. The hot melt is later heat-activated on the packaging machinery to effect sealing. Although hot melt application on the packaging machine is common, some carton users find it advantageous for the carton manufacturer to preapply the hot-melt adhesive.

Windowing or Couponing

When product visibility is desired, a hole is cut out of the carton blank. To protect the product or prevent it from spilling out of the carton, pieces of an adhesive pattern are applied around the edge of the opening, a rectangular piece is cut from a roll of film and is then pressed in place. Registered application of printed films or printed coupons in roll form to interior or exterior surfaces adds value and function to the carton. Devices are also available that adhere coupons supplied in sheet form.

Gluing

Although more and more packaging machinery is designed to accept flat carton blanks (see Cartoning Machinery), gluing still represents a major and important converting operation. The simplest operation converts a flat blank into a side-seamed tube or glued shell (see Figure 2**b**). Carton blanks are removed one at a time from a stack and carried by sets of endless belts. Stationary curved plows move one or more panels of the blank out of the original plane to either prebreak scores or form the glue seam. Prebreaking of scores assists packaging-machine operation, since the force required to bend a previously bent score is greatly reduced. Sealing is accomplished with cold glues, hot melts, or heat sealing of polymers. Side-seamed cartons are discharged into a shingled delivery that provides compression and time to set the bond; case or bulk packing for shipment follows.

Gluers in which the cartons move in a continuous straight line, transported by belts, are known as straight-line gluers. Although straight-line gluers are most commonly used to produce glued shell-type cartons, attachments provide the ability to produce automatic-bottom as well as certain collapsible-tray styles. Paper or paperboard bridges can be attached to main panels during straight-line gluing. For simple styles, the feeding of carton blanks into the gluer does not need to be timed into specific folding actions. Complicated folding devices may dictate that blank feeding be timed, which generally reduces speeds. Compound folds in both directions on the blank cannot be handled by straight-line machines.

For more complicated carton and collapsible-tray styles, right-angle gluers are employed. As the name implies, midway through the machine the travel direction of the blank is changed by 90°. All parallel folds can be made in the direction of blank travel, resulting in simplified machine setup and more positive and accurate folding. Generally, speed is limited by the transfer section, which changes blank travel direction. Right-angle gluers combine flexibility and precision in the manufacture of complex folding cartons.

Setup and nested tapered trays are also produced in folding-carton manufacturing plants for shipment to customers. These trays are produced on plunger-type gluing equipment that is designed to accept either blank or roll feeds. Blank-fed machines first apply adhesive, then form the tray as a moving plunger forces the previously printed and creased blank through a stationary folding and forming device. Roll-fed machines incorporate printing as well as cutting and creasing units in-line prior to gluing. Nested trays are not as space efficient as unglued blanks; they do, however, have application in uses for which it would be uneconomical or impractical to operate a forming device at the location of use. Paperboard french-fry scoops and sandwich containers used by fast-food outlets are good examples of these trays.

DISTRIBUTION OF THE PRODUCT

The consumer eventually takes possession of the cartoned product. This can take place in a number of ways. For self-service retailing, the appearance of the package is important. Damaged or faded cartons probably would not be purchased. For a pharmaceutical product, the package must have a hygienic image. For supermarket transit, the package must be conveniently handleable, easy to open, and recyclable. A new consideration is to assure the consumer that the product is genuine and not counterfeit. Several techniques are available: for example, printing an identification on the carton using transparent varnish that is visible under UV light; incorporating a clear mark that is similar to a watermark; fingerprinting using near-IR technology; and the use of RFID labels on pallet loads and transit packs (6).

CARTONS, GABLETOP

R. E. Lisiecki
Ex-Cell-O Corporation
Updated by Staff

INTRODUCTION

The gabletop folding format is one of the oldest and most basic end closures possible for a paperboard package. The first patent dates back to 1915 and was issued to J. Van Wormer for what he called a “paper bottle and later Pure-Pak (1). However, 20 years passed before the first commercial installation began to operate at a Borden Company plant, after the patent was acquired by Ex-Cell-O Corp. In 1997 Elopak bought Ex-Cell-O Packaging and the Pure-Pak license (2). Today a number of manufacturers supply machinery to make gabletop cartons for milk and other still liquids.

Early gabletop milk packages were precision-cut folding boxes with an adhesively sealed side-seam and bottom closure and a stapled top closure (see Figure 1). Semi-formed cartons were dipped in hot paraffin for sanitization and moisture proofing prior to filling. Tops were stapled. The first packages had no convenient opening device. Subsequent designs had convenience openings based on secondary patch seals adhesively secured to either the inside or outside of a side panel. The secondary patch was eventually eliminated in favor of an integral pouring spout.

The modern gabletop carton retains a simple basic geometry but includes design refinements acquired over 50 years of development and commercial use. The transition from the wax-coated carton to precoated paperboard came in 1961, necessitating several new developments in package and materials technology (see Extrusion Coating; Paperboard). The use of precoated board eliminated paraffin, wire, and adhesives from a filling plant’s inventory. Also eliminated were the associated mechanical systems, including carton-coating chiller units, wax melters, adhesive applicators, and related instrumentation. Precoated blanks simplified the form/fill/seal process and permitted the design of faster, more-efficient equipment with filling rates up to 300 cartons per minute. To retain the essential pouring-spout feature, an antisealant or *abhesive* was

Figure 1. Early gabletop container. It is paraffin-coated with a patch-type opening device.

developed. This allowed the carton top seal to be tightly sealed, yet easily opened (see Figure 2). Gable top cartons are also available with screw caps. These caps have external tamper-evident security plastic rings, which have to be broken in order to access the contents.

Figure 2. Current gabletop container. It is polyethylene-coated with a pitcher-spout opening device.

FABRICATION

A typical blank for a quart (946.25 mL) gabletop container is shown in Figure 3. With a panel width of 2.764 in. (7.02 cm) and a body height of 7.375 in. (18.73 cm), the apparent contained volume of 56.34 in.^{3} (923.25 cm^3) falls short of the quart volume of 57.75 in.^{3} (946.35 cm^3). The needed extra volume is found in the bulge of the side panels after filling, which leaves the filled product line below the top horizontal score, providing "headspace" necessary to compensate for foam generated during filling and to allow for a certain amount of splash as the filled container is conveyed through the top heat-sealing machine function.

The standard square cross section of the quart (946.25 mL) carton is used for a full range of containers from 6 fl. oz (177.4 mL) through the Imperial quart (1182.8 mL). Other cross sections in the same carton format have panel widths of 2.240 in. (5.69 cm), 3.3764 in. (8.576 cm), and 5.531 in. (14.05 cm), with container volumes from 4 fl. oz (118.3 mL) through one gallon (3.785 L). For quart-series containers, the typical paperboard structure consists of 195–210 lb (88.5–95.3 kg) per ream paperboard with a coating of 0.0005 in. (12.7 μm) of polyethylene on the outside surface and 0.001 in. (25.4 μm) of polyethylene on the inside surface. Other structures that include aluminum foil, ionomer (see Ionomers), and other barrier materials are also used (Figure 4).

A modification of the existing design is the Sahara bottom, which reduces water absorption by the raw edge. It is a feature that can be applied on the forming and filling machine. It has the effect of raising an uncoated paperboard edge in the sealed bottom away from contact with a wet surface. It is claimed that this reduces uptake of water by the raw edge of paperboard by 80% and prevents the bottom of the carton from becoming saturated with water (3).

Coated-paper containers for liquids provide relatively short shelf life. It is possible, however, to tailor the

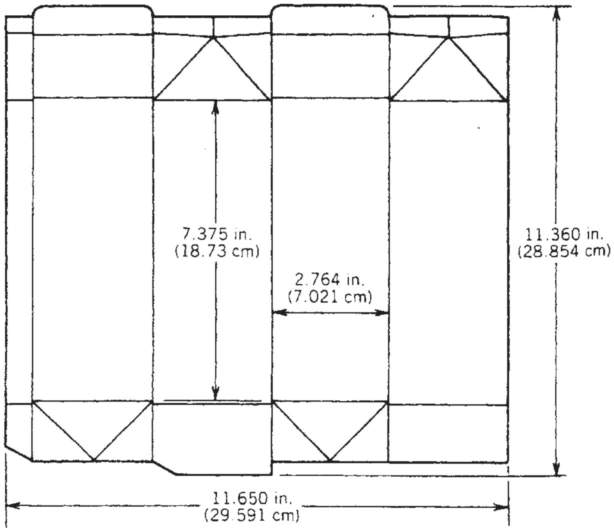

Figure 3. Typical profile for the quart (946-mL) series.

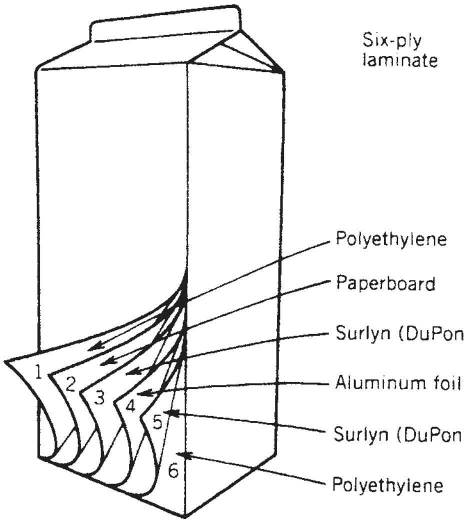

Figure 4. A typical six-ply laminate.

container to its contained product. Liquids with high solids content, such as milk or fountain syrups, are relatively easy to contain, since there is little product penetration of cut edges or random flaws in the coating. Other products require (a) near-hermetic seals, dictating a continuous high barrier such as aluminum foil, and (b) the elimination of cut edges in the finished containers.

This can be accomplished by a number of mechanical techniques including (a) skiving and hemming of the cut edge of the side seam and (b) refining the folding of the bottom closure to protect the cut edge from liquid contact. These techniques permit the successful packaging of oils and alcohol-bearing liquids with little problem. Special treatment of the paperboard may also be necessary to ensure package stability. A form/fill/seal machine erects cartons from flat blanks; and after filling, it seals the bottom. This machine is capable of handling 24,000 cartons per hour, similar to that of a modern canning line (2). Today's form/fill/seal equipment contributes to shelf life by enclosing the processing line. Some machines feature air filtration and carton sanitization systems.

APPLICATIONS

At its peak, the gabletop carton was the premier package for milk and other fluid products in the United States. Process refinements permitted its use for other likely products, such as fruit juice and fountain syrups, and a few unlikely products, such as candy and epsom salts. Newer applications include the packaging of cooking oil, liquid egg products, and dry food. Tetra Rex, 750 g in 2-L cartons, has been used to launch a high-fruit-content muesli. Freeze-dried vegetables are packed in large Pure-Pak cartons for the catering and institutional markets (3). In the United States, the plastic blow-molded bottle (see Blow Molding) has become the container of choice for gallons (128 fl oz or 3.785 L) of milk, but the paperboard gabletop carton is still favored for smaller sizes.

CASE LOADING

Walter Warren
Salwasser Manufacturing
Company, Inc.,
Decatur, Georgia

The corrugated case is still the most universally accepted method of packaging and shipping products from one destination to another (see the Boxes, corrugated article). It offers excellent product protection in both storage and shipping with the additional benefit of full-panel graphic identification or advertisement exposure. The terms *case packing*, *case loading*, and *casing* all refer to the method of placing product into corrugated shipping containers. This can be accomplished by the fundamental method of hand loading or by semiautomatic or automatic case-loading machinery. This article is structured to demonstrate a normal sequence of conversions from hand loading to fully automatic loading. Cases, whether manually or automatically loaded, are classified as top load, side load or end load. The top-load case has flaps in the largest panel and is the most expensive because of the large flap area. An end-load case, with flaps on the smallest panel, is the least expensive. Proper machinery selection depends on many variables such as the type of package, style of case, production rates, automatic versus semiautomatic machinery, floor space, and rate of investment return. The following basic case-loading methods are discussed below: hand loading, horizontal semiautomatic case loading, horizontal fully automatic case loading, vertical drop-load and gripper-style case loading, wrap-around case loading, and tray former/loader.

HAND LOADING

This is the simplest version of case loading. It requires limited machinery involvement, but it is highly labor intensive. As packages are delivered to the packing area, personnel manually open, load, and seal the corrugated cases using a variety of closing methods including cold glue, hot-melt glue (see the Adhesives article), tape (see the Tape, pressure sensitive article), or metal staples (see the Staples article). Cold and hot-melt adhesive applicators are most common (see the Adhesive applicators article). Replacing the case-closing operation with an automatic top-and-bottom case-sealing machine is the first step in automation. This unit can always be used later as the packaging line converts to fully automatic. To decrease labor and increase production, the manual loading operation is replaced with a semiautomatic case-loading machine integrated with the existing top-and-bottom case sealer.

HORIZONTAL SEMIAUTOMATIC CASE LOADER

With this type of equipment, the product is loaded from the side (see Figure 1). This method offers considerable flexibility in obtaining the desired case pattern, which is defined as the position or orientation of cartons grouped inside the case. It is ideally suited for handling cartons, cannisters, cans, or any product that takes a rigid or semirigid shape. The most common product handled is consumer-type cartons, which are loaded in a variety of configurations and counts. The semiautomatic case loader requires an operator to open manually a flat premade corrugated case, fold the bottom flaps, and place it on the machine-loading tube or funnel ready for package insertion. All other machine functions are performed automatically. All other machine functions are performed automatically. Typically, an operator can open approximately 10–12 cases/min. Higher case rates would require fully automatic case-loading machinery, which is described below. Package speeds in excess of 500/min are obtainable, but the number of cartons per case and the dexterity of the operator dictate if it can be done semiautomatically.

The basic unit includes an infeed conveyor to receive packages and deliver to the machine accumulator section, where the product is grouped or stacked to the prescribed case pattern and loaded into the already opened and formed corrugated case. Single tier and multitier case patterns are easily accommodated. Multitier applications require the cartons to be stacked prior to loading. Functionally, the infeed conveyor delivers cartons to a lifter plate, where the prescribed number is accumulated. Through a pneumatically operated cylinder, the cartons are lifted and deposited on stacker bars. The lifter returns and continues this cycle until the correct number of cartons have been grouped in front of the loading tube. A pneumatically operated side-ram cylinder pushes the final load into the case. Because of the slower case rates of semiautomatic machines, air cylinders are normally used for the product lifting and side-ram load motions. Mechanical cam/crank and/or servo drives usually perform these same motions on automatic high-speed machines. Many machine configurations and accessories are available including multilane units for higher package production rates. Standard upstream filling and packing machinery usually discharge product in a single lane; the use of multilane casers would require some type of package lane dividing systems. Many packages must be repositioned to coincide with the case pattern; this is accomplished through rail twisters, upenders, turn-pegs, and so on. Converging equipment is also available if the output from several upstream packaging machines must be converged into the caser single-lane infeed. After final loading, the filled case is lowered onto a short discharge conveyor ready for final case sealing. The existing top-and-bottom case sealer can be used or any other type of sealer. This approach to case loading is ideal for lowercase rate applications. It requires minimal capital investment, but it is a major step in automation. At this point, the horizontal semiautomatic case loader has eliminated the hand-load operation and reduced the personnel to one operator. The next sequence in automation replaces the operator with an automatic corrugated-case erector, forming a fully automatic case-loading system.

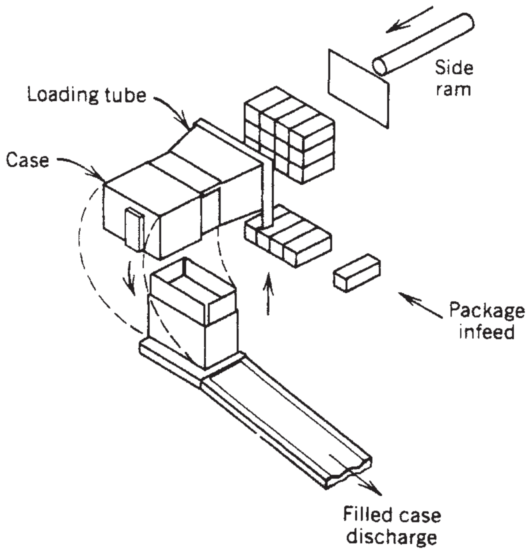

Figure 1. Horizontal semiautomatic case loader.

STEPS TOWARD FULLY AUTOMATIC CASE LOADING

There are normally two approaches to automatic case loading a fully automatic integrated system including a case erector, loader, and sealer or a case erector loader that uses an existing case sealer. Most case-loading machinery is manufactured in modular design to allow the proper equipment selection for the application. Consideration should always be given to how existing equipment can be used in conjunction with new equipment. A decision to automate, and how to do it, is based on many considerations: case rates in excess of 10–12 min, high package-production rates, packages more easily loaded automatically, large-size cases more easily handled automatically, labor reduction, floor space reduction, and increased line production and efficiency.

Case Erector/Loader. This machine is equipped with a flat-corrugated storage magazine that will, on demand, extract a case from the magazine, open it, fold in bottom

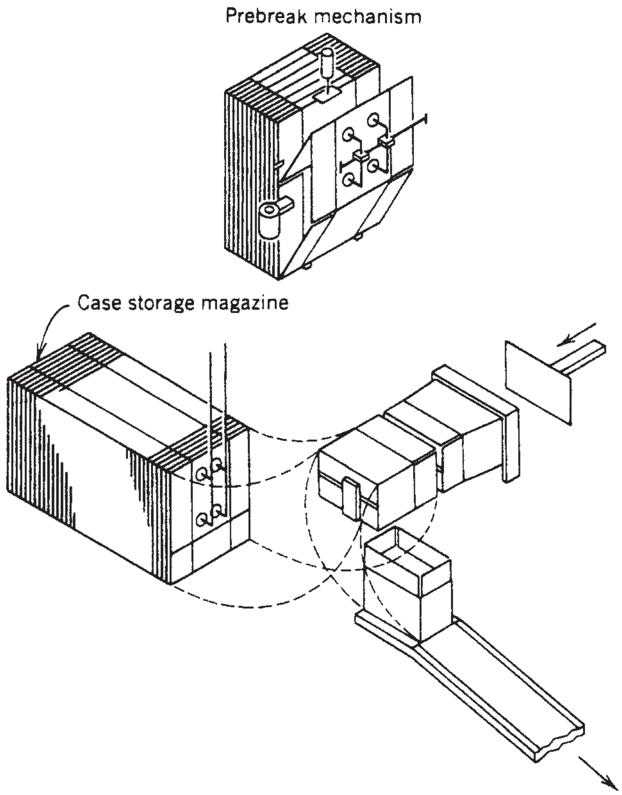

Figure 2. Case erector loader.

flaps, and automatically place it on the caser loading tube for final package insertion (see Figure 2). After loading, the filled case is lowered onto a discharge conveyor and transferred into a new or existing case-sealing machine. Case extraction and opening are the most critical functions of an automatic erector. Corrugated cases have a built-in memory (resistance), and proper blank scoring will increase opening efficiency. Although more expensive, experience has proven that equipment offering mechanisms to prebreak or restrict the case back panel during opening are well worth the investment. Generally, vacuum/pneumatic mechanisms seem to function well up to approximately 20 cases/min. Higher case rates normally require a mechanical/vacuum/pneumatic combination with several stations for case extracting, opening, and loading. Both horizontal and vertical case magazines are available. The automatic case erector can be added to an existing semiautomatic case loader with its separate sealer, or it can be offered as part of a new integrated system interfaced with the existing case sealer. The case erector eliminates the operator who would otherwise open cases manually; therefore, the erector flat-case storage magazine must have sufficient capacity for at least a 30–60 min supply. If floor space permits, additional magazine capacity is encouraged. Vertical-style magazines are offered with bulk-storage feed systems where several stacks of cases are loaded on a floor-level conveyor and on demand, feed automatically to the magazine (see Figure 3). A variety of case erectors is offered for various case rates of ≤ 30 cases/min.

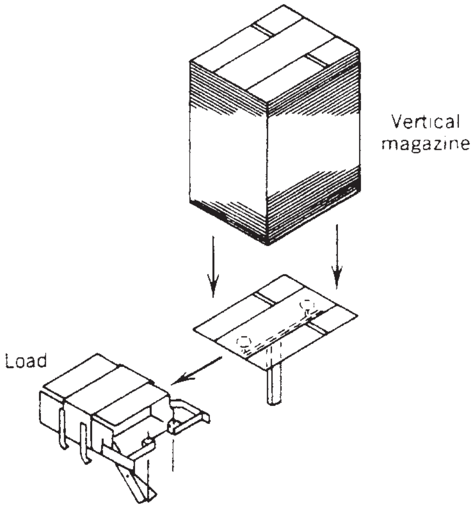

Figure 3. Vertical magazine.

HORIZONTAL AUTOMATIC CASER ERECTOR/LOADER/SEALER

The final approach in automation incorporates a completely integrated system. A new automatic case extractor/sealer can be integrated with an existing semiautomatic caser to form a fully automatic line, but the case erector/loader/sealer is normally purchased new as a part of the complete packaging line. Case extracting/loading functions are the same as those discussed above, but after loading, the filled case is transferred horizontally through the glue-application section and into the compression unit using heavy-duty continuous-motion cleated chains. Minor case flaps are folded closed and major flaps are opened ready for adhesive application. After gluing, stationary plow rods fold in major flaps as the case is deposited into the intermittently driven side-sealing compression unit (see Figure 4). A secondary set of top chains may be employed to ensure that the case is presented squarely to the compression unit. Vertical compression units for use in overhead filled-case conveying systems reduce initial floor-space requirements. The compression-section length is a function of the type of adhesive used and its corresponding drying time. Both hot-melt and cold-glue adhesives are commonly used (see Adhesives). Hot-melt adhesive has a faster setup time and requires a relatively short compression section, usually 4–5 ft (1.2–1.5 m). Cold-glue adhesive takes longer to set and requires more compression-section length. The hot-melt adhesive unit takes less space, but it is somewhat more expensive than the cold-glue system. Polyvinyl chloride (PVC) sealing tapes are becoming an attractive sealing method for various reasons, and most automatic machines can be equipped with tape heads in place of glue heads (see the Tape, pressure-sensitive article). Compression-section length can usually be reduced, because no drying time is required. As with all automatic machines, the flat-corrugated case magazine storage capacity should be large enough to ensure that an operator is not constantly

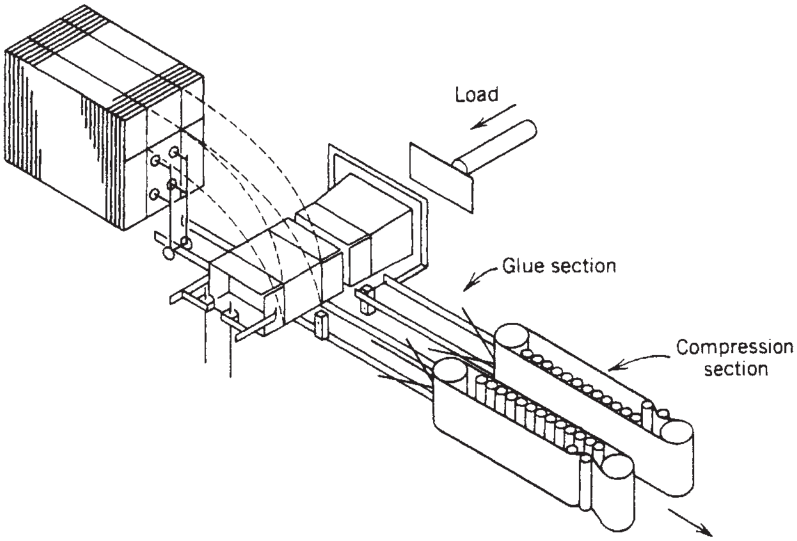

Figure 4. Horizontal fully automatic case loader.

replenishing the supply hopper. A complete automatic system offers many advantages including higher case rates, increased line efficiencies, labor reduction, and the operational technology of programmable logic controllers (PLC). The machine functions are now computerized and programmed accordingly. This information can be coordinated into the main control center, providing valuable information to the production department. This new electronic technology offers many specialized options, such as operator interface panels, data highway information systems, and troubleshooting diagnostic displays. In summary, the horizontal fully automatic case opener, loader, and sealer can receive product from upstream packaging equipment and delivering that product to the shipping department in a sealed corrugated case. This is all accomplished in a relatively small area at speeds of ≤ 30 cases/min. Continuous-motion machines are available for case rates in excess of 50/min but require considerably more floor space.

VERTICAL CASE LOADERS

This method of case loading is used primarily in the beverage, glass, can, and plastic container industries, where fragile or irregular-shaped containers require some special packing considerations. As with the horizontal case packers, the product is delivered to the machine infeed conveyor from upstream filling equipment to the accumulator section. Tabletop chain is commonly used in delivering the product to reduce backpressure during the load cycle and for infeed washdown applications. Cylindrical-type products are divided automatically into several lanes using oscillating or vibrating dividers to form the accumulated load pattern. Irregular-shaped containers such as blow-molded plastic bottles must be divided by special equipment. When all lanes are filled in the accumulator area, a formed corrugated case is positioned underneath the loading mechanism ready for depositing. At that point, retractable shifter plates in the accumulator area move out, which allows the containers to drop vertically through fingers into the cells of the case (see Figure 5). Special fingers guide and reduce side shock to the containers during the load cycle. The use of cells or corrugated partitions inside the case to eliminate container contact is based on product-protection requirements. Usually glass containers have partitions, and plastic containers do not. Case rates of up to 25/min are achieved for intermittent motion machines, whereas newly developed continuous motion equipment approaches 40–50/min. The vertical case loader can be interfaced with many different kinds of corrugated-case erecting equipment. Manual case set up and placement under the load area tied into a case sealer is one alternative. Another technique used by the glass and plastic bottle industries, is

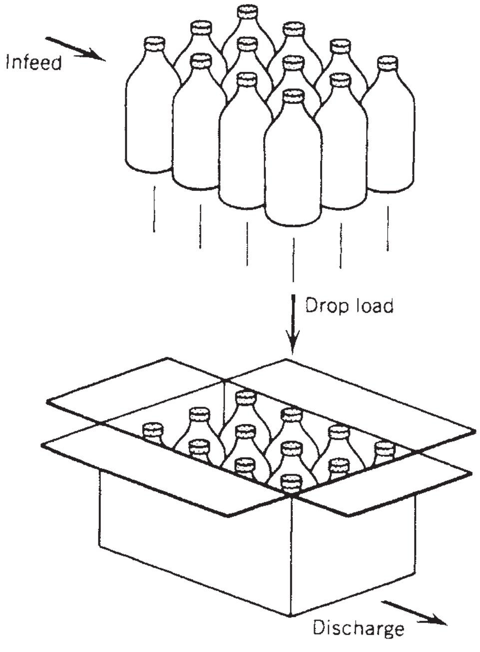

Figure 5. Vertical drop-load case packer.

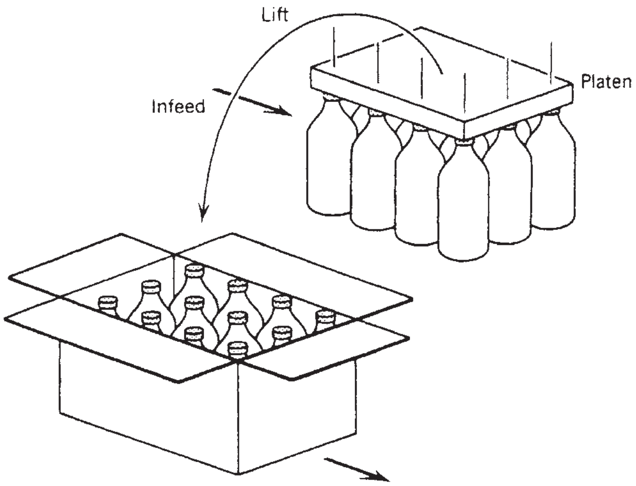

Figure 6. Vertical gripper-style case packer.

to ship empty bottles in cases to the filling plant where they are emptied, filled, and loaded back into the reshipper cases using a top-case sealer. A third method is to incorporate an automatic case erector, vertical loader, and sealer. The machinery selection is based on floor space, capital investment, type product to be handled, and most important, the case-rate requirement.

Another vertical-load method for handling fragile or heavy containers and flexible pouches is one that utilizes vacuum or mechanical grippers to lower the containers into the case (see Figure 6). This approach is ideal for containers that can be gripped at the top, such as glass or plastic bottles. The containers are delivered and accumulated in the same manner as with the vertical drop loader, but a special plate or load head incorporating vacuum or mechanical grippers moves down and picks up approximately 12 containers at a time and places them in the opened corrugated case. Generally, both the drop-load and vacuum or mechanical gripper-style machines are offered in multiload station modules to obtain speeds of 40–50 cases/min with automatic case erectors. Although slower, flexible pouches, cartons, and irregular shaped containers are currently being loaded in the same manner using robotic multiaxis motions with a variety of vacuum and mechanical grippers. Robotic case loading is emerging as a viable alternative to conventional vertical loading because of its product handling versatility, less floor space, and quick changeover.

Equipment is also available that loads cartons, cans, tapered cannisters, and so on vertically up through the bottom of a case. This method is usually limited to top-load cases, but it does offer the advantage of eliminating possible package repositioning. A case is extracted and opened in the conventional method over the accumulated product. On demand, the product is lifted up into the case, which is then transferred horizontally into the sealing section. For the most part, both horizontal and vertical case-loading equipment are of the intermittent-motion design, which is somewhat speed limited. Requirements for higher speed have led to the development of faster filling machinery and continuous-motion casing equipment that runs in excess of 2400 cases/min and 1200 boxes/min. This special machinery is an integrated system handling multiple cases. Continuous-motion horizontal case-loading equipment using both premade RSC and wraparound blank cases (see the Boxes, corrugated article) have exceeded the 50/min range. These rates apply to some special tray forming/loading applications as well. Because upstream filling equipment for cartons and flexible packages has not achieved the high rates of the can and bottling fillers, the requirement for continuous-motion carton-type casers has been limited.

AUTOMATIC WRAPAROUND CASE LOADING

An entirely different approach to case loading uses a five-panel corrugated blank instead of a flat premade corrugated case with the manufacturer's joint already glued. Vertical or horizontal corrugated blank-storage magazines are employed that extract the blank and position it between chain lugs by either vacuum or mechanical mechanisms. During this motion, both side panels are folded into a vertical position forming half the case. The blank is then positioned in front of the loading machine where the product is either pushed onto the blank or dropped vertically (see Figure 7). After loading, the top panel is folded down over the product and final flap folding and gluing is completed. Depending on the type equipment, the manufacturer's joint is then glued and folded down to one of the vertical panels for final sealing. Wraparound casers are usually larger and more complex than loaders for premade cases owing to the additional functions that must be performed, but depending on the size of the case, there may be some economical board-cost advantages using a five-panel blank. Pneumatically operated machines can achieve speeds up to 20 cases/min; higher rates of approximately 30 cases/min would require a more mechanical/pneumatic design. Continuous-motion wraparounds are available for special applications with speed requirements in the 40–50/min range. Both horizontal and vertical blank storage magazines are available

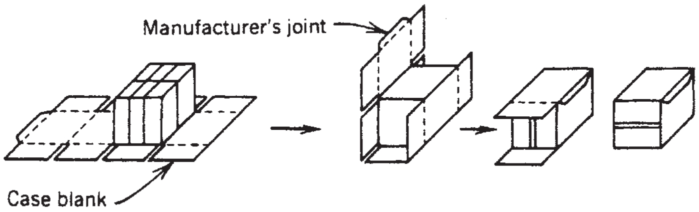

Figure 7. Wraparound case loader.

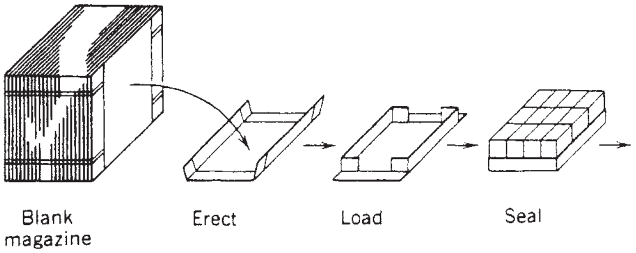

Figure 8. Tray former/loader.

as well as vertical compression sections suited to overhead case-conveyor systems (see the Conveyors article). The selection of a wrap-around versus a premade case machine requires close scrutiny of the particular application requirements including type of case, potential board savings, machine cost, floor space, case rate, size case, and so on.

TRAY FORMER/LOADER

The concept of replacing a corrugated case with a shrink-wrapped tray was developed as part of an ongoing effort to reduce packaging material costs. The tray former/loader (see Figure 8) with a shrink wrap is ideally suited for those products, e.g., cans and bottles, that do not require the complete product protection provided by a full case. Corrugated trays that are 1–2 in. (2.5–5.1 cm) high are preferred, but there are a host of different tray designs suited to the product, distribution, display, and so on. Many machine alternatives are available, including equipment to make a tray and present it to a vertical or drop-load caser. There are also integrated systems that extract a blank from the magazine, fold up two or three sides of the blank, index to the load area (where the product is deposited horizontally or vertically), and transfer, folding remaining panels, and gluing to form the final tray. At this point, the filled and sealed tray is indexed into a shrink-wrapping machine (see the Wrapping, shrink article) where film (see the Films, shrink article) is completely wrapped and shrunk around the complete load. The film unitizes and holds the product in the tray and provides protection from the external environment. The cost for the corrugated tray and shrink film is considerably less than a full corrugated case, but consideration must be given to product protection and warehouse stacking strengths because now the product must bear the full vertical load, warehouse identification, and so on. Tray rates for intermittent-motion machines are approximately 30/min, whereas continuous-motion machines can run in excess of 70/min.

OTHER CONCEPTS

The case-loading field is extremely broad, and many other different types of machines are available for sp ecial markets and applications too numerous to describe in detail. For example, there is automatic case-opening/bottom-gluing machinery that presents an opened case with the bottom flaps glued for the manual loading of large or irregular-shaped items. This same equipment can also present an opened/glued case to a vertical or drop-load caser, increasing the operating speeds of hand-packed lines. Automatic case openers are available that bring a case down vertically over the accumulated product and then fold and seal the flaps or that lift the acculated product vertically up through the bottom of a corrugated case, folding and sealing flaps accordingly. There are case loaders that role the product into the case and manual machines that are used for handling irregular-shaped products in a wrap-around blank. All these variations and concepts are necessary in providing the unique machinery to meet the changing markets and products of today.

CAST, POLYPROPYLENE

Eldridge M. Mount
EMMOUNT Technologies,
Canandaigua, New York

Cast polypropylene film is made primarily by the chill-roll cast film process using multilayer coextrusion systems (Figure 1). Other methods can also be used to produce cast polypropylene film such as slot die extrusion into a water bath or a tubular water quench processes. However, these have been largely superseded by the cast film process due to the higher productivities and superior film flatness possible with the chill roll process. Because cast polypropylene film does not go through the solid-state orientation process (see Film, oriented polypropylene), the barrier properties, low temperature durability, and mechanical strength are not as well developed as in mono- or biaxially oriented polypropylene film. Typical cast polypropylene films are desired for their increased temperature resistance, high clarity, and gloss compared to typical cast or blown polyethylene films. Other desirable properties of the cast polypropylene is the films stiffness, oil and grease resistance, and heat sealing properties when used as a sealant layer in a lamination to paper, cellophane, oriented polyester, or oriented PP. Barrier properties of cast polypropylene may be significantly enhanced by vacuum metalization allowing the film to compete directly with oriented metalized films in laminations.

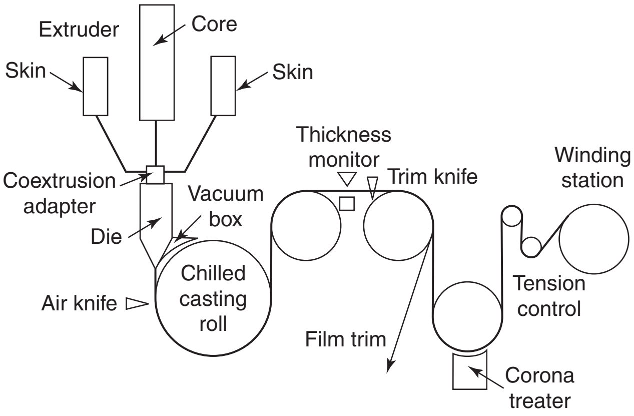

Figure 1. Three-layer cast-film line.

A typical product design of a 1 side corona treated, three layer cast PP film is shown in Figure 2. Depending on the desired film surface properties, the films can have the same or different outer skin polymers to give coextruded films with A/B/A, B/B/A or A/B/C structures. Product designs of this type are alone or for inner sealing webs in laminations, where the treated surface is the lamination surface. Suitability of the films for metalization of the treated surface will depend on the type and level of migratory and particulate additives added to the film.

Typically, the film design of Figure 2 would have 500–3000 ppm of a migratory slip additive, such as erucamide, added to the skins and the core of the film to reduce the film coefficient of friction (COF). The outer skins will also have 2000–6000 ppm of a mineral antiblock particle such as amorphous silica (of 1.5–8-micron average diameter) added to aid in blocking resistance, COF control, film winding, and packaging machine performance. Metalization grade films would be produced without any migratory or particulate additives in the treated (metalization) surface and a reduced level of migratory additives in the core layer.

Five-layer product designs add considerable flexibility to the ability to tailor film properties by both layer polymer selection and film layer additive control. Figure 3 shows a product design for optimizing the effectiveness and cost of expensive film additives such as antiblock particles. In this design, the antiblock particles are confined to the outermost thin surface layers to enhance their effectiveness and decrease the overall additive concentration in the film. This reduces the cost of the film by reducing the consumption of additive concentrates and helps improve film clarity by lowering film haze induced by the particles. The potential number of product designs possible with five or more layers is enormous and greatly aids in the production of products focused for various end uses while enhancing product properties.

Corona treated surface

10%-25% random copolymer PP outer layer
80% to 50% homopolymer PP core
10%-25% random copolymer PP outer layer

Figure 2. Typical three-layer cast PP film product design.

Cast polypropylene films are being used in both packaging and nonpackaging applications. In the packaging area, the majority of applications are food-related. In food packaging, the cast polypropylene film accounts for a major share of the candy twist wrap application, because cast polypropylene film is particularly suitable for newer high-speed twist wrap machines. In cheese-wrapping applications, polypropylene/low-density polyethylene (PP/LDPE) coextruded film is used because of improved moisture barrier and film stiffness supplied by the cast polypropylene layer compared to single-layer LDPE.

Cast polypropylene film lamination using a high-strength outer web for snack-food packaging are widely used in Asian markets and represents a large potential market in North America, particularly in applications and laminations using metalized polypropylene films. In the metalized laminations, the cast polypropylene is metalized and represents the addition of a high-barrier sealant to the lamination. In addition, the use of the metalized cast polypropylene in laminations permits the use of reverse-printed outer webs giving improved graphics and print durability when compared to laminations of surface printed metalized films to LDPE sealants. In laminations that do not require the low-temperature durability and mechanical strength of metalized oriented polypropylene films, cast polypropylene film can offer an improved heat sealing capability readily producing hermetic seals, a distinct advantage in some applications and markets.

Other applications include tapes, labels, diaper components, photograph holder, page protectors, medical

packaging, and textile packaging. The advantages for using cast polypropylene film in textile packaging are faster bag production rates and better contact clarity and gloss for PP compared to LDPE. The use of cast polypropylene film for medical packaging is a potential growth area, due to PP's higher temperature resistance in steam sterilization. Cast polypropylene film laminated with high-temperature-resistant outer web is particularly suitable for retort pouch applications due to the high-temperature resistance for cast polypropylene film in the retort process. This is also an advantage in microwavable cook in bags emerging in the market. Cast multilayer polypropylene films are being used for industrial stretch film applications. In the stretch film application, the use of multilayer coextrusion of PP with PE resins is being used (1, 2) to increase the toughness of the stretch films.

FILM FABRICATION

Cast polypropylene film is commonly made by chill roll casting drum process. Today three- to five-layer cast lines of 6000-mm widths running at speeds of 350 m/min producing rolls of up to 1.2-M diameter are available. Typical extrusion melt temperatures are from 480°F to 520°F. Screw designs are varied but will tend toward longer L/Ds and barrier designs typical of PP extrusion. Today many new cast polypropylene film products are made by the coextrusion process using a multilayer feedblock–single cavity die combination, or a multicavity flat die or a combination of a feedblock and a multicavity die. Film product design complexity is increasing as the use of microlayer films is increasing due to claimed physical and barrier property advantages.

Once melted and formed in the coextrusion system, the polypropylene extrudate emerges out of the flat die and is immediately quenched on the chill roll with an air knife or vacuum box. This melt pinning forces the extrudate into intimate contact with the chill roll (see Figure 1). Increasing the chill-roll temperature and/or increasing chill-roll takeoff speed normally improves film stiffness but decreases optical clarity. After the quenching station, there is an edge trimming station to slit off the thickened edges formed as the melt is drawn from the die. Then, a film-thickness monitoring device, typically with a β-radiation source, is repetitively moved across the film on a rigid

MD	500	600	D882
TD	650	650	
1% secant modulus, psi			
MD	70,000	100,000	D882
TD	70,000	100,000	
Heat-seal temperature range, °F	270–330	330–370	
Water-vapor transmission rate, $g \cdot mil/100\,in.^2 \cdot 24\,h$ 90% rh/100°F	0.8	0.7	Mocon
Oxygen permeability, $C(mL \cdot mil)/(100\,in.^2 \cdot 24\,h/atm$ 23°C, 0% rh	240–300	240–300	Mocon

track to scan the film width and report the transverse-direction (TD) thickness (gauge) profile. Automatic control systems then adjust the die opening to control film thickness to specified thickness tolerances. Film thickness variations of 1–2% are readily achieved.

Between the thickness monitoring station and the film winding station, a corona treatment station is located to enhance film surface energy of the film. This is done to improve the wetability of the film surface for better ink printability, metalization, or lamination adhesion.

Tension control for cast polypropylene film winding is very important due to the relatively low modulus of the film. With very high tension, the film tends to stretch as it is wound in the area of any areas of thicker film. These stretched areas form harder raised bands in the wound roll which are called a “gauge band.” When such a roll with hardened gauge bands is unwound for use, it will not lay flat in the stretched area and will show defects that are called “baggy lanes” in the film. Films with baggy lanes are unsuitable for subsequent slitting, printing, metalization, or lamination. To aid in minimizing gauge bands, winder oscillation in the transverse direction, of up to 10 cm, can be added to randomize the gauge profile. This can, in some cases, avoid the buildup of the gauge band and minimize or eliminate baggy lane formation.

After winding up, the mill rolls normally need post-treatment (aging) to stabilize the film properties. A general aging condition is 40°C for 72 h. This aging is necessary because polypropylene undergoes a secondary crystallization. The secondary crystallization is most pronounced over a period of 7 days but can continue for up to 21 days. The impact of the secondary crystallization can be observed as an increase in film modulus with time (Figure 4) (3).

Film surface coefficient of friction (COF) can, and often must, be modified with antiblock particles and migratory slip additives, such as fatty acid amides, to improve the film-handling characteristics on packaging machines. However, these additives reduce film clarity by increasing film internal (particulate additives) and surface (migratory additives) haze. The balance of film clarity and surface COF must be optimized to insure a balance between appearance and film machineability. Coextrusion technology is used to minimize the level of particulate additives by limiting them to the films outermost surface layers, maximizing the surface effects while minimizing the additive effect on clarity. Film COF will decrease with storage time as the migratory additives diffuse (Bloom) to the film surface (Figure 5) (4) and create a thin layer of additive on the surface which serves as a surface lubricant. The time required to complete the additive migration will depend upon the storage temperature and the migratory additive chosen. Migratory slip technology is difficult to control with any precision and can result in films with too high a COF (low migration) or too low a COF (high migration). Too high a migration can create a weak boundary layer on the film surface and prevent proper ink, metal, or adhesive bonding. Too high a migration will also interfere with film optics giving lower gloss and increased haze.

FILM PROPERTIES

Cast polypropylene films can be a monolayer or multilayer coextruded film to balance barrier, printing, heat seal, COF, and other properties. Typical properties for cast polypropylene film are shown in Table 1. Oriented polypropylene film is superior to cast polypropylene film in barrier properties and mechanical strength. However, cast polypropylene film has excellent tear resistance and is cost effective. Each type of film has benefits and disadvantages, which must be weighed in determining which film is most appropriate ("fit for use") for a particular application.

CELLOPHANE

Updated by Staff

INTRODUCTION

The word *cellophane* was derived from the first syllable of cellulose and the final syllable of diaphane, meaning transparent. It was invented in the early 1900s in France and introduced in this country in 1924 by E. I. du Pont de Nemours & Company, Inc. In the early stages, cellophane was somewhat of a curiosity that was very expensive, and its use was limited to the packaging of luxury items.

The growth of cellophane paralleled the growth and development of the entire flexible-packaging industry, from printing presses and inks to automatic packaging machinery. For 30 or more years, the dominant flexible packaging material was cellophane because it was so well suited to offer the marketplace a wide variety of characteristics adaptable to product needs at reasonable costs. The large markets were in the areas of baked goods, candies, and tobacco products.

The advent of plastic materials such as polyethylene and polypropylene started the corrosion of cellophane consumption that resulted in the closing of many cellophane plants, due mostly to the higher prices of cellophane. However, in a new more environmetnally conscious market, cellophane may return in popularity. Cellophane is 100% biodegradable and made from a renewable source.

Cellophane is a thin, flexible, transparent material used worldwide mainly in packaging applications. The primary raw material used in manufacturing cellophane is “dissolving” wood pulp purchased from wood pulp suppliers. Since its introduction in 1924, additional types of cellophane have been introduced to meet changing packaging needs. The primary markets for cellophanes are the food, pharmaceutical, and healthcare product markets. In the food sector, cellophane is used to package nuts, candies, dried fruits, spices, cake mixes, and greasy or oily products (1).

FEATURES

Cellophane has various attributes that have accounted for its continued acceptance and ongoing utilization in flexible-packaging applications. These include:

- *Dead-Fold.* Once shaped in certain packaging applications, cellophane, unlike plastic films, can maintain its shape. This is especially true in twist-wrap applications such as packaging for hard candies.
- *Ease in Tearing.* Differentiated tensile strength within cellophane allows for ease in tearing and opening products that utilize this material for packaging and for tape.
- *Machinability.* Cellophane can be cut and sealed easily and economically. Many competing flexible-packaging materials require more sophisticated and expensive packaging equipment to process them. A method and device for finishing cellophane packets has recently appeared in the literature (2).
- *Appearance.* Cellophane has a high level of gloss and haze versus certain competing flexible films. These factors are important to customers desiring a premium appearance for their packaging.
- *Resistance to High Temperatures.* Cellophane can be used in temperature ranges above those of many common plastic films, which is critical for hot-fill applications and for use in shrink tunnels.
- *Barrier to Air and Moisture.* Cellophane, when coated with poly(vinylidene chloride) copolymer (PVdC) or other barrier resins, has increased strength, seal, and barrier properties. Uncoated cellophane has good barrier to gases and aroma, but poor barrier to moisture.

FILM TYPES

Cellophane film is produced in various types, which vary with respect to (*1*) film thickness, (*2*) film width, (*3*) type and degree of coating, and (*4*) combination with other materials.

1. *Film Thickness.* Cellophane can be supplied in varying thickness depending on customers desire for strength, flexibility, and resistance to air and moisture.
2. *Film Width.* The films can also be produced in numerous widths, which are custom cut to specific packaging needs.
3. *Type and Degree of Coating.* A large percentage of cellophane products are coated, generally on both sides of the film. These coatings increase the

cellophane's durability and seal qualities. Two of the major coating materials are poly(vinylidene chloride) copolymer (PVdC) and nitrocellulose (NC). PVdC offers more durability and higher moisture and gas barriers than NC. NC-coated films are typically used to package cookies, snacks, cheese, gum, and cough drops.

4. *Combination with Other Materials.* Cellophane film can be laminated to other films such as biaxially oriented polypropylene (BOPP) or metallized polyester film. These products offer enhanced qualities of both cellophane and the particular reinforcement material that is used. The end result is a flexible film that has excellent resistance to breakage and a high-quality appearance. Reinforced cellophane is used primarily to package pretzels, popcorn, chips, nuts, meats and cheeses.

PHYSICAL PROPERTIES

The physical properties of cellophane are closely related for all the film types. They are differentiated according to coatings, reinforcing structures, and thicknesses. All of them are clear with the exception of two of the reinforced structures: metallized polyester and white opaque polypropylene core.

The nitrocellulose-coated films range from 16,000 to 18,000 psi (lb/in.^{2}) tensile strength in machine direction and 8000–9000 psi in transverse direction. Elongation is 15–25% in machine direction and 30–45% in the transverse direction. The heat-sealable coatings have a wide sealing range, usually requiring temperatures of 225–350°F, depending on machine speed and pressure.

Water-vapor transmission rate (WVTR) for the moisture-proof film types averages about 0.5/100 in.^{2} per h, and the breathable types range between 30 and 50. Oxygen permeability averages about 2 mL/(100 in.^{2}) (24 h) (atm) for most two-side-coated nitrocellulose film types.

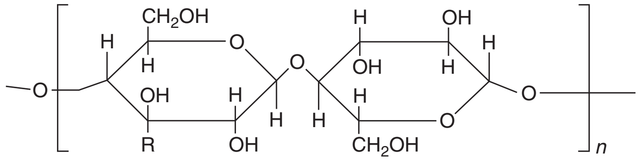
The PVdC- or saran-coated films utilize very similar and in some cases identical cellulose base sheets; but as previously described, the PVdC coating results in improved keeping characteristics.

Machine direction (MD) and transverse direction (TD) tensile strengths and elongations are roughly equivalent to the nitrocellulose-coated films. PVdC-coated films exhibit superior gas barrier properties to nitrocellulose coated films. Where the average oxygen barrier for nitrocellulose is about 2 mL/100 in. per h, the PVdC-coated films are about 0.5. Coefficient of friction is about 0.30–0.35 for both PVdC- and NC-coated films.

The third major type of cellophane film is plain, uncoated film. This film is used most widely in producing pressure-sensitive tapes and also for applications where high-quality printing is desired. This uncoated film prints most easily with almost any flexographic printing ink. The reason for this wide range of ink receptivity is that the surface being uncoated readily absorbs liquids.

CELLOPHANE PRODUCTION

Cellophane is a regenerated cellulose film derived from chemically purified wood pulp known in the trade as "dissolving pulp." Cellulose, the primary repeating molecule of regenerated cellulose film, is shown below:



Cellulose

The cellophane production process involves five major steps: (*1*) soaking of the wood pulp in sodium hydroxide solution for several hours to form alkali cellulose; (*2*) polymerization of the alkali cellulose, under controlled conditions; (*3*) reaction of the alkali cellulose with carbon disulfide to form an alkali-soluble sodium xanthate; (*4*) formation of viscose by dissolving sodium xanthate in a solution of sodium hydroxide; and (*5*) extrusion of the viscose through a slit die into a water/sulfuric acid/sodium sulfate coagulating bath. After the regeneration of the cellulose, the process is completed by neutralizing, washing, and drying the film (3).

ENVIRONMENTAL ASPECTS

Packaging accounts for 30% of all solid waste by weight. The increasing cost of disposing solid waste has forced the adoption of new methods of packaging that promote recycling and degradability. Cellophane is made from cellulose, a component of plants and trees. Trees are farmed and harvested. No rainforest or old growth trees are used in the production of cellophane. Cellophane is 100% biodegradable. When buried, uncoated cellophane degrades in 28–60 days, coated cellophane degrades in 80–120 days. In comparison, the other packaging materials such as poly(vinyl chloride), polyethylene, poly(ethyl terephthalate), and polypropylene show no signs of degradation over long periods of time (1). Nevertheless, the polluting effects of carbon disulfide and other byproducts produced during the production of cellophane should also be considered.

CHANGEOVER OF PACKAGING LINES

John R. Henry

In the part, one popular soft drink was available in a single flavor, bottle and size. Changeovers were unknown. That same product today is available in over 100 variations. The company went from no changeovers to multiple daily changeovers. Most companies are in the same boat. They face more frequent and more changeovers as product variations proliferate. This trend is expected to increase into the future. Changeover is a key issue in the operation of almost every packaging line today.

This article will define and describe changeover and changeover time. It will also provide a roadmap and techniques to improve the quality of changeover while reducing the time lost to it.

Caution: While it is important to reduce changeover times, this must never be done by taking shortcuts that can jeopardize the safety of people, plant, or product.

CHANGEOVER

The words changeover and setup are often used interchangeably. This is a mistake because setup is only one component part of changeover. Changeover is defined as follows:

Changeover is the total process of converting a machine or line from running one product to another.

Note: Changeover can and often does take place on a single machine. In most instances it involves several machines that operate together to form a packaging or production line. The term “line” is used in this article for simplicity.

The key word in this definition of changeover is “total.” Changeover must include every task necessary for the conversion. Some of the tasks that may not be readily apparent are material handling to ensure that excess components, materials, and scrap are removed and disposed of. Documentation and line clearance are part of changeover as well. All of these tasks must be done correctly at the correct time.

It cannot be overemphasized that the changeover process includes everything.

As with many large concepts, it can help to subdivide changeover. One way to consider changeover is to break it down into the “three ups”: clean-up, setup, and start-up.

CLEAN-UP

Clean-up is the process of removing all product, material, components, and contaminants from the line. In some cases, this is very simple. A line filling hardware components into bags may require no cleaning at all other than removal of the previous nuts and bolts. In other cases, clean-up may be complex and time-consuming. The machinery in a sterile pharmaceutical filling line may need to be completely disassembled, washed, autoclaved, and tested for residual contamination in the laboratory. Meanwhile, the entire filling room will be washed from floor to ceiling, sterilized, inspected, and tested. Copious amounts of documentation are usually involved and must be considered part of changeover.

These examples represent extremes of clean-up. Most instances will fall in between.

SET-UP

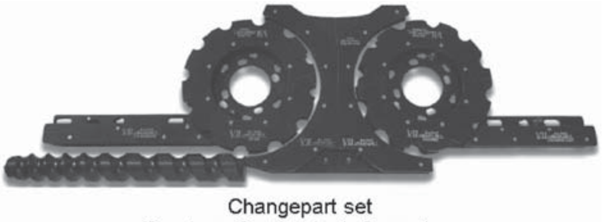
Setup is the process of changing the line to accommodate the next product. It is mostly, but not only, the resetting of the machinery to the next product. This may be done via adjustment of machine components. An example is raising or lowering the turret on a capper to accommodate a different bottle size.

Different products may also be accommodated by the use of “changeparts” (Figure 1; also see Changeparts). Changeparts are product-specific machine parts. They should normally be designed to mount in a single, specific, fixed position with no adjustment in order to minimize variability in the setup. No tools should be required for mounting or dismounting.

Virtually all machines will have some settings made by changeparts and other settings made by adjustment. There is some disagreement about the relative preferability of changeparts versus adjustment. Some feel that emphasis should be on package-specific changeparts with no adjustment, whereas others feel that all machine components should be adjustable. There is some merit to both sides. Eliminating the need to make adjustments not only saves time, it eliminates the possibility that the adjustment will be made imprecisely or improperly. On the other hand, changeparts can be expensive, especially if there are many package sizes. The nonadjustability of changeparts can be a liability as well as a benefit. If components are at the high or low range of their specification, it is impossible to adjust the changeparts to accommodate them.

Setup may also include a number of tasks not directly related to machinery:

- Bring all the materials, including product, for the next run to the line.



Changepart set
Courtesy Septimatech Group Inc.

Figure 1. Typical changepart set.

- Charge machines with product, components, and materials.
- Test the setup for correct fill volumes, label placement, and cap torque.
- Document the setup.
- Inspect the line and approve for production.

Once the final approval to run is obtained, the line must be brought up to speed. This is usually relatively brief and involves filling the line with production. In some cases, this must be done at a slow speed. Some bottles may have a tendency to fall down without other bottles nearby to support them. Some machine infeeds, timing screws, or starwheels may require manual assistance to get the initial products into them. Once the line has been fully charged and initially brought up to speed, setup is concluded.

START-UP

Start-up is sometimes called "run-up" or "ramp-up." It is the period of time between the end of setup and when the line begins operating at normal speed and efficiency. Start-up is characterized by frequent product jams, fine-tuning of machine adjustments, damaged product, and false rejection of good product, as well as nonrejection of bad product, line stoppages, and other abnormal conditions. In some plants, start-up time is negligible. In others, it takes longer than the rest of changeover combined. A few plants run entire production lots without ever getting out of start-up mode.

The cause of start-up can be described with one word: variability.

Variability comes in two forms. The most obvious in many cases is variability of the setup and occasionally clean-up. A too-frequent tendency in changeover is to perform an approximate setup and then fine-tune by trial and error once the line is running. One cause of this practice is the absence of the knowledge or tools to perform a precise setup. Each mechanic will have a different technique of setting up a machine. They will have different opinions about how tight a carton should be held in the cartoner lugs. They will guess at machine speeds (if tachometers are not provided) differently. Another cause is inadequate training and supervision. It must be noted that meaningful training is impossible if the proper setup specifications and tools are not available in the first place.

Variability can come from the product. The same liquid products may vary in characteristics such as density or foaminess from lot to lot. This may be impossible to predict in advance. If so, it means that the filler can never be completely set until actual product can be filled.

Packaging components and materials can vary. If hot melt glue comes from two different suppliers, or even two different plants of the same supplier, it may run differently depending on the source. This can prevent the glue system from being finally set until it is in production.

Paper products such as labels, cartons, and cases may vary in physical dimensions or they may vary in stiffness, depending on humidity levels during manufacture, transport, and storage. Again, this variability prevents a proper setup from being performed.

There is little that can be done on the packaging floor to avoid these problems. If the set-up is not under good control, it is often difficult to determine whether the startup is caused by variability of setup or variability of materials. If the changeover process, particularly setup, is brought under control, it becomes easier to focus on the material variability issues. If the amount of time lost due to material issues can be documented, it may be possible to justify obtaining better-quality materials with less variation.

The traditional definition of quality is usually expressed along the lines of "meets specifications" or "within tolerance." John S. McConnell does not think that is enough. In his book Safer than a Known Way (1) he defines quality as "absence of variation." It is consistency, not simply conformance to the range of a specification, which is required for success. This is as true of changeover as it is of any other process.

Start-up ends when the line is running at normal speed and efficiency.

Clean-up and setup can be simplified and shortened but can seldom be completely eliminated. Start-up exists because of variation; and, if variation can be eliminated, start-up will be eliminated as well. Total elimination will almost never be achieved in the real world. That does not make it any less worthy a goal to continuously strive for.

CHANGEOVER TIME

Changeover time is the key metric usually associated with changeover. It is defined as follows:

Changeover time is the total elapsed time between the last unit of good production of the previous product run, at full line efficiency, and the first unit of good production, at full line efficiency, of the succeeding product run.

Changeover time may be more compactly defined as "elapsed time between good products", provided that it is understood by all that this incorporates the normal speed and efficiency criteria of the full definition.

In some cases, a line must be slowed down before production actually stops. A liquid filler may, as the reservoir runs down, need more time to complete a fill cycle. This time of slower-than-normal production is called purgeout. It is when the line slows down or stops running at "full speed and efficiency" that the changeover clock must start. Likewise, the clock on changeover time cannot be stopped until the start-up is over. Marking the beginning of changeover time is generally fairly easy and obvious. Marking the end can be trickier.

One way is with a SCADA or other automated system that can display a graph of line performance. When the graph flattens, indicating a normal steady state, start-up is over.

Electronic counting displays that calculate and average line speeds over periods of time (5–15 minutes) can also provide good visual indication of when start-up has ended. When the extended average speed achieves target, start-up and changeover is complete.

Another technique is to end the start-up period when the line has run for 15 continuous minutes without stoppage or reject.

Still another technique does not measure start-up time directly but does give an indirect measure of how well the changeover has been done. This technique calculates how much product would normally be produced in 15 minutes (or some other period). Once the line has been fully charged and enters the start-up phase, the length of time it takes to produce that quantity of product is measured. As an example, a line may run at three cases per minute as measured at the discharge of the case packer. In 15 minutes of normal operation, the line should produce 45 cases.

If 45 cases are produced in the first 15 minutes, changeover has been done perfectly. If it takes 30 minutes to produce the first 45 cases, this indicates that time was lost due to start-up.

Graphing the time to the first 45 cases will provide a relative indication of how well changeovers are being performed.

This may not be as good a technique as direct measurement. However, it is simple and provides a good illustration of trends in start-up times.

The key is that start-up must be measured. If changeover time is defined only by clean-up and setup, because they are easy to measure, there will be a tendency to perform these more quickly and imprecisely at the expense of extending start-up and overall changeover time.

It is the elapsed time that is important to the changeover time metric, not the total labor hours used. Labor time is relatively inexpensive, measured in tens of dollars per hour. Line downtime is very expensive and measured in hundreds, thousands, or even tens of thousands of dollars per hour. The goal of changeover must be to get the line up and running again in the shortest possible amount of time.

CHANGEOVER COST

Downtime from changeover is expensive. Many plants do not even know how expensive because they have never calculated the cost. Some plants that have calculated it count the cost in hundreds of dollars per hour. Most plants that have calculated it find it to be thousands of dollars per hour. These calculations need to be done, and they need to be done by the finance department. It needs to be calculated because management needs to know its costs. It needs to be calculated to enable cost-benefit analysis for improvement. It needs to be calculated by the finance department, rather than the engineering or packaging department, because only calculations by finance are “official” and readily accepted throughout the company.

Changeover costs can be divided into two broad categories, tangible and intangible:

Tangible costs are those for which it is relatively easy to calculate a monetary value. They include lost production output, lost capacity, direct labor, and lot size and inventory effects. Not all will apply in all plants, and different factors will differ in importance from plant to plant. The plant that is operating at 100% capacity will value lost output differently from the plant operating at 75% capacity. For one, the sale of the unproduced product is lost and gone forever. For the other, the lost production can be made up, perhaps with overtime, and may not represent lost sales.

Intangible costs are those costs that are difficult or impossible to value in monetary terms. Perhaps the most important is responsiveness to customers. If extended changeover times inhibit meeting a customer’s changing demands, there is certainly a cost for that even if it is not easily measured.

If unnecessary time is lost on changeover, this allows less time for maintenance and forces the team to work harder to produce. This causes stress on machines and on people. The time consumed by lengthy changeover also reduces the time available to develop and implement improvement ideas.

In addition to the costs mentioned above, different plants and industries may have other costs not shown.

However measured, changeover time is expensive. Reducing it is critical to any company’s long-term strategic health.

REDUCING CHANGEOVER TIME

The first thing to realize about reducing changeover time is that it requires participation by everyone in the company, not just the packaging team (Figure 2).

The primary effort must come from them, it is true, but if they reduce line changeover from two hours to one and quality still takes two hours to sign off the line clearance, nothing has been gained. Marketing/package design must be involved. Sometimes minor changes in product design can have a major impact on changeover time. If families of bottles are chosen with common footprints, varying height for volumes, changeover times can be reduced significantly.

Human resources may need to review and modify job descriptions. Engineering must provide various services as well as reviewing improvements before they are put into practice. The safety department must make sure that safety is never jeopardized, and so on. There is no department that does not have some role to play.

It should go without saying that top management support is vital. They must provide moral support by making changeover reduction a priority. They must also provide material support as necessary. Without management support, no changeover program can succeed. With it, it cannot fail.

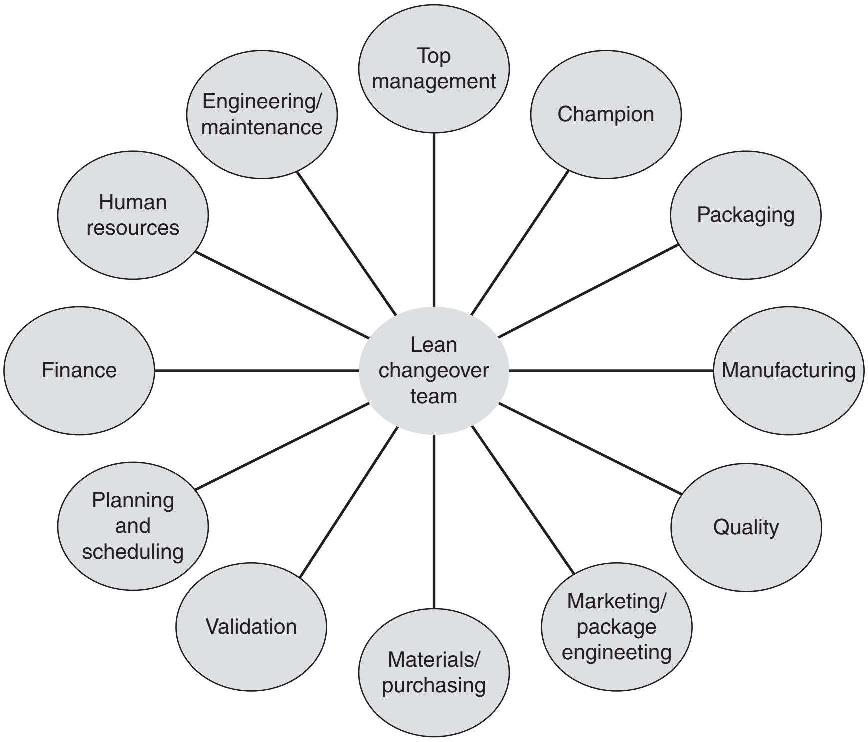


Figure 2. Lean changeover team members.

CHANGEOVER TIME REDUCTION

Changeover reduction can be accomplished using a four-step process expressed by the acronym ESEE (pronounced easy). ESEE stands for eliminate, simplify, externalize, exactly. The acronym establishes the priority order of the four steps, but these are not set in stone. It might be that changeover can be eliminated by package redesign. This may be a good idea but a long-term project. While changing the package, benefits from simplifying, externalizing, or making measurable changeover tasks must not be ignored.

ELIMINATE

It makes no sense to improve something that does not need to be changed at all. The first step in reducing changeover time is to identify those tasks that can be eliminated.

One common task is the application of shipper labels to a corrugated case. In many instances, the label is placed in the center of the case. This satisfies the natural human urge toward symmetry, but it is hardly necessary for identification or, in most cases, for aesthetics. If the label is centered on the case, it means that each time the case size changes, the labeler must be reset.

It may be possible to relocate the label to a common position, relative to the lower leading corner of the case. If this can be done, it eliminates any need to reset the labeler during changeover.

A pouching machine has a cutoff arm controlled by a cam. This arm and cam must be adjusted for three pouch sizes. The original 3/4-in.-wide cam was replaced with a custom-made cam of the same profile but 3 in. wide. The additional width eliminated the need to reposition the cam during changeover. This eliminated the need for a mechanic, allowing the length to be changed, toollessly, by an operator. This freed the mechanic to perform more valuable tasks.

Some larger machines may require ladders for access to some adjustments. Time will be spent looking for the ladders. Worse, instead of using ladders, a chair may be used, creating a safety hazard. Ladders, platforms or step plates incorporated into the machine eliminate the need to fetch ladders.

Electronics can eliminate changeover tasks. Traditionally packaging machines have been built with a single, relatively large motor (Figure 3).

This would power the various machine functions we connected through an often elaborate system of shafts, belts, chains, and gears. Changeover involves physically adjusting timings or changing gear sets for the next size. Some newer packaging machines replace the linkages from the main motor with smaller servo motors at the point of use. These are controlled and operating parameters are changed, via software. Many of the physical adjustments have been eliminated.

Cleaning can be eliminated or greatly reduced by modifying machines to eliminate areas that catch dust and dirt. Instead of mounting a filler on a closed cabinet that must be cleaned internally, it may be mounted on an open frame constructed of tubular stainless steel. If this is not possible, at the very least the cabinet should be thoroughly sealed to minimize or eliminate the need to clean inside.

SIMPLIFY

All changeover tasks that cannot be eliminated must be simplified to the maximum degree possible. Simplification

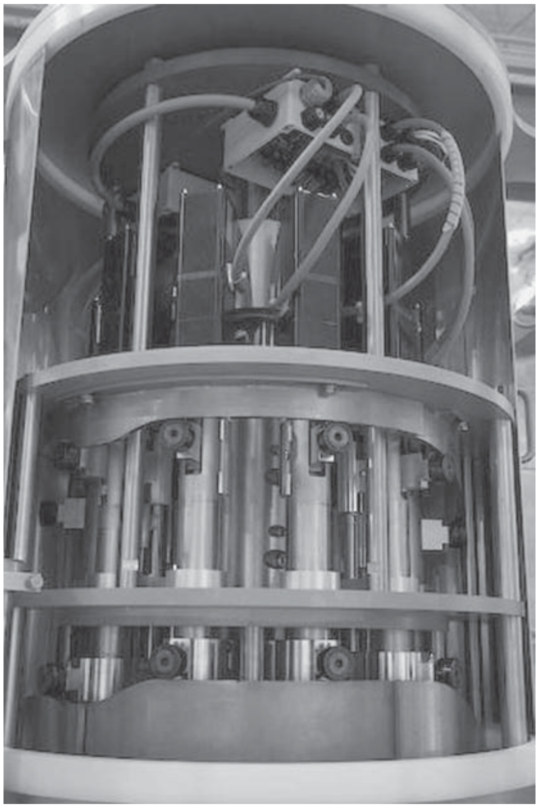

Figure 3. Servo driven capping chuck, with permission from Elau Inc.

is thought of as applying mainly to the setup portion of changeover. That is important, but it applies to clean-up as well as other areas such as documentation and material handling.

Older home cooking ranges have individual burners that can be time-consuming and difficult to clean. Newer ranges have a flat ceramic surface that can be easily wiped clean in a single motion. This concept can be applied to machinery by replacing exposed nuts, with acorn nuts and replacing exposed hex head bolts with round head bolts or, better, flat-head bolts. These provide a smoother surface, easier to clean (Figure 4).

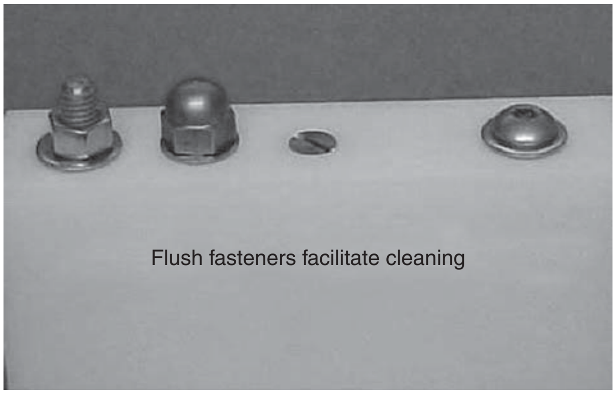

Figure 4. Flush surfaces simplify cleaning.

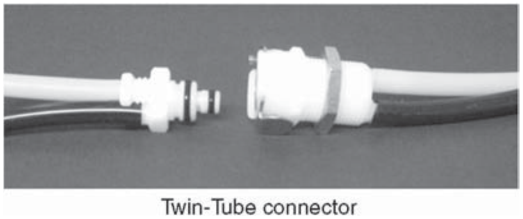

Figure 5. Multiple tube connector.

If walls need to be wiped down during cleaning, systems designed to facilitate this should be provided rather than relying on rags and buckets.

Adequate and appropriate tools are a must. If mechanics do not have the right tool when they need it, time is lost searching for it. Lack of the correct tool, readily available, increases the temptation to use the wrong tool, such as pliers. Improper tool usage not only causes delays, it frequently damages the machine so that every future changeover is delayed. Each machine should have a shadow board with the correct tools needed for changeover. The shadowboard should be located on or inside the machine for maximum convenience.

Repetitive operations, where a large number of fasteners need to be loosened or removed, may benefit from the use of power tools. Pneumatic or battery-powered wrenches or screwdrivers should be permanently mounted at the point of use with the appropriate bit or wrench.

Ideally, no tools at all should be used in changeover. There are a number of devices that can be used to substitute for bolts or other fasteners. These include handknobs and handlevers, toggle clamps, cam locks, magnetic, pneumatic and vacuum fixturing devices, and various types of pins.

When pneumatic, fluid, or electrical connections need to be made, they should be made by quick connects with multiple inputs. A pneumatic cylinder requires two air connections. If a dual quick connector is used, it not only cuts connection time, it also makes it impossible to connect them backwards. Connectors are available that allow simultaneous connection of multiple electrical, control, pneumatic, and fluid supplies (Figure 5).

Photoeyes can be time-consuming and difficult to reset between products. Multiple photoeyes, one for each product, should be permanently mounted and adjusted. Changeover goes from requiring positioning and adjustment of a photoeye by a mechanic to turning a selector switch by an operator. Depending on the machine, this may be done automatically via the PLC (Figure 6).

Einstein said: “Imagination is more important than knowledge.” Simplification of changeover is a good place to turn creative imaginations loose.

EXTERNALIZE

Changeover tasks can be broken into two categories: internal and external. (These are sometimes called intrinsic and extrinsic.) This concept was first described by Japanese industrial engineer Shigeo Shingo after he had been tasked

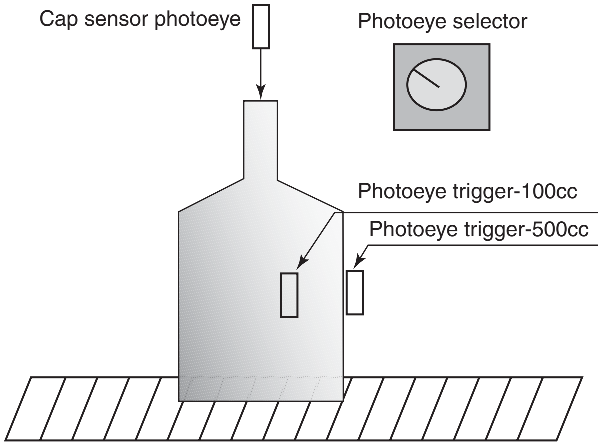

Figure 6. Multiple photoeyes with selector switch.

with reducing changeover times on stamping presses at Toyota. Shingo documented this in detail in his book A Revolution in Manufacturing: The SMED System (2).

Internal tasks are those that are performed when the line is stopped. External tasks are those that are performed while the line is running. In almost every changeover process, it is possible to find tasks that may be shifted from internal to external. They can be performed either before or after changeover while the line is running.

One example is cleaning of the pumps on a liquid filler. If only a single set of pumps is available, these must be removed, cleaned, and reassembled before changeover is complete. This may extend total changeover time. If there is an additional set of pumps, the “dirty” set may be removed and set aside, and the clean set can immediately be mounted. After the line has restarted, the other set of pumps is cleaned and stored in readiness for the next changeover.

Managements may object to spending money on an additional set of pumps. They can be expensive, perhaps \$5000–10,000 per set or more. This is why it is critical for the plant to know the costs of changeover downtime. It is difficult for management to justify the expenditure of dollars to save minutes. It is comparing apples and oranges and can’t be done in any meaningful way.

If costs are known, a cost–benefit analysis is simple. If having an additional set of pumps saves 15 minutes per changeover and changeover cost is \$2000/hr, the pumps save \$500/changeover. If the set cost \$5000, the payback is 10 changeovers. If changeover is daily, this is a two-week payback.

Other opportunities for externalization include:

Install additional liquid product transfer piping from the formulating area to the line can be equipped with clean-in-place (CIP) systems (Figure 7). This allows one transfer line to be cleaned while the other is in use.

Organize changeparts and materials required for the next run prior to the end of the current run. These should be staged as close to the line as possible.

Prepare documentation, such as line clearance, setup sheets, batch records, production orders, and the like, during the current run.

Change out instead of changing over machines. At least one labeler manufacturer builds machines in which the entire labeling head is mounted on rollers. It is disconnected from the labeler base, and rolled out; and a different head, which is cleaned and changed externally, is rolled into place. Several manufacturers of fillers do the same.

EXACTLY!

The key to successful changeover is eliminating variability from the process. This means that changeover must be

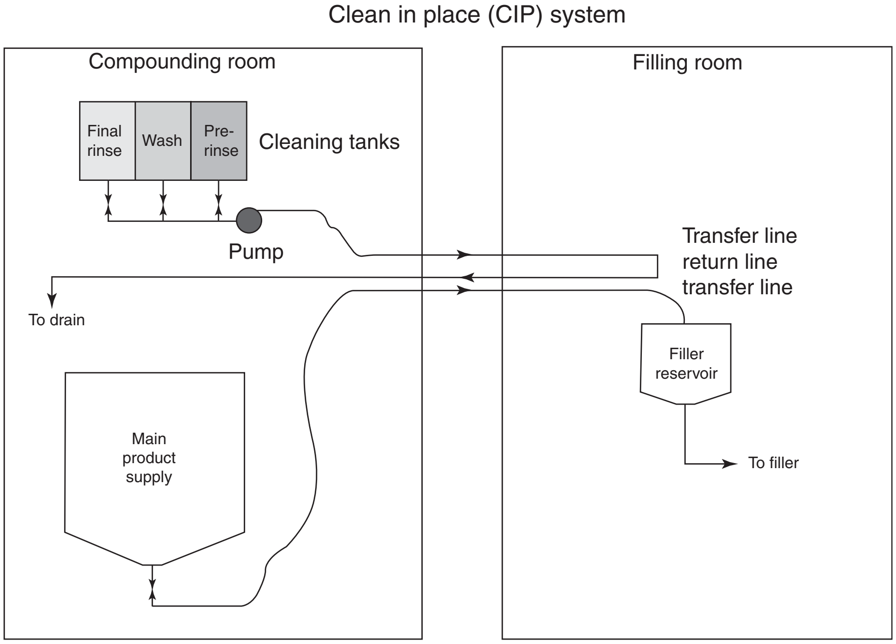

Figure 7. Clean-In-Place (CIP) system.

performed exactly the same way, to the same settings every time. There are two components to this. The first is to completely describe and document what is to be done during changeover and how. The second is to provide measurable and repeatable setpoints for each required adjustment. Neither is of much use without the other.

The document describing the changeover process is often called a Standard Operating Procedure (SOP) but will have various names in different companies and industries. In addition to the SOP, or as part of it, a checklist should be provided. The SOP describes, in great detail, exactly how the changeover is to be carried out. It should include a list of parts and materials required, safety precautions to be taken, and tools to be used. It will include, often as in tabular form, a complete list of all setpoints for each product and size. Annotated photographs or diagrams should be incorporated as needed for maximum clarity. In short, the SOP should be detailed enough that a person with minimal training will be able to successfully perform a changeover using it. This document will often be too cumbersome for daily use. If it is not used, variation in the setup will invariably result. To ensure daily use, an abbreviated checklist is required in addition to the SOP. This should be a one- to three-page document detailing what is to be done. It assumes that the person is trained, so there does not need to be much detail as to how it is to be done.

One way to achieve this is to write the SOP as an outline in MSWord. The major headings are the what items with the subheadings covering the how. Once complete, a table of contents can be generated showing the major headings. This becomes the checklist.

There are many other formats that will work, and some companies will have existing formats that must be used. The important thing to bear in mind is that if the process for changeover is not written down, changeover cannot be done the same way twice. If supervisors and managers do not continually make sure it is being followed, changeover will not be done the same way twice.

The SOP will tell how the changeover is to be performed and will document the setpoints for each adjustment. This is a good start but not enough. If the tools are not available to reliably achieve those setpoints, the SOP cannot be reliably performed.

All adjustments must have easy and foolproof means of measurment. These may be as simple as scribe marks on the machine. These work but are not generally recommended. They can be a source of confusion as they build up over time. Obsolete scribe marks are difficult to remove.

Scales, denominated in inch or metric, can be another tool. The scale by itself is not enough, there must be a good pointer to go with it. Where scales are used, they should be in either metric or decimal inch because fractional scales can be difficult to read.

Digital indicators are available in a variety of styles. If properly applied and mounted, they are rugged and easy to read. The advantage to digital indicators is that they are much harder to misread or misinterpret than the scale (Figure 8).

Figure 8. Digital position indicator.

Gauges, unless they are permanently mounted to the machine, should be avoided. They can be easily mislaid. When that happens, the machine will be adjusted, imprecisely, by eye. Gauges can be permanently mounted in several styles such as a leaf gauge. This consists of several gauges, hinged by a pin in a common mounting block. In use, the appropriate gauge leaf is swung up and the machine is adjusted to touch (Figure 9).

Temperature, pressure, time, and other settings should be made using digital rather than analog controllers for the least chance of error.

Speed is a critical parameter that is often not measured. Conveyor speeds may be set based on the position of a single-turn potentiometer. Tachometers are a must on all machines, including conveyors. The optimal speed of each machine must be noted in the SOP and set during changeover.

It is only be providing the capability of performing all changeover tasks exactly that variability can be reduced or eliminated.

OVERALL OPERATIONAL EFFICIENCY (OEE)

OEE is used in many plants to measure and compare line efficiency. It is the product of performance, availability, and quality. One way to improve OEE is to reduce variability in changeover. Reducing changeover variability impacts all three components.

Performance is improved because better changeovers result in smoother running machinery. Smoother running machinery will result in fewer minor stoppages.

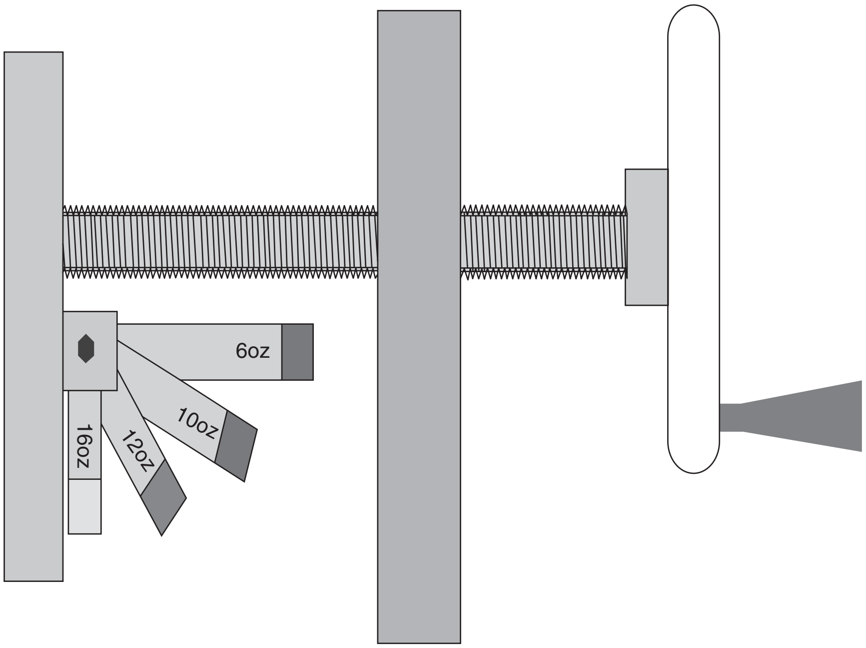

Figure 9. Leaf gauge.

Availability is increased because better changeovers will take less time.

Quality is doubly improved. Properly adjusted machinery produce more closely to target parameters as well as reducing the amount of rejected product.

Changeover of packaging lines has grown greatly in importance in recent years. It will continue to do so as the number and variety of products demanded by the market increases. Ever-increasing competitive pressures mean that it can no longer be ignored or treated as simply a necessary evil. A company with reduced changeover times will have a significant market advantage over companies with long changeovers.

Changeover must be viewed as both a tactical and a strategic competitive opportunity.

CHECKWEIGHERS

Automatic, in-line checkweighers have long been used to perform basic weight-inspection functions. These units, as distinguished from static, off-line check scales, perform 100% weight inspection of products in a production process or packaging line. Furthermore, these machines perform their functions without interrupting product flow and normally require no operator attention during production.

These charactertistics allow the machines to be used in several different ways. The applications can be broadly categorized as weight-regulation compliance, process control, and production reporting. This article describes a number of checkweigher applications in these categories. The emphasis is on problem solutions and benefits, although some description of the machine hardware and features employed is necessary.

WEIGHT-REGULATION COMPLIANCE

The earliest use of in-line checkweighers was to help producers guard against shipment of underweight products, and today various regulatory agencies set standards for weight compliance of packaged goods. Most of these standards are adopted from recommendations made by the National Bureau of Standards (NBS) in their various handbooks. In general, these standards recommend that the average product weight shipped by the producer be equal to or greater than the declared weight and that no unreasonable underweights be shipped. The in-line checkweigher provides assurance to the producer that these general requirements are met. With proper adjustment of checkweigher and process, an additional benefit of reduced product giveaway can be enjoyed.

The equipment required to carry out the basic weight-compliance requirement consists of a weighing element (weighcell), associated setup controls and indicators, a product transport mechanism for continuous- or intermittentmotion product movement, and a reject device for diverting off-weight items out of the production stream. A typical machine comprising these elements is shown in Figure 1.

The central portion of this machine shows a weighcell consisting of a strain-gauge loadcell that is connected to the integrally mounted electronics enclosure. Associated

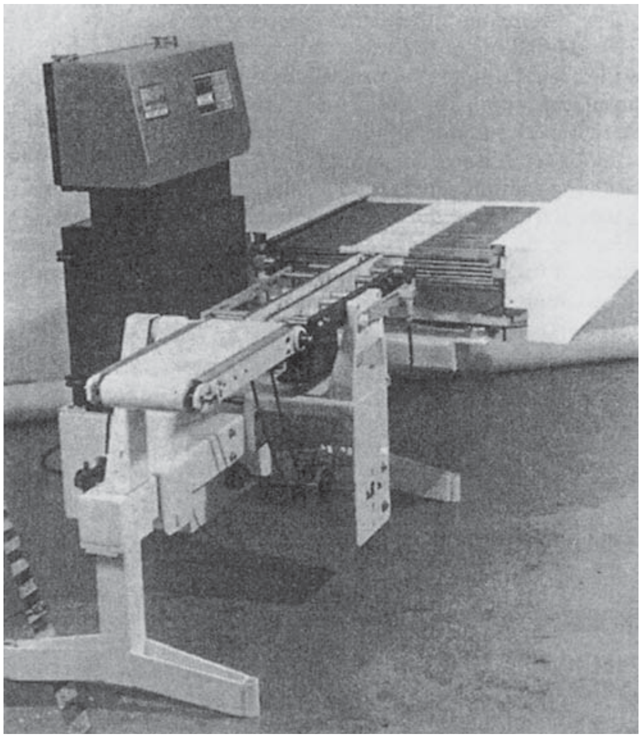

Figure 1. A typical checkweigher.

with the weighcell is a product transport, in this case consisting of a pair of stainless-steel roller chains. Shown on the left (upstream) side of the unit is an infeed belt conveyor, which serves as a product-spacing (speedup) device and ensures that only one product at a time passes over the weighcell. On the right (downstream) side of the unit is a channelizer product-reject device. This unit receives signals from the checkweigher and provides a gentle lateral displacement of rejected product by carrying it to the side on sliding carrier plaques. Other commonly used reject devices include air blasts, air pushers, swing gates, and drop-through mechanisms.

Rejection of underweight products (and in some cases overweight products, such as critical pharmaceutical packages or expensive products) provides the required consumer protection. The added benefit to the producer of reduced product giveaway frequently provides additional incentive to install the checkweighing machine. The information from the typical modern checkweigher allows the producer to control the target weight of the process and ensures minimum average product weight, and it minimizes rejected underweight products. The following application example illustrates these points.

New-Contents Weight. Company A prepares a variety of expensive frozen-food products. These products are clearly labeled showing net-contents weight and come under close scrutiny from regulatory agencies. Some ingredients, such as chunky pieces, are of somewhat nonuniform piece weight. Until an accurate in-line checkweigher was installed, the producer was forced to overfill most packages to prevent underweight shipments. The company installed a number of checkweighers that provide the required controls. Now, by means of digital displays and easily adjustable reject cutpoints on the checkweigher, the processor is able to closely monitor the filling process and establish the best compromise between product giveaway and excessive rejects.

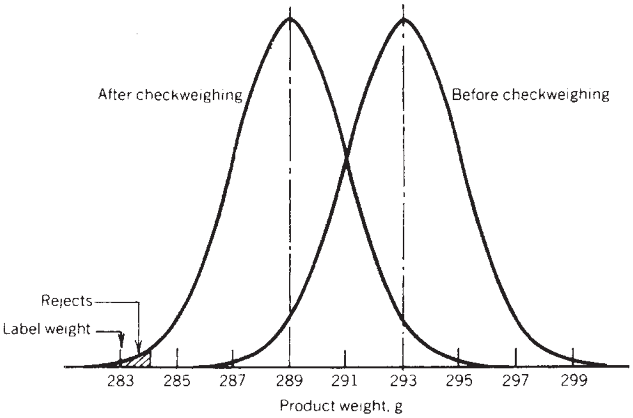

Figure 2. Weight distributions before and after checkweighing.

Product-Weight Distribution. Figure 2 illustrates a typical product-weight distribution curve before and after a suitable checkweigher is installed.

Before checkweigher installation, the mean product weight was maintained at approximately 293 g to ensure against underweight shipments. After checkweigher installation, the mean product weight is reduced to approximately 289 g. This results in less than 1% underweight rejects but saves an average of 4 g per package. The economics of this checkweigher installation is illustrated below:

Package labeled weight	283 g
Average overweight per package	10 g
Possible reduction in average overweight	4 g
Annual production	900,000 kg
Value of product	$0.75/kg
Cost of checkweigher (including freight and installation)	$10,000
RESULTS	
Product savings	1.4%
Product saved per year	12,720 kg
Savings per year	$9540
Payback period, approx.	1 yr

PROCESS CONTROL

Many products that are sold on the basis of a declared (labeled) weight are packaged by a volumetric filler or count or other nongravimetric processes. These processes frequently yield products of varying weight because of product density changes. Density changes typically occur with hygroscopic products under conditions of changing humidity. Also, material-handling methods can cause bulk-density changes in other products. Frequently, the

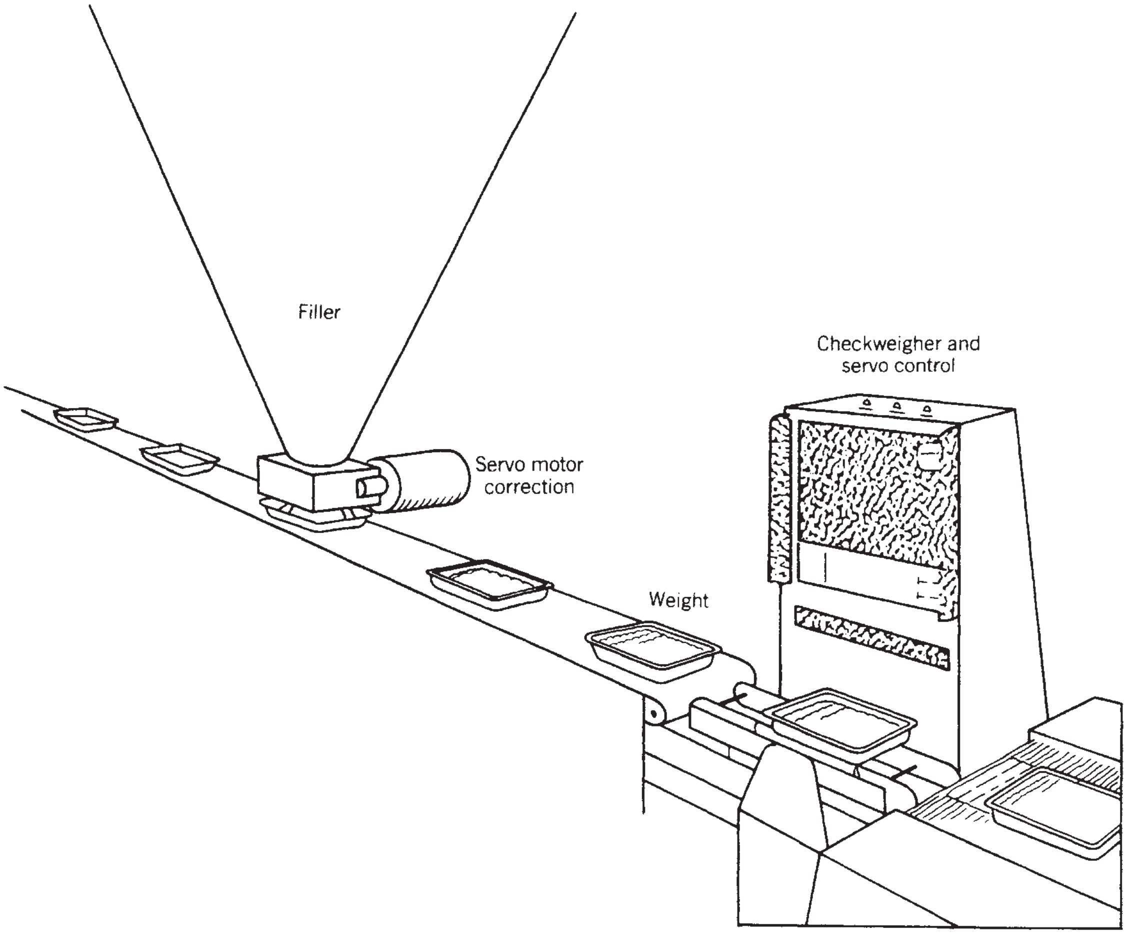

Figure 3. Checkweigher feedback-control to filler.

density changes occur in the form of a drift or periodic change. These changes lend themselves well to automatic-feedback control from a weight sensor (checkweigher) back upstream to the process controller. Figure 3 diagrams a checkweigher/filler feedback-control system.

This feedback loop continually adjusts the process setpoint and maintains delivered product weight within acceptable limits, even under conditions of density variations. These adjustments in turn reduce the long-term weight standard deviation of the packaged products. This allows the process setpoint to be set at a lower average value while minimizing the number of underweight (rejected) packages. The result is product savings. Two applications are described to illustrate the use of checkweighers with feedback for process control.

Feedback Control. Company B packages a low-density, hygroscopic product using a volumetric filler. Spot checks revealed that moisture variations from batch to batch and humidity changes throughout the day resulted in substantial density changes. These changes often went unnoticed until a large number of off-weight packages were produced, which caused either excessive product giveaway or an excessive number of underweights being rejected by the old checkweigher. In the former case, the giveaway represented considerable revenue loss and in the latter case resulted in product waste due to the impracticability of recycling and repackaging the rejected product.

The company purchased a replacement checkweigher equipped with feedback-control features for signaling their existing filler. The checkweigher is located as close as possible to the filler to achieve maximum responsiveness of the feedback loop. In this case, the feedback signals are electronically adjusting the setpoint of the filler. However, other control arrangements are possible that include signaling a servo motor attached directly to the control shaft of a filler. This company was able to justify purchase of the checkweighing system solely on the basis of product savings. Figure 4 illustrates how long-term standard deviation reduction allows lowering of average setpoint with resultant product savings. Short-term standard deviation that results from package-to-package filler errors is inherently beyond the control capability of the checkweigher.

Company C packages sliced luncheon meats. The “stick” or “load” of luncheon meat is fed through a slicer that counts a preset number of slices per draft to be packaged. Because of density changes of the meat, the correct slice count did not always yield the declared weight of the draft within allowable limits. With no on-line way to detect these

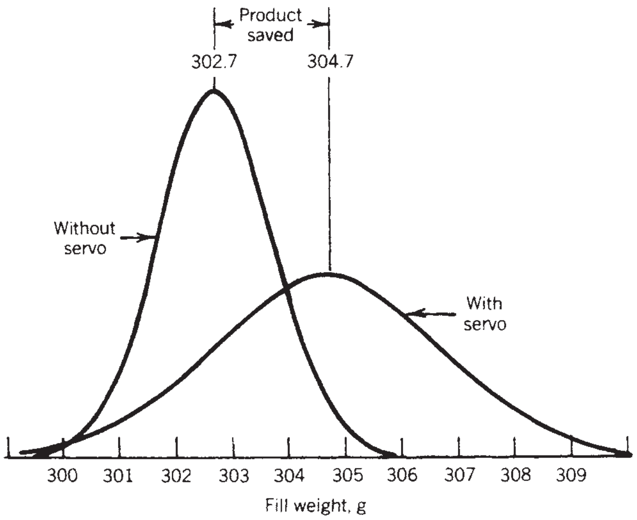

Figure 4. Filler setpoint reduction with servo system.

density changes, the company had to supply an extra number of slices to ensure labeled weight or take a chance on packaging underweights with correct slice count. It installed an in-line checkweighing machine that very accurately weighs each draft of sliced meat just after it leaves the slicer. Error signals, which represent departures of delivered weight from target weight, are fed back to the slicer controls. The controls in turn cause slice thickness to be adjusted so that the preset slice count results in correct draft weight within very narrow limits. The result was control over the slicing process that economically justified the checkweigher quickly.

PRODUCTION REPORTING

Automatic production reporting by a checkweigher can provide running analysis of packaging-line performance. Checkweigher-generated production data can be transmitted to printers, computers, terminals, and other data receivers. Whatever the reporting medium, the result is virtually instantaneous indications of production-line performance or automatically kept records of production data. Productivity gains and material savings result from such uses. Here are two applications of the checkweigher for production recording:

Company D requires that a statistical sampling procedure be carried out on each of its production lines. Historically, quality assurance personnel periodically removed a number of product samples from the production line, weighed them on manual scales, recorded the weights, and returned the samples to the production line. Using the raw data they had collected, quality-assurance personnel manually calculated statistical information about the samples. From this information, they prepared a product sampling report. Because of the frequency of the sampling procedure and the number of lines involved, a full-time quality-assurance (QA) person was employed to perform this task. Furthermore, the manual nature of the weighing and recording resulted in reports of questionable accuracy.

Microprocessor-Controlled Checkweigher. The company purchased a modern microprocessor-controlled checkweigher that is capable of accumulating production-weight data in real time and performing the required sampling calculations for transmission to a printer in the QA supervisor's office. Data reported to the supervisor include data and time of report, product code, operator identification number, average weight, standard deviation, and total weight for both accepted and rejected product over the selected sample size. Additionally, verification of checkweigher setup parameters, such as target weight and reject cutpoint settings, are recorded. Installation of the checkweighing system results in cost savings in personnel for acquiring the sample data and virtually instantaneous feedback of production data to QA and production personnel.

Company E ships large quantities of product to customers for further processing. To corroborate material-amount reports between supplier and customer, accurate total production records were required. In addition to actual weight of shipped product, an accounting of underweight (rejected) packages would yield important production-efficiency data.

The company installed an automatic checkweighing system and appropriate data-collection capabilities along with a printer for location in the accounting office. On command, accumulated data are transmitted from the checkweigher to the printer, which provide subtotals and totals of average weight, total weight of product shipped and rejected, package counts, and a figure for "yield" (shipped product divided by total production) on the basis of both weight and package count. The result of this installation is a true and accurate summary report for the accounting department of product shipped to each of their customers, thereby minimizing protests. The additional benefit is a more accurate report of actual production efficiency.

The application examples presented here describe a few of the many kinds of packaging lines that can and should benefit from the use of in-line automatic checkweighers. A few additional applications are suggested below:

- Piece-count verification in packages and cases
- Product-safety assurance by detecting undesirable underfills or overfills
- Multizone classification of natural products such as chicken parts, fish, etc.
- Detection of missing components in "recipe" food packages
- A survey of product weights in any processing/packaging line may reveal opportunities for substantial cost savings through use of an automatic checkweigher.

CHILD-RESISTANT PACKAGING

Richard Ward
Perritt Laboratories, Inc.,
Hightstown, New Jersey

Child-resistant (CR) packaging, a term synonymous with poison-prevention packaging (PPP) and special packaging (SP), is defined as "packaging that is designed or constructed to be significantly difficult for children under 5 years of age to open or obtain a toxic or harmful amount of the substance contained therein within a reasonable time and not difficult for normal adults to use properly" (1). This can include hazardous substances such as drugs, household cleaning agents, and pesticides. Packaging of this nature may take a number of forms, including bottles, drums, pouches, and blister packs. Many children have been saved from bodily harm and even death as a result of CR packaging.

HISTORICAL ASPECTS

Designs for CR packaging can be traced back to 1880, when the first U.S. patent was issued for a CR package. The U.S. Congress began to take direct interest in 1966, in response to public concern about the large number of children gaining access to harmful substances in the home. As a result of Congressional hearings that year, the commissioner of the FDA appointed Dr. Edward Press to be chairman of a committee to review the "state of the art of safety packaging." The Press committee, as it came to be known, comprised members from U.S. industry and government. The committee reviewed the 63 patents on CR packaging that had been awarded between 1880 and 1966 and decided that the most realistic and practical approach to this problem was to establish a performance standard, using children to test the units. A series of closure studies was conducted, involving more than 1000 panelists: adults from 18 to over 65 years of age and children between the ages of 18 and 52 months. From the data obtained in these studies, a protocol to evaluate child-resistant packaging was derived. This protocol, submitted to the FDA in 1970, is reflected in the protocol cited in the Code of Federal Regulations (CFR) (1), with the exception that the Press committee protocol contained two 3-min test periods for adults, one before a demonstration and one after a demonstration. The FDA-revised protocol, as it appeared in the CFR, cited one 5-min test period for adults without a demonstration. This was later changed in 1995 to a 5-min, 1-min test (2).

The U.S. Poison-Prevention Packaging Act (PPPA), signed into law December 30, 1970, was under the jurisdiction of the FDA. The protocol for the evaluation of poison-prevention packaging appeared in the Federal Register in July 1971 (3). FDA standards began to appear in the Federal Register in 1972, first for aspirin and then for controlled drugs, methyl salicylate, and furniture polish. In May 1973, jurisdiction was transferred from the FDA to the newly formed U.S. Consumer Product Safety Commission (CPSC), and additional products came under regulation. The CPSC was given the responsibility for medicines and household substances, and in 1979 the U.S. Environmental Protection Agency (EPA) was delegated to administer the compliance of pesticides.

Household pesticides of a hazardous nature were regulated in March 1981 (4). The initial EPA regulation was more stringent than the CPSC regulation, but much of the initial draft regulation was deleted to a point where the EPA regulation (5) approximates the CPSC regulation regarding testing requirements and standards. The major difference between the two regulations, at this point, has been that the CPSC regulation makes provisions for a noncompliance package that can be used by older adults and/or households without children, and the EPA regulation does not.

EFFECT OF REGULATION

As of 2007, there were 31 substances regulated by the CPSC. They are listed in Table 1. Regulations were placed on these substances because of their harmful nature to small children and the large number or severity of incidences of ingestions noted. The substances appear in this table by virtue of the ingestion patterns they have demonstrated from the data generated by poison-control centers located in the United States and compiled by the CPSC. Because of the increased sophistication of data collection since the government began collecting this information, in some cases it is difficult to measure actual reductions in ingestions by children. However, it was

Table 1. Regulated Substances—CPSC

Aspirin	>45 grains
Furniture polish	≥10% petroleum distillates
Methyl salicylate	>5% by weight
Controlled drugs	All oral forms
Na or K hydroxide	≥10% by weight

Kindling and illuminating preparations	≥10% petroleum distillates
Methyl alcohol	≥4 by weight
Sulfuric acid	≥10% by weight
Prescription drugs	all oral forms
Ethylene glycol	≥10% by weight
Iron-containing drugs	≥250 mg elemental iron
Dietary iron supplements	≥250 mg elemental iron
Solvents	≥10% by weight
Acetaminophen	>1000 mg acetaminophen
Diphenhydramine	>66 mg diphenhydramine
Glue removers	>500 mg acetonitrile
Permanent-wave neutralizers	>600 mg Na bromate >50 mg K bromate
Ibuprofin	>1000 mg ibuprofin
Loperamide	>0.45 mg loperamide
Lidocaine (April 10, 1996)	≥5 mg
Dibucaine (April 10, 1996)	≥0.5 mg
Mouthwash (ethanol)	≥3 g
Naproxen sodium (February 6, 1996)	≥20 mg
Ketoprofen	>50 mg
Fluoride	>50 mg elemental fluoride + >0.5% elemental fluoride
Minoxidil	>14 mg
Methacrylic acid	>5%
OTC drugs	From prescription drug
Low-viscosity hydrocarbons	10% or more by weight and viscosity >100 SUS at 100°F

possible to present comparative ingestion data up until 1982 showing considerable ingestion reductions in many regulated products, with reductions of up to 86% as shown in Table 2. Currently, tables of mortality rates can be used to demonstrate the reduction of deaths because of CR packaging. These figures can be noted in Table 3, which cites deaths of children under age 5 involving household products and aspirins. This table indicates that there has been a considerable reduction in child deaths as a result of the ingestion of either household products or aspirins.

Testing Procedures

The first U.S. test procedures protocol for the evaluation of child-resistant packaging were published in the *Federal Register* in 1971. As a result, the packaging field has had decades of experience in generating data utilizing this protocol. Poisoning statistics have demonstrated that the use of CR packaging aids in the reduction of child ingestions and deaths from harmful materials. Nevertheless, as data gathering methodology became more sophisticated, it appeared that there was an area still to be addressed when it came to child-resistant packaging. It was the use of CR packaging by older adults. This point was demonstrated by the fact that the ingestion statistics for prescription drugs showed the highest level of the regulated products. Older adults were the major users of these products and were thought to be contributing to child ingestions. Further studies conducted under contract to CPSC found this to be true (6). In interviews with these older adults, it was found that they misuse CR packaging often due to poor initial opening experiences. They either did not secure the packaging properly, left the caps off completely, or transferred their drugs to easy-to-open unsafe containers. Recognizing that older adults had problems opening CR packaging, the CPSC devised new test procedures to encourage the design and manufacture of easy-to-open so-called "senior-friendly" CR packaging.

Initially, the CPSC let contracts to three universities to design new CR packaging concepts that would satisfy "senior-friendly" criteria, and then a mockup and a unit cavity production package was prepared from the best concept. From this point over a period of time, changes were made to the test protocol to ensure that senior adults could access newly designed packaging of the universities

Table 2. A Comparison of the Number of Regulated Substances by Children Under 5 Years Old

Regulated Substances	Effective Year	Ingestions During the Effective Year	Ingestions During 1982	Decrease Since Effective Year (%)
Aspirin	1972	8146	1753	78
Controlled drugs	1972	1810	541	70
Methyl salicylate	1972	161	49	70
Furniture polishes	1972	697	229	67
Illuminating and kindling preparations	1973	1736	452	74
Turpentine	1973	777	110	86
Lye preparations	1973	508	69	86
Sulfuric acid[a]	1973	7	1	86
Methanol[a]	1973	37	21	44
Prescription drugs (oral)	1974	4180	2251	46
Ethylene glycol	1974	138	59	57
Iron preparations	1977	359	163	55
Paint solvents	1977	641	180	72
Acetaminophen	1980	1511	1118	26

[a] Since these figures are based on a few cases, the percent decrease may not be reliable.

Table 3. Deaths of Children Under Age 5 Involving Household Products[a]

Deaths Due to All Household Chemicals			Deaths Due to Aspirin Products		
Year	No. deaths	Decline (%) Since 1972	Year	No. deaths	Decline (%) Since 1972
1972	216	—	1972	46	—

[a] Data obtained from the National Center for Health Statistics in Washington, DC.

design as well as packaging designed by individual inventors and designs developed within the packaging industry. Concepts that were devised included ones that required cognitive skills to activate. That is, they relied on the mental ability of the adults to determine how to open units versus high forces as push and turn or pull as have been required with the ongoing type CR packaging systems. In addition to the new cognitive skill concepts, package manufacturers refined their current CR packaging design to make them easier to open for senior adults yet still difficult for children.

The first U.S. CR packaging test procedure (protocol) appeared in the *Federal Register* in the spring of 1971, and this protocol was adhered to up until the summer of 1995, at which time a new and modified CR protocol appeared in the *Federal Register*. The original 1971 protocol cited the need to employ 200 children between the ages of 42 and 51 months of age equally divided according to age and sex with an allowance of 10% variance, and also 100 adults between the ages of 18 and 45 years representing 70 women and 30 men. The children were to be tested in pairs in familiar surroundings and would have two 5-min test periods, one without a demonstration and one with a demonstration and they were told they could use their teeth if they had not used them in the first 5-min test period. The adults were allowed a 5-min test period and were told that they should open and resecure (if appropriate) the packaging according to the directions.

Standards for the children were set as 85% unsuccessful before demonstration and 80% total after demonstration. Ninety percent of the adults had to open and close (if appropriate) the package in a 5-min test period.

The 1995 CR protocol takes into consideration a number of features that have been observed over the years that would help standardize the testing procedure from one test agency to the next. In addition, it includes major changes in the ages of the adult test group. These features will be discussed later. The ages of the child panelists has remained 42–51 months, but instead of immediately utilizing a group of 200 children, 42–51 months of age, the test is conducted in groups of 50 children on a sequential basis up to 200 if it is required according to an established pass–continue–fail pattern based upon package openings (see Table 4). In order to make it easier to obtain child panelists, the number of chronological groupings has been changed from 10 to 3. The three selected groups are to include

30%	42–44 months of age
40%	45–48 months of age
30%	49–51 months of age

Table 4. Number of Openings: Acceptance (Pass), Continue Testing, and Rejection (Fail) Criteria for the First 5 min and the Full 10 min of the Children's Protocol Test

		Package Openings					
		First 5 min			Full 10 min		
Test Panel	Cumulative Number of Children	Pass	Continue	Fail	Pass	Continue	Fail
1	50	0–3	4–10	11+	0–5	6–14	15+
2	100	4–10	11–18	19+	6–15	16–24	25+
3	150	11–18	19–25	26+	16–25	26–34	35+
4	200	19–30	—	31+	26–40	—	41+

The standard for the child test has remained the same 85% unsuccessful before demonstration and 80% unsuccessful after demonstration.

Included in the U.S. testing procedure for CR packaging from its inception in 1971 is a provision for testing nonreclosable packaging (unit packaging, such as blister packs, strip packs, and pouches). The test procedure follows the same pattern as the reclosable packaging; but instead of just access to a container, an individual package failure with the nonreclosable package for the children is the case whereby the child gains access to greater than eight units of the package (blisters packs or pouches) or the amount of product that would cause harm (for toxicology, based on a 25-lb child), whichever is less.

The truly major changes in the new CR protocol involves the changes in the ages of the 100-member adult panel and the time frame in which they are tested. The new age groups are as follows:

25%	50–54 years of age
25%	55–59 years of age
50%	60–70 years of age

Of these, 70% of the 50- to 59-year-olds are to be female and 70% of the 60- to 70-year-olds are to be female. The standard for the adult test is a 90% successful pattern.

As for the time of the test, in order to become familiar with new CR packaging concepts, they are tested as follows. The adults are tested individually with a 5-min test period to learn how to open and close the test unit. They are then given a 1-min test period to open and close the test unit. A panelist who is unsuccessful in opening the unit in the first 5-min test period is given a non-CR screw cap and a non-CR snap cap to open to attempt to open and close. In this case an opening and closing of the two non-CR units would constitute a failure in the case of the test unit. On the other hand, a panelist who fails to open and resecure the non-CR units is not included in the test unit pattern.

The U.S. Environmental Protection Agency (EPA) follows the lead of the CPSC in the regulation of CR packaging, but the EPA may also rely on, when necessary, an adult panel of 18–45 years of age to evaluate CR packaging.

ENFORCEMENT

CPSC and EPA are the two federal agencies in the United States that are responsible for enforcing the CR packaging regulations: the CPSC for household products and medications and the EPA for pesticides and pool chemicals utilized in and around the home. Both agencies have their own legal staffs, which can act with the Justice Department against companies whose products are not in compliance with packaging regulations. The U.S. federal government relies on product samplings from retail stores and warehouses, complaints from the public, and the number of child ingestions to determine which products should be evaluated for compliance purposes. Producers of products found not to be in compliance are approached by the agency are informed of their problem and advised to improve their packages. If the package is still found not to be in compliance, the federal agency involved can go to the extent of halting further production of the package form and ordering a product recall and imposing fines. This, of course, can result in loss of revenues and undesirable publicity for package and product manufacturers. Voluntary recalls of products by manufacturers have occurred in the past because of packages not satisfying the regulation.

SIMILAR TESTING STANDARDS

ISO8317, entitled "Child-Resistant Packaging—Requirements and Testing Procedures for Reclosable Packages," is most often cited by countries outside of North America. The ISO standard is similar to the U.S. standard in the manner in which the procedures are carried out. The ISO standard includes children 42–51 months that are tested in pairs using two 5-min test periods before and after demonstration as cited in the U.S. regulation. However, the children are not informed that they can use their teeth as they are in the U.S. standard, although the use of teeth is allowed. Testing procedures are conducted on a sequential basis utilizing special sequential statistically devised charts to fill in the test results and determine the pass–fail pattern. Using the ISO test chart, it is possible to complete the child portion of a CR study by employing a total of 30 children to test the CR package. The senior-adult portion of the ISO CR test is similar to that of the U.S. test.

EN14375, entitled "Child-Resistant Non-reclosable Packaging for Pharmaceutical Products," is also similar to the U.S. testing procedures. This standard differs in using the sequential charting method of ISO8317, and it defines an individual package failure differently from the U.S. test. EN14375 defines an individual package failure as access to more than eight units, whereas the U.S. test defines an individual package failure as the point at which a hazardous amount would be accessed or, in the case of a low hazard, greater than eight units.

CAN/CSA Z76.1 and Z76.2 are the two Canadian standards for Reclosable and Non-Reclosable Child-Resistant Packages, respectively. These standards are similar to the above standards, but include more details of the test procedures as well as the option to utilize the ISO/EN style sequential test scheme. In addition, it also suggests the use of certain ASTM International mechanical CR packaging test standards to evaluate test units. Certification of pharmacy vials in Canada is required through the Canadian Standards Association.

CLASSIFICATION

The ASTM International D10.31 subcommittee has established what can be considered the official classification system for child-resistant packaging.. This ASTM standard, *D3475 Classification of Child-Resistant Packages*, is based on the style of function of the CR packaging. In 2007 there were 13 major types of packages included in this classification system, each with a number of subgroups totaling 99 functional subtypes in all. Examples of the different types of packages, along with their producers, are presented in the standard. Since 2004 this standard has been updated annually (7).

In 2005 the U.S. Consumer Product Safety Commission and the U.S. Environmental Protection Agency each have added a child-resistant packages guide to their web sites (8, 9).

CLOSURES, BOTTLE AND JAR

J. F. Nairn
T. M. Norpell
Phoenix Closures, Inc.,
Naperville, Illinois

The cork stopper and the continuous-thread cap represent two epochs in closure evolution. The cork stopper began its slow ascendency 25 centuries ago, attaining its broadest use by the middle of the 19th century. With the arrival of the standardized continuous-thread cap and the introduction of plastic closures, both in the 1920s, the modern closure era was underway.

Cork provided an incomparable friction-hold seal. A material of high cellular density, cork is compressible, elastic, highly impervious to air and water penetration, and low in thermal conductivity—a natural panacea for the elementary problems of closure. Historical antecedents of the cork stopper are found within the Roman Empire. The art of glass-blowing matured commercially there, resulting in a vast commerce of vases, jars, bottles, and vials. Bottles and jars were more common during the Roman Empire than at any period before the 19th century (1). The use of cork floats and buoys by the Romans, with subsequent applications as bungs (large stoppers) for casks, suggests the likelihood of fabricated cork bottle-stoppers. Yet with the fall of the Roman Empire, glass-blowing and the use of the cork stopper declined until after the Renaissance. Other sealing methods used at the same time as the rise of the cork stopper in the 16th century include a Near Eastern method of covering the container with interlaced strands of grass, or strips of linen, and applying a secondary seal of pitch. Western Europeans used glass stopples and various lids of glass and clay before the common use of cork. Wax was a very common closure, inserted into the neck and covered with leather or parchment. Raw cotton or wool, sometimes dipped in wax or rosin, was also employed, frequently covered with parchment or sized cloth, which was then bound to the neck (2).

The aftermath of the Industrial Revolution was characterized by a heightened quest for technical sophistication. Steam and, later, electric power provided quicker realization of more complex goods. The ethic of the economy of scale, "the more you produce, the less costly it is to produce it," became the momentum for the sudden explosion in manufacturing technology. During this time the world was colonized on vast scales, and population doubled in 150 years. These forces of urbanization and industrialization created an unprecedented demand for bottled goods by the 19th century. Closure evolution of this period reflects the search for a practicable seal through a variety of mechanical devices. By mid-19th century, cork was the predominant closure, providing a friction seal for foods, beverages, and patent medicines.

Many attempts were made then to attune the concept of threaded closure to the demands of a new industry. A major contributor was John Mason. His 1858 patent of the

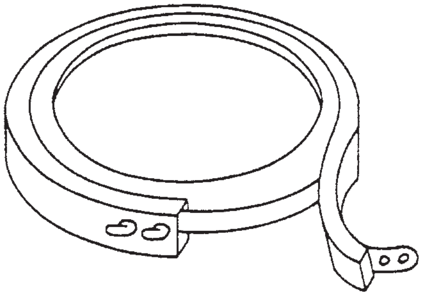

Figure 1. The Phoenix band closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

Mason Jar redesigned glass threads to accomplish a tighter and more dependable seal. Developing closure and container industries were to remain a chaos of varying pitches, lengths, and thicknesses throughout the century as manufacturers tried to perfect some particular feature that would require their exclusive manufacture. Intermediate to the development of the standardized continuous thread cap was the Phoenix band cap (see Figure 1), a popular closure among food packagers because it could provide a hermetic seal in a world of imperfect finishes. Invented in France by Achille Weissenthanner in 1892, the closure provided adjustability to finishes by means of a slit-and-tongue neckband, an improvement over the original neckband closure patent of 1879 by Charles Maré of France (3). This cap also introduced the custom that later became standard in the industry: measuring closures in millimeters (mm).

By the end of the century, some form of external mechanical fastener, such as Henry W. Putnam's bailed clamping device known as the "Lightning Fastener," was the leading closure for beer and ale. Internal stoppers provided the seal for most carbonated soft drinks, most notably Hiram Codd's glass-ball stopper and Charles Hutchinson's spring stopper (4).

In the early 1900s, Michael J. Owens successfully automated the production of jars and bottles, which in turn created latent market demand for inexpensive, easy to use, standardized closures. The crown cap, devised by William Painter around 1890, provided a solution for the beverage industry. Shortly after World War, glass and cap manufacturers, through the Glass Container Association, designed and standardized the shallow, continuous-thread cap. Subsequent forces shaping today's closure were the emphasis on package styling created in the 1930s and the development of thermoplastic-molding technologies. During the 1970s, plastic closures showed a 60% market increase (5). In the 1980s the forces of consumer demand for convenience, society's need for access control, and industry's need for cost-efficient innovation continue to redefine the closure.

CLOSURE FUNCTIONS

A closure is an access-and-seal device that attaches to glass, plastic, and metal containers. These include tubes, vials, bottles, cans, jars, tumblers, jugs, pails, and drums. About 80 billion (10^9) closures are produced annually in the United States (6). The closure works in conjunction with the container to fulfill three primary functions: (a) to provide protective containment through a positive seal, (b) to provide access and resealability according to varying requirements of convenience and control, and (c) to provide a vehicle for visual, audible, and tactile communications.

Protective Containment

Protective containment and seal are achieved when closure and container are integrated to form a unified protection system for the product during its cycle of use. Protective containment has a twofold meaning: (a) containing the product so that neither the contents nor its essential ingredients escape and (b) providing a barrier against the intrusion of gases, moisture vapor, and other contaminants.

A Positive Seal

A packaged product is vulnerable to many forms of natural deterioration, including migration of water or water vapor, contamination by oxygen or carbon dioxide, and assaults by microbiological life. The packaged product is further challenged by extremes of heat and cold, as well as dryness and humidity, and by physical stresses imposed upon it during the distribution cycle (7).

A positive seal is attained when the contact points of the closure and the top of the container (its "land" surface) are pressed together to form a seal. Frequently a resilient lining material, compressed between the closure and the container, provides a tighter, more secure seal. A liner may be made of paper, plastic, or metal foil and is often a composite of many materials (8). A seal may also be formed by caps containing flow-in compounds where a gasket is devised by pouring a liquid sealing compound into the closure. A variety of linerless thermoplastic closures utilize molded-in sealing devices. These embossed or debossed features press against the land surface and provide a seal when the closure is applied and tightened. Sealing specifications may range from mere containment to the preservation of highly sensitive food, pharmaceutical, household, and industrial products. Three common types of seal applications are sterilized, vacuum, and pressurized.

Two closure methods provide containment and seal: (a) friction-fitting closures, including snap-ons, stoppers, crowns, and press-ons, and (b) thread-engagement closures, including continuous-thread and lug caps. A positive seal depends upon such factors as the type of product, closure, container, and seal desired, the resiliency of the liner, the flatness of the sealing surface, and the tightness or torque with which the closure is applied (9).

Access

Contemporary closure design is shaped by the demands of a pluralistic marketplace where strong consumer preferences for convenient access exist alongside legal mandates for access control. Many packages today are ergonomically designed systems capable of easy opening and dispensing, and also affording critical access control. Closure technology has always sought to provide “a tight seal with easy access,” but today’s simultaneous demands for easy access and access control are the most polarized in the industry’s history. Access to a product can be said to exist on a continuum of convenience. This may range from the knurls (vertical ribbing) on the side of a continuous-thread cap, designed to provide assistance in cap removal, to what can be called convenience closures, which have a variety of spouts, flip-tops, pumps, and sprayers to facilitate easy removal or dispensing of the product.

Control

Concurrent to greater demand for convenient, often one-handed, access to a product, legal mandates and consumer preferences press for more access controls. These access controls are of two major types: tamper-evident (see Tamper-evident packaging) and child-resistant (see Child-resistant packaging). Regulated tamper-evident (TE) closures may be breakable caps of metal, plastic, or metal/plastic composites. In one variety the closure itself is removable but a TE band remains with the neck of the bottle. In another, the TE band is torn off and discarded. Another system not specifically addressed in the regulations incorporates a vacuum-detection button on the closure. Other TE systems include paper, metal foil, or plastic innerseals affixed to the mouth of the container. The FDA has stated 11 options for making a package tamper-evident, two of which apply to closures (10). Child-resistant closures (CRCs) are designed to inhibit access by children under the age of five. This is frequently accomplished through access mechanics involving a combination of coordinated steps which are beyond a child’s level of conceptual or motor skills development. Of these closures, 95% are made of plastic; the remaining 5% combine metal with plastic (11).

Verbal and Visual Communications

The closure is a focal point of the container. As such, it provides a highly visible position for communications, an integral aspect of today’s packaging. Three communication forms include styling aesthetics, typography, and graphic symbols. Since the closure is handled and seen by the consumer every time the product is used, the audible, visual, and tactile message (often subconscious) becomes very important to the packager.

Styling Aesthetics. Aesthetics are an important consideration because package design has the same basic goal as advertising: to promote brand awareness leading to brand preference. The closure and the container provide a visual symbol of the product, creating imagery through aspects of styling. Three important aspects are form, surface texture, and color. The form of a closure can be utilitarian to suggest value, or it can assume elaborate and elegant forms to suggest luxury. The surfaces of glass, metal, and plastic can provide a variety of surface textures unique to the materials used. Metal caps and decorative overshells of steel, aluminum, copper, or brass can be burnished, painted, screened, or embossed. Plastics can be molded in vivid colors, anodized to assume metallic sheens, or printed, hot-stamped, screened, or embossed. Glass can provide the kind of design statement exclusive to the glass arts, creating imagery of luxury or elegance. Many closures today are styled simply, with brand-identification or functional embossments (e.g., stacking rings) appearing on the closure top.

Color is the most pervasive form of closure decoration. A closure may be purely functional in form; yet, with color, it can take on dramatic significance. With the advent of color-matching systems in industry, such as the Pantone Matching System (Pantone, Inc.), the closure, container, label, and point-of-purchase display can be coordinated to produce a strong emotional reaction. The emotion may be one of action and excitement, as the hot primary colors used in soap and detergent packaging, or cool and subdued colors that characterize many cosmetics and fragrances. In addition to its decorative aspects, color can provide functional assistance. Color contrast directs the eye to areas of emphasis, and this direction can be important in teaching the mechanics of container access and use. In a crowded environment of dispensing options found at point of purchase, color can help identify a closure as one that the consumer already knows how to use. A great many dispensing closures today, for example, differentiate the spout from its surrounding fitment by strong color contrast. Closure color can also be used to identify the flavors of a food product or beverage and help to differentiate these flavors quickly within a product line.

Typography. Common forms of written communications found on a closure may include brand identification, a listing of ingredients, nutritional information, access instructions, or consumer advisories. These can be printed, screened, hot stamped, or molded onto a closure. For purposes of impact at point of purchase, a brand name frequently appears on the closure top.

Graphic Symbols. A graphic symbol frequently found on the closure is a company or product logo. Another common graphic is the arrow, a symbol that has gained importance with the advent of safety, convenience, and control mechanisms of modern closures. Arrows direct the consumer to proper disengagement of the closure, indicate engagement points where access is possible, or signify the direction of dispension (e.g., in the control tips of spray-type mechanisms). The scannable bar code is a more recent functional graphic to appear on closures (see Code, Bar) (12).

METHODS OF CLOSURE

Removable closures attach to containers by two principal methods: thread engagement and friction engagement. Threaded closures include continuous-thread caps, lug caps, and metal roll-on caps. Friction-fit closures include crowns, snap-fit, and press-on types. Thread engagement is the most widely used method of attaching a closure to a container (13).

Thread-Engagement Types

Three closure types provide a seal through thread engagement: continuous thread (CT), lug, and roll-on caps. CT designs attain a seal through the attachment of a continuously threaded closure to a compatibly threaded container neck. The lug cap uses an abbreviated thread design, with access and reclosure accomplished in one-quarter turn. The roll-on is supplied as a blank unthreaded metal shell which then becomes a closure on the capping line when it is compressed to conform to the finish of a bottle. The press–twist closure also has its threads formed after it is applied to the container.

The CT Closure. Threaded closures were standardized in the 1920s and continue to prosper due to the basic soundness of their principle, which offers a mechanically simple means of generating enough force for effective sealing, access, and resealing (14). Today the CT design is manufactured in plastic, tin-free steel, tin plate, and aluminum. Some CT control-closures combine metal and plastic by using a regular CT metal cap and a plastic overshell. The CT closure provides a seal for the container by engagement of its threads with the corresponding threads of the container (see Figure 2). As the thread structure (or "finish") is designed on an inclined plane, the engagement and application torque cause the threads to act like the jaws of vise, forcing closure and container into contact to form a positive seal. Critical sealing applications typically include a liner placed between the closure and the container. When tightened, the material is compressed between the sealing surfaces to form a seal. The thermoplastic "linerless closure" employs a variety of molded devices which can also provide a positive seal. All CT closures are designated by diameter (as measured in nanometers) followed by the finish series number. A closure with the designation number "22-400" refers to a closure with an inside diameter of 22 mm designed in the 400 finish of a shallow continuous thread.

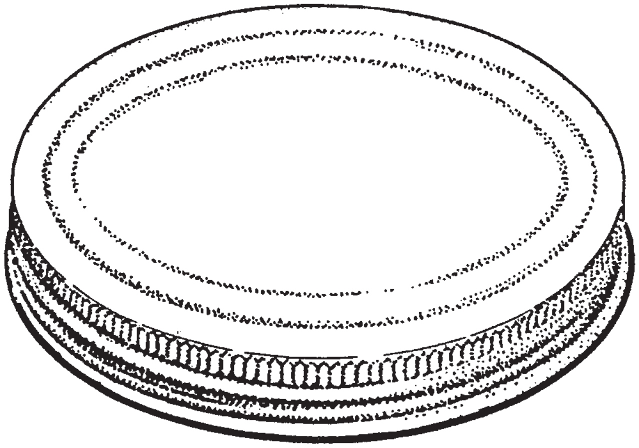

Figure 2. A metal CT closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

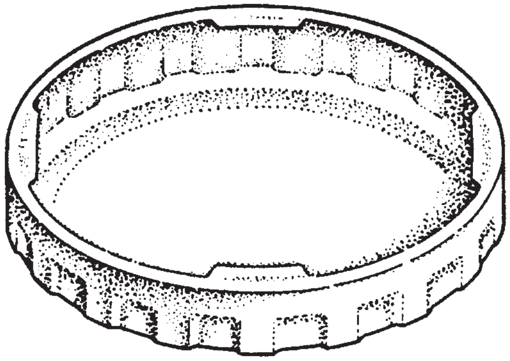

Figure 3. Lug closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

Lug Cap. The lug cap operates on the principle of thread engagement as does the CT cap. The thread structure of the lug is not continuous, but consists of a series of threads which may be inclined or horizontal depending upon finish variations. The lugs of the cap are positioned under corresponding threads on the container finish (see Figure 3). When tightened, the engagement of two, four, or six lugs pulls the closure and lining material onto the container. The lug cap is the most popular steel vacuum-closure today (15). Frequently a flow-in plastisol inner gasket is used as the liner. The lug cap is used extensively for vacuum packs in the food industry, and it is suitable for use on many products packaged in glass containers. The lug cap's design allows application and removal with a one-quarter turn. This means not only consumer convenience, but also quick capping. The common finish designations for lug caps are 120, 140, and 160 referring to 2, 4, and 6 lug finishes respectively (16).

Roll-On. The aluminum roll-on cap was an innovative method of closure that won immediate acceptance within the packaging industry in the 1920s (17). Although frequently categorized separately from threaded closures, the roll-on nonetheless utilizes thread engagement to accomplish seal and reseal. What makes this closure unique is the capping process. A lined, unthreaded shell (or "blank") is furnished to the packer. During capping, the blank is placed on the neck of a container and the capping head exerts downward pressure, which creates a positive seal as the liner is pressed against the container finish. Next, rollers in the capping head shape the malleable aluminum shell to conform to the contour of the container thread (see Figure 4).

The roll-on closure is used in the food, carbonated beverage, and pharmaceutical markets where pressure sealing is required. It is considered one of the most versatile sealing devices for normal-, high-, and low-pressure seals. A widely used version today is the tamper-evident roll-on. A tear band perforated along the bottom of the closure skirt is tucked under a locking ring during capping by a special roller. When opened by the consumer, the band separates from the closure to provide visible evidence of tampering. The roll-on cap can be applied at high speeds, approaching

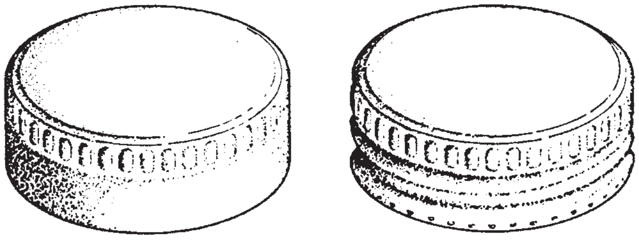

Figure 4. Roll-on closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

1200 bottles per minute. In the standard bottle finishes, the 1600 series designates roll-on.

Press-Twist. The "press-twist" is another closure which attains its threads on the capping line (see Figure 5). Primarily used for baby foods, it also provides closure for sauces, gravies, and juices. Applied in a steam atmosphere, the plastisol side gasket in the heated cap forms thread impressions when pressed against the glass finish. As it cools, permanent impressions are formed in the compound so the cap can be twisted to open and reseal similar to a CT cap.

Friction-Fit Closures

Many bottles are sealed with simple metal or plastic closures that are pressed onto the top and held in place by friction. The four basic types of friction-fit closures are crowns, snap-fit caps, press-on caps, and stoppers.

Crowns. The crown beverage cap was a major innovation in friction-fitting closure. It has been widely used since the turn of the century for carbonated beverages and beer. Crowns are made of tin-free steel and tin plate. Matte-finish tin plate is used for soft drinks and a brighter finish is used for beer. The crown has a short skirt with 21 flutes that are crimped into locking position on the bottle head. The flutes are angled at 15° in order to maintain an efficient seal (see Figure 6) (18).

The crown contains a compressible lining material, which over the years has included solid cork, composition cork or plastic liners, and foil and vinyl spots. Though simple in concept, the crown provides a friction-fit sufficient to seal pressurized beverages. The flared cap skirt in conjunction with the smoothness of the bottle neck provides easy access through the prying motion of the bottle opener. As convenient access came to be demanded in the marketplace, easy-open crowns were developed. The twist-off beverage crown first appeared on beer bottles in 1966 and gained in popularity (19). Designed for convenient access, it could be twisted off by hand or removed with a bottle opener. Bottlers switched to this cap because no special capping equipment was required for the new closure. In 1982 many companies moved away from this cap because of potential tampering. The crown is currently capable of application speeds exceeding 1000 units a minute.

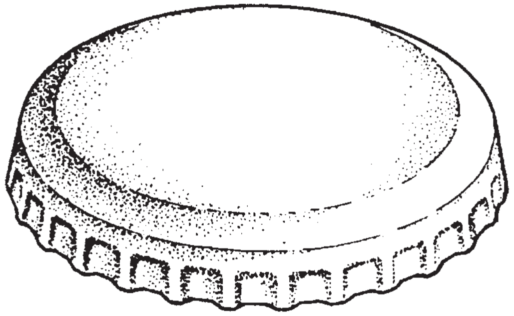

Figure 6. Crown closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

Snap-Fit Caps. The snap-fit caps are simple lids that can be pressed onto the tops of bottles. They may be held in place by the friction of a tight fit or by supplementary flanges, ridges, or grooves that grasp the bottle finish (20). The skirts of some metal snap-fit caps are rolled under to form a spring action as the cap is pushed against the lip of the bottle. Some types of snap-fit caps have ridges on the inside of the caps that match the grooves in the ridges on the bottle. The simplest form is designed to fit so snugly that the friction between the surfaces of the cap and bottle is sufficient to hold the cap in place. Snap-fit caps may be made of metal or plastic. They are used for such food products as jellies and for over-the-counter medicines such as headache remedies. An important variation is the press-on TE closure, frequently used on milk and juice products. When these caps slide over a ridge near the bottom edge, they fit so tightly that they cannot be pulled off. The bottle is opened by pulling a tear tab located above the ridge. This separates the top of the cap from the bottom portion that was locking it in place.

Press-on Vacuum Caps. Sealing for the press-on vacuum closure is obtained from atmospheric pressure when air is withdrawn from the headspace of the container by steam or mechanical sealing methods. Sometimes further security for this type of seal is provided when the edge of the cap is forced under a projection of the glass finish or held under a similar projection by snap lugs. In many vacuum caps, it is the pressure of a gasket against the top of the container finish which provides a seal. In others, atmospheric pressure alone is adequate. A recent press-on variation is the composite cap, a gasketed metal disk and plastic collar used in sealing dry-roasted nuts and seafood products. Its plastic collar is used as a TE device.

TYPES OF CLOSURE

It is impossible to place all closures into clean-cut categories where there is no overlap of functions. Yet despite these limitations, a classification can provide focus for understanding contemporary closure trends. As defined by their utility, the four classes of contemporary closures are: containment, convenience, control, and special purpose.

Containment Closure

Though all closures provide containment, a containment closure is defined here as a one-piece cap whose primary function is to provide containment and access on vast production scales. CT caps (for general-purpose sealing), crowns and roll-ons (for sealing of pressurized beverages), and lug and press-on caps (for vacuum sealing of foods) are within this class of containment closure.

Convenience Closure

Closure development in recent years has been in response to consumer preferences for convenient access to the product. Convenience closures provide ready access to liquids, powders, flakes, and granules for products that are poured, squeezed, sprinkled, sprayed, or pumped from their containers. There are five types of convenience closures: spout, plug-orifice, applicator, dispensing-fitment, and spray and pump types.

Fixed-Spout Closures. A spout is a tubular projection used to dispense liquid and solid materials. It may be fixed or movable and may be capable of dispensing a product in a wide ribbon or a fine bead, depending on size and configuration of the orifice. Fixed-spout caps incorporate a cylindrical or conical projection into the center of a threaded or friction-fitting closure. Spouts on reusable containers are often sealed by a small sealer tip on the end of the spout. On some sealed spouts, dispensing control can be attained by cutting the spout at various heights, thereby providing different orifice sizes. A more contemporary form of fixed-spout closure is molded with a smaller sealed spout on the top of the cap. Called "snip-tops," they are one of the most inexpensive forms of dispensing closure (see Figure 7). Contemporary "dripless pour spouts" have recently been introducted to provide "No-Mess" dispensing of viscous, sticky products packaged in large containers, such as liquid detergents and fabric softeners. Large pour spouts are protected by screw-on overcaps that double as measuring caps. Upon reclosure, the measuring overcap is designed to drain residual product directly into the container through the spout.

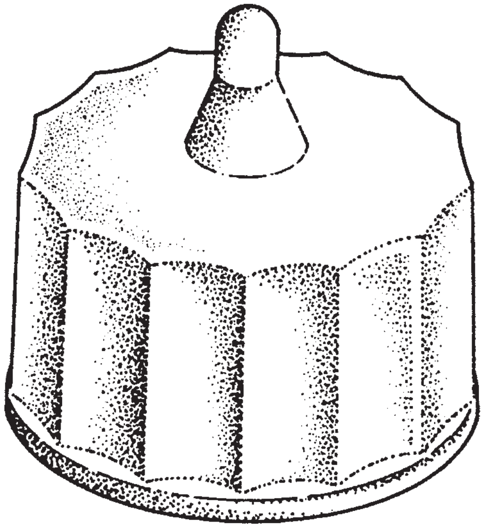

Figure 7. Snip-top closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

Movable-Spout Closures. Also referred to as turret, swivel, or toggle types, the movable-spout concept features a hinged spout that can be flipped into operating position and reclosed with the thumb alone to provide one-handed access and reseal (see Figure 8). Most movable spouts are two-piece constructions, though a one-piece swivel spout design requiring one manufacturing operation has recently been introduced. Newer refinements of this type include the incorporation of a tear band across the spout to provide tamper evidence. Valves-pout closures, such as the "push–pull" closure, are opened and closed in a straight-line, vertical fashion (see Figure 9). "Twist spouts" employ a tapered flange design and open and close by a twisting motion.

Plug-Orifice Closures. These closures first aided in the dispensing of personal-care and cosmetic products, and

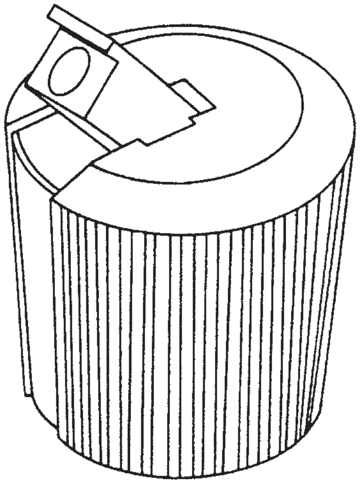

Figure 8. Flip-spout closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

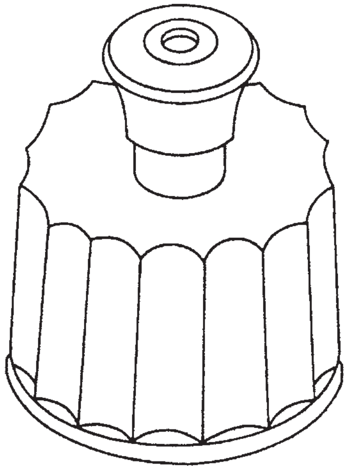

Figure 9. Push–pull closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

they are now used in conjunction with multilayer high-barrier plastic bottles for convenient dispensing of food products (see Multilayer plastic bottles). To some, the hinged-top designs represent the wave of the future in food packaging (21). The closure consists of (a) a dispensing orifice incorporated into a screw-on base closure and (b) a plug, or "spud," hinged within the top of the closure or molded into a flip-up hinged cap (see Figure 10). In the polypropylene plastic versions, the plug and orifice provide a friction-fitting seal that produces an audible "snap" when engaged, an instance where a closure can communicate its sealed state by sound. The top of a "snap-top hinged closure" swings open on two or three external hinges. The "disk closure" is another plug-orifice type, a two-piece design consisting of an orifice closure base and a plug fitment hinged to a round disk which is set into the closure top. By pressing upon the access point, the disk fitment swings up upon its hinges, deactivating the plug seal from the orifice for one-handed dispension. Some of these designs also produce audible "snap" upon engagement and disengagement.

Applicators. There are many different kinds of convenience applicators, many specialized for particular product applications. Four major types are brushes, daubers, rods, and droppers. Brush caps range from small cosmetic brushes to large applicators used for applying adhesives. Sponge, cotton, felt, or wool pads affixed to applicator rods are used to apply a wide variety of household and cosmetic products and are known as dauber caps. Glass and plastic rods are used in the drug and cosmetic industries, such as the balled-end rod used to apply medicines. Glass and plastic droppers, with straight, bent, and calibrated points, are frequently used to provide precise dosages for medicinal products. The three components of the dropper are an elastomeric bulb, the cap, and the pipette.

Fitment Closures. Fitments and fitment closures are designed to regulate the flow of liquids, powders, flakes, and granules. Fitments are inserted into the neck of the container or are permanently attached. Fitment closures incorporate regulating devices into screw-on or press-on caps. Those which plug inside the neck finish include dropper and flow-regulating fitments. "Dropper tips," used with squeeze-type bottles, dispense liquid in increments of one drop and are usually covered with a protective overcap. "Pour-out fitments" control the splashing of liquids by retarding their flow, a frequent problem when precise, small-volume pouring is required from cumbersome containers. Those fitments or closures that regulate solid materials include sifter and shaker designs. Most contain a number of sifter holes in which powdered material can be dispensed evenly. Others incorporate options that permit the material to be shaken-out, poured-out, or spooned. "Shaker caps" and "powder sifter caps" dispense powdered or granular products, sometimes incorporating revolving fitments that provide containment. A wide variety of sliding panels or hinged covers provide the consumer with sprinkling, pouring, or spooning options. Many variant designs combine spouts, sifters, dial disks, and sliding covers.

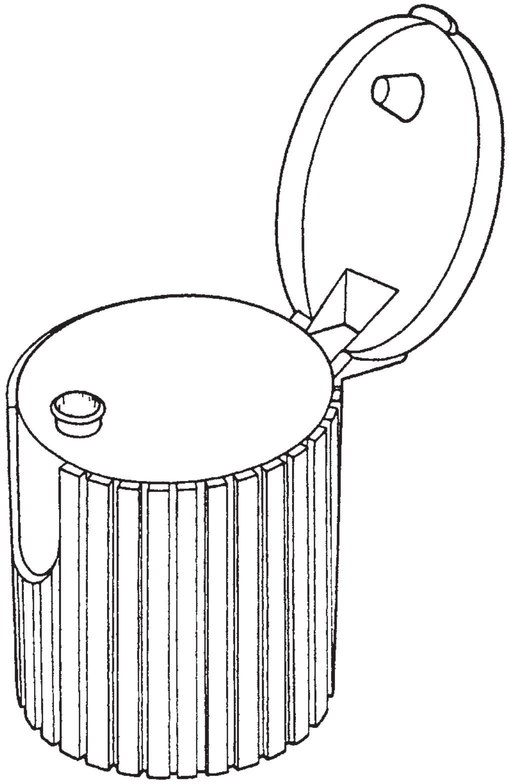

Figure 10. Hinged plug-orifice closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

Spray and Pump Dispensers. "Regular sprayers" operate on a basic pump principle and function with a piston, accumulator, or cylinder. Dispensing a heavier particle size, these sprayers are often used for household and personal-care products. Generally, the smaller the orifice size, the finer the spray pattern. "Fine mist sprayers" dispense in finer particle size as required by some personal-care products. "Trigger sprayers" are larger and more complex in design, offering convenient dispensing for large volumes of liquids. The bulb-and-piston-drive trigger-sprayer units emit spray patterns ranging from a fine mist to a stream. The amount of product delivered by piston-driven "pump dispensers" depends upon its viscosity: The more viscous, the more strokes to prime and the lower the output per stroke (22). Regular dispensing pumps dispense in volumes from less than 0.5 cm^3 to slightly more than 1 cm^3 per stroke in water. Large-volume dispensers range in capacity from 1/8 oz (3.7 mm) to 1 oz (29.6 mm) per stroke.

Control Closure

The first "clerkless" food store appears to have been opened in 1916 by Clarence Saunders. By 1930 there were 3000 of them, soon to be known as "supermarkets" (23). These stores raised new problems of hygiene as more and more products were available in unit packs that had to be capable of withstanding repeated handling, attempts at sampling, and occasional malicious intrusion. The need for consumer product safety grew along with this new concept in food retailing, a need that would become a matter of increasing concern for the U.S. Congress as the number and variety of products increased. Among the legal mandates developed to protect the public against harmful substances are those which specify access controls for containers.

Tamper-Evident Closures. Tamper-evident caps have been in use for years, though earlier they were referred to as "pilferproof caps." Today these metal and plastic caps provide visible evidence of seal disruption and are used for over-the-counter (OTC) drugs, beverages, and food products. The two kinds of TE closures are (a) "breakaway" or "tear band" closures used for pressurized and general sealing applications and (b) TE vacuum designs for vacuum-sealing applications. The closure user can also fulfill tamper-evident requirements through the use of innerseals that cover the container mouth (see Tamper-evident packaging).

Breakaway Caps. In 1982 the FDA established requirements for tamper-evident packaging for over-the-counter (OTC) drug products. The agency defined such packaging as "having an indicator or barrier to entry which, if breached or missing, can reasonably be expected to provide visible evidence to consumers that tampering has occurred" (24). The FDA did not issue rigid standards of compliance but instead listed 11 suggested and approved methods from which a packer may choose. Regulation 6 describes paper or foil bottle seals covering the container mouth under the cap as a means to provide tamper-evidence. Regulation 8 describes breakable caps as another option. The FDA defined these caps as being plastic or metal that either breaks away completely when removed from the container or leaves part of the cap on the container. The breakaway cap is the most common form of tamper-evident closure. With other options, such as shrink bands and strip stamps, a packager needs additional operations and equipment to achieve tamper evidence. Two forms of tamper-evident caps are mechanical breakaway and tear bands.

Mechanical Breakaway. These are threaded caps with perforations along the lower part of the skirt which form a "break line" in the closure (see Figure 11). When the closure is twisted for removal, the band, which is locked to the finish by crimping or rachets, separates from the closure along the break line. The cap is removed and the lower part of the skirt remains on the container neck. The breakaway cap can be efficiently applied, is highly visible, familiar to consumers, and is durable enough to maintain its integrity throughout distribution. Metal closures of this type frequently crimp the band to the container neck for a friction hold. Variations in this type of TE closure include different band designs and methods of off-torque resistance—for example, ratchets on the band that lock to mated protrusions on the finish. TE bands on some plastic closures are shrunk by heat to form a tight fit around the container neck.

Tear Bands. These types, frequently called tear tabs, employ a locked band to prevent cap removal (see Figure 12). Access is accomplished by completely removing the band from the container. Frequently, a protruding tab is evident for the consumer to grasp and commence tearing. Many nonthreaded TE closures utilize this type, such as the press-on friction fit closures found on milk containers. The closure is removed by tearing off the lower skirt, which overrides a bead on the container finish. Most of the removable-band types are made of plastic, usually polyethylene.

TE Vacuum Caps. Marketing leverage, rather than legal mandate, accounts for the expansion of TE into food packaging (25). These measures are not referred to as "tamper-evident" in label or closure communications, but are placed in a more positive light, such as "Freshness

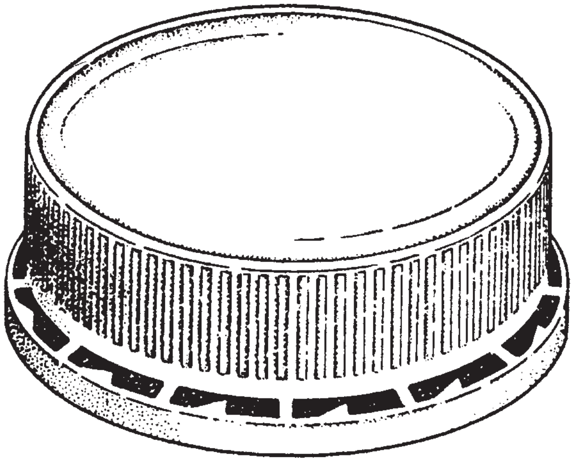

Figure 11. Mechanical breakaway closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

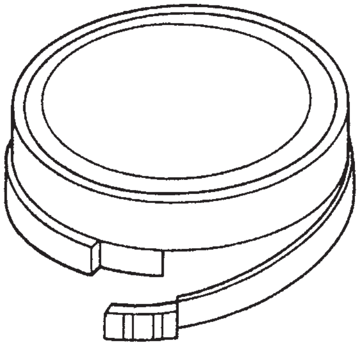

Figure 12. Tear band. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

Sealed" or "Safety Sealed." The two major types of TE vacuum closures are vacuum button and vacuum tear-band caps.

A popular TE option for food products packaged in glass containers under vacuum is the "button-top closure." These include (a) lug versions used for jellies, sauces, and juices and (b) the threaded-seal version popular with the baby-food industry. A safety button, or coin-sized embossment on the top of the cap, pops-up as the jar is opened and its vacuum is lost. Accompanying this is the "pop" that serves as audible evidence of an undisrupted seal. When capped, the embossed button is held down by vacuum pressure, providing the consumer with visual evidence that the container has not been opened. Another type, the "vacuum tear-band closure," is a two-component closure used for the packaging of nuts and condiments. It consists of a metal vacuum lid inserted into a plastic tear-band closure skirt. Protrusions molded into the plastic collar provide friction-fitting resealability for the container.

Child-Resistant Closures. Alarmed by the increasing number of children being harmed through accidental poisoning, Congress acted in 1970 to pass the Poison Prevention Packaging Act. This act, Public Law 91-601, established mandatory child-resistant closures for rigid, semirigid, and flexible containers of such compounds as the Consumer Product Safety Commission (CPSC) deemed dangerous to children (see Child-resistant packaging). Studies revealed that the accidental-poisonings curve in children peaked at 18–24 months, but the manual dexterity curve increased with age, peaking in 4- to 5-year-olds children. Therefore, protocol testing requires testing of children aged 42–51 months. Four major premises were considered in the development of child-resistant closures (26): children 42–51 months of age could not perform two deliberate and different motions at the same time; children of that age could not read, nor could they determine alignments, but they can learn quickly by watching; children are not as strong as adults, but through ingenious use of teeth, table edges, or other tools around them, their persistence would give them leverage to make up for their strength; and although their hands and fingers are smaller than those of adults, children's teeth and fingernails are thin and sharp and can slide under and into gaps. Childhood deaths involving all household chemicals have declined 75% since the first regulation under the act was passed. Packages designed to protect children, however, have come under fire for restricting access by the handicapped and the elderly. Most OTC drug packagers agree that CR devices are generally more burdensome than TE devices. Efforts are underway to develop new CR closures.

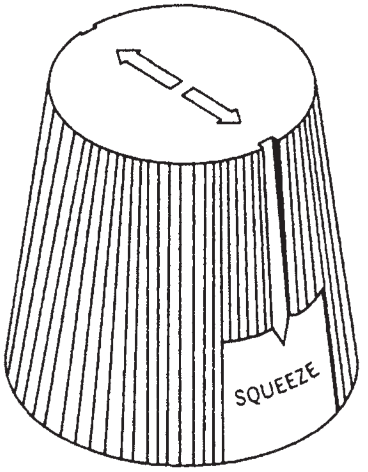

Figure 13. Child-resistant "squeeze-and-turn" closure. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

Child-resistant measures are defined by the CPSC as packaging that is designed to be significantly difficult for children under 5 years of age to open within a reasonable time, yet not difficult for adults without overt physical handicaps to use properly. Under current regulations, a package fails to be child-resistant if more than 20% of a test panel of 200 children are able to gain access, or if more than 10% of a test panel of 100 adults are unable to open and properly resecure the test package (27). The three most frequently used child-resistant closure types are press-turn, squeeze-turn, and combination-lock. The "press-turn" cap is removed by applying downward force while simultaneously turning the cap. "Squeeze-and-turn" caps employ a free-rotating soft-plastic overcap which engages an inner threaded cap or disengages a locking mechanism when sidewall pressure is applied (see Figure 13).

The "combination-lock" caps use interrelated components formed into the cap which must be oriented before the cap can be removed. A common low-cost variety of this closure is the one-piece "line-up, snap-off cap" (see Figure 14). A slight interruption of the thread on the container serves as an engagement point for these caps. A protrusion on the cap fits under the single thread. When the cap is turned, it becomes "locked" onto the container. As with TE closures, many packagers add CR closures to packages not required to have them, even though the cost may generally add 1–5% to the cost of the package.

Special-Purpose Closure

Special-purpose closures are those which are of specialized application or premium design. These include

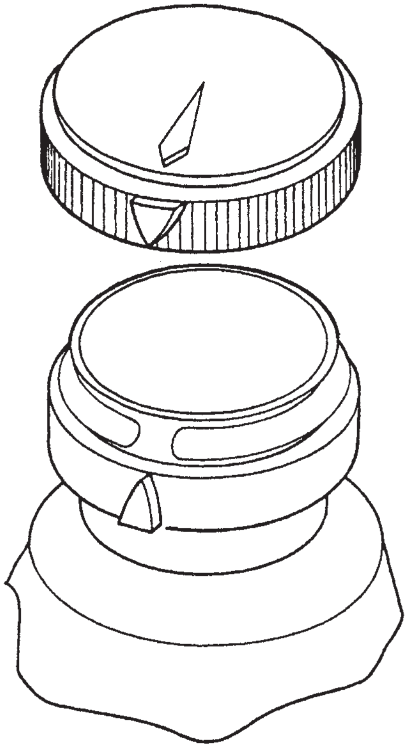

Figure 14. Child-resistant “snap-off closure”. (Courtesy of S. Kiefer and B. Zemlo, Phoenix Closures, Inc.)

aesthetic closures, special-function closures, stoppers, and overcaps.

Aesthetic Closure. The aesthetic closure is an important sales-promotion aspect of the package. It is designed to communicate clearly and powerfully by imagery. Original private-mold glass stoppers used in fragrance bottles, some with lavish sculptural representations, are an example of this type. These are frequently the most expensive forms of closure.

Special-Function Closures. These closures serve a specialized function in the marketplace. There are, for example, closures that vent containers which sustain a pressure buildup. Such pressures can cause the container to rupture, or violently expel the product when the cap is removed. Since venting closures can leak when the container is not in an upright position, they must be used in controlled circumstances. Many manufacturers require a “hold-harmless” agreement as a condition of sale for such closures. Another special-function closure is the twist-off closure for injectables, a two-piece aluminum cap used on parenteral vials.

Stoppers. The wine and champagne industry is the largest user of stoppers. Cork stoppers are standardized by size and grades, the latter according to the degrees of product vintage (28). Stoppers of natural rubber, synthetic silicone rubbers, and thermoplastic materials provide closure in some chemical and biological applications. Rubber plug closures are crimped onto ampules with metal bands and allow for the insertion of a hypodermic needle in medical uses.

Overcaps. The overcap is a secondary cap designed to protect the primary closure, dispenser, or fitment of a container. Metal or plastic overcap designs attach to the container by friction-fit or thread engagement, and they are used to protect aerosol and dispensing fitments. Overcaps frequently double as measuring caps for mouthwash, liquid detergents, and fabric softeners.

SEALING SYSTEMS

Though often the smallest aspect of a package, the seal is responsible for keeping the entire concept intact. If the seal is not maintained by the closure, liner, and container working together, the success of the product is at stake.

Liners

Today’s lining material is either a single substance (usually paperboard or thermoplastic) or a composite material. Synthetic thermoplastic liners include foamed and solid plastics of varying densities. A composite lining material consists of a backing and a facing. The backing, usually made of cellulose or thermoplastic, is designed to provide the proper compressibility to affect the seal and proper resiliency for resealing. Facing materials, representing the side of a composite liner that comes into direct contact with the product, are numerous, as are the variables of product chemistry with which they must contend. Generally, facing materials are thermoplastic-resin-coated papers, laminated papers of foil or film, or multilayer types devised for special applications (see Closure liners).

Innerseals

The innerseal affords TE protection by sealing the mouth of the container. Three common types are inserted by the closure manufacturer into the cap (29). A waxed-pulp backing and glassine innerseal is common within the food industry. After the filling operation the container runs under a roller system which applies an adhesive to the lip of the container, and then the cap is applied. Upon removal, the glassine adheres to the container while the pulp backing remains in the closure. Pressure-sensitive innerseals, generally a foamed polystyrene, adhere to the lip upon application and require several hours to set. Heat-induction innerseals are plastic-coated aluminum foils, often adhered to a waxed pulp base liner. After the cap is applied, the container passes under an electromagnetic field which causes the aluminum to generate heat. The plastic facing on the aluminum subsequently melts and adheres to the container.

Linerless Closures

Plastic linerless closures provide a positive seal in certain circumstances, foregoing the need for intermediary materials and secondary liner-insertion operations. To many packagers, the cost savings provided by the linerless closure can be considerable. The seal of a linerless closure is achieved by molded embossments forming diaphragms, plugs, beads, valve seats, deflecting seal membranes, or rings which press upon, grasp, or buttress the sealing surfaces of the container. Over a dozen types of linerless closures are in common use, each designed to provide a seal at one or more critical sealing surfaces of the container, which include the land surface, the inside edge of the land surface, or the outside edge of the land surface. Some form of land seal in conjunction with a valve or flange represents one type of effective linerless closure design. The land is typically the most consistent sealing surface. A land-seal ring can bite into plastic container finishes or deflect on glass finishes. An inner buttress can correct ovality problems in plastic containers by forcing such off-round finishes back into proper shape.

CLOSURE MATERIALS

Closures are made of plastics, metal, or glass.

Plastic Closures

Molded plastic closures are divided into two groups: thermoplastics (e.g., polyethylene, and polypropylene, and polystyrene) and thermosets (e.g., phenolic resins and urea components) (see Polymer properties). Thermoplastic materials can be softened or recycled by heat; thermoset materials cannot be recycled once they are molded.

Thermoplastics. In general, thermoplastic closures offer the packager light weight, versatility of design, good chemical resistance to a wide range of products, and economical resins and manufacturing processes. Their relative flexibility is essential to contemporary closure design with its emphasis on convenience and control devices. Thermoplastics provide good application and removal torque. They maintain a good seal and tend to resist back-off. Unlike thermosets, thermoplastics can be pigmented in the full-color spectrum in strong, faderesistant intensities.

Most thermoplastic closures are produced by injection molding (see Injection molding), although some are made by thermoforming (see Thermoforming). Polypropylene and polyethylene account for about 90% of all thermoplastic closures.

Polypropylene. Polypropylene (see Polypropylene) has unusual resistance to stress-cracking, an essential characteristic of hinged closures. In thin hinged sections, it has the quite remarkable property of strengthening with use. The homopolymer has limited impact resistance, but it can be modified for better performance. It has excellent resistance to acids, alkalies, oils and greases, and most solvents at normal temperatures. It has the best heat resistance of the polyolefins, with a high melting point suitable for sterilized products, but it becomes embrittled at low temperatures. Polypropylene has better printability than polyethylene, but both are inferior to polystyrene or thermosetting plastics in that respect. As a relatively rigid molded material, it has outstanding emboss and deboss potential for closure communications.

Low-Density Polyethylene. LDPE (see Polyethylene, low density) is resilient and flexible. It is relatively tasteless and odorless, although some organoleptic problems are more prevalent with LDPE than with polypropylene. It provides outstanding moisture protection, but it is not a good gas barrier. LDPE's economy as a closure material is provided by low-cost resins and relatively short injection-molding cycle times. Though it is considered to have good resistance to stress cracking, problems may occur in the presence of certain chemicals such as detergents. Communications embossments or debossments are good but limited by the softness of the material.

High-Density Polyethylene. Compared to LDPE, HDPE is stiffer, harder, and more impermeable (see Polyethylene, high-density). It is tasteless, odorless, and impact-resistant, but it will stress-crack in the presence of some products such as detergents unless it is specially formulated. Its heat resistance and barrier properties are superior to LDPE. HDPE resin is more expensive than LDPE, but it is still considered a relatively low-cost material. A particular drawback to HDPE closures is a potential for warpage and loss of torque.

Polystyrene. Polystyrene (see Polystyrene) is used for about 10% of the closures produced today. Polystyrene homopolymer is attacked by many chemicals, is very brittle, has relatively low heat resistance, and does not provide a good barrier against moisture or gases. Many of the disadvantages of polystyrene are overcome by rubber modification and/or copolymerization.

Thermosets. Phenolic and urea compounds have a wide range of chemical compatibility and temperature tolerances. Some thermosets can sustain subzero temperature without embrittlement and can survive at temperatures higher than 300°F (149°C) (30). The density and rigidity of thermosetting plastics give the material its heavy weight and guard against slippage over threads, a problem with softer thermoplastics such as LDPE. Thermosets cannot provide the color range or intensity of thermoplastics, but they accept vacuum metalizing decoration in silver and gold with superior adhesion qualities. During the molding process, thermosets undergo a permanent chemical change and cannot be reprocessed as thermoplastics can. Thermoset closures are manufactured by compression molding (see Compression molding). Cycle time for thermosets is generally longer than thermoplastics, (30–120 s), depending upon thickness of the product and additives.

Phenolics. Phenol–formaldehyde closures are hard and dense. They are the stiffest of all plastics, but are relatively brittle and low in impact strength. The properties of phenolics depend to a large extent upon the filler material used. Wood flour improves impact resistance and reduces shrinkage. Cotton and rag fiber additives increase the impact strength; asbestos and clay additives improve chemical resistance. Phenolics are resistant to some dilute acids and alkalies and attacked by others, especially oxidizing acids. Strong alkalies will decompose phenolics, but they have excellent solvent resistance. Their heat resistance is outstanding. Phenolics cost less than ureas and are easier to fabricate, but they are limited in color to black and brown unless decorated.

Urea. Urea–formaldehyde is one of the oldest plastic packaging materials, first used in the early 1900s. The resin produces extremely hard, rigid closures with excellent dimensional stability. It has the highest mar resistance of plastics discussed, but is the most brittle. Urea compounds are odorless and tasteless, with good chemical resistance. They are not affected by organic solvents but are affected by alkalies and strong acids. They show good resistance to all types of oils and greases. They will withstand high temperatures without softening. Urea compounds are available in white and a wide range of colors, but with muted intensities compared to thermoplastics. Urea compounds, like phenolic resins, do not build up static electricity, which leaves them free of dust. They are the most expensive of the plastic closure materials.

Metal

Metal caps, the strongest of closures, are used today for general, vacuum, and pressurized applications. Tin-plate and tin-free steel (see Tin mill products) are used in the production of continuous thread, and vacuum press-on closures, lugs, overcaps, and crown caps. The largest market for steel closures is vacuum packaging. Aluminum closures are primarily continuous thread caps and roll-on designs.

Steel Closures. Steel closures are of two materials: tin-plate and tin-free steel. Tin-plate closures are plated steel with a thin coating of tin on both sides that helps protect the base steel from rust and corrosion. There are limitations to tin's protective abilities, however, because tin plate is susceptible to rust when exposed to high humidity. Additional coating operations offer increased protection. Tin plate is graded according to temper. Temper T-1 is soft, and T-6 is quite hard. Closures can be fabricated in any temper, but are predominantly T-2 to T-5. The more common base weights used include single-reduced 80- and 90-lb (36.3- and 40.8-kg) with a cost-reducing trend toward double-reduced 55- and 65-lb (25- and 29.5-kg) plate (15).

Tin-free steel shows promise of becoming the dominant steel closure material. Crown closures are now made primarily of tin-free steel produced as single-reduced stock in a 90-lb (40.8-kg) plate weight for conventional crowns and a lighter, 80-lb (36.3-kg) plate for twist-off crowns.

Aluminum Closures. Light weight, malleability, and resistance to atmospheric corrosion characterize aluminum closures. Some products more corrosive to aluminum than tin plate require special coatings for optimum protection (31). The composition of aluminum alloys varies according to intended use with up to 5% magnesium and lesser elements such as manganese, iron, silicon, zinc, chromium, copper, and titanium (32).

Metal-Overshell Closures. Steel, aluminum, copper, or brass shells slip over plastic closures to form composite "overshell" caps. Freed from finish contours, the smooth, often-tall sidewalls of polished and burnished metals provide aesthetically pleasing characteristics much in demand by the cosmetic and fragrance industries. There is a greater willingness to pay a premium for appearance in these industries because the closure assumes a greater role in sales promotion.

Glass

Glass stoppers are used in commercial glassware and in cosmetic and fragrance packaging. Frequently, a polyethylene base cap assists in friction-fitting the stopper into the bottle. Stoppers for the premium fragrance industries represent superlative designs in molded glass.

CLOSURE SELECTION

Selection

Who selects and specifies the closure depends upon the size, nature, and organization of a company. It may be a president or general manager, a brand manager, package engineer, purchasing agent, or a packaging committee. General guidelines for closure selection are provided below by "The 5 Cs of Closure" (33).

Containment

The essential requirements of containment are product compatibility and the ability to provide functional protection. This objective is reached by evaluated choices in closure method, type, material, and sealing system. Determining the sealing system, for example, may involve decisions as to whether lining materials or a linerless closure will resist permeation of the product to standards. Other important variables arise in the interaction of closure and container and how they affect the efficacy of engagement and seal. Torque considerations include seal pressure (the amount of pressure exerted on sealing surfaces) and strip torque (the torque at which a closure slips over the container threads). As torque is affected by different coefficients of friction between the liner surface and the container, as well as by materials used in closure manufacture, each closure system should be individually evaluated to ensure it meets applicable performance criteria.

Convenience

Opportunities for convenient dispensing may begin with a containment closure that provides a reduced number of turns, or broader "knurls" on the wall of the closure skirt to provide surer opening and closing. Convenience

Table 1. Common Finishes and Descriptions

Finish Designation	Description
120	Two-lug Amerseal quarter-turn finish
140	Four-lug Amerseal quarter-turn finish
160	Six-lug Amerseal quarter-turn finish
326	Pour-out snap cap CT combination
327	Snap cap CT combination
400	Shallow CT finish
401	Wide sealing surface on 400 finish
405	Depressed threads of 400 finish at mold seam
410	Medium CT concealed-bead finish
415	Tall CT concealed-bead finish
425	8- to 15-mm shallow CT
430	Pour-out CT
445	Deep S CT finish
450	Deep CT Mason finish
460	Home-canning jar finishes
600	Beverage crown finish
870	Vacuum side seal pry-off

closures provide many options including simple spouts, plug-orifice snap caps, and, at the mechanically complex end of the continuum, variable-dispersion sprayers and pumps. The method of closure engagement, the requirements of containment, the type of sealing system required, and the premium placed upon convenience will determine options in dispensing closures.

Control

A variety of substances are mandated by law to be packaged as tamper-evident or child-resistant. Cost and sealing needs will determine options in control closures, as well as whether secondary sealing systems are required. More consumer complaints result from inadequate opening and closing of product containers than any other package function. Careful review and testing of control-closure and lining system can prevent potential access problems with elderly or handicapped consumers.

Communications

The shelf appearance of a closure is perceived as a reflection of product quality. The closure communicates this by style and brand signature. In addition it often gives

Table 2. CT Closure Finishes and Pitch

Finish	Description	Sizes (mm)	Threads per inch (Pitch per centimeter)
400	Shallow continuous thread	18, 20, 22, 24	8 (3.2)

a detailed list of ingredients, and sometimes instructs on disengagement. The larger the closure the more it may augment the label in communicating ingredients or nutritional information. Today's closure not only communicates visually, but audibly as well. Steel vacuum button closures "pop" to confirm the freshness of a product, and polypropylene plug-orifice types "snap" when the seal is engaged. Determining the kinds of communications required, and selecting the graphic options which maximize readibility and impact, specify the final appearance, or point-of-purchase impact, of the closure.

Cost

Some cost considerations depend on production requirements. Thermoplastic-mold costs, for example, are generally more expensive than those for thermosets, but faster cycles and resin economy may prove more economical in larger volumes. A cost savings can be realized through the use of linerless closures if they can maintain seal integrity. Lightweighting the closure by selection of an appropriate material has helped to reduce transportation costs for packagers. Another cost consideration is whether a "stock" or a "privately tooled" closure is required. A privately tooled closure is far more expensive to produce, but, again, the packaging concept or production volumes may "economize" it. There is a trend toward specifying stock closures with market-tested designs. Many manufacturers and distributors offer extensive stock-closure lines to the packer.

CLOSURE SPECIFICATION

A closure is designated by a series of numbers and/or letters. An example is the designation 48–400. The first number refers to the inside diameter of the closure as measured in millimeters. Common closure diameters range from 22 to 120 mm.The second set of numbers, the 400, is the finish designation.

The "finish" of a closure is its thread design, and the size, pitch, profile, length, and thickness of the engagement threads on plastic and metal closures and containers. Today there are over 100 glass-finish designations for a great variety of glass containers (see Table 1). Series designations for the most popular CT closures are 400 and 425 for shallow continuous thread designs, 410 for medium CTs, and 415 for tall CTs. For all glass finishes, tolerances have been established by the Glass Packaging Institute, whose closure committee became the Closure Manufacturers Association (CMA) in 1980. Voluntary standards for closures have been issues by CMA which include closures for both glass and plastic container finishes (see Table 2) (34).

Closures developed for glass containers were used for plastic containers when the latter were introduced, but it was soon realized that the contour of a glass bottle thread is not an optimum profile for the plastic bottle. It does not provide accurate closure centering on the finish, nor does it permit higher capping torques required to provide a positive seal on plastic containers (35). The Dimensional Subcommittee of the Society of the Plastics Industry developed specific finish dimensions, tolerance, and thred contours for blown plastic bottles. The two basic contours are the M-style and the L-style. Where a typical glass thread is rounded in contour, the M-style thread engaging surfaces are angled at 10° and the L-style is angled at 30°. Both contours increase sealing abilities for closures on plastic bottles.

Four critical closure dimensions are represented by the four letters T, E, H, and S (see Figure 15). T is the dimension of the root of the thread inside the closure. E is the inside dimension of the thread in the closure. H is the measurement from the inside top of the closure to the bottom of the closure skirt. S is the vertical dimension from the inside top of the closure to the starting point of the thread. These critical closure dimensions and tolerances for metal and plastic closures designed for glass and plastic containers are represented in the voluntary standards for closures as issued by CMA.

CLOSURE TRENDS

Closure concepts seem to have changed more in the last 40 years than in the last 4000 years. Yet changes in state-of-the-art concepts, materials, and manufacturing processes do not represent the real driving forces behind today's closure developments. The industry is consumer-driven. More and more, a premium is readily paid for convenience. The industry has also been awakened, sometimes with great shock and alarm, to the powers of human foible, which demands a redefinition of access control.

Functional Trends

Today's consumer has been characterized as oriented toward health, diet, appearance, longevity, and convenience

(36). Households with two working spouses, increased single households, and retiree households all command a market for convenience packaging (37). The dispensing closure is no longer a functional appendage, but is seen as an integral part of the total package (38). Today's convenience closure is time- and labor-saving. It prevents spills, leaks, and drips. It provides measured-dose dispensing and can visually signal tampering (39). As plastic containers continue to penetrate the food market, the closure will broaden squeeze-dispensing. Other functional trends include the expansion of TE food packaging, larger closure sizes, increased use of stock caps to avoid private-mold costs, and new concepts in linerless closure design. Since innovative packaging can increase market share, special emphasis is being placed on improved tamper-evidence, child-resistance, and convenience designs. These functions will no doubt become more and more integrated into one cap. Closures are now being marketed which provide for both TE and CR.

Conclusion

The ductility of plastics accounts for the fast progress of plastic closures, which will undoubtedly take a still-larger share of the market in years ahead (40,41). Polypropylene represents the largest volume and highest growth plastic material with 200 million (10^6) lb (90,700 tons) used in the production of plastic closures in 1984, an increase of 33% within 4 years (42). Polystyrene has shown slight growth in recent years, with 72 million lb (32,700 tons) used in closure production in 1984. Closures accounted for 66 million lb (29,900 tons) of HDPE consumption, an amount that has remained relatively stable over recent years. LDPE (37×10^6 lb or 16,800 tons) and PVC (35×10^6 lb or 15,900 tons) have both remained stable in recent years. As for thermosets, 15×10^6 lb (6800 tons) of phenolic resins and 11×10^6 lb (5000 tons) of urea compounds were used in closure production in 1984 reflecting little growth in recent years.

Metal thread-engagement closures continue to assume a position in the food and pharmaceutical industires due to new fabricating, plating, and light-weighting technologies which will keep steel and aluminum closures competitive.

CLOSURES, BREAD BAG

G. E. Good
Kwik Lok Corporation

INTRODUCTION

Packaging bread in polyethylene bags is an almost universal method of bread packaging. Customer preference for easy opening and reclosing the package influenced the development of bag closures at the very start of bread bagging. Closing by tape, which had been used in connection with early bagging methods, was quickly discarded when the bulk of the bakery production lines changed to the new polyethylene bagging and closing equipment. Tape was neither convenient for the consumer nor fast and dependable for the bakers. Two types of closures and automatic equipment systems have emerged as the standards of the baking industry. Developed simultaneously, these are the wire tie and the plastic-clip closure.

WIRE TIES

The predominant automatic wire-tie equipment now being used by the United States baking industry is from the Burford Corporation, Maysville, Oklahoma. Different models are required to attach to the different types of installed bread and bun baggers. This type of automatic bag-closing equipment is limited to about 60 packages per minute. The wire ties used in automatic application are 4 in. (10.2 cm) long. The wire comes on reels of 6000 ft (1829 m), 18,000 closures per reel, and is cut to length as it is applied to the package. Colors are available for color-coding purposes (see Figure 1).

The wire tie has a left- or right-hand twist, depending on the production equipment. Wire ties are available with all-plastic, laminated plastic/paper, along with all-paper covers over the wire core. The quality of the wire tie must be carefully maintained; otherwise, separations of the laminations occur, leaving the bare wire exposed. Source of the wire ties is Bedford Industries, Worthington, Minn.

PLASTIC-CLIP CLOSURE

Plastic-clip closures are produced from medium-impact polystyrene (see Polystyrene). The material has a resiliency that allows it to return to its original shape after many reuses by the consumer (see Figure 2). They are

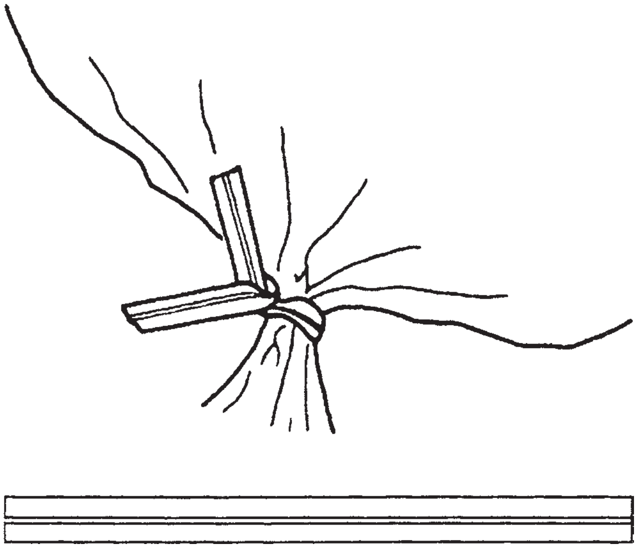

Figure 1. A wire tie for a bread bag.

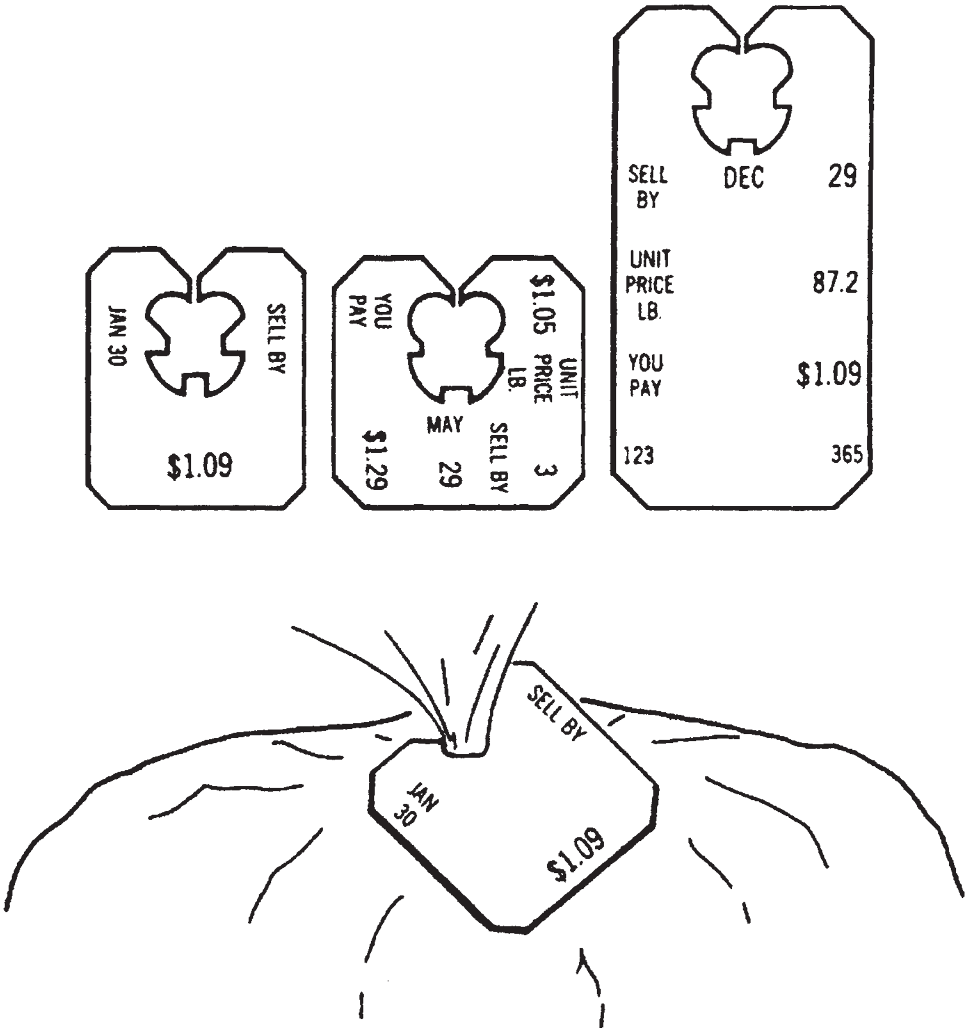

Figure 2. A plastic-clip closure for a bread bag.

furnished with various aperture sizes to accommodate the different polyethylene bag widths and thicknesses. The proper selection of aperture size can result in an almost air-tight package. Colors are available for color-coding purposes. The plastic-clip closures are provided in reels of 4000 or 5000 closures per reel.

The Striplok closures and closure-applying equipment are manufactured by the Kwik Lok Corporation, Yakima, Washington. The equipment is simple and dependable, with production speeds up to 120 bakery bags per minute. The Kwik Lok Corporation manufactures two basic machines that attach to any of the common bagging machines from Formost Packaging Machines, Inc., Woodinville, Washington; United Bakery Equipment, Compton, California; and AMF, Inc., Union Machinery Division, Richmond, Virginia. By mounting an imprinter on the closing machine, imprinting can be done on the plastic clip. Many bakeries are required to print on the package the price per pound, the unit price of the package, and the "sell by" date (see Code Marking and Imprinting). Printing on the polyethylene bag lacks legibility and is often obscured by the package graphics. Three sizes of Striplok closures are available to facilitate compliance with regulatory coding and dating requirements.

COATING EQUIPMENT

Stefano Farris
Food Science and Microbiology,
University of Milan, Milan,
Italy

Coating is defined as the process of applying at least one layer of a fluid or melt substance onto the surface of a material (paper, plastic, metal) in the form of films, sheets, or shaped structures (i.e., bottles and jars). The coating process differs from laminating, which encompasses all processes in which two or more plastic or nonplastic materials (paper, aluminium foil, cellophane) are combined together to form a composite multilayers structure. Bonding between the different layers can be achieved by means of several techniques, including thermal or chemical treatment, use of tie layers (adhesives), and curing systems. As for the lamination, the main advantage arising from the coating process is obtaining composite structures having specific properties and characteristics not available in any of the individual parts taken alone. Some functional performances that can be improved, for instance, include mechanical properties, barrier to gas and water vapor, and acceptance of printing and labeling. In addition, it is a common practice to use multilayered films for food packaging applications for an economical reason. In fact, combining different films often lead to a reduction of the costs that should be incurred if monolayered structures were used for the same purpose. This is because each different single thin layer can function in a specific way (e.g., as a barrier against light or gases, as a heat or cold sealant, as a protection against abrasion), differently from the performances of a single layer.

Even if similar to other processes (e.g., lamination), some prerequisite properties of materials are specific for the coating method. These include: the capacity to be applied from high-speed rolls without forming foam; the ability to be spread uniformly and quickly over the wide surfaces of fast-moving substrates; generating fairly strong initial bonds to enable handling in the coating machinery; and rapid conversion to the final desired forms as well as the retention of necessary bonding after drying or curing. In addition, the coating process is useful and suitable only when very thin layers have to be applied (from about 0.5 to 15 μm). For thickness greater than 15 μm, solution coatings or dispersions are not often applied, except by different subsequent steps. Finally, coating when applied must be sufficiently fluid to be spread into an evenly thin layer across the web. For that reason, the only polymers practical as coatings are those that can be made directly by emulsion polymerization. Therefore, coatings are applied as solutions in organic solvents, as aqueous solutions or emulsions, as a hot melt (solid molten or softened by heat), or as a reactive liquid that solidifies by a polymerization reaction induced either thermally or by radiation. Extrusion coating, which is similar to hot-melt coating, is discussed separately (see Extrusion Coating).

Coating equipment and processes have been reviewed in several books (1–7). As a result of new materials being recently developed and the always increasing demand for high-performance solutions, an interest in the world of coatings has rapidly increased, and the opportunity of using new deposition techniques has become broad and various. Consequently, different equipments have been developed, and summarizing them in few pages will not be an easy task. Dedicated and updated textbooks provide, in an exhaustive manner, detailed information (8–10).

Coating is usually applied to the web material wound in rolls. This process requires unwinding the web, applying coating, drying, and then rewinding the web again. For this purpose, different coating and handling equipment are required. Coating equipment is intended as the collection of machines and devices used to put into practice the related process. It consists of four main components: (1) a surface treatment device, (2) a coating head, (3) a dryer or other coating solidification station, and (4) web handling equipment and accessories (drives, winders, edge guides, coating thickness controls, etc.).

SURFACE TREATMENT DEVICES

Some webs (e.g., polyolefin films) show low surface energies such that the application of a coating is very difficult to achieve. For that reason, these substrates must be treated before the coating process, in order to modify their surface energy level and hence increase the probability of a satisfactory bond between them and the coated substances. The same treatments are needed for other processes such as printing or laminating. The most important concept is that after the treatment, the surface energy of the polymer (i.e., its surface tension) must be higher than that of the coated substance to accomplish the right bond between components.

Different methods can be employed for surface treatment: corona discharge, gas plasma, etching with chemicals of continually moving webs, and gas flame treatment of molded objects for example. The most widely used is corona discharge, which consists of impinging a high energy electrical discharge on a surface, leading to a surface more suitable to adhere to other substances. Plastic film is unrolled between both a metal roll and a high voltage source, producing a voltaic arc (also called corona) which generates oxidation and other effects on the surface. In most cases, webs are treated in line (Figure 1), just before they undergo the specific coating process. This is because of the disappearing nature of the treatment, which effect gradually dissipates over time. Ozone is a byproduct of the corona-discharge method, and provision must be made for its removal.

Different methods can be used in practice for evaluating the goodness of the treatment, such as ink retention, contact angle, and water spreading. However, the most widely used is that referring to the ASTM standard method (11). Further methods have been successfully set, as the simple and rapid one to be used in production proposed by Sprecher (12).

COATING HEADS

The coating head accomplishes two functions: applying the coating to the substrate and distributing a metered amount uniformly over the surface. Metering may be combined with the coating application, or it may be carried out separately immediately following the coating deposition. There are many designs of coating heads, but they fall into three major categories: (1) roll coaters; (2)

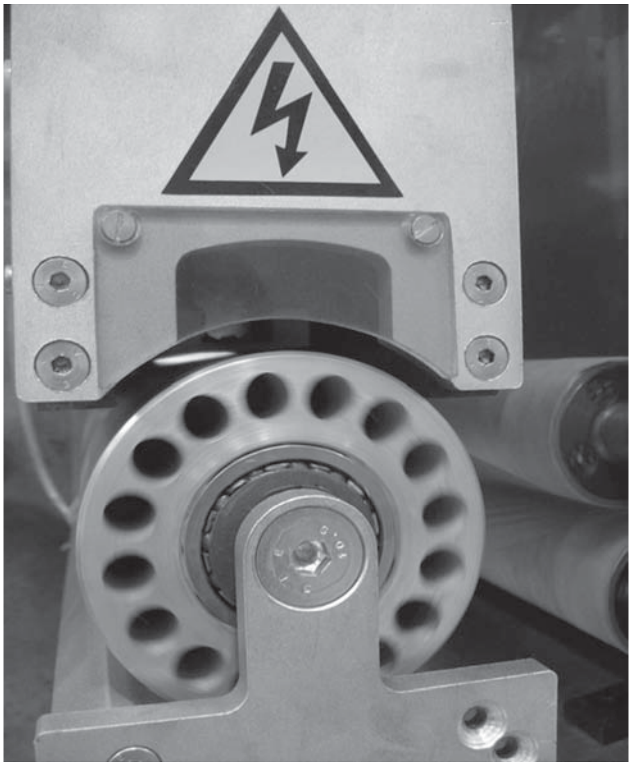

Figure 1. Corona treating equipment mounted on a coating line. Note the voltaic arc (the small clearest zone in the center). (Courtesy of Metalvuoto Spa, Roncello, Italy.)

knife, blade, and bar coaters; and (3) hot melt coating. General characteristics of most important coating heads are shown in Table 1.

Roll Coaters

Roll coaters are most widely used and can be subdivided into several major types: direct, reverse, gravure and calender coaters.

Direct Roll Coaters. In this case, substance is deposited by contact between the moving web and the rotating applicator roll. The roll picks up coating from a specific source, either a different roll (transfer roll) or a bath, and then transfers it onto the web surface. The web carrying roll and the coating applicator roll rotate in the same direction. The thickness of the coating can be modified by the speed of both the application roll and the web, and also by considering the physical properties of the coating and those of the web. In fact, the more viscous the coatings and the lower the speeds for their application, the thicker will be the final dry coatings. Conversely, the thinnest will be obtained with low-viscosity coatings applied at high speeds. The coating is split evenly between the roll and the substrate as shown in Figure 2. Coating splitting produces an uneven surface, which sometimes can be a problem. For that reason, a steel backing roll covered by rubber represents a useful tool for accommodating some irregularities in thickness of the substrate. This is particularly evident when working with fibrous webs (e.g., paper). They offer a sponge-like surface that quickly absorbs water from wet coating. On one hand, this speeds the drying of coating; on the other hand, it may interfere with the achievement of smooth and not porous coatings. As a result, several primers of polymers can be used in order to avoid the coating penetrate into the substrate as paper. On the contrary, plastic films do not absorb water or solvent-dissolved coatings. However, also for this kind of substrate, primers are often used to improve the adhesion between the substrate itself and the coating—that is, to bond the coating to the film. Many different coating heads utilize the direct roll-coating principle. A squeeze-type roll coater is shown in Figure 3. Direct roll coaters can be used to coat sheeted material as shown in Figure 4. The coating is metered in a gap between accurately machined metering and applicator rolls. Sheets are fed through a nip formed by applicator and carrier rolls. Direct roll coaters are used widely for packaging materials: paper sizing, paper color coating, overcoating of blister packaging board, and heat seal coating.

Kiss roll coaters apply the coating to the web from a pan (Figure 5). The amount of coating deposited is not controlled by the coater; therefore, kiss roll coaters usually employ a metering device, such as wirewound rod, to remove the excess coating. Such a rod is installed immediately after the coater and is a part of the coating head. Kiss roll coaters can be also run in the direction opposite to the web travel. In such cases the web wipes the roll clean.

Transfer roll coaters of modern design are used for deposition of very lightweight coatings accurately (Figure 6). One of the important uses is the application of 100%

Table 1. Characteristics of Various Coaters

Coating System	Deposit Weight Range (g m^{-2})	Coating Speed Range (m min^{-1})	Viscosity Range (cP)
Knife-over-roll	10–100	150	1000–30,000
Floating knife	2–30	150	500–15,000
Air knife	3–30	500	100–1000
Blade	5–20	100–1200	2000–10,000
Wirewound rod	5–20	150	100–2500

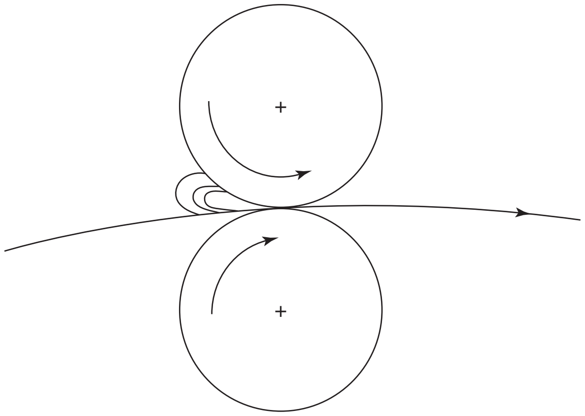

Figure 3. Squeeze coater.

solids radiation curable silicone release coatings, which are used for pressure-sensitive adhesive labels and other products. The transfer roll coater is a direct roll coater. The rubber-covered applicator roll is run 5–25 times faster than the transfer roll, and this decreases the amount of coating transferred to the substrate by that factor.

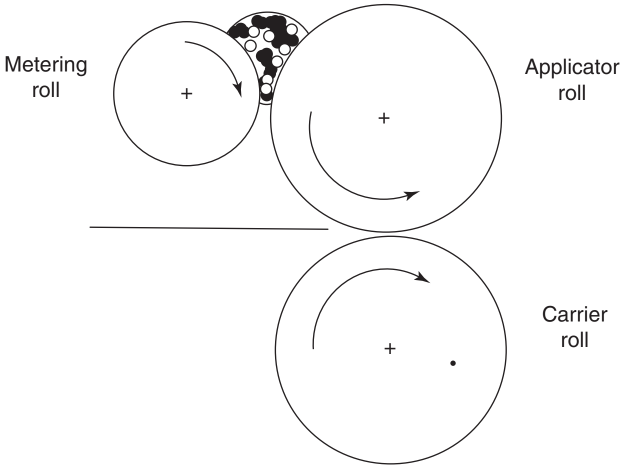

Figure 4. Direct roll sheet coater.

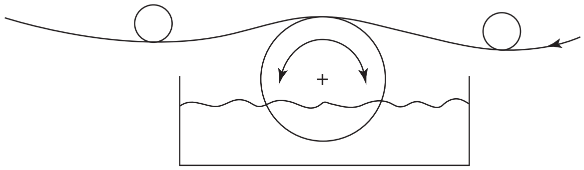

Figure 5. Kiss-roll coater.

Reverse Roll Coaters. The main feature of the reverse roll coater is that the applicator roll rotates in the direction opposite to the web travel (therefore, reverse roll) and transfers the coating by wiping. These coaters are versatile machines. Among the advantages of reverse roll coating are (a) the possibility to handle a wide range of coating thickness and viscosities and (b) greater weight of coatings. Solids in the range of 10% (w/w) are typical. Moreover, the reverse roll coating leads to a more thorough and uniform deposition of the wet coating and a smoother dry coating as well. In addition, this kind of equipment can work at higher line speeds than the direct system, achieving excellent results while handling weak webs. Solvent solutions, aqueous coatings, and less frequently hot melts are coated on these machines. Reverse roll coaters are expensive; rolls must be accurately machined. These coaters are available in several designs: Feed location may be varied from nip to pan; three or four rolls may be used. In the case of a nip-fed coater as shown in Figure 7, the coating is delivered to the nip between metering and applicator rolls, and dams are used to contain the coating. A gap set between these two accurately machined rolls determines the amount of coating carried by the applicator roll. The web usually runs faster than the applicator roll, and the amount of coating deposited depends on the ratio between the speed of these two rolls (wipe ratio) as well as on the gap between metering and applicator rolls.

Gravure Coaters. These machines are inexpensive and highly reliable, but limited to the coating thickness and viscosity that can be handled. The main advantage of this system is related to the possibility of controlling

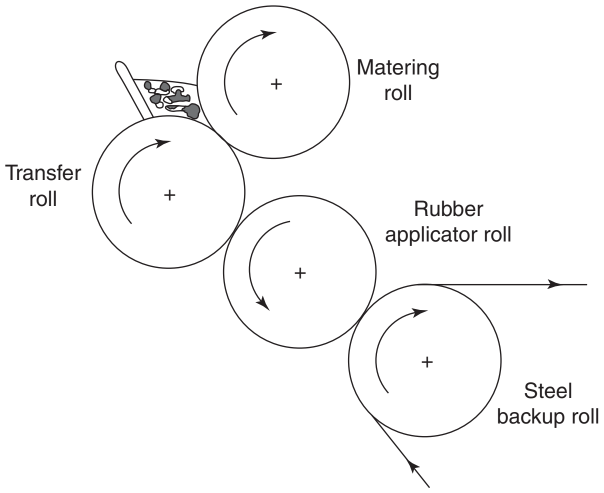

Figure 6. Transfer coater.

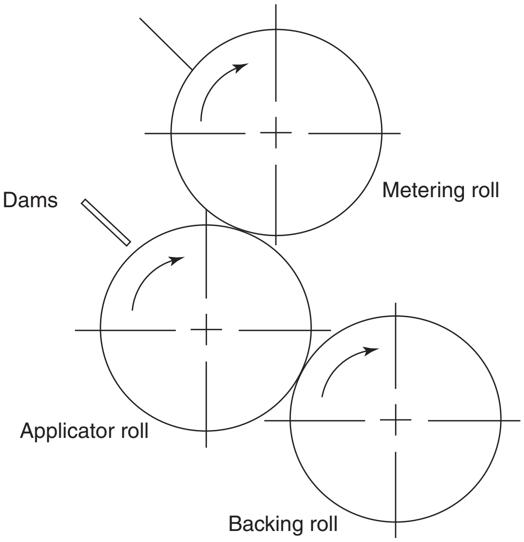

Figure 7. Nip-fed reverse roll coater.

accurately the amount of substance applied on the web (i.e. the thickness of dry coatings) as well as its homogeneity. It is agreed that gravure coating represents the most uniform and reproducible system to coat moving web of material. An engraved chrome-plated (sometimes ceramic coated) copper roll is wetted with the coating, excess is removed by a doctor knife (scraper) (Figure 8), and the coating remaining in the engraved cells below the roll surface is transferred to the web at the gravure roll/backup roll nip (Figure 9). Three engraving patterns are commonly used for coating purposes: pyramidal, quadrangular (truncated pyramid), and tri-helical. The amount of coating depends on the liquid volume retained in the cells—that is, on the cell depth and their density, referred to as *screen* or *ruling* (the number of cells per unit length). The coarser the screen, the larger the diameter and depth of cells and the higher the deposit. It is important that the amount of coating entrapped in the depressions of the gravure roll remains constant over the life of the roll, guaranteeing a virtual constant uniformity during the whole production process. The fluid viscosity must be sufficiently low to allow the transfer of the coating from the cells to the web at nip pressure. Thickness typically ranges between 3 and 25 μm, even if lower values (0.5 μm) can be easily obtained. In the direct gravure arrangement (Figure 9), the engraved roll contacts the web directly. In offset gravure the coating is first transferred to a rubber-covered roll and then transferred to the web. In this case, it should be important to use a covering elastomer resistant to solvents eventually present in the coating solution. Offset gravure allows the use of higher nip pressure and is therefore more suitable for coating rough-surface substrates. It also allows the coating to level on the roll surface before its transfer to the web. Different matrices, substances, and formulations can be used as coatings to be applied through this system. Latexes, solvent-based coatings, water-based coatings, hot melts, and reactive (curing) coatings are the most frequently employed. Gravure coating is widely used for various decorative and functional lightweight coatings on plastic films, paper, and other packaging substrates. The same technique is suitable for printing, wherein coating deposition takes place only to limited areas of the substrate. In this case, a given roll delivers a fixed amount of coating; that is, it deposits noncontinuous coating.

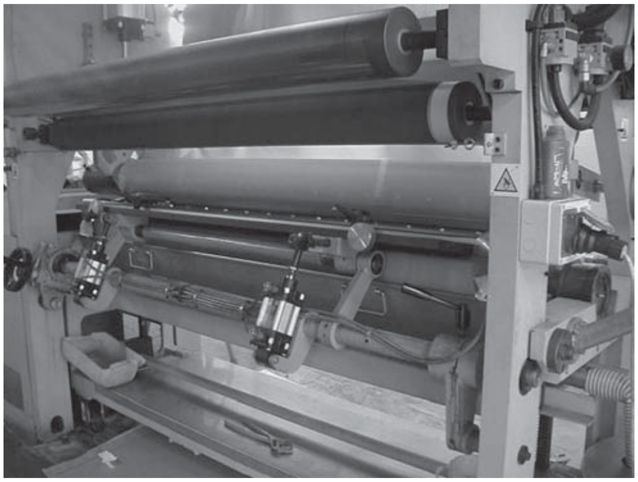

Figure 8. Gravure coater showing the doctor blade supported by two pistons. (Courtesy of Metalvuoto Spa, Roncello, Italy.)

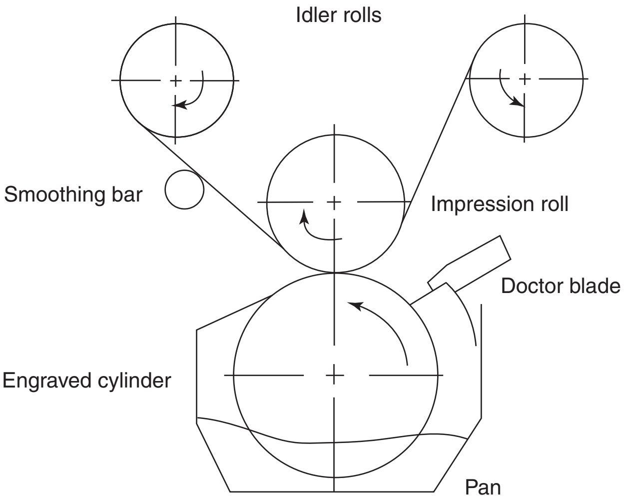

Figure 9. Direct gravure coater.

The most recent machines are able to handle different substrates continuously—that is, without arresting the whole plant in order to substitute the coated roll with another one. Hence, the coating application can take place by replacing automatically online the just-coated web with a new one previously mounted on the machine (Figure 10). Obviously, to avoid the stop of the coating line, the different rolls must have the same width and have to be coated with the same matrix. The final result will be the increased line speed in the coating process and the enhancement of the output.

Calender Coaters. The calendering process involves squeezing a polymeric material between steel rolls into a

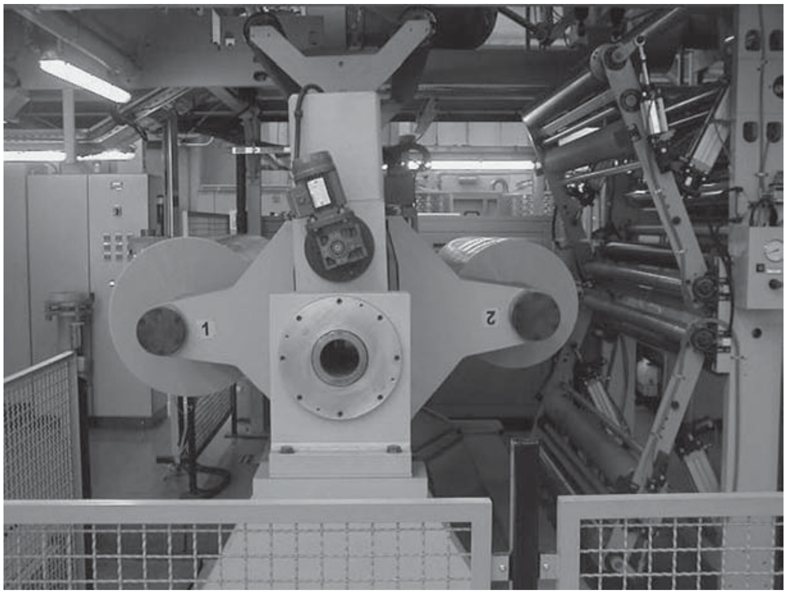

Figure 10. Two rolls simultaneously placed on the same coating line. Roll 2 (working) will be automatically substituted by roll 1 (not working). (Courtesy of Metalvuoto Spa, Roncello, Italy.)

thin sheet. The formed sheet may be then laminated to a substrate. Rubber and PVC are most often used for calender processing. Calendering is rarely used for manufacturing packaging materials.

Knife and Bar Coaters

Knife and bar coaters are metering devices that remove excess coating and allow only a predetermined amount to pass through.

Knife-over-Roll Coaters. Knife-over-roll is a useful inexpensive method for the application of coating, having both high viscosity and heavy weights. As a result, it is primarily used to coat paper and textiles. A knife-over-roll coater consists of a knife placed against a roll. The knife may be either straight-edged or "J"-shaped, depending on the specific application. The coating weight is adjusted by setting a gap between the roll and the knife. An excess coating is delivered to the bank before the knife, and the desired amount is metered by the gap. An accurately machined steel roll and knife are used (Figure 11). In another version of a knife-over-roll coater, a rubber-covered roll is used and the coating weight is determined by the gap and rubber hardness (its capability to deform because of hydraulic pressure).

Other Knife Coaters. Knife coaters are used in many other configurations: floating knife, knife-over-blanket, knife-over-channel, and inverted knife. These methods are used more frequently in the textile industry.

Blade Coating. Flexible-blade coating is the dominant process for applying pigment coating over paper and board. Clay coatings give a smooth and printable surface. Blade coating processes are suitable for high-speed application such as required in paper converting. The coating head consists of a coating applicator, such as roll or fountain, which applies an excess of coating to the paper. The excess coating is removed by a blade (Figure 12).

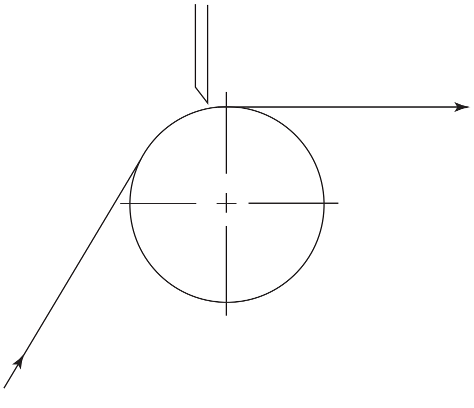

Figure 11. Knife-over-roll coater.

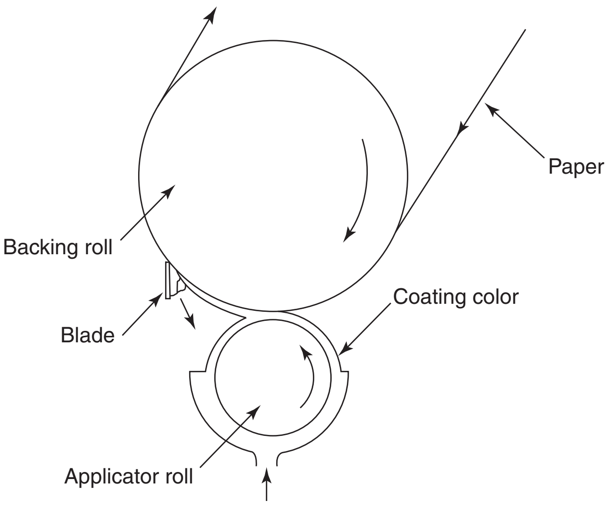

Figure 12. Blade coater.

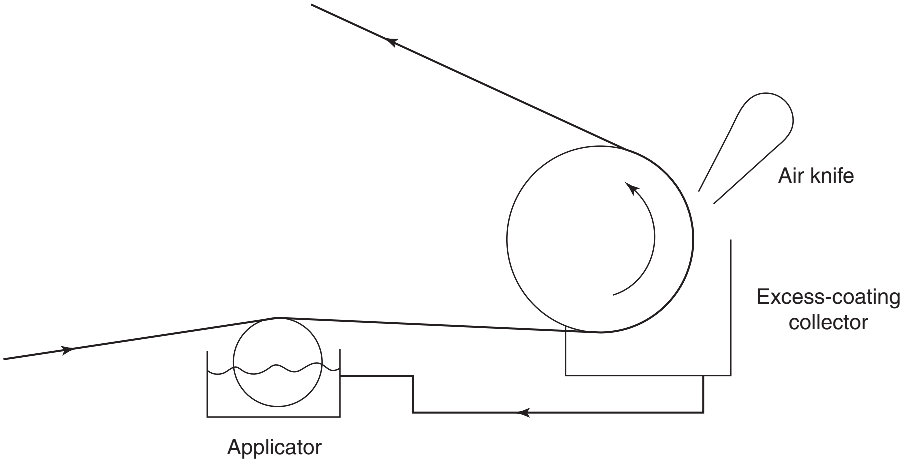

Figure 13. Air-knife coater.

Several modifications of blade coaters are available employing different blade designs, different methods of applying and regulating blade pressure, and different ways of applying the coating to the paper. Machines capable of applying coating to both sides of the web are available.

The air-knife system consists of a head with a narrow slot emitting a ribbon of pressurized air through nearly the width of the web being coated. In air-knife coating an excess of material is applied to the web surface usually by a kiss-roll applicator or by spraying as a wet matrix to be dried as quickly as possible. The excess is removed by the air knife, wherein pressurized air is forced into the head and is accelerated at the slotted nozzle. The escaping airstream impinges on the coated web and removes excess coating (Figure 13). Air-knife coaters provide an even thickness of the coating rather than a flat-surfaced coating. It is the preferred method for coating paper, although in the recent years it is being replaced by more developed blade coaters for paper-coating applications.

Wirewound-Rod Coater. *A* wirewound-rod coater (Meyer rod) is a simple metering device widely used in applying lightweight coatings over film and paper packaging materials. The coating is firstly applied by an applicator, usually a kiss roll, and then uniformly spread by a rod wound spirally with stainless-steel wire; finally, the excess of coating is removed by the scraping action of the rod. Usually, the wire-wound rod is rotated counter to the rotation of the web, allowing a more precise control of the process. Moreover, the rod is rotated to help dislodge any particles that might become trapped between the wire and the web and to ensure uniform wear of the wire. The rod wipes the surface clean, except what escapes through the spaces between the wires. The thickness of the wet coating can be easily established by selecting the diameter of the wire winding on the rod. In particular, the following equation can be taken into consideration for this purpose:

$$K = D\left(0.5 - \frac{\pi}{8}\right) = 0.1073(D)$$

where K and D are, respectively, the thickness of the wet coating and the diameter of the wire, expressed in the same units. As it can be seen, K is practically 10 times less than D. It means that, for instance, a wire 125 μm in diameter will spread a wet coating 12.5 μm thick. In some cases a rod wound with two wires could be used, with the second one of lesser diameter than the first. This allows us to spread coatings thicker (about 500 μm) than those obtained by using a single wire and to provide for coatings that flatten out faster. Wire rod coating is particularly useful to lay down thin layers of PVDC latex to paper. In general, paper should not be extensible, to avoid the fact that the tension developed to hold the web tightly against the rod coater will stretch the extensible film (such as a polyolefin) enough to jeopardize the process. On the contrary, stiff plastic films like PET as well as cellophane, papers, and paperboards are suitable to be worked in rod coaters.

Hot Melt Coating

Hot melting coating concerns the application of molten polymers characterized by an intermediate molecular weight. It can be considered as a variation of extrusion coating. Both processes use a heated coating material to be applied onto a moving web. The major difference is linked to the viscosities, much lower for the hot melting coating. Another further difference concerns the magnitude of pressure applied during deposition of the coating. In fact, hot melts are applied with little pressure. Different materials can be used in the hot melting process, such as waxes, resins, and thermoplastics of low molecular weight. However, blends of polyolefins and poly(ethylene-vinyl acetate) with resins and waxes represent the majority of applications in food packaging. In particular, these hot melts are widely used to obtain (a) heavy coatings to wrapping cases for waterproofing and (b) lighter layers to food cartons for frozen foods. Typical hot melt coating methods include: slot-orifice coating, curtain coating, and roll coating.

Slot-Orifice Coating. In the slot-orifice coating, the coating is forced through a narrow slot extending the full width of the web. The slot die is designed to give a uniform coating thickness across the width. A slot-orifice coater is widely used for manufacturing hot-melt

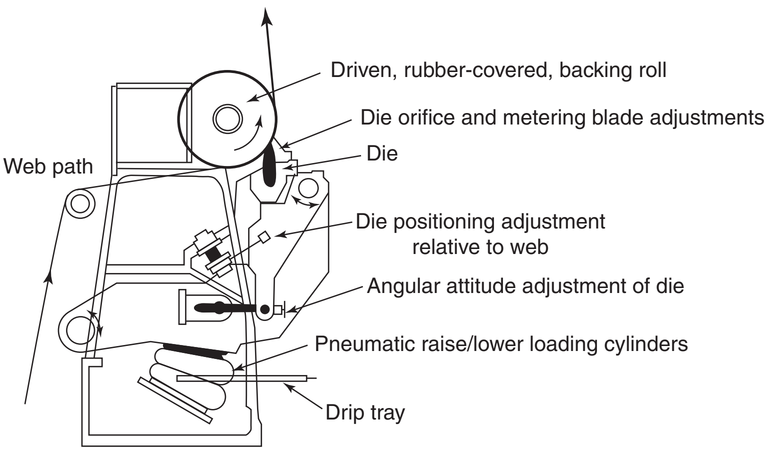

Figure 14. Hot-melt slot-orifice coater. (Courtesy of Black Clawson Co.)

pressure-sensitive adhesive packaging tapes (13) and for applying waterproof coatings over paper. It also found applications in aqueous emulsion coating. A slot orifice coater is shown in Figure 14.

Curtain Coating. Curtain coating is similar to slot-orifice coating, except that the liquid curtain coming from the die is allowed to drop down some distance to the material to be coated. The slot width is adjustable and the flow is regulated by the slot width, by the liquid level (in weir-type coaters), or by pressure and pump speed in enclosed-head coaters, as well as by the distance between the slot and the coated material, which determines the acceleration of the curtain. This technique is used for heavier coatings. In the packaging area, curtain coating may be employed to deposit a hot wax coating over corrugated board.

Roll Coating. Both direct and reverse roll methods can be used for the application of hot melt coatings to the substrate. Moreover, the rolls used for spreading the coatings can be either smooth or engraved.

The application of the hot coatings usually takes place at speeds ranging from 100 to 500 $\mathrm{m\,min^{-1}}$ at coating weights of 3 to 600 $\mathrm{g\,m^{-2}}$.

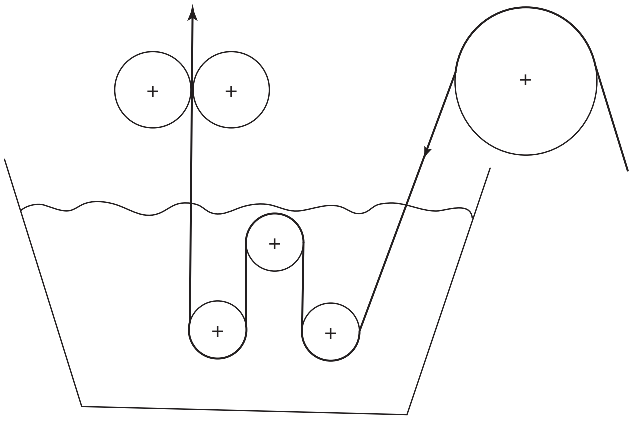

Figure 15. Sawtooth saturator.

SATURATORS

The saturation or impregnation process is used to treat paper and paperboard with a polymeric binder to improve the web's strength, barrier properties as packaging material, and resistance to water and grease. The process consists of immersion of the web into a coating bath, or applying an excess of coating on both sides and then squeezing or scraping to remove the excess. The coating may penetrate the web or most of it may remain on the surface, depending on the product needs.

Saturating machines consist of a web-immersion section and a metering section. Several saturating arrangements are used. Figure 15 shows a conventional sawtooth saturator followed by squeeze-roll metering. Other types of metering arrangements are inflatable bars, bar scrapers, doctor blades, and similar devices.

DRYING

Coatings applied as solutions or emulsions must be dried in order to remove the liquid vehicle. Heat and mass transfer take place simultaneously during the drying process. Different methods are used in commercial practice, including convection drying with heated air; hot air impingement; infrared; conduction heating; and radiofrequency heating.

In the *convection* drying method, the wet web is passed through a tunnel oven heated by a flux of hot air forced in the same direction (sometimes in the opposite direction) as the web.

Impingement drying consists of a forced air flux able to dry the wet web more rapidly than convection drying. This is because the method exploits the increased heat transfer achieved by blowing rapidly heated air over the web surface.

Infrared drying is carried out by using a heating source emitting infrared rays. Indeed, infrared radiation is usually used in combination with convection and impingement drying, to raise quickly surface temperatures and hence to increase the efficiency of the solvent removal by forced air.

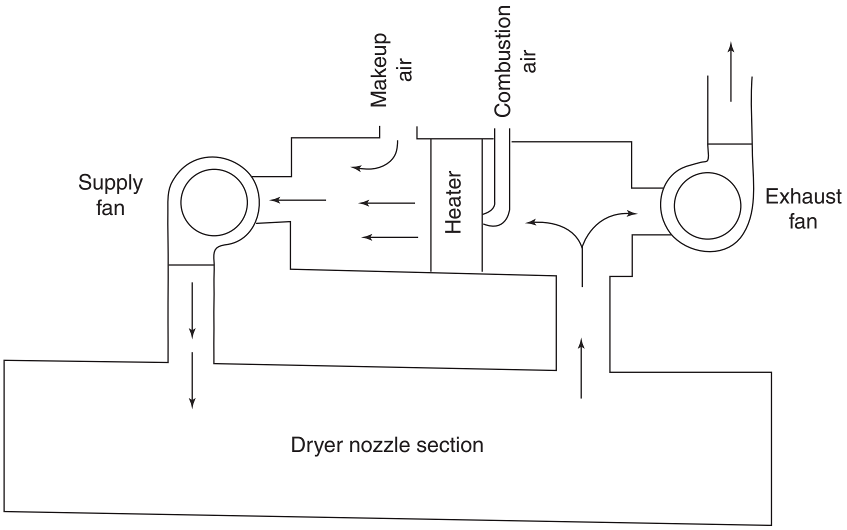

Figure 16. Airflow in a convection oven.

Conduction drying is obtained by the direct contact of the web with a heated surface. The final dried substrate (paper, paperboard, pulp, and laminations of porous webs) is generally obtained very quickly, usually using heated rotating cylinders.

Radio frequency (or dielectric heating) is a powerful drying method especially for heavy coatings and water-based systems.

Drying is a fundamental step in the coating process. Incomplete or partial drying could lead to serious problems affecting the further converting phases, such as bubble formation between layers, haziness, and separation of layers, among others. It is also to avoid the overdrying a web.

The drying equipment also has a means of vapor removal and recirculating and heat-exchange equipment to conserve energy. Figure 16 schematically shows the airflow in a convection dryer. If a coating from a solution in an organic solvent is used, the solvent vapor must be removed from the exhaust in order to satisfy the environmental laws and to decrease solvent costs. Solvent adsorption on activated carbon, incineration, or condensation in an inert-gas dryer are used. Drying equipment (see also Figures 17 and 18) may be subdivided according to the heat-transfer mechanism or according to web handling as listed in Table 2.

Extruded, hot-melt, and wax coatings do not require drying and are solidified by chilling. Such coating machines require considerably less space than do the coating lines with drying ovens.

Some coatings are applied as reactive monomers or polymer/oligomer/monomer blends and may be cured by either ultraviolet or electron-beam irradiation. Such irradiation units are incorporated into the coating line.

WEB HANDLING

Coating machines may apply the coating or the adhesive to the packaging material supplied as a continuous web on

a roll, and the finished product is rewound after completion of the operation (see Roll Handling). Unwind and rewind stands, web-carrying equipment, and web controls and other accessories are used (14). Controls are needed to track the web properly on the machine and may consist of tension-sensing devices and means of controlling the tension and of edge-sensing devices and means of keeping the web centered on the coating machine. Many packaging materials are coated as sheet, requiring sheet-feeding and sheet-handling devices. There is less of a choice between various coating heads for sheet coating.

CODE, BAR

Henri Barthel
GS1 Global Office, Brussels,
Belgium

A *bar code* may be defined as a series of bars and spaces arranged according to the encodation rules of a particular specification in order to represent data. Its purpose is to represent information in a form that is machine-readable. Bar codes are read by scanning devices that are programmed to analyze the structure of the bars and spaces and transmit the encoded data in electronic format. These data can then be stored on a file or transmitted to a computer for processing.

Techniques other than bar codes achieve the same objective: capturing automatically data encoded using a particular technology. These include optical character recognition, magnetic stripe, and radio-frequency identification. The concept of encoding and reading data automatically is called *automatic data capture* (ADC).

BENEFITS OF BAR CODES

The main benefits of bar codes are *speed* and *accuracy*. Capturing data automatically by reading a bar code can be done in a fraction of a second, much faster than manual key entry. It is commonly agreed that an operator doing key entry makes one error for every 300 characters typed. Reading bar codes makes data capture almost error-free. The error rate depends on the type of bar code and equipment being used, but usually it is lower than one error per 1,000,000 readings.

BAR-CODE SYMBOLOGIES

A *bar-code symbology* is a set of rules describing the way bar and spaces have to be organized to encode data characters.

Since the invention of the bar code concept in the United States in the late 1950s, hundreds of bar-code symbologies have been developed, but only a few of them are actually being used on a large scale.

Typically, a symbology is qualified as being discrete or continuous. In a discrete symbology, the spaces between symbol characters do not contain information because each character begins and ends with a bar. In a continuous symbology, there is no intercharacter gap; that is, the final element of one symbol character abuts the first element of the next symbol character, and all the elements carry data contiguously. The most popular bar-code symbologies are briefly described below.

Code 39 was launched in 1975. It is widely used for industrial applications. Code 39 is a discrete, variable-length symbology encoding the 36 numeric and uppercase alpha characters (A–Z, 0–9) and seven special characters: space, dollar sign ($), percent (%), plus (+), minus (–), dot (.), and slash (/). A symbol character is composed of nine elements, five bars and four spaces. An element is either wide or narrow. There are three wide elements and six narrow elements in a symbol character. A Code 39 symbol begins with a start character and ends with a stop character. It can be read from the right to the left and from the left to the right.

Interleaved two of five (abbreviated ITF) has been found to be well adapted to the materials and printing conditions frequently used on fiberboard cases. It is a continuous symbology encoding only numeric digits. A pair of digits is represented by five bars and five spaces. One of the pair is represented by the dark bars and the other by the light bars, and the dark and light bars are interleaved. Because the digits are represented in pairs, the symbol can only encode even number of digits. In addition to the digit characters, there are two auxiliary characters used as guard bars at the beginning and at the end of the digit representation. The symbol is designed to be read bidirectionally by fixed or portable scanners.

Code 128 was introduced in 1981 in response to the need for a compact alphanumeric code symbol that could be used to encode complex data. The fundamental requirement called for a symbology capable of being printed by existing data-processing printers. Code 128 uniquely addresses this need with the most compact, complete, alphanumeric linear symbology available. In addition, Code 128 has been designed with geometric features to improve scanner reading performance and to be self-checking.

EAN/UPC was developed in the late 1960s when researches were conducted in the United States to improve the efficiency of checkout operations in retail stores. EAN/UPC is a continuous symbology encoding fixed-length numeric digits. Several variants exist, known as EAN-13, UPC-A, EAN-8, and UPC-E. In addition, the symbology enables to encode two small symbols encoding two and five digits. These are called add-ons because the information they contain supplement the main symbols. A symbol character is composed of seven modules, two bars, and two spaces. A bar or a space is composed of one to four modules. An EAN/UPC symbol begins and ends with a guard pattern. In the EAN-13, UPC-A, and EAN-8 version, a center pattern separates the symbol into segments that can be read separately by a decoding equipment, thus making the symbol omnidirectionally readable. The EAN/UPC symbology is widely used to encode the identification number of consumer products.

The symbologies described above are all linear symbologies. The symbol is always formed of a single row of symbol characters. Since the early 1990s, two-dimensional symbologies have been developed. Some are qualified as multirow symbologies consisting of two or more vertically adjacent rows of symbol characters. Others are known as *matrix symbologies*, which take the form of a two-dimensional graphic that is decoded in its entirety and not row by row. Two-dimensional symbologies can encode a large amount of data in a small amount of space.

PDF417 is a two-dimensional, stacked bar-code symbology. In PDF417, the basic data unit or minimum segment containing interpretable data is called a codeword. Every codeword in the symbol is the exact same physical length, and each codeword can be divided into 17 equal modules. Within every codeword, there are four bars and four spaces. The minimum number of modules of any bar or space is one; the maximum is six. The PDF417 symbology defines 929 distinct codewords and supports 12 modes. Each mode specifies the meaning of the codewords. The standard modes are Extended Alpha Numeric Compaction Mode, Binary/ASCII Plus Mode, and Numeric Mode. The number of data characters that can be encoded in a PDF417 symbol depends on the mode being used. In the extended alphanumeric compaction mode, the maximum number of ASCII characters per symbol is 1850. In numeric mode, a symbol can encode a maximum of 2725 digits.

Data Matrix is a two-dimensional matrix symbology that is made up of nominally square modules arranged within a perimeter finder pattern. Each Data Matrix symbol consists of data regions that contain nominally square modules set out in a regular array. The data region, or set of data regions and alignment patterns, is surrounded by a finder pattern, and this is in turn surrounded on all four sides by a quiet zone border. The number of data characters per symbol is up to 2335 alphanumeric characters or 3116 numeric only characters. Data Matrix Symbols are read by two-dimensional imaging scanners or vision systems. Most other scanners that are not two-dimensional imagers cannot read Data Matrix. Data Matrix Symbols are designed for use with applications that involve imaging scanners throughout the supply chain.

DATA CONTENT

The purpose of bar-code applications is to capture data automatically and to process these data in computer applications. Rules are therefore required to specify the way data should be encoded in a symbol. Similarly, when reading a bar code, there must be a way to know accurately what data have been captured. Three methods exist to specify the rules of encoding and decoding data in bar-code symbols:

1. The first method is to establish a one-to-one relationship between the symbology and the data content. In this case, a particular symbology is exclusively reserved to carry certain types of data. The EAN/UPC symbology is an example of this method. EAN/UPC bar codes always carry a number that is a unique identifier of the item on which the bar code is affixed.
2. The second method is based on conventions defined either by a party for its own applications or established on the basis of mutual agreements between two or more parties. The conventions describe the symbology to be used and specific rules indicating the way data elements are to be encoded. This method is appropriate only in internal or closed applications, because the rules are relevant only to the parties agreeing to follow the convention.
3. The third method is based on the concept of *data identifiers*, which are prefixes used to define data

fields. Each prefix uniquely identifies the meaning and the format of the data field following it. Two sets of identifiers have been standardized and are used in many bar-code applications.

In the late 1980s, a body called FACT (Federation of Automated Coding Technologies) was formed in the United States to examine existing standards and to produce materials that would permit coexistence of standards from all industries. A dictionary of FACT data identifiers has been put together and was formally approved as an American National Standard by the American National Standards Institute (ANSI) in 1991. On December 31, 1992, the FACT organization was dissolved. Prior to its dissolution, the Subcommittee 8 of Accredited Standards Committee (ASC) MH10 agreed to continue the maintenance of data identifiers. ANSI MH10 identifiers are composed of one alpha character preceded by up to three digits. These data identifiers usually have to be complemented by industry guidelines providing additional clarifications regarding the definition and format of the data fields.

Following the requirements of their membership, EAN International and UCC jointly developed a system of *application identifiers*, permitting the encodation of a wide range of information. EAN International and UCC merged into one single global organisation called GS1 in early 2005. The GS1 system is characterized by the management of a unique identification scheme for products, services, and locations, by a clear and unambiguous definition of data elements and by the strict recommendation of protected symbologies, offering a high level of security.

When considering the use of data identifiers for their bar-coding applications, users should consider the following guidelines:

- *Made-to-Order Products*. When the products are manufactured for and shipped to individual customers operating in a specific industry sector, the ANSI MH10 data identifier set can be suitable.
- *Products for General Distribution*. When products are traded with more than one customer and possibly with more than one industry sector, the GS1 application identifier set should be used.

APPLICATIONS

The bar-coding technology has gained wide acceptance in numerous applications. Today, virtually all packages, from the smallest units intended for sale to a consumer to the biggest transport units, bear one or several bar codes carrying their identification number and other data relevant to the parties shipping, carrying, or receiving goods.

Scanning at retail point of sale is a major application using bar-code technology. Millions of stores around the world have implemented scanning systems relying on the GS1 identification number and the associated EAN/UPC bar-code symbol. Scanning at point of sale enables us to automatically register the sales through price-lookup files. It also opens up the opportunity to implement a wide range of applications such as inventory management, automatic reordering, and sales analysis.

A rapidly growing field of applications using bar-coding technologies lies within the supply chains. Goods ready for shipment by a supplier are packed, and each package is numbered and bar-coded with a unique number. Before the physical delivery of the merchandise, the supplier sends an electronic message to the delivery point, advising about the arrival of the goods. This electronic message contains the unique identification number of each package and the description of its contents. When processed by the receiver, the electronic message is matched against the original purchase order and stored in a computer database. When goods arrive, a bar-code reading device scans the unique number identifying the goods, and the computer makes the link with the information previously stored. The system is then able to show what has to be delivered, and the actual delivery can be checked. Inventories can then be updated automatically, because the information is already available in electronic form.

PRINTING BAR CODES

Virtually any printing technology can be used to print bar codes, provided that it is accurate enough to achieve the right level of required quality. The printing processes fall into two categories: commercial and on-site. The choice between these two approaches is determined by the nature of the information to be encoded and the number of codes to be printed. Typically, if the information is static (e.g., the identification number of a product to be placed on a package) and if the number of codes to be printed is large, the traditional commercial method using film masters is appropriate. If the information is variable (i.e., different for each item or short series of items or if the quantity required is small), then on-site printing processes should be used.

The commercial printing techniques use a master image of the bar code on the printing plate. Film masters are very accurate and are available on the market from commercial companies. The printing process itself generally generates a print gain due to the ink viscosity, the pressure of the printing plate, or the type of substrate being printed. This print gain can be evaluated and compensated in the film master itself by reducing the size of the bars. The party ordering the film, the film master supplier, and the printer must work closely together to achieve a quality bar code.

The on-site printing techniques may use a piece of hardware acting as graphics controller between the computer and the printer. They may also use “intelligent” printers incorporating the controller equipment. Finally, software is commercially available to generate the picture of the bar code and send it to a printer. The printing systems may be based on character-by-character impact, on serial dot-matrix, or on linear-array technologies. The choice of the appropriate technology depends on many parameters linked to the application requirements.

READING BAR CODES

Many types of devices are commercially available to read bar codes. They all illuminate the symbol and analyze the resulting reflectance. Areas of high reflectance are interpreted as spaces, while areas of low reflectance do represent bars. The reflected pattern of bars and space is converted to an electric signal that is then digitized. The decoder assigns a binary value to the signal and forms a complete message. The message is checked by the decoder's software and transformed into data according to the appropriate decoding algorithm relevant to the symbology being read.

Fixed-beam readers depend on external motion to read the symbol. This can be provided by an operator moving the reader across the symbol or by providing movement to the symbol in front of the reader. A low-cost popular reading device is the handheld contact scanner. It requires an operator to move the reader smoothly over the symbol.

Moving-beam readers use a mirrored moving surface to provide the illumination. The light source appears as a continuous line of light. The most common moving-beam readers in use are generally referred to as *laser scanners*.

Imaging devices are also used to read bar codes. They operate similarly to a camera. The reflected image of the bar code is projected onto photodiodes composed of many photodetectors. The photodetectors are sampled by a microprocessor and produce a video signal that is then decoded.

The choice of a reading device is dictated by many parameters linked to the application and to economic criteria.

COEXTRUSION FOR SEMIRIGID PACKAGING

This article pertains to a flat, semirigid coextruded sheet, which is a minimum of 0.010 in. (0.25 mm) thick (see Coextrusion machinery, flat). These coextruded sheet structures are thermoformed to produce high-barrier plastic packages (see Barrier polymers; Thermoforming). A similar concept is used to produce high-barrier plastic bottles, except the bottles are formed from coextruded multilayer tubes instead of a flat sheet (see Blow molding).

The production of coextrusions for semirigid packaging was made possible by technology developed in the late 1960s and early 1970s (1, 2). Utilization of this technology was initially limited to "simple" structures, such as two-layer systems (a general-purpose polystyrene cap layer on a high-impact polystyrene base layer) for drink cups. Commercialization of high-barrier coextrusions occurred in the 1970s in Europe and Japan. Large-scale commercial barrier coextrusion applications did not surface in the United States until the 1980s. For the purposes of this discussion, barrier materials are defined as those that exhibit an oxygen transmission rate of less than $0.2\,\mathrm{cm}^3 \cdot \mathrm{mil}/(100\,\mathrm{in}^2 \cdot \mathrm{day} \cdot \mathrm{atm})$ $[0.777\,\mathrm{c}^3 \cdot \mu\mathrm{m}/(\mathrm{m}^2 \cdot \mathrm{d} \cdot \mathrm{kPa})]$ (see Barrier polymers). Other techniques that can be used to produce multilayer barrier structures are coating and lamination (see Coating equipment; Laminating). Some advantages coextrusion offers versus these other two methods are thicker barrier layer capability, single-pass production, barrier layer sandwiched between cap layers, and generally lower cost. The potential markets for packages formed from these high-barrier coextrusions include both low- and high-acid food products sterilized by aseptic, hot-fill, or retort methods. These markets obviously represent a significant opportunity for barrier coextrusions.

BARRIER MATERIALS

On the basis of the barrier definition above, only two commercially available thermoplastic resins can be considered as barrier resin candidates for these extrusions: ethylene–vinyl alcohol (EVOH) (see Ethylene–vinyl alcohol) and poly(vinylidene chloride) (PVDC) (see Vinylidene chloride copolymers). The barrier properties of specific grades of these two materials are listed in Table 1. The resins identified in the table are currently the highest barrier, commercially available, coextrudable resins of their respective polymer classes. Other formulations of both resin types are available offering certain property and processing improvements at the sacrifice of barrier properties.

The most significant technical issue concerning the use of EVOH as a barrier material is its moisture sensitivity. The material is hygroscopic, and its barrier properties are reduced as it absorbs moisture. The importance of this property to the food packager is dependent on the sterilization process, food type packaged, and the package storage conditions. The most severe conditions are encountered during retort processing (see Canning, food). Special consideration to coextrusion structure design and postretorting conditions may be required to achieve the desired oxygen barrier for packages produced from EVOH coextrusions (3).

PVDC is not moisture sensitive and does not exhibit the deterioration of barrier properties shown by EVOH. The challenges associated with using heat-sensitive PVDC are faced by the coextruded sheet producer. Equipment and process design are critical to the production of coextrusions containing PVDC. Concern relating to the reuse of scrap generated in the production of coextrusions based on

Table 1. Barrier Materials

Resin	O_2 Transmission Rate[a]	Water-vapor[b] Transmission Rate	Mid-1985 Price, $/lb ($kg)
EVOH (Eval F, Kuraray)	0.035 [0.136]	3.8 [1.50]	2.41 [5.31]
PVDC (Saran 5253, Dow Chemical)	0.15 [0.583]	0.10 [0.04]	1.02 [2.25]

[a] $cm^3 \cdot mil/(100\,in.^2 \cdot d \cdot atm)$ $[cm^3 \cdot \mu m/(m^2 \cdot d \cdot kPa)]$ at 73°F (23°C), 75% rh.

[b] $g \cdot mil/(100\,in.^2 \cdot d)$ $[g \cdot mm/(m^2 \cdot d)]$ at 100°F (38°C), 90% rh.

PVDC is an economic issue. Development of new material forms and recycle-containing structures is underway with commercialization targeted for 1985 (4). In the meantime, resin manufacturers are working on the development of other types of barrier materials for coextrusion applications (5).

STRUCTURAL MATERIALS

The materials generally used to support the barrier resins in coextrusions are listed in Table 2. The maximum process temperature listed is the highest sterilization temperature that packages based on these resins should experience. Polystyrene, polypropylene, and the polyethylenes are the predominant structural materials used in coextrusions for semirigid packaging applications. Structural resin selection is dependent on use requirements, coextrusion processability, and container-forming considerations.

Polystyrene (see Polystyrene) exhibits excellent coextrudability and thermoformability. It can be used in applications that require low-temperature processing and in some hot-fill applications. Polypropylene (see Polypropylene) is also excellent from a coextrusion-processing standpoint, but it requires special forming considerations. Deep-draw containers from polypropylene-based sheet are most commonly formed using solid-phase forming techniques. Polypropylene can be retorted, but some grades exhibit poor low-temperature impact characteristics, which limit their use in applications that require resistance to refrigerated or freezing temperatures.

High-density polyethylene (see Polyethylene, high-density) offers a significant improvement in low-temperature properties compared with polypropylene, but its suitability in applications that require retort processing is marginal. Low-density polyethylene would be incorporated in coextrusions that require good heat sealability (see Sealing, heat) for applications involving low-temperature-fill conditions.

Although coextrusions based on crystallizable polyester (see Polyesters, thermoplastic) and polycarbonate (see Polycarbonate) are not commercially available at this time, these materials are included as structural materials because of their future potential in retort applications. The success of these relatively expensive materials will be dependent on the cost and performance achieved. Considerable developments of coextrusion and forming techniques need to be completed prior to commercialization of coextrusions based on polyester and/or polycarbonate.

APPLICATIONS

Three representative commercially coextruded structures are shown in Table 3. The transition layers in these structures are materials used to ensure the integrity of the coextrusion. The technology of transition layers is complex and maintained as proprietary by coextrusion manufacturers. The first structure, which uses polystyrene as both cap layers, finds use in form/fill/seal applications because of the particularly good thermoformability of polystyrene (6) (see Thermoform/fill/seal). The second structure has one polystyrene cap layer to maintain thermoformability and one polyolefin cap layer. The polyolefin layer, in this case, would be the food-contact layer. This structure would comply with the current Food and Drug Administration (FDA) regulations for aseptic H_2O_2 package sterilization (see Aseptic packaging). The resins that comply with current FDA regulations for H_2O_2 sterilization are polyethylenes, polypropylenes, polyesters, ionomers (see Inonomers), and ethylene vinyl acetates (EVA). Petitions have been submitted for FDA clearance of polystyrene and ethyl methyl acrylate (EMA) as food-contact layers as well. Containers formed from this structure, with polypropylene as the food-contact surface, can also be hot-filled (7).

The last structure shown in Table 3 has the most potential of those listed, because it can be used in applications including retort processing. The primary market target for coextrusions with polypropylene as the cap layers is processed foods currently in metal cans (8, 9).

In addition to the food-packaging markets, barrier coextrusions can be used in the medical (see Healthcare

Table 2. Structural Materials

Resin	Maximum Process Temperature, °F (°C)	Mid-1985 Price $/lb ($kg)
Polystyrene	195 (90.6)	0.49–0.51 (1.08–1.12)
Polypropylene	260 (127)	0.43–0.47 (0.95–1.04)
High-density polyethylene	230 (110)	0.44–0.50 (0.97–1.10)
Low-density polyethylene	170 (77)	0.40–0.44 (0.88–0.97)
Polyester, thermoplastic (heat-set)	>260 (>127)	0.63–0.67 (1.39–1.48)
Polycarbonate	>260 (>127)	1.69–1.81 (3.73–3.99)

packaging), pharmaceutical (see Pharmaceutical packaging), and industrial packaging markets where barriers to oxygen, moisture, and hydrocarbons are required.

ECONOMICS

Simply using resin prices to calculate a material cost for a coextruded sheet structure can be unreliable in determining the economics of barrier plastic package. Using material prices only to compare the economics of several coextruded sheet structures on the basis of different resins can result in erroneous conclusions. Items such as required equipment costs, coextrusion output rates, package-forming method and rates, amount of scrap generated, amount of scrap reutilized, container design, and container performance are some of the cost considerations that can be dissimilar for different coextruded sheet structures. Economic comparison of various coextruded barrier packages with alternative packaging materials should be based on a total packaging systems analysis. The current commercial applications and market tests underway show that packages from coextruded sheet offer economic and/or performance advantages versus other packaging materials.

COEXTRUSION MACHINERY, FLAT

Multilayer coextruded flat film and sheets are produced on single-slot T dies. The overall process is similar to that used for single-layer products of the same dimensions (see Extrusion). The specialized design considerations for coextrusion are discussed below.

MACHINERY

Extruders. Each product component requires a separate extruder. Several layers may be produced by the same extruder using suitable feed block or die connections. Systems range from two extruders for a simple BA or ABA structure to five or six extruders for high barrier sheet (see Coextrusions for semi-rigid packaging).

Since all of these extruders feed one die, the area behind the die can become a crowded place. Extruders are therefore built as narrow as possible. Vertical gearboxes permit tuck-under motors that reduce space requirements and provide good service access to the motor and other components.

Smaller extruders can be mounted overhead at various angles. Larger machines present an access and height problem when located overhead. The most effective and

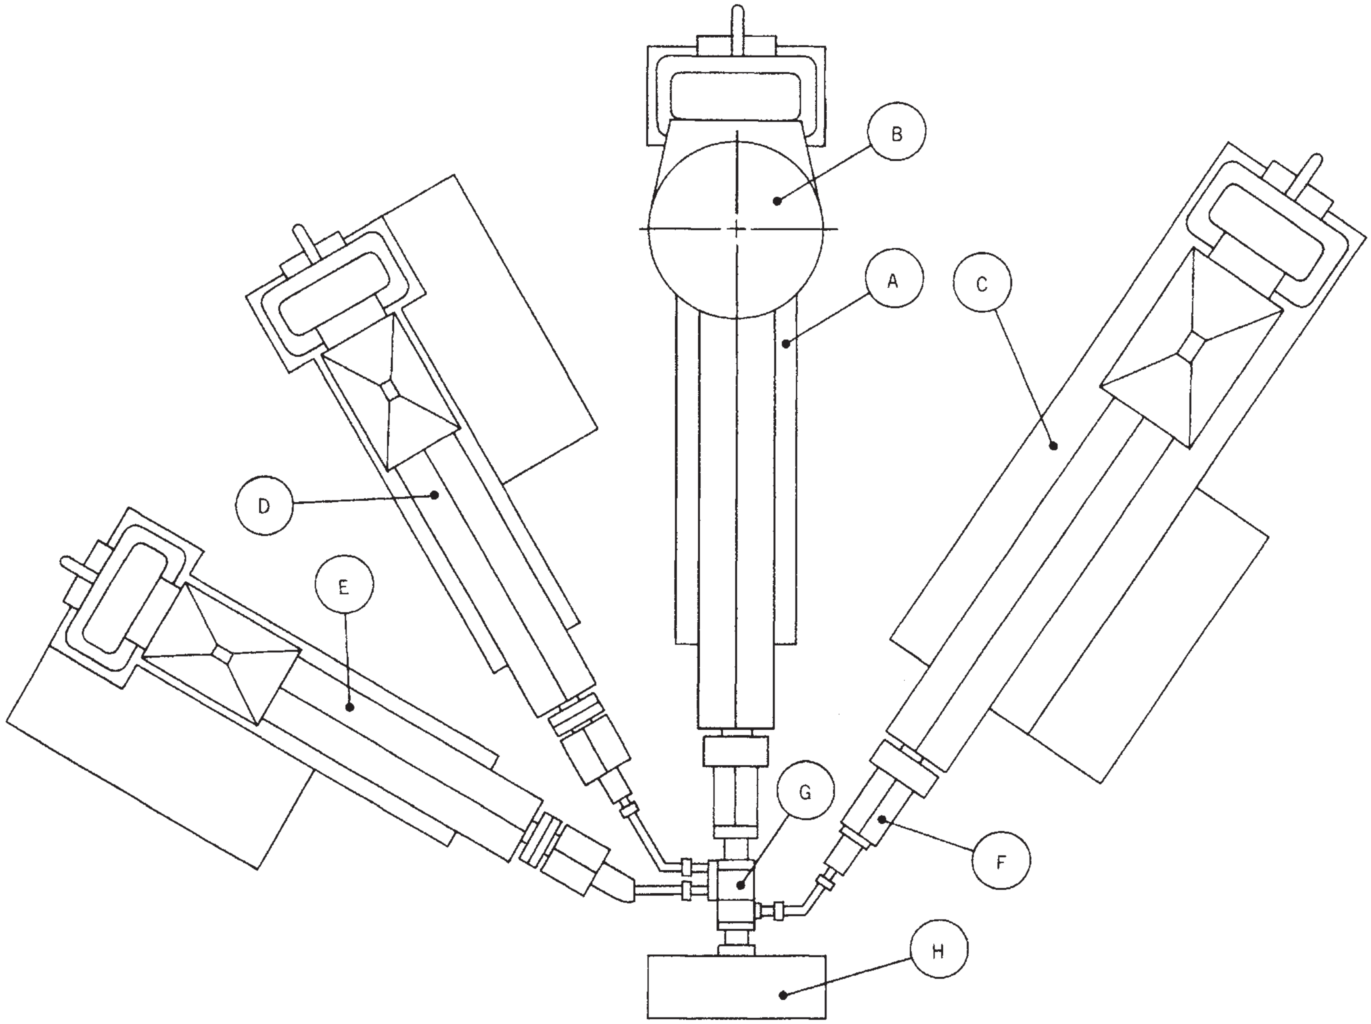

Figure 1. A typical layout for coextrusion (1): A, recycled layer extruder; B, crammer feeder; C, virgin layer extruder; D, glue layer extruder; E, barrier layer extruder; F, static mixer; G, feed block; H, sheet die.

accessible arrangement is usually a fan layout of larger extruders with some small machines overhead (Figure 1).

Thermal expansion requires that all but one and sometimes all machines to be mounted on wheels with expansion capability both axially and laterally. Height adjustments must also be provided to permit accurate alignment to the interconnecting piping.

PVDC requires special corrosion-resistant extruder construction (see Vinylidene chloride copolymers). High-nickel cylinder lining and Z nickel screws are essential to avoid corrosion and polymer degradation. The optimum ratio is 24 *L*/*D* (length/diameter) for this heat-sensitive material. Everything associated with the PVDC extruder is critically streamlined, and all flow surfaces normally contacting or possibly contacting PVDC must be nickel. No screens or breaker plates are used. A long conical tip with matching adapter assures streamlined flow. A PVDC extruder can run over barrier materials equally well with different suitable screw designs.

All other extruders can be of conventional materials of construction. A ratio of 30 *L*/*D* is desirable for best performance in most cases. These can also be vented for devolatizing when necessary to remove entrapped air or moisture. Venting cannot be used with high backpressures or low screw speeds. Screen changers are used on most extruders to avoid laborious disassembly when screens are plugged. Good screening is essential in barrier sheet extrusion to avoid plugging critical flow passages and pinholes in some layers. Remote-control hopper shutoffs help quick startup and shutdown.

Ethylene–vinyl alcohol (EVOH) requires predrying. Otherwise, it degrades during extrusion with a reduction of melt viscosity. An increase in melt index will disturb layer distribution (see Ethylene–vinyl alcohol).

Scrap or recycled material is often used as a 100% constituent of one layer. This may require special feed handling such as a grooved feed section or the addition of a crammer feeder. If the scrap contains PVDC, the extruder must also include the appropriate materials of construction and streamlined design.

Good mixing with special screws is necessary to homogenize the components.

Melt quality and uniformity are absolutely critical for good multilayer coextrusion. Small variations that are invisible in a single-layer sheet can cause severe disturbances in coextrusion resulting from layer interactions. It therefore cannot be assumed that an extruder that works well in single-layer service is suitable for critical coextrusion work.

Cylinder Cooling System. Melt viscosity is the major factor controlling layer distribution. The ability to control melt temperature level upward and downward to some extent is essential to permit layer distribution control. This requires conservative speed extruder operation. Complex sheet extruders should therefore always be larger for a given capacity than those used for single-layer extrusion. Closed-loop liquid cooling rather than air cooling is desirable on larger extruders to achieve desired melt temperatures.

PVDC extruders of any size should be liquid-cooled for fast cooling in case of problems. Automatic fail-safe liquid cooling is often used to cool the extruder in case of a power failure.

Layer uniformity and stability can be improved by two devices that are relatively new to extrusion.

Gear Pump. Gear pumps provide positive output delivery systems for extruders. They permit accurate control of the content of each layer and ensure that all layers are present in the preselected proportions. The pump is run at an accurately controlled speed. The extruder speed is automatically regulated to maintain a constant feed pressure into the gear pump. All variations in extruder output are therefore automatically compensated. The regrind extruder, which is subject to the largest variability, should be fitted with a gear pump.

Static Mixer. Static mixers play an important part in stabilizing melt uniformity. This is particularly important with viscous polymers such as PP and HDPE, which have long stress–relaxation times.

The mixer also provides an extended residence time at low shear rate for stress relaxation after the high shear in the extruder and gear pump. The static mixer is best installed as the last element prior to the feed block.

Piping. The extruder output is conveyed to the feed block or die through a feed pipe. There are a number of important considerations regarding this technical plumbing (Figure 2):

It should be as short as possible with a minimum of bends. All bends should be smooth to avoid material hangup.

The internal diameter should be large enough to avoid large pressure drops, which cause a rise in melt temperature, but not so large as to create stagnation.

The wall thickness should not only take operating pressure into consideration but also act as a good heat sink and distributor. Polymer-filled pipes can be subjected to enormous thermal expansion pressures during heating.

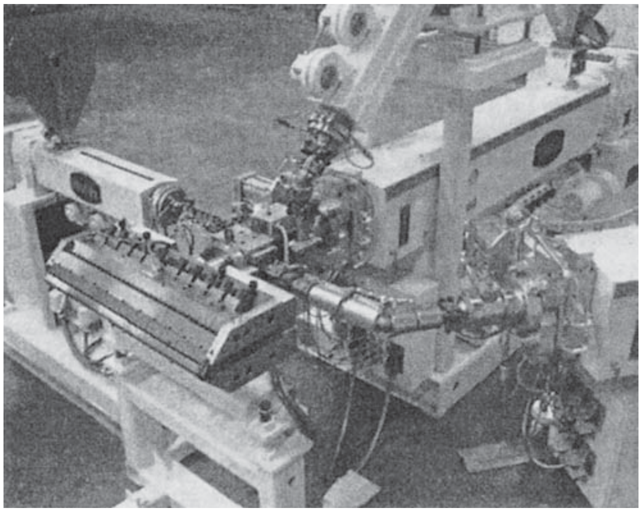

Figure 2. Feed block and piping.

Heating must be very uniform to avoid hot and cold spots.

Low-voltage density heaters with almost complete pipe coverage are desirable. Heater tapes are dangerous owing to the possibility of poor uniformity of heat distribution.

Control thermocouples must be carefully located to sense the actual pipe temperature.

The construction material must suit the polymer to be conveyed.

Pipes should be easily and quickly disconnected for cleaning and access. Longer pipes should be sectionally assembled to help with this. C clamps are ideal for coupling feed pipes. These also permit rotational motion and compensation for minor misalignment without leakage.

METHODS

Two different methods are used to coextrude flat film and sheet: multimanifold die and feed-block coextrusion.

Multimanifold Die. The molten polymer streams are fed to separate full-width manifolds in a T die. They are merged prior to exiting from a common slot. These dies are complex and expensive but provide for accurate adjustment of individual layer profiles. The number of layers is limited by the die design, and five appears to be the practical upper limit. The layer capability can be increased by using a feed block on one of the manifolds. Layer adjustment is tedious owing to the great number of adjustment points, and these dies are usually limited in use to single-purpose applications.

Feed-block Coextrusion. The product is coextruded on a conventional single manifold T die preceded by a feed block in which the layers are formed. This is the most frequently used process for complex structures. It has been the object of many patents and much litigation.

Feed blocks combine the polymer layers in the structure arrangement desired for the finished sheet in a narrow width and a relatively thick cross section. This makes the layer assembly fairly easy. Thereafter, laminar and nonturbulent flow in the die is necessary to maintain the desired structure.

Viscosity matching of components is essential; that is, the viscosities of the separate components must be alike. Higher viscosity material displaces lower viscosity material at the edges of the die. Even materials having apparently identical viscosity may not flow evenly because of interfacial slip or die surface drag. Despite this, viscosity matching works very well for many complex structures. Viscosity differences can often be compensated by temperature adjustments. Feed blocks also incorporate mechanical compensating devices. Consequently, layer distribution uniformity in the 1% range is attainable across the sheet.

Three major feedblock systems are in use commerically. Each has its advantages and disadvantages. All use the principle of nonturbulent laminar flow through the die to achieve good results. The difference between the systems is in how the layers are assembled before the die.

The *Dow system* (Dow Chemical Co.) uses a square die entrance with the height of the die manifold. The layers are assembled in one plane through a series of streamlined flow channels. Details are covered by secrecy agreements and therefore cannot be disclosed. This coextrusion technology has been developed around Dow's saran PVDC, and it excels in this field. The Dow feed block incorporates several flow adjustments. These feed blocks are available from Dow machinery licensees who include most sheet extrusion system builders (1).

The *Welex system* uses a circular flow passage, which is the usual die entrance configuration for single-layer extrusion (see Figure 3). The layers are assembled sequentially in and around the cylindrical flow. The system is modular so that more layers can be added to a given feed block at any time. Inner- and outer-layer feed components are fixed but are removable for correction or adjustment (2).

The *Cloeren system* uses a rectangular die entrance with the height of the die manifold and a width of about 4 in. (100 mm) (see Figure 4). The block is essentially a miniature multilayer sheet die with movable separating vanes. These permit adjustment of the relative flow gaps during operation. The number of layers is predetermined by the number of flow channels. The feed to each channel can be selected by interchangeable inlet plugs. They are available from Cloeren Company or through builders of sheet extrusion systems. Cloeren also builds multimanifold dies similar in structure to the feed block. These can be fed by a feed block into the central manifold. Although this may seem complex and expensive, it offers a solution to structures with widely differing melt viscosities (3).

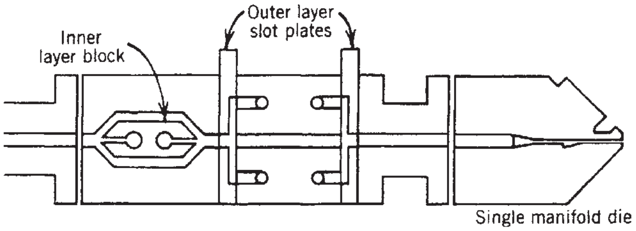

Figure 3. Welex feed block (2).

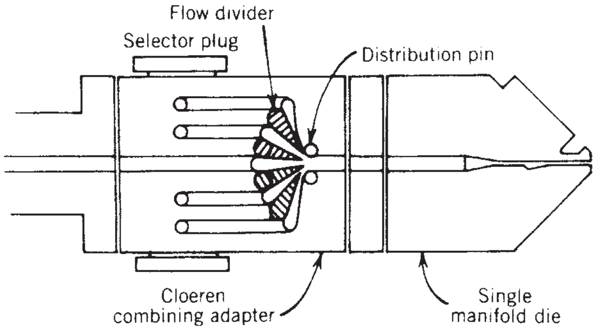

Figure 4. Cloeren feed block (3).

ENCAPSULATION AND LATERAL ADJUSTMENT

It is generally desirable to limit the width of the barrier layer to less than the full sheet width. This is essential with PVDC to avoid contact with the die surfaces and much of the feed block. This not only permits the use of normal materials of construction but also totally eliminates degradation of PVDC by stagnation on a metal surface. This problem is solved by encapsulating or totally surrounding the barrier layer with other polymers so that it is floated through the die.

The accurately adjustable width of the barrier layer permits major savings in barrier-material cost and reduces recycling problems. Preferably, this layer should extend only to the tooling width in the thermoformer. Edge trim from the extrusion operation and from the thermoforming should be single layer.

All three feed-block systems incorporate adjustments for this purpose. This is usually achieved by a flow mechanism in the feed block that adjusts the flow width of the barrier layer. Other layers such as the glue layers can be similarly controlled.

OTHER EQUIPMENT

Controls. The most important aspect of multilayer sheet and film extrusion is control. A system includes a tremendous number of variables and adjustments that affect the layer thickness and distribution. Since 100% inspection is impossible, reliance is placed on the consistency and stability of operation.

A microprocessor control system is ideal to help maintain good control and to alarm process deviations. It can also be easily programmed for rapid product changes and for critical startup and shutdown procedures.

Gauging. Single-layer gauging and control have reached a high state of perfection. Tolerances better than 1% are readily achieved. Measurement of individual layers is possible in certain cases. In thin transparent structures, selective infrared absorption bands permit the separate measurement of widely differing polymers. This method does not work on thick and opaque products, and it does not give the layer location within a structure. Continuous nondestructive-layer measurement remains under intensive development.

Downstream Equipment. Multilayer sheet and film use conventional sheet and film takeoff equipment. Nickel-plated rolls are preferably used when processing product containing PVDC to avoid damage to chrome plating in the event of a breakdown. Multiple-edge trimming is sometimes used to separate single-layer from multiple-layer material to reduce scrap recycling problems.

COEXTRUSION MACHINERY, TUBULAR

Tubular coextrusion for packaging applications is generally referred to as *blown-film coextrusion*, which distinguishes it from other similar tubular processes that produce products such as pipe and heavy-wall tubing. Blown-film coextrusion therefore refers to the process of forcing more than one molten polymer stream through a multimanifold annular die to yield a film consisting of two or more concentric plastic layers (see Extrusion; Films, plastic). The laminar characteristic of polymer flow permits the maintenance of discrete layer integrity such that each polymer in the film structure can fulfill a specific and individual purpose (see Coextrusions for flexible packaging).

Coextruded film structures are designed to incorporate one or more of the following objectives: heat sealability; barrier against gas or moisture transmission; high strength (ie, tensile, impact, and tear); color differential; surface frictional properties; adhesive between layers; stiffness (modulus of elasticity); optical quality (clarity and gloss); and reclaim carrier. Combinations of these properties can be achieved by the arrangement of polymer layers in which each polymer exhibits the specific desired property.

PROCESS EQUIPMENT

A tubular coextrusion process fundamentally consists of the extruders, die, air ring, collapsing mechanism, haul-off, and winder. These elements are similar to those of single-layer film extrusion except for the die, which must contain more than one flow manifold, i.e., layer channel, for extrusion (see Figure 1).

The added complexity of multilayer die components, coupled with the inherently superior quality requirements for coextruded films, make the die the highest design priority of the extrusion system. The most critical die-design considerations for multilayer applications are (a) structural integrity, i.e., the hardware's ability to withstand typical internal pressures of 3000–6000 psi (21–41 MPa); (b) dimensional integrity, the interlocking of and machining precision related to mating parts defining flow-stream concentricity; (c) polymer-flow distributive quality, in order to use a range of diverse materials; and (d) reduction of design-flow restriction, permitting extrusion of high-viscosity polymers.

Closely related to the die issue is the frequent need to rotate (or, preferably, oscillate) the die assembly for the

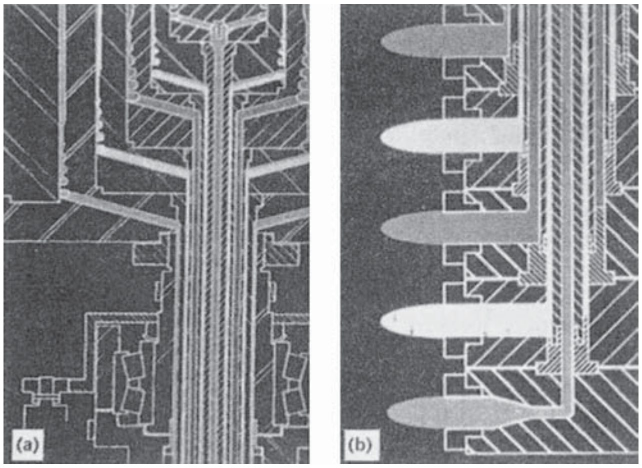

Figure 1. Typical rotating tubular five-layer configuration: (**a**) die structure; (**b**) extruder inlet arrangement.

purpose of randomizing film-thickness variations across the entire windup width. In the seal section, where there is an interface between fixed and oscillating members, polymer pressure is large, i.e., typically 5000 psi (34.5 MPa). Because the seal must act against this force, the seal design must be well qualified, and thrust-bearing, and the seal-maintenance costs are likely to be high.

Alternative methods sometimes used for thickness randomizations are oscillating haul-off assemblies, rotating winders, or rotating extrusion systems. Each method poses some significant technical difficulty worthy of extensive selection and design consideration.

SPECIALIZED PROCESS DESIGN

Because coextruded films often employ polymers uncommon to those used in single-layer extrusion, some unusual process design criteria, discussed below, are added for multilayer systems.

Degradable Polymers. Most of the gas-barrier resins are vulnerable to temperature degradation. This imposes a need for specialized die streamlining and extruder-feedscrew design. The feedscrew configuration is critical in minimizing melt temperature and in ensuring uniformity of temperature and viscosity across the melt-flow stream.

High Modulus of Elasticity (Film). Many barrier and high-strength polymers exhibit modulus, i.e., stiffness, characteristics that cause unique web-handling and winding difficulties. The elimination of web wrinkles and flatness distortions becomes a critical design objective related especially to collapsing geometry, idler and nip-roll size, as well as line-drive quality. The handling of stiff webs usually entails relatively high equipment costs because higher tension levels are required, along with more precise tension control. Use of highly accurate regenerative de drive equipment is usually advisable for coextruded films. The high-modulus webs also dictate greater hardware rigidity and tighter roll-alignment tolerances.

Four-side Treatment Capability. Because of layer-thickness structure considerations in coextrusion, the surface to be printed may be extruded as the inner layer of the bubble. This shifts corona-treatment requirements (for subsequent ink adhesion) from the outer to the inner layer. Two treater stations are sometimes installed on coextrusion systems; one is for the treatment of the inner layer downstream of the web separation.

High Film Surface Coefficient of Friction (COF). For many high-speed sealing applications, as well as such products as stretch film, multilayer film surfaces are abnormally tacky. One of the principal advantages of the coextrusion process is its ability to create such properties with relatively low additive content concentrated in individual layers. However, very high resultant COF values can cause unusual web-handling difficulty, especially in relation to the bubble-collapsing function. This aggravated geometric problem, i.e., flattening a cylinder (bubble) into a single plane, can be alleviated with the use of very low friction collapsing means. In contrast to the more conventional wood-slat configuration, low friction systems employ rollers on ball bearings or air-cushion surfaces to minimize film-surfacing drag forces during collapsing.

QUALITY-CONTROL REQUIREMENTS

Multilayer films, because of their enhanced physical properties, frequently command premium selling prices; however, these films also necessitate several added cost factors and engineering complications related to process design. The cost differential is due to the film's added value, exemplified by more stringent thickness-uniformity and winding-quality standards. These are described below.

Temperature Control. In addition to plant-space problems associated with multiple extruders, tighter film-quality specifications dictate improved temperature control in a smaller control console. Most recent coextrusion-system plans employ microprocessors to save space and take advantage of digital-control logic. Achieving process-temperature stability is often essential for coextruded films, in contrast to the fluctuations and errors normally tolerated in single-layer processes.

In-line Blending. Because of the many types of raw material used in coextrusion, the purchase and storage of specialized-resin blends is impractical. There is an advantage to in-line blending of additives, and investment plans for a complex coextrusion system generally include a high priority for blending equipment. This is also logical in view of the relatively high per pound (kg) cost of the special resins and additives involved and the particularly high quality demanded of multilayer products.

Layer-thickness Control. Individual layer thickness must be carefully monitored either by tedious off-line measurement or in-line by gravimetric (weigh-feeding) extruder loading. A difficult technical objective unique to coextrusion, layer-thickness control is a key process-control priority that provides the opportunity to achieve cost savings or the liability to waste raw material and produce defective film. Although layer-thickness measurement can be achieved with spectrophotometers, weigh feeding seems the most practical and reliable means of controlling layer percentages.

Roll-winding Quality. Roll-conformation requirements associated with multilayer films are usually severe, representing a more costly and complicated winder configuration. In-line slitting is a common cost-saving requirement, encouraging the use of advanced web-handling technology in the categories of alignment precision, web spreading concepts, as well as tension and speed control (see Slitting and rewinding machinery). Typical high multilayer line speeds, often 200–500 ft/min (61–152 m/min), dictate the incorporation of automatic cut and transfer mechanisms. Manual roll transfers are not practical at these speeds and with multiple slits. Additionally, the broad range of film elasticity, stiffness, thickness, and surface tack encountered in coextruded applications demands extraordinary winder versatility and performance quality.

ECONOMIC FACTORS

Most blown-film coextrusion systems operate in an output range of 200–1000 lb/h (91–454 kg/h). A typical average rate is 300 lb/h (136 kg/h). Although some two-, four-, and five-layer systems exist, a common installation uses three extruders, even when producing two-layer products. Usual extruder combinations include 2.5-in. (6.4-cm) diameter and 3.5-in. (8.9-cm) sizes, although many 4.5-in. (11.4-cm) extruders are also used. Some lines operate at 2000 lb/h (907 kg/h) with 6-in. (15.2-cm) extruders.

In the United States, the coextrusion industry consists of a large population of in-line multilayer bag operations in addition to those requiring film winding. Investment levels and process-quality requirements are usually not as high for the bag operations. A three-layer, 300-lb/h (136-kg/h) in-line bag extrusion system, for example, costs approximately $300,000; a film-winding version with the same output specification would probably cost at least $400,000.

Operating costs for coextrusion systems are similar to those of single-layer extrusion except for the higher initial investment, i.e., typically 50% higher for coextrusion of the same output category. Energy costs are equivalent ($0.03–0.05/lb or $0.07–0.11/kg) to those of single-layer extrusion, and man-power requirements vary only slightly. Labor costs per unit weight are often higher for coextrusion, not as a function of manpower requirements but because more elaborate processes require greater skills.

A frequent important economic incentive for the manufacture of coextruded films is that premium film pricing reduces the cost percentage of raw materials, e.g., resin. Therefore, multilayer products are generally reputed to offer higher profit margins than their single-layer counterparts.

Scrap reclaim can often be an economic disadvantage with coextrusion. It may be limited or prohibited by incompatibilities between the polymers of corresponding layers, which is a complication particularly prevalent among specialty food-packaging films that contain gas-barrier resins. In these cases, reclaimed scrap may only be eligible for insertion into a thin adhesive layer, thus severely limiting reclaim percentages. Conversely, some coextruded films are designed specifically to exploit high scrap-input potential. In these cases, high loadings of scrap or reprocessed resin are sandwiched between skin layers of virgin polymer.

COEXTRUSIONS FOR FLEXIBLE PACKAGING

Updated by Staff

INTRODUCTION

Multilayer coextrusion of thermoplastic film and sheet has developed into an important plastic fabrication process, providing large growth opportunities for the plastic industry. Coextruded multilayer plastics are challenging such traditional materials as metals, glass, paper, and textiles (1). Flexible packaging is the second largest type of packaging in the United States. It represents 18% of the $\$135 \times 10^9$ market (2). The attraction of coextrusion is both economic and technical. It is a single-step process starting with two or more plastic materials that are simultaneously extruded and shaped in a single die to form a multilayer sheet or film. Thus, coextrusion avoids the costs and complexities of conventional multistep lamination and coating processes, where individual plies must be made separately, primed, coated, and laminated. Coextrusion readily allows manufacture of products with layers thinner than can be made and handled as an individual ply. Consequently, only the necessary thickness of a high-performance polymer is used to meet a particular specification of the product. In fact, coextrusion has been used commercially to manufacture unique films consisting of hundreds of layers of individual layer thicknesses less than 100 nm. It is difficult to imagine another practical method of manufacturing these microlayer structures.

Layers may be used to place colors, bury recycle, and screen UV radiation, and provide barrier properties; for example, additives such as antiblock, antislip, and antistatic agents can be placed in specific layer positions. High-melt-strength layers can carry low-melt-strength materials during fabrication.

The largest market for coextruded films and sheets is in packaging applications—for example, two- or three-layer films for trash bags or five- to nine-layer structures for flexible and semirigid packages. As many as five different polymers may be used to obtain heat sealability, barrier, chemical resistance, toughness, formability, and aesthetics. Coextrusion is also suitable for applying thin multilayer films as coatings on substrates. Food packaging is a growing application.

ADVANTAGES OF COEXTRUSIONS OVER BLENDS

The layers of a coextruded film are generally composed of different plastic resins, blends of resins, or plastic additives. The difference between a coextruded film and a resin blend lies in the existence of distinct layers in the coextruded film as opposed to the blend. Figure 1 illustrates the differences.

Some structures would not function as blends, but perform very well as coextrusions. For example, a film requiring aroma barrier and easy sealability would be very difficult to make as a blend. As a coextrusion the product could look something like the structure shown in Figure 2.

If the structure shown in Figure 2 were run as a blend, the EVA would degrade at the temperature required to melt the nylon, and the nylon would lose much of its aroma barrier because it would be contaminated by the EVA.

PRINCIPAL MANUFACTURING PROCESSES

Five principal manufacturing processes utilize coextrusion technology in producing flexible-packaging material: cast-film coextrusion, blown-film coextrusion (tubular), coextrusion coating, coextrusion lamination, and oriented coextruded films.

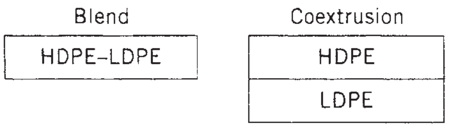

Figure 1. Cross section of film composed of resin blends and coextrusion.

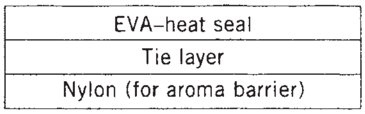

Figure 2. Cross section of functional coextruded film.

The coextrusion processes for cast film, extrusion coating, and laminations are similar in that the coextrusions pass through a flat die. However, there are differences in the remainder of each process. The cast-film process requires extruding the molten extrudate on to a chill roll, quenching it into a multilayer film and eventually winding into a roll.

In extrusion coating, the molten extrudate is extruded onto a substrate such as paper or foil, cooled, and wound into a roll. A coextrusion lamination occurs when (a) the molten polymer is extruded between two substrates, thereby gluing them together, (b) the polymer is quenched, and (c) the lamination is wound into roll form. A typical example of a coextrusion lamination process is illustrated in Figure 3.

Oriented coextruded films can be made by either the cast or the blown process but require additional processing before being wound into a finished roll.

Cast-Film Process

The main focal points of technology in the cast processes are the designs of the dies and melt-flow properties of the resins.

Two types of design are used: a multimanifold die and a single-manifold die with an external combining adapter. A schematic of each die design is shown in Figure 4.

In the single-manifold die, separate resin melt streams are brought together in a common manifold. The resin streams are combined in a combining adapter (or feedblock) prior to the die where distinct layers are maintained. In a multimanifold die, resins streams flow in separate channels and are combined inside the die after attaining full width. The important advantages of the single manifold are capital costs, flexibility of operation, thinner layers, and a larger number of possible layers.

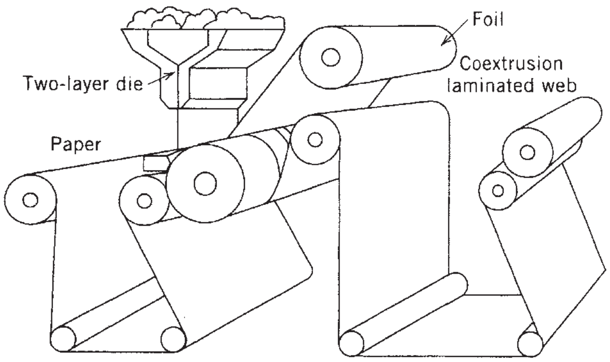

Figure 3. A typical coextrusion lamination process.

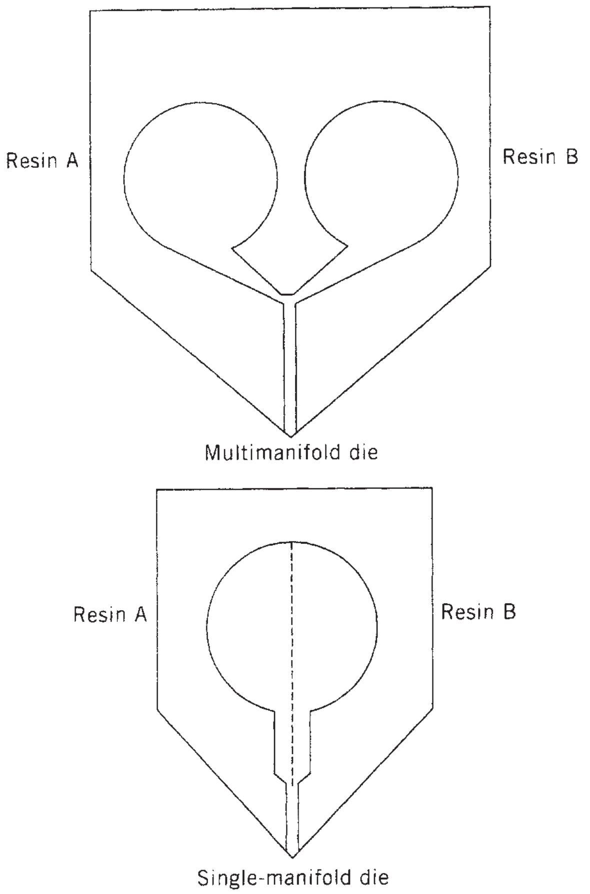

Figure 4. Schematic of a single-manifold die and multimanifold die.

Coextrusions of over 2000 layers have been reported (3). The design of feedblocks and control of laminar flow of the various components are critical to successful operation of this process.

A potential disadvantage of the single-manifold die is the need to carefully select materials with relatively similar meltflow properties. The multimanifold system allows for easier processing of dissimilar materials. In addition to a broader range of melt properties, a greater differential of temperatures between layers is possible. In practice, almost all coextrusion is done with the combining adapter and the single-manifold die.

Blown-Film Process

The blown-film coextrusion process is illustrated in Figure 5. In this process, separate resins are extruded into a circular die. The molten-resin streams are blown into a bubble, cooled by air rings, and collapsed in the primary nip. The tubular film is generally slit for specific packaging applications. The die design for blown film, in addition to being circular, is different from the cast process in that separate melt streams are combined near the die exit or external to the die.

Compared to cast films, blown films generally have more balanced physical strength properties, higher moisture barrier, and greater stiffness. Optical properties such as clarity and gloss, however, are generally inferior to those of the cast process because of the slower rate of crystallization in the blown process. (Blown films are more crystalline than the corresponding cast films.)

Coextrusion Coating and Laminating Processes

Die designs for coextrusion coatings and laminations are similar to those used in the manufacture of cast film. The polymers used are usually lower viscosity and are extruded at higher temperatures, resulting in easier flow properties. Therefore the dies are usually smaller in bulk and rigidity when compared to cast-film dies. The higher temperatures are required to achieve good adhesion to the various substrates. On an extruder with two dies, it is possible to extrusion laminate the paper with aluminum foil and then extrusiom coat the aluminum foil in one pass (4).

Oriented Coextruded Processes

Coextruded films are often oriented to enhance their physical or barrier properties. Orientation of the film is the result of stretching the film after it is quenched. Coextrusions can be oriented in three ways: (1) monodirectional—either MD (machine direction) or TD (transverse direction-cross machine), (2) sequentially MD and TD, or (3) simultaneously MD and TD. The method of orientation chosen is dependent on the materials used and the desired final properties.

PRINCIPAL RAW MATERIALS

The majority of coextruded structures are made up of polyolefins (polyethylene and polypropylene). This class of material is preeminent because of low cost, versatility, and easy processability. LDPE–LLDPE resins (see Polyethylene, Low-Density) are used extensively in coextruded structures for their toughness and sealability. HDPE resins are selected for their moisture barrier and machinability characteristics (see Polyethylene, High-Density). Polypropylene is chosen for its ability through orientation to provide machineable films with high impact and stiffness properties.

Although the polyolefins are the workhorse grades for coextruded packaging, they are almost always combined with other resins to achieve multilayer functionality. Copolymers of ethylene–vinyl acetate (EVA), ethylene–acrylic acid (EAA), and ethylene–methacrylic acid (EMA) are regularly used as skin layers for their low-temperature sealing characteristics. When oxygen, aroma, or flavor protection is necessary, polymers such as poly(vinylidene chloride) (PVDC), nylon, and ethylene–vinyl alcohol (EVOH) for clarity ethylene–vinyl alcohol copolymers are used (see Nylon; Vinylidene Chloride Copolymers). Nylon and EVOH do not readily adhere to polyolefins, so an adhesive or tie layer is necessary to hold the coextruded structure together. Other polymers such as polycarbonate (see Polycarbonate) or polyester (see Polyesters,

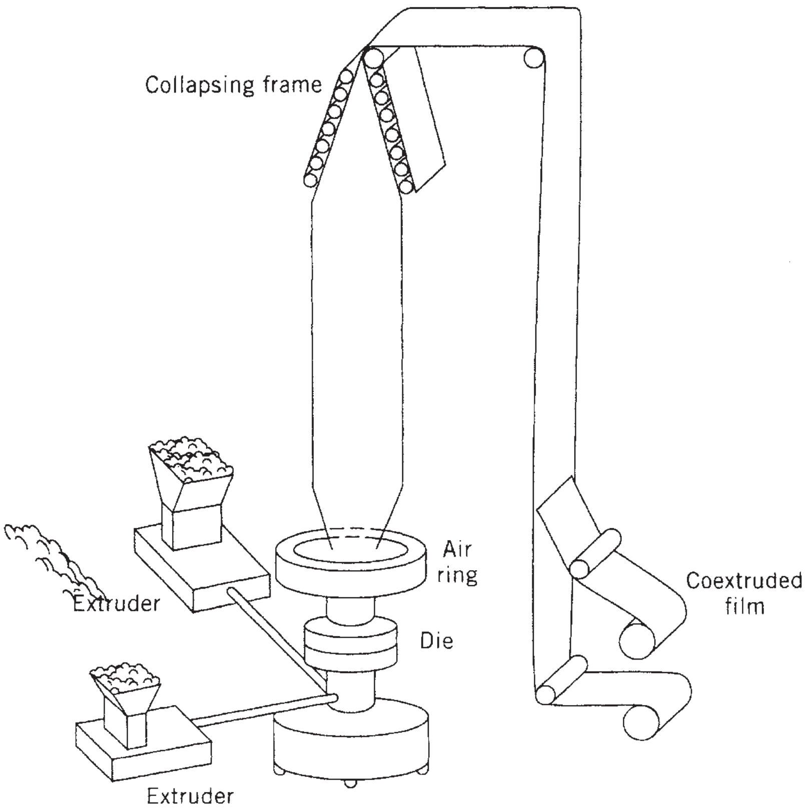

Figure 5. Blown-film coextrusion process.

Thermoplastic) many be used as skin layers to provide unusual thermal integrity for packaging machine performance.

STRUCTURES

Coextruded flexible-packaging applications include coextruded films (see Table 1 for a list of structures), laminations, and coatings. In general, coextruded films are preferred to coextruded laminations and coatings because of their cost-effectiveness in use. Because lamination and coating require an extra value-added stage, they tend to cost more.

Coextruded multilayer structures can be divided into three categories: single-resin, unbalanced, and balanced. Many structures that are based on the performance properties for a single resin are coextruded for performance or cost reasons. Unbalanced structures typically combine a functional layer with a heat-seal resin. Balanced structures generally have the same heat-sealable resin on both sides of the film.

Single-Resin Structures

Single-resin films are coextruded for a variety of reasons. Many commodity film applications may not appear to be multilayer films, yet they actually have three or more distinct layers. Bakery, produce, and trash-bag films, for example, are often three-layer structures. The core material may contain pigment or recycled material, while virgin skin layers control surface quality and machinability. Single-resin coextrusions can also provide a differential coefficient of friction on the two surfaces.

Unbalanced Structures

Typical of the unbalanced structures are films designed for vertical form/fill applications with a fin seal. A base resin such as HDPE is augmented by an EVA skin layer for sealability. For horizontal wrappers a polypropylene skin layer is sometimes selected for its higher thermal resistance. In another important unbalanced application, cast polypropylene, which has a limited sealing range, is combined with more sealable polyethylene for single-slice cheese wrappers.

Table 1. Typical Coextruded Film Structures

Outside Layer	Core Layer	Inside Layer	Remarks
LDPE	White LDPE + recycle	LDPE	Virgin skin layers control surface quality
HDPE	HDPE + recycle	EVA	EVA provides rapid fin seal machinability
EVA	LLLDPE1+ recycle	EVA	EVA increases lap seal cycle time
LDPE	LLDPE + recycle	LDPE	LDPE limits film’s elongation under load
EMA	OPP	EMA	Oriented polypropylene sealability poor without coextruded or coated skin layers

There are multilayer films using only one polymer (AAA), unbalanced coextruded films with two or more polymers (ABC), and balanced multilayer structures with two or more polymers (A/B/C/B/A).

Balanced Structures

Balanced coextruded structures typically have a core resin selected for its functionality plus two skin layers that are heat-sealable. Oriented polypropylene films, for example, are increasingly coextruded instead of coated to attain machinable surfaces (see Film, Oriented Polypropylene). Frozen-food films are typically constructed with an EVA skin layer for enhanced sealability. Heavy-wall bags are regularly coextruded with LLDPE (linear LDPE) cores for impact strength and LDPE skins to limit the film's elongation under load. Primal meats are packaged in PVDC shrink film with EVA skins for seal integrity.

Two main applications that have shifted from monolayer films to coextrusions are overwrap and stretch wrap (see Wrapping Machinery, Stretch Film). Horizontal overwrap machines typically use an MDPE film or an LDPE–HDPE blend.

Coextrusions can provide comparable overwrap machinability at lower gauge. Stretch wrap is difficult to produce as a single-layer structure without blocking. By splitting stretch wrap into a multilayer structure, its LLDPE core can be provided with controlled tackiness on the surface layer.

COLORANTS

Updated by Staff

INTRODUCTION

Colorants for packaging materials fall into two broad categories: pigments and dyes. Used for both decorative and utilitarian purposes, their diversity is at least as broad as the diversity of packaging materials. This article focuses on their use in inks, plastics, and paperboard. The emphasis is on pigments, which are far more prevalent than dyes in packaging applications.

Pigments are black, white, colored, metallic, or fluorescent organic or inorganic solids that are insoluble and remain essentially unaffected by the medium into which they are dispersed or incorporated. They are small in particle size, generally in the range of 0.01- to 1.0-μm diameter. Pigments produce color by selective absorption of light, but because they are solids, they also scatter light. Light scattering is undesirable in a transparent material, but desirable if opacity is the goal. Some organic pigments that are extremely small in particle size scatter very little light and therefore act like dyes—for example, Benzimidazolone Carmine HF3C, with a particle size of 0.05–0.07 μm. Some colorless pigments, relatively large in particle size (up to 100 μm), are used as fillers or extenders.

Organic pigments are characterized by high color strength, brightness, low density, high oil absorption, transparent and translucent properties, bleeding in some solvents, and heat and light sensitivity. In the world at large, the major user of organic pigments is the printing-ink industry. In packaging, they are useful for numerous applications such as printing on cartons, labels, and flexible bags. Naphthol reds, for example, are used for soap- and detergent-carton printing because of bleed resistance. Barium lithol is a most important red for packaging flexo and gravure inks, and alkali blue is used in glycol-type inks (see Inks; Printing).

Compared to organic pigments, inorganic pigments are more opaque, less bright, and weaker in tint; but they are more resistant to heat, light, chemical attack, bleed, migration, and weathering. They have higher density, lower cost, and less antioxidant effect. The major use of inorganic pigments is the paint industry. In packaging, they are useful for printing on cartons, bags, and glass bottles. Examples are molybdate orange for gift wrap and vinyl film, titanium dioxide for glass beverage bottles, and cadmium reds for plastics. Metallic pigments such as gold, platinum, and silver help vivify colorants for glass bottles.

Dyes are intensely colored solubilized organic substances that are retained by the medium that they color by chemical bonding, absorption, or mechanical retention. Dyes produce color by absorption of light, without affecting transparency and high optical purity. The major user of dyes is the textile industry. In packaging, dyes are used to some extent in inks for special effects, for coloring paperboard, and to produce tinted transparent plastic containers or films.

PIGMENTS IN PACKAGING

Properties of pigments are a function of the chemical composition as well as other physical and chemical parameters such as particle size, particle shape, particle-size distribution, and the nature of the pigment's surface. Particle size affects a number of pigment properties. Lightfastness improves with increasing particle size, and oil absorption and strength decrease. Hue is also affected by particle size; for example, an orange pigment usually appears yellower as the size decreases. Narrower particle-size distribution leads to cleaner hue, higher gloss, and lower oil absorption and viscosity. A pigment's light absorption, light-scattering power, and particle size contribute to determining the hiding power of the pigment. Opacity is also affected by refractive index differences between the pigment and the dispersing medium. Selection of a pigment for a specific application depends on a great many physical properties and characteristics. Some of the factors involved in pigment selection are listed in Table 1. Table 2 lists most of the pigments used in packaging materials.

SPECIAL-EFFECT PIGMENTS

Nacreous pigments, like basic lead carbonate and titanium-coated mica, are used for luster effects for cosmetic containers. Fluorescent pigments and dyes are used in gravure inks for carton printing and special effects in gift-wrap printing. They are also used as colorants for blow-molded bottles, closures, tubs, cartons, and pails. Other special-effect pigments include luminescent and phosphorescent pigments, as well as metallics (e.g., aluminum flake and various copper bronzes that vary in shade, depending on their chemical composition).

DYES IN PACKAGING

When dyes are used for coloration, as in plastics, they must be checked for migration, heat stability, lightfastness, and sublimation.

For plastic materials, dyes that are widely used are azo dyes, anthraquinone dyes, xanthene dyes, and azine dyes that include induline and nigrosines. Azo dyes such as Solvent Red 1, 24, and 26, Solvent Yellow 14 and 72, and Solvent Orange 7 are colorants for polystyrene, phenolics, and rigid PVC. Better heat stability and better weatherability are obtained from anthraquinone dyes such as Solvent Red 111, Blue 56, Green 3, and Disperse Violet 1 in the coloration of acrylics, polystyrene, and cellulosics. Basic Violet 10 is a xanthene dye used in phenolics. Solvent Green 4, Acid Red 52, Basic Red 1, and Solvent Orange 63 are used for polystyrene and rigid PVC. Azine dyes produce exceptionally jet blacks and are used in ABS, polypropylene, and phenolics. A perinone dye, Solvent Orange 60, has good light and heat stability for ABS, cellulosics, polystyrene acrylics, and rigid PVC. ABS, polycarbonate, polystyrene, nylon, and acrylics may be colored with quinoline dye. Methyl Violet and Victoria Blue B, two basic triphenylamine dyes, find limited use in phenolics.

For printing inks, five dye families are of particular interest: azo, triphenylmethane, anthraquinone, vat, and phthalocyanine. *Certified food colorants* are used in packaging applications where the printed surface is in direct contact with food. The package is the immediate container and is not a shipping container or other protectve container (1). Dyes for paper include acid, basic (including resorcine and alizarine), and direct dyes. Basic directs are used to color containers, boxboards, wrapping paper, and multiwall bags.

COLORANTS FOR PRINTING INKS

Most priniting-ink pigments are organic. Printing inks are used for a broad range of packaging items such as cartons,

Table 1. Some Factors Involved in Selection of a Pigment

For Printing Ink	For Plastics	For Paper and Paperboard
Color	Color	Whiteness
Masstone	Nature of resin	Brightness

Naphthol Red (dark blue shade)	Red 23 12355	[*6471-49-4*]	1,3	60^{DFL}	30^{FL}		A,D,E,H,J,K,N,O	Printing inks for packaging
Pyrazolone Red	Red 38 21120	[*6358-87-8*]	1	50–75^{DF}	15–50^{F}	A,P	C,D,E,H,J,K,N,O	Metal decorating and packaging printing inks
Dianisidine Red	Red 41 21200	[*6505-29-9*]	1				K,P,Q	Packaging printing inks
Permanent Red 2B (barium)	Red 48:1 15865:1	[*7585-41-3*]	1,2,3	10–30^{DFL}	10–20^{FL}	K,L,M,N,O,P	A,D,E,J,Q	Carton and label printing inks; excellent brightness
Permanent Red 2B (calcium)	Red 48:2 15865:2	[*7023-61-2*]	1,2	20–100^{DFL}	10–50^{FL}	E,K,P,Q	D,J,L,M,N	Printing inks for labels and cartons; bright and good tint strength
Permanent Red 2B (strontium)	Red 48:3 15865:3	[*15782-05-5*]	1,2	10–30^{D}	5–30^{F}			Excellent brightness; solvent-based printing inks
Permanent Red 2B (manganese)	Red 48:4 15865:4	[*5280-66-0*]	1	80–120^{DFL}	30–40^{DFL}			Poor alkali and soap resistance
Lithol Red (sodium)	Red 49 15630	[*1248-18-6*]	1	5–10	2–5			Excellent tint strength
Lithol Red (barium)	Red 49:1 15630:1	[*1103-38-4*]	1	5–40^{DL}	2–20^{FL}		P	Resination increases transparency; poor alkali and soap resistance
Lithol Red (calcium)	Red 49:2 15630:2	[*1103-39-5*]	1	2–5^{DL}	2–5^{FL}			Excellent brightness and tint strength
Red 2G (calcium)	Red 52:1 15860:1	[*17852-99-2*]	1,2	10–15^{D}	5–10^{FL}	N	B,C,D,E,H,J,K,O,P,Q	Process magenta for printing inks
Red Lake C[d] (barium)	Red 53:1 15585:1	[*5160-02-1*]	1,2	5–50^{DFY}	1–25^{F}	A	C,D,E,H,J,K,L,N,O	Standard warm red; foil coatings
Lithol Rubine[d] (calcium)	Red 57:1 15850:1	[*5281-04-9*]	1,2	15–50^{DFL}	5–25^{FL}	E,K	C,D,H,J,L,M,N,O,P,Q	Standard process magenta; foil coatings
Pigment Scarlet (barium)	Red 60:1 16105:1	[*15782-06-6*]	1,2	25–50^{D}	20–30^{B}	A,C,E,K,L,N,O,P	D,H,J,M,Q	Printing ink for gloss labels, waxed papers, metal decorating; foil coatings

(Continued)

Anthosine Red 3B (Ba, Na)	Red 66 18000:1	[*68929-13-5*]	1					Metal decorating printing inks
Anthosine Red 5B (Ba, Na)	Red 67 18025:1	[*68929-14-6*]	1					Metal decorating printing inks; transparency
Rhodamine Y (PTMA)	Red 81:1 45160:1	[*12224-98-5*]	1	15–30^{D}	5–10^{F}			Brillant, color purity, good tint strength
Rhodamine Y (SMA)	Red 81:3 45160:3	[*63022-06-0*]	1	15–30^{D}	5–10^{F}			Process magenta printing inks
Rhodamine Y (PMA)	Red 81:x 45160:x	[*63022-07-1*]	1	15–30^{D}	5–10^{F}			Poor alkali and soap resistance
Alizarine Red B	Red 83 58000:1	[*72-48-0*]	1	120	30		A,D,E,H,J,N,O,P,Q	Metal decorating inks, butter and soap packages
Thioindigold Red	Red 88 73312	[*14295-43-3*]	2	120–160	80–120	P,Q	D,H,J,K,L,M,N,O	Clean color with excellent fastness
Phloxine Red (Lead)	Red 90 45380:1	[*1326-05-2*]	1	$<20^{DF}$	$<20^{F}$			Poor chemical, light, solvent and heat resistance
Synthetic Red^{d} iron oxide	Red 101 77491	[*1309-37-1*]	1,2			A,E,H,J,K,L,N,P,Q	C,F,G,M	Foil coatings, Fe embrittles certain plastics
Molybdate Orange	Red 104 77605	[*12656-85-8*]	1,2	20–160^{D}	20–160	D,H,J,P,Q	A,B,K,L,M,N,O	Poor alkali and acid resistance
Cadmium Sulfoselenide Red	Red 108 77202	[*58339-34-7*]	2	500	200^{GF}	A,B,C,D,E,G,H,I,J,K,L, M,N,O,P,Q	F	Bright, clean, intense colors
Cadmium Sulfoselenide Lithopone Red	Red 108:1 77202:1	[*58339-34-7*] and [*7727-43-7*]	2	500	150^{GF}	A,B,C,D,E,G,H,I,J,K,L, M,N,O,P,Q	F	Sensitive to mineral acids
Naphthol Red FGR	Red 112 12370	[*6535-46-2*]	1,2,3	60–160	40–160			Excellent brightness, very good lightfastness; paper coatings
Mercadium Red	Red 113 77201	[*1345-09-1*]	2			A,B,C,D,E,F,G,H,J, K,L,M,N,O,P,Q		Poor lightfastness when light and moisture present
Cadmium mercury Lithopone Red	Red 113:1 77201:1	[*1345-09-1*] and [*7727-43-7*]	2			A,B,C,D,E,F,G,H,J, K,L,M,N,O,P,Q		Low tint strength
Quinacridone Magenta Y	Red 122 73915	[*980-26-7*]	1,2	140–160^{D}	80–120^{F}	K,L,M,P,Q	A,B,C,D,H,J,O	Soluble in nylon and certain plastics
Perylene Vermilion	Red 123 71145	[*24108-89-2*]	1,2			A,B,C,E,J,K,P,Q	L,M,N	Transparent; good fastness properties
Disazo Red	Red 144	[*5280-78-4*]	1,2	160	100–140	C,E,H,J,K,L,M,N, O,P,Q	D	High-performance pigment
Naphthol Carmine FBB	Red 146 12485	[*5280-68-2*]	1,2,3	60^{D}	30^{D}	C,E,H,J,K,L,M,N, O,P,Q	D	Packaging and metal decorating inks, paper coatings
Perylene Red BL	Red 149 71137	[*4948-15-6*]	1,2	40–80^{D}	20–80	A,B,C,E,H,I,J,K,L, M,N,O,P,Q	G	Metal decorating
Disazo Scarlet	Red 166	[*12225-04-6*]	1,2			C,E,H,J,K,L,M,N, O,P,Q	D	High-performance pigment
Brominated Anthanthrone Red	Red 168 59300	[*4378-61-4*]	1			J,K,L,M,P,Q		Metal decorating printing ink
Rhodamine 6G	Red 169 45160:2	[*12224-98-5*]	1	30^{D}	10^{F}			Gravure printing inks, excellent tint strength
Naphthol Red F5RK	Red 170 12475	[*2786-76-7*]	1	80–120^{D}	60^{D}	C,L,M,N,O,Q	A,E,F,I,J,K,P	Brilliant excellent chemical resistance
Benzimidazolone Maroon HFM	Red 171 12512	[*6985-95-1*]	1	120	120	C,K,L,N,P,Q	A,B,E,G,J	Foil coatings; very transparent
	Red 175 12513	[*6985-92-8*]	1,2	160^{F}	120^{F}	C,K,L,N,P,Q	A,B,E,G,J	

(*Continued*)

Table 2. Continued

				Color Permanency,[b] Indoor Fadeometer, Max *h*		Plastic Applicability[c]		
Common Name	Color Index Name Number	CAS Registry Number	Application[a]	Masstone	Tint	Wide Use	Limited Use	Some Other Data
Benzimidazolone Red HFT								Highly transparent; inks for packaging and metal decorating
Benzimidazolone Carmine HF3C	Red 176 12515	[*12225-06-8*]	1,2	80^{D}	40^{F}	C,K,L,N,O,P,Q	A,E,F,I,J,M	Transparent, bright, chemical resistant; packaging and metal decorating inks
Anthraquinoid Red	Red 177 65300	[*4051-63-2*]	2	120	70–100	C,D,G,H,J,K,L,M,P,Q	B,E,I	Transparent
Perylene Maroon	Red 179 71130	[*5521-31-3*]	2			A,B,C,E,J,K,P,Q	L,M	Excellent fastness properties
Naphthol Rubine F6B	Red 184		1	60^{F}	15^{F}			Printing ink for packaging
Benzimidazolone Carmine HF4C	Red 185 12516	[*61951-98-2*]	1,2	60^{D}	30^{F}	C,K,L,N,O,P,Q	A,E,F,I,J,M	Process magenta for metal decorating
Naphthol Red HF4B	Red 187 12486	[*59487-23-9*]	1,2	80^{F}	40^{F}	K,L,N,P,Q	C,E,I,J,M	Bright, transparent; packaging and metal decorating inks
Naphthol Red HF3S	Red 188 12467	[*61847-48-1*]	1,2	80^{D}	60^{D}	K,L,N,P,Q	C,E,I,J,M	Superior chemical resistance; packaging inks
Perylene Scarlet	Red 190 71140	[*6424-77-7*]	2					Transparent, dull tints
Rubine Red (calcium)	Red 200 15867	[*58067-05-3*]	1,2	$20–70^{FL}$	$10–15^{FL}$			Oil-based printing inks, poor soap, solvent and alkali resistance
Quinacridone Scarlet	Red 207	[*1047-16-1*] and [*3089-16-5*]	1,2	$120–320^{D}$	$80–120^{F}$			High-performance pigment
Benzimidazolone Red HF2B	Red 208 12514	[*31778-10-6*]	1,2	80^{F}	40^{F}			Bright medium red; packaging and metal decorating inks
Quinacridone Red Y	Red 209 73905	[*3089-17-6*]	1	120^{D}	120^{F}			Soluble in nylon
Naphthol Red F6RK	Red 210		1	60^{D}	30^{F}	C,J,K,L,M,N,O,Q	A,E,F,I,J,K,P	Packaging printing inks
Perylene Red Y	Red 224 71127	[*128-69-8*]	2	>500	>500			Transparent; very good strength and fastness properties
				Orange Pigments				
Dinitraniline Orange[d]	Orange 5 12075	[*3468-63-1*]	1,3	$40–80^{DFL}$	$5–10^{DFL}$			Good chemical resistance
Pyrazolone Orange	Orange 13 21110	[*3520-72-7*]	1	$10–60^{DFL}$	$5–10^{FL}$	K,L,N,O,P,Q	A,C,D,H,J,M	
Dianisidine Orange	Orange 16 21160	[*6505-28-8*]	1,2	$25–75^{DF}$	$5–50^{F}$	J,P,Q	K,L,M	
Persian Orange Lake (A1)	Orange 17:1 15510:2	[*15876-51-4*]	1					Inks for waxed bread wrappers
Pure Cadmium Orange; Cadmium Sulfoselenide Orange	Orange 20 77202	[*12556-57-2*]	2	500	100^{GF}	A,B,C,D,E,F,G,H,J,K,L,M,N,O,P,Q		Lightfastness needs protection from moisture
			2	500	100^{GF}

[a] Key to application: 1, printing inks; 2, plastics; 3, paper and paper coatings.

[b] Key to permanency failures: F, fades; D, darkens; L, loses gloss; B, turns bluer; G, turns gray or greener; Y, turns yellower; Z, bronzes.

[c] Key to plastic: A, ABS; B, acetal; C, acrylic; D, amino resins; E, cellulosics; F, fluoroplastics; G, nylons; H, phenol–formaldehyde; I, polycarbonate; J, polyester or alkyd; K, polyethylene, low density; L, polyethylene, high density; M, polypropylene; N, polystyrene, general-purpose; O, polystyrene, impact-resistant; P, flexible vinyl; Q, rigid vinyl.

[d] Pigments having an FDA status.

bags, labels, metal cans, rigid containers, and decorative foils. Table 2 highlights the pigments used for printing (see Inks). Important qualities of pigments for printing inks are contribution to printing properties (i.e., rheology and bleeding), print appearance (i.e., the color has sales appeal), and useful service life (i.e., resistance to fading and chemicals). The advantage of optimizing particle size to provide good rheology is frequently compromised by simultaneously deteriorating coloristic properties. Such changes may be prevented by a suitable pigment preparation or by predispersing a pigment in nitrocellulose resin (NC chips) (2).

In general, most ink pigments can be utilized in most types of inks; but there are minor differences in a pigment's performance that must occasionally be considered. For example, pigments for lithographic inks must not bleed in water or very mild inorganic acidic (phosphoric acid) solutions. Glossy finishes require small-particle-size pigments. Metal deco printing is a speciality area. Traditional inks, which are processed at temperatures of 140°C and more, must be quite thermally stable to retain ther color value during application. Printed metal sheets that are to be used in food cans must be capable of being sterilized in the presence of food without degradation (2).

Extender pigments are essentially transparent or translucent and contribute to neither hiding power nor color. They are formulated into inks to extend the covering power of strong pigments and enhance the working properties (e.g., to increase viscosity without affecting color).

COLORANTS FOR PLASTICS

In selecting a colorant for plastics, in addition to the colorant characteristics listed in Table 1, the resins, their properties and compatibility, and the method by which they are processed are critical factors. Because PVC and its copolymers liberate acid at high temperature, acid-sensitive colorants like cadmium reds and ultramarine blue must be used with care. Hansa yellow tends to crock (smudge) in polyethylene. In polyethylene, impurities in pigments such as cobalt and manganese should be avoided. Polyacetals and thermoplastic polyesters are sensitive to moisture. Molten nylon acts as a strong acidic reducing agent and can decolorize certain dyes and pigments.

Colorants must have enough heat stability to withstand processing temperatures, which are sometimes very high [e.g., ~600°F (316°C)] for injection-molded polycarbonate. Some organic pigments processed at 350°F (177°C) for 15 min begin to show signs of darkening, but some cadmium pigments can withstand 1500°F (816°C) without noticeable color change. When processing temperatures are particularly high, the choices for colorants are few. Colorants may also interact with other additives used in the plastic such as heat and light stabilizers; for example, sulfur-containing cadmium pigments react with the nickel-bearing stabilizers used in some film-grade polypropylenes.

Dispersion

Dispersing the pigment to develop color strength and maximum optical properties is an extremely important issue that is continually being addressed. Dispersion of dyes is not as great a problem because of their solubilizing nature. Pigments need to be properly wetted by vehicles or the plastic medium. Mixing does not change size and surface area of particles, dispersion does (3). Colorants must be able to be uniformly dispersed in any plastic system. If the system is unable to tolerate the shear energy required to disperse a given colorant, no matter how desirable the colorant may be, it is not usable in that system. Poor dispersion can lead to processing difficulties for thin films. Agglomeration and aggregation in pigments are due to many reasons, such as different particle sizes and shapes, presence of soluble salts or impurities, and improper grinding. Improvements in pigment dispersion have been obtained through surface treatments of pigments and better grinding techniques.

PIGMENTS FOR PAPER AND PAPERBOARD

Two reasons for the use of pigments, fillers, and extender pigments for paper goods are as follows: (a) to load or fill the sheet during manufacture to increase bulk and improve such properties as opacity, printability, and brightness and (b) to coat the paper to provide opacity, black out defects, or color and provide a receptive surface for printing. Table 3 lists some pigments and extender pigments used in the manufacture of paper goods for packaging. Organic pigments are used as paper coating wherever improvements in finishing efficiency, sheet gloss, or print gloss are important. They are used extensively in coated folding boxboard and woodfree-coated printing papers (4).

Table 3. Some Pigments for Use in Paperboard and Paper

Filler	Composition	Refractive Index	Brightness	Use
Titanium dioxide (rutile, anatase)	TiO_2	2.7 for rutile	98–99	Board, waxing stock, board liner, paper, specialties
		2.55 for anatase	98–99	
Clay (kaolin)	Aluminum silicate	1.87–1.98	80–85	Board, papers, specialties
Calcium carbonate (natural and precipitated)	$CaCO_3$	1.56	95–97	Printing, cigarette papers
Talc	Magnesium silicate	1.57	70–90	Board, printing papers
Gypsum	$CaSO_4$	1.57–1.61	80–90	Boards, specialties
Diatomite (natural)	Diatomaceous earth	1.40–1.46	65–75	Improves bulk and drainage of board stocks

SUPPLY OPTIONS

Colorants are supplied in a number of different forms.

Dry Powder. Pigments and dyes are sold in a dry powder form. Pigments are ground to suitable working particle sizes for ink manufacture or for dispersion into a plastic. The maximum working particle size of most dry pigments is about 44 μm. These pigments should pass through a 325-mesh (44-μm) screen with less than 1% retention.

Presscake Form. This is an undried form in which the presscake may typically contain 25–50% solids. Presscake is used for the preparation of water-based inks.

Flushed Colors. Pigments are dispersed in a varnish or mineral oil forming a paste that has a pigment content of $\geq$30%. The flushing operation involves exhanging water in a presscake for the organic vehicle by a kneading action in a Sigma blade mixer.

Chip Dispersion. Pigments dispersed in resin with little or no solvent content. Usually prepared by milling on a two-roll mill.

Resin-Bonded Pigment. This is a dry flush in which the vehicle phase is a resin.

Easy-Dispersing Pigments and Stir-In Pigments. Pigments treated with surfactants or polymeric materials to make them readily dispersible in various ink vehicles, particularly gravure ink types.

Color Concentrates. Colorant dispersed in resin that is let down with virgin resin to make final product. Color concentrate is supplied in chip or pellet form. Liquid- and paste-color concentrates are used for vinyls.

Slurry. Titanium dioxide and other white pigments or extenders are supplied to the paper industry in this manner.

REGULATORY REQUIREMENTS

In the United States, the FDA and USDA administer the laws of interest to colorists. The Federal Food, Drug and Cosmetic Act, the Federal Hazardous Substances Act, and the Poison Prevention Packaging Act of 1970 are relevant FDA statutes. The Meat Inspection Act and the Poultry Inspection Act of the USDA relate to colored plastics where food contact is a concern. The Food, Drug, and Cosmetic Act (1938) was modified by the Food Additives Amendment (1958) and the Color Additives Amendment (1960) (revised in 2007). Pigments that have an FDA status are noted in Table 2 (see Food, drug, and cosmetics regulations).

The regulations do not deal with colorants in printing inks. Four groups of colorants are presently permitted in the coloring of plastics for food, drugs, and cosmetics: (1) certified colorants are those in the list of FD&C certified dyes and alumina lakes; (2) purified nonaniline colors include iron oxides, carbon black, and titanium dioxide for use in and on plastics; (3) use of a noncertified colorant may be petitioned—responsibilities for compliance with regulations rests with user; and (4) a colorant is not subject to the color-additive amendment if there is an impermeable barrier between colorant and food, drug, or cosmetics, and no chance of contact.

Product packaging constitutes about one-third of municipal solid waste and is usually decorated with various colors. Some of them containing heavy mtetals. The Coalition of Northeast Governors developed a model to regulate cadmium, hexavalent chromium, lead, and mercury in packaging to a decreasing content, not leachability, of 100 ppm. Currently, 19 states have enacted this legislation with some limited variations (5). Lead pigments and other toxic pigments have been eliminated from inks for food packaging. For nonfood packaging, the three major lead pigments for inks are chrome yellow, molybdate orange, and phloxine red. No other heavy metal pigments are used in significant quantities.

COMPRESSION MOLDING

INTRODUCTION

Compression molding is used to produce parts from thermosetting plastics that cannot be processed by thermoplastic processing methods (see Blow molding; Extrusion; Injection molding; Thermoforming). In compression molding, polymerization takes place in a closed mold. Under heat and pressure, the materials fill the mold cavity, and with continued heat and pressure, the part hardens as crosslinking takes place (see Polymer properties). The irreversibility of the process rules out thermoplastic-processing methods, but it also imparts excellent heat resistance and dimensional stability to the part. These properties are essential for many nonpackaging applications (e.g., electrical components, automotive and aircraft body panels). The use of compression molding in packaging is very limited. Thermosets rarely provide the best balance of properties, and compression molding is not economical for high-volume production.

Compression molding is sometimes used to prepare thermoplastic test specimens. For example, in the ASTM

D4703-93 method, thermoplastic resins in the form of pellets are loaded into the mold, heated above their melting points, formed, and cooled into a plaque or sheet for making test specimens.

APPLICATIONS

Compression molding has some advantages compared to injection molding, including lower tooling costs and fewer stresses in the part, but design flexibility and production rates are limited (1). For many years, the only significant packaging application for thermosets was closures (see Closures). The main application today remains screw caps (2, 3). At one time, phenolic and urea–formaldehyde molding compounds were the only plastics available for the purpose. Also used today are melamine-formaldehyde and polyester molding compounds (4).

A resurgence of interest in thermosets and compression molding occurred in recent years because of the heat required for "ovenable" packages. Compression-molded glass-filled thermoset polyesters, which had been used for some time for heat-and serve airline trays, moved into the consumer market with the advent of frozen dinners that could go from the freezer to the convection or microwave oven and then to the table.

COMPUTER APPLICATIONS: PALLET PATTERNS

Brad Leonard
Cape Systems, Inc., Allen,
Texas

THE PALLET PATTERN

A *pallet pattern* is a group of finished products in a single layer that is organized onto a pallet base of slip-sheet. The most common form of finished product container is the corrugated shipping case. Multiple layers of product on a pallet or slip-sheet are used to create a unitized pallet load. The efficiency of the pallet pattern, as well as the resulting pallet load, is determined by the quantity and size of the product in the corrugated shipping case. For example, a 16-in. × 12-in. case gets 10 cases per layer in a pallet pattern on a 48-in. × 40-in. pallet surface. However, a 16 1/8-in. × 12-in. case can only get 8 cases per layer, a 20% decrease. Therefore, optimizing each case size, the product inside, the pallet pattern, and the number of layers can have a dramatic effect on the utilization of space within the entire distribution system. Typically, companies average 80–85% utilization on the pallet. This underutilization of space offers many industries the opportunity to realize tremendous savings.

THE USE OF THE PALLET

Pallets were first used for handling finished goods in the distribution environment in the 1930s. Modern wooden pallets were introduced on a larger scale during World War II by the military. Then, in 1946, the food-processing industry along with transportation companies, as well as the pallet manufacturing industry, recommended the adoption of the 40-in × 32-in. and the 48-in. × 40-in. pallets.

Today, hundreds of millions of pallets are sold each year to support the handling and movement of all types of manufactured products. Pallets are produced in many shapes and sizes; however, the most common size in North America is 48 in. × 40-in. The most common materials are wood, plastic, corrugated board, and metal.

THE PALLET PATTERN PROCESS: MANUAL METHOD

Traditionally, companies used laborious manual methods for calculating pallet patterns, and they used "pallet pattern charts" and lookup tables to create very basic styles. This manual method of calculation was slow and inaccurate. Manual methods also proved to be inconsistent. They considered only a few alternatives and were narrow in scope, and communicating the results made preplanning difficult. With increasing mass-production techniques and the growth of product distribution on a nationwide basis, manual methods were simply inadequate.

COMPUTERS IN PACKAGING

The earliest use of computers, in the traditional packaging function, dates back to the early 1970s. At that time, the mainframe computer was a large room-sized machine used to crunch numbers for activities related to accounting, sales, and inventory control. Its use by the packaging department was limited primarily to providing simple pallet pattern configurations and a small amount of secondary package design work. Both of these tasks were performed without the use of scaled diagrams or graphics. However, mainframe programs were expensive and not readily available. Therefore, the computer did not play a significant role in packaging until much later.

The introduction of the first PCs in the mid-1980s brought about a very different opportunity as the use of these personal computers became more prominent in the business world. The PC, with the advantage of its small size, ease of use, and computing power, brought many changes. One of the most important changes was the quick acceptance of its emerging role in the area of packaging, where an ideal use was the creation of pallet patterns and packaging design.

THE PALLET PATTERN PROCESS USING THE COMPUTER

In the packaging process, the pallet base is usually considered to be fixed in size and cannot be easily changed. However, there are many variables relating to the loading of the pallet that can be evaluated to produce the optimum pallet pattern. These parameters include the maximum load height and weight, underhang and overhang requirements, minimum area and cube utilization, the size of the corrugated case, and the dimension loaded vertical on the pallet. The final compression strength of the corrugated case and the various pattern styles that can be considered for each pattern type are also important factors to be considered.

To add to these requirements, in 1988 a Joint Industry Shipping Container Committee (drawn from the membership of the Food Marketing Institute, the Grocers' Association) published the *Voluntary Industry Guidelines for Dry Grocery Shipping Containers*. These guidelines were aimed at reducing the damage from poor palletization standards. The two major components of these guidelines were to standardize on the 48-in × 40-in. pallet surface without the use of any overhang. This move also prompted other industries to adopt similar guidelines.

WHAT BENEFITS THE COMPUTER CAN PROVIDE

It is virtually impossible for the human mind or a simple lookup chart to consider the combinations of all these factors and individual user requirements. This is why today's computers and pallet loading programs are ideally suited to the task.

In a PC-based pallet pattern/loading program, the user simply types in the basic information required for the specific analysis. This information usually consists of the corrugated case size, the dimension vertical for stacking on the pallet, the weight of the filled case, the pallet size and type, allowable underhang and overhang, the maximum finished load height and weight, and the pattern types to be considered. This information is then saved in a file format that can be retrieved for later use and from which the various solutions are generated.

From the information provided by the computer, the user can then determine which pattern arrangement will best meet their needs. Hundreds, even thousands, of potential solutions can be considered in the process. The computer's calculations are consistently accurate and enable rapid evaluation of all patterns and load plans that fit within the restrictions applied by the user.

From the list of available solutions, the user can select one or more options for viewing and printing (both text and graphical reports) showing the exact location of each case, the layout of the cases within the layer, and the arrangement of each layer on the pallet. After viewing a satisfactory solution, the user can then use the software to model the compression strength performance of the corrugated case.

Using modern computers to calculate the pallet patterns is highly effective. Studies have shown that a 10% improvement is pallet load utilization is common. Often improvements are much higher than 10%. This is especially important because these improvements directly affect the profitability of an organization. In larger organizations, such savings can be many hundreds of thousands of dollars annually.

THE FUTURE OF COMPUTERIZED PALLET PATTERNS

Today's users of computerized pallet pattern/loading programs are looking for even more sophistication and reality in their ability to create reports and share this information with others.

Current pallet loading programs are far more sophisticated. They are used throughout the world to evaluate different pallet pattern options, the best pallet size to use, and which packing medium will do the best job. All of these tasks are now calculated in seconds. Each solution created can be viewed as three-dimensional color diagrams. Graphics technology now allows users to select the rotation and stacking of individual pattern layers. Even the layout of individual cases can be edited to meet any special pattern layout requirements. High-quality, very detailed and customized reports can be produced in seconds.

Modern programs can also be used to export palletizing information directly to other programs. Examples are word-processing applications, spreadsheets, specification systems, manufacturing systems, and CAD programs. Information from pallet loading programs can even provide the necessary information to drive robotic and mechanical palletizing equipment. Such information can then be shared with other departments to create a finished product specification, which can be easily communicated, controlled, and monitored for future updates and modifications.

Manufacturing companies are now beginning to understand the importance of multiple product pallet patterns, for retail store shelf replenishment and as end-aisle displays for promotional use. Programs to deal with these "multiproduct loading" situations work with many of the same inputs as standard pallet loading software. The one exception is that many different products are calculated on the same pallet at the same time, adding an extra level of complexity to the final solution.

For many multinational companies, the key to future growth is importing and exporting their products to or from other countries. This means considering how to palletize their products on at least two different pallet sizes: one for domestic use and one for import and export. This type of application is also ideally suited to modern computers and pallet loading programs.

Technology is now available that allows pallet loading programs to merge artwork and graphic images onto the surfaces of both cases and pallets. This brings a new and extremely powerful "visual reality" to the world of computerized pallet patterns and allows the most comprehensive pallet pattern reports and specifications to be created "at the touch of a button."

SUSTAINABILITY

Sustainability is a key to the future role of product palletization, and the use of the computer has never been needed more. The computer can model thousands of palletizing alternatives, across a wide range of sustainability variables, and quickly determine the most sustainable alternative. Companies will soon be measured by a number of sustainable benchmarks, one of which is efficient palletization. Using the current sustainability scorecard, cube utilization and transportation, two major elements of optimum palletization, count toward 25% of the total scorecard value.

SUMMARY

The use of computers for creating pallet patterns has come a very long way in the past 30 years. Because of the increasing pressures for modern industries to continue to change and become more competitive, there are still many opportunities that lie ahead, such as the combining of product design, packaging, and palletizing, to speed time to market. Computer models are now being used to explore the entire product life cycle, from start to finish, in an attempt to drive all the unnecessary costs out of the product. As technology continues to advance and computers become more powerful, the computerization of pallet patterns and their impact on the total business operation will grow in many directions.

CONSULTING

Howard R. Leary
Howard R. Leary Associates

Consultants are available in many technical and commercial areas of packaging. There are as many specialties among packaging consultants as there are disciplines in the packaging industries. They are independent experts who provide a temporary resource to fill the needs of a company for various reasons and purposes. This article defines who consultants are, what they can do for an organization, where they can be found, and how to best use them, evaluate them, and do business with them.

ROLES OF A PACKAGING CONSULTANT

There are any ways that an independent packaging expert can help an organization in its packaging-related business. The consultant brings skill and experience as well as a fresh point of view to a project or problem. The consultant's expertise can go to work for large and small organizations in a variety of ways:

Solve Problems. A company may have a need to resolve a concern or pursue and opportunity that can be most effectively addressed with outside expertise. Examples may be package failures in the field, loss of packaging line efficiency or the desire for higher efficiency, quality issues with packaging material, material incompatibility with packaging equipment, changing or revising the package to make it more appealing to the consumer, complying with regulations, or the desire to reduce packaging material cost.

Because the consultant is independent and perceived as an expert, he or she has certain situational power. An independent consultant can have the ability to convince members of an organization of the effectiveness of a solution better than another member of the organization can because the outside expertise validates the information. Often a factor in an operation is overlooked or generally accepted, and a fresh view from a consultant can expose the value of that factor.

The consultant has had many different experiences, usually in different industries. People working in a company generally do not have the opportunity for such varied experience, so the consultant can bring a fresh point of view and different assumptions to a situation that can lead to new and useful ideas.

Typically, a consultant would be hired first to investigate the issue and prepare a written report of recommended action. This might involve monitoring the packaging line operation, doing store or warehouse checks, testing package samples, evaluating the proficiency of line personnel, working with a material supplier on process control or other forms of evaluation. Often the implementation of the recommended action is carried out, led or supported by the consultant under a separate contract.

Augment the Packaging Staff. For companies with in-house package development or packaging engineering staffs, occasions arise when extra help is needed temporarily. This could be a major project that brings a greater workload than the group can absorb without falling behind on other committed work, or the loss of a key member of the group. In such a case a consultant can bridge the gap. Also if a major project employs a form of package different from the usual, the consultant can provide expertise in the new area for the current project as well as train the staff members who will provide continuing support.

True consultants will work on a project basis, according to a defined scope of work. The consultants need not work in the client's office, except for occasional meetings. It is wise to have a company contact person to handle the internal communication, so that the consultant can concentrate on the technical matters, in which case the client will get the most value for the fees spent.

Hiring a consultant to fill a temporary need may be a wise choice compared to a new hire, not only because there is no commitment of continued employment but because the company has use of a highly skilled expert.

Be the Packaging Staff. Some companies may not have a permanent staff devoted to developing packages or designing packaging lines, either because they are relatively small, they are in a startup situation, or their normal production historically didn't required new things. The need for a packaging specialist may be for a special project, in which case the consultant would work to a specified scope of work to achieve the goals of the project, such as design a new package or a new packaging line. In the case of a startup company, the objectives may be to design packages for new products, then source them, and then set up a packaging operation, which could be set up as separate consulting contracts. For a company that has occasional need for packaging technology support, keeping a consultant on a retainer may be the best arrangement.

Set Up a Packaging Design or Engineering Department. Many packaging consultants got their experience working in companies. If a company wants to start a package development or engineering function, or evaluate the way it is organized within the company, an experienced consultant can fill this need.

Assessment. Many companies see a need to evaluate what their company has as compared to what they could or should have. A consultant can be brought in who has had experience with other businesses to assess the shelf impact of the package, efficiency of the packaging operation, cost effectiveness of the packages, and so on. The consultant typically would examine the issues in question and prepare a report with recommendations. Implementing the recommendations may then be a second consulting contract.

In a case like this, the consultant's varies experience makes him or her uniquely qualified to achieve the desired result.

Source for Ideas. Many marketing-oriented businesses are always looking for new ideas to improve the acceptance of their products. "Creative design" consultants will brainstorm a product application and develop presentation drawings and/or models for review. These consultants are typically industrial or graphic designers with creative skill and a penchant for consumer appeal issues.

Provide Focus on an Issue. A problem or concern can sometimes persist in an organization and not be effectively addressed within an organization. In such cases, bringing in an outside expert can highlight the issue and draw attention to it. Consultants tend to be listened to more than regular members of the organization are, probably because they are a novelty or because they're being paid for their opinion. The consultant is independent of any group or department within the organization so he or she is free to dig into the roots of the issue wherever they lie. Often a fresh look from an outside perspective can easily see factors that can be less obvious to insiders. Examples of issues to which this might apply are (a) low-quality performance in a packaging or package manufacturing operation and (b) unsatisfactory packaging line efficiency or waste level.

Expert Witness. Many packaging consultants make themselves available as expert witnesses for attorneys. They investigate the evidence on the matter in litigation and provide an expert's report. In some cases they will testify in court or in deposition.

Validation. In regulated industries, particularly pharmaceutical and medical device, all packages and packaging machinery must be formally validated. Some consultants provide validation-related services such as preparation and execution of functional requirements specifications, preparation and execution of factory acceptance test protocols and qualification protocols, engineering studies to determine qualifyable process parameters, and package specifications for New Drug Approval submissions.

TYPES OF CONSULTANTS

There are various sources of consulting services, and each has its characteristic strengths and situations in which they can best serve. Different consultant types and their applications are described below.

Independent Individual Consultants. Experienced package developers or engineers sometimes choose to work independently as consultants. These are typically people that have gained experience in a company that packages or manufactures packages. They could be package developers, machinery engineers, marketers, graphic designers, industrial designers, logistics experts, regulatory specialists, polymer chemists, or other practitioners of other packaging-related technology. They typically work on limited-term defined projects, although some will accept longer-term assignments. When a project requires expertise beyond that of the consultant, he or she will bring in "associates," other consultants that will share the project to provide a complete solution for the client. When you see a consulting firm listed as "(name) & Associates" the firm is usually a single person who uses a network of other consultants. This can be a very effective approach, because the consultants brought in are known to the lead consultant to be effective in their area, and the lead consultant is free to pick the best people for the project.

Independent consultants are best for creative ideas and flexibility in their work approach and business arrangements. They have limited hours per week availability, so they may not be able to handle very large projects. They can be effective on large projects as advisors who bring special expertise. When using an independent consultant, you know that the person whose expertise was the reason for selecting them is doing the work.

Independent consultants should be defined as people who are dedicated to consulting as a practice, as compared to people who seek to consult until a new position in a company comes along, or who moonlight after hours. A full-time professional consultant will provide the most reliable results for a client.

Small Consulting Firms. Some consultants will form small companies that have support staff. One or two consultants typically lead the technical work, and others, such as designers or technicians, perform tasks that complete the project work. The support staff generally works under close direction of the lead consultants.

These firms are similar in their creativity and flexibility to independent individuals, but can usually handle more or larger projects.

Large Consulting Firm. There are no large consulting firms that specialize only in packaging, but there are numerous large engineering and construction firms that have packaging groups. For these firms, packaging is usually part of a larger project, such as the design and construction of a new manufacturing plant. These firms also have validation specialists who can provide packaging system validation specialists.

College Professors. Professors at the colleges that offer packaging degree programs offer themselves as consultants and sometimes employ students to assist in testing activities. They generally work on primary technology investigations as compared to implementing projects for manufacturing facilities for example.

Material Suppliers. Some companies that supply packaging materials offer technical services to large customers at no charge as a means to bring in or support sales. This work can often be effective and useful, but it is, of course, not independent of specific commercial interest. If the customer has a strong technical packaging leader in control of these activities, they can provide useful results. If there is an issue involved that requires independent judgment, an independent consultant may be required who has no commercial ties.

Who Are Not True Consultants. Commissioned sales representatives or brokers sometimes present themselves as consultants in that they provide design expertise to potential customers. These people can take care of the packaging needs for a customer, helping them make decisions and selling them materials or machinery. These firms are primarily sales organizations and should not be classified as consultants.

Contract engineers and designers should not be classified as consultants. They work regular hours at the customer's offices in place of permanent employees, rather than consult on a project basis.

As mentioned previously, people between jobs or moonlighters should not be classified as full-time professional consultants.

VALUE OF CONSULTING SERVICES

Most consultants charge by the hour, and in the case of a fixed price contract the price is based on the estimated hours at the consulting rate. Rates are generally higher than the hourly pay rate of a company employee, which can give the impression that the consultant is expensive. If used properly, however, the consultant can offer very good value for the fees spent.

The consultant will only spend the time required to meet the objective set, assuming that he or she is allowed to work independently of the client's location and office hours, so the time is used efficiently. He or she should have a high level of skill for the task assigned and as such should be capable of achieving the result in the least amount of time practical. The company, of course, has no overhead expense for the time spent by the consultant. Most independent consultants have a good deal of experience and expertise, which in most cases is at a very high level compared to less experienced packaging professionals employed in a company packaging group.

DOING BUSINESS

A good business arrangement will assure satisfactory results from a consulting assignment. Requirements and expectations should be clear for both parties. The first step is to define the scope of work to be performed. The detail of this depends upon the need. If a project is in the conception stage, such as the creation of a new package, the scope may be to define what needs to be done to bring it from idea to production. In a more mature project, a detailed scope of activities would be appropriate, such as design line layout, prepare bid specifications, write package specifications, and so on. Based on these requirements, the consultant should develop a proposed budget to perform the specified tasks. A good proposal should list the tasks specified. This will help if requirements change during the project's course, in which case the consultant should advise the client in advance if changing requirements affect the budget.

There may be situations when research is required to enable the consultant to develop the desired proposal. An example might be a requirement to improve a packaging process, where it is necessary for the consultant to spend a day at the client's plant, including travel, and a day developing an approach to the project. In such a case it would be appropriate for the consultant to charge for this, and the recommended plan in the proposal is something of value that the client has even if the consultant is not hired.

Consultants generally work on a time and expense basis, charging for the actual time spent and any costs incurred. This does not mean that the budget cannot be controlled. Companies generally issue a purchase order for the proposed budget amount; and if invoicing exceeds the purchase order amount, it won't be paid.

Commonly, the consultant will require a down payment to provide cash flow, especially on longer projects. Independent consultants are individuals that need a steady income, so they are not in a position to wait for project completion for payment.

Sometimes a consultant will be willing to offer a fixed price for a project if the efforts required are deemed to be predictable. This is typically when the consulting is part of a larger project done by a large engineering firm. The consultant will be careful to clearly define specified deliverables in such a case.

A retainer is a regular fee, usually paid monthly, to retain a consultant for occasional work not defined in a purchase order. The consultant is treated as a vendor, not an employee. This can work in a situation where both parties know that the needs and required work level are fairly consistent. A retainer arrangement can be convenient but lacks control of work scope and spending, so it is not frequently used.

QUALIFYING A PROSPECTIVE CONSULTANT

A consultant should be someone whose opinion you respect and value. To be sure that that will be the case, his or her qualifications should be investigated. One can ask the consultant what ideas might be pursued for the subject project, how his or her experience was gained in the relevant technical area, what other project work he or she may have done that have similarity, and what other clients he or she has worked for. Get references and ask them if the work was satisfactory. The consultant should be able to provide a resume of experience for your examination.

An ethical consultant will not take on a project for which he or she does not have the proper skill and knowledge. In such a case, he or she should recommend another consultant that will be reliable in that area. On some projects, consultants can join together to provide a complete solution.

If one has been consulting for a long period of time, that would indicate a professional level of capability and a commitment to the profession.

When considering a firm rather than an individual consultant, find out who will be doing the work and/or who is in responsible charge of it. Check the qualifications of those people.

WHERE TO FIND THEM

Referrals are the most reliable source of good consultants. If you know someone willing to recommend one based on positive experience, the selection process is simplified and short. If this is not the case, there are sources that list or find consultants.

Searchable Internet directories are available that include packaging materials, machinery, and services, including consulting. Packaging trade publications sponsor these (*Food & Drug Packaging, Packaging Digest*), as well as PMMI (Packaging Machinery Manufacturers Institute) and ASTM (American Society for Testing Materials). Thomas Register includes packaging consultants among their all-encompassing industry lists.

There are services that have consultants' abilities on file and locate them for clients, both industrial and legal IMSD Expert Services and others. These firms typically bill the client and pay the consultant directly.

IoPP (the Institute of Packaging Professionals) has a Consultants' Council that hosts a directory accessible through the institute's web site (www.iopp.org) or directly at www.packagingconsultants.org. The directory lists the council's members by expertise and industry served, and requests for information or proposals can be sent to the members of the group. All the consultants listed have been qualified by the council to be committed experienced consultants who agree to uphold the Consultants' Council's code of ethics.

If the requirements are of a research-based nature, the colleges and universities that have packaging programs can refer professors for consulting in their field of specialty.

CONSUMER RESEARCH

Joseph O. Eastlack, Jr.
Saint Joseph's University,
Philadelphia, Pennsylvania

It goes without saying that strong and effective packaging has to be an integral part of the marketing mixture. A strong package is equity. A strong package, sells a product, and a strong package justifies premium pricing.

But who defines a strong package? The shopper, because the shopper is the individual who ultimately picks up and buys the product or quickly bypasses or totally ignores it. From both the shoppers' and the marketers' point of view, the shopping experience is a battle. On the one hand, the shopper has to battle through competing items, through heavy shopper traffic, and through the checkout lines. The marketer, on the other hand, has to break through the clutter to get a few precious seconds of consideration. Several startling facts about shopping in the United States are now available. Examples include the following:

- The average supermarket contains over 25000 items, with 17000 new products being introduced each year.
- The average shopper is spending approximately 24 min in his/her normal shopping trip. This time translates to 1440 s to consider 25000 items. Not surprisingly, approximately one third of the packages on the shelf were being completely ignored. Even with more than 8200 products by-passed, the U.S. supermarket shopper still is faced with 16000+ items being considered in 1440 s; not much time for a marketer to sell his/her product.

In the United States, it is now generally acknowledged that 80% of the decisions made in today's supermarkets are in-store decisions and, of equal importance, 60% are impulse purchases. This observation means that the packaging and its effectiveness in breaking through the clutter and conveying the right imagery can determine, and does determine, a product's success or failure.

How do marketers research packaging to ensure that our products will receive a fair share of nonplanned or impulse purchases? Initially, we must define an effective package. An effective package is as follows:

- Is simple
- Quickly communicates what the product is
- Makes use of focal points
- Stands out from the competition
- Makes selection within a product line easy
- Has the right quality impression
- Reflects the image of the product
- Retains a visual connection with the past when redesigned

Package research must address each of these criteria. Effective packaging research must also be conducted with the appropriate target audience—the same target audience that is used when developing marketing strategy, planning TV commercials, and producing print ads.

GOOD PACKAGING RESEARCH

What is good packaging research? Let us begin with the premise that the packaging must be compatible with the long-term strategy and positioning of the brand. The packaging must close a sale in the store.

If we can define what the package should be, then certainly we should be able to design research to uncover whether the packaging is delivering in all the key areas.

Research should uncover shoppers' attitudes and feelings toward packaging. It should consider whether the shopper takes the time to pick the package up, consider it, and hopefully, buy it. We recognize that a designer can create a gimmick package that gets attention but does not close a sale. Conversely, a marketer can have a unique product with unique benefits, yet its packaging may be lost or buried on the cluttered store shelf. A strong package must be strong in many areas. It must have stopping power, it must generate readership and involvement with the labeling, and it must convey the imagery that helps close a sale.

Packaging for a well-established brand represents equity. Changing that package represents a risk. Packaging research must profile the equity the marketer has in his/her existing packaging and the risk he/she may encounter by making a change. Thus, packaging research must be evaluative. This statement means that it must profile to the marketer the strengths as well as the limitations of his/her package, and, at the same time, it must be diagnostic. It must generate information or fine-tune packaging designs, if fine tuning is necessary.

CONDUCTING RESEARCH

Three methods of conducting packaging research exist:

- Focus group sessions
- Mall intercept interviewing
- Test market auditing

Focus groups have several advantages as well as serious limitations. They alow you to see and hear consumer reaction. They also can provide valuable diagnostic input. However, we are all familiar with one dominant respondent totally controlling the focus group and biasing the responses of the other attendees. Many of you also have learned from attending focus groups that we often hear what we choose to hear. Often, four or five observers walk out of a focus group session with four or five different interpretations.

We noted earlier the importance of shelf visibility. It is impossible to measure the shelf prominence of a package in a focus group session. To ask a shopper whether he/she would or would not take notice of a package on the shelf is naive at best. What you gain from focus group sessions is an overall insight of "acceptable or unacceptable." If you are looking for serious negatives, then the focus group will begin to uncover problems. If you are looking for quantitative decision-making information, then the focus group session is not appropriate.

MALL INTERVIEWING

Mall intercept interviewing is widely used. In the shopping malls, we are generally able to reach target shoppers and interview them individually. The mall intercept interview is conducted on a one-to-one basis (shopper and interviewer). Accordingly, one strongly opinionated shopper cannot make or break a package, as so often occurs in the focus group session.

Areas that should be covered in the questionnaire include the following:

- Aesthetic appeal of the packaging
- Perceived product imagery conveyed by the packaging
- Believability of claims
- Effectiveness of the package in stimulating interest in trial
- Functionality of the packaging (easy to store, easy to pour, easy to hold)
- Confusion (if any) with labeling claims and instructions

Test market auditing, on face value, seems to be an effective way of documenting the impact of packaging in the store. In actuality, it is probably the least efficient method, because it is subject to so many uncontrollable variables, such as competitive pricing, positioning on the shelf, number of facings, and in-store sales. In addition, in-store auditing requires the packaging to be produced in finished form and in sufficient quantities to stock the shelves. Unfortunately, if your packaging is deficient, then the marketer will not find out until he/she has wasted a lot of time and money.

MEASURING SHELF IMPACT

Researchers have tried a variety of tools to measure shelf impact. Some have strengths and some have serious limitations. Let's consider the following:

- Tachistoscopic research
- Findability tests
- Recall questioning
- Eye tracking

Tachistoscopic Research. This method is simple to administer and provides a measure of quick recognition. The shopper is exposed to a series of scenes at brief time intervals (0.2, 0.5, 1 s) and asked to identify what he/she saw. The package that is identified most quickly is generally considered to be the best.

Unfortunately, many serious limitations exist to T-scope research. The most fundamental is the arbitrary time the researcher chooses to show each package. Does it really matter that package A communicates faster (in 0.2 s) than package B? Who determines whether 0.2 s (1/5 of a second) is a relevant timeframe?

An even greater drawback is the aspect of familiarity. As you might imagine, the familiar brands are generally those that are identified faster. Thus, when a marketer is considering a packaging modification, the T-scope may put his/her new design at a distinct disadvantage.

Findability Tests. Findability tests simply are those that ask a shopper to look at a cluttered in-store shelf scene and find specific products. Again, it is assumed that the package that can be found fastest is the most effective. We mentioned earlier that 80% of the purchases made in the supermarket are nonplanned. Thus, the findability tests that ask the shopper to locate a specific brand he/she is looking for is relevant only to those 20% who are going into the store looking for that brand. In actuality, the marketer's concern is with the other 80% who might make a nonplanned purchase. The 20% who plan to buy your product will find it, regardless of where it is located on the shelf.

Recall Questioning. A third commonly used measure of shelf impact is recall questioning. Recall, like T-scope research, is often influenced by familiarity. The well-known brands receive the higher recall scores. The new products or low-awareness brands suffer from a lack of previous exposure.

Eye-tracking Research. Eye-tracking research to document shelf prominence overcomes many of the limitations of the T-scope, findability tests, and recall. The eye tracker enables researchers to observe the shopper behavior, see what they see, see what they consider, and most importantly, observe what they ignore. Eye tracking is not hampered by the need to select an arbitrary viewing time. Researchers are able to observe what people do and how they shop the category, be it one second, one minute, or one hour. The eye tracking is not biased by familiarity.

One might even argue that the uniqueness of new brands would have an advantage, rather than a disadvantage, in drawing shopper attention. Many major marketers in the United States are using the eye tracking method to develop planograms and to pinpoint the pros and cons of additional shelf facings and horizontal and vertical layouts, and to uncover the competitive products that are strong on the shelf.

Some may argue that the eye-tracking viewing situation is artificial, and they are correct. However, the reality is that no one can duplicate the "real world," because it differs from store to store. How many times have we seen beautiful planograms never implemented in the supermarkets?

Often we refer to eye-level shelf placement as being optimal. But does eye level assume the shopper is 6 ft 2 in., 5 ft 10 in., or 4 ft 9 in.? With eye tracking, we can watch the shopper discriminate and, most importantly, see what he/she ignores. We know from eye tracking the packaging that is breaking through the visual shelf confusion.

LABEL READERSHIP

Label readership is another vital area that comprehensive packaging research must address. The designer has positioned key elements on the label to be seen and to be read. The three research tools commonly used to evaluate label readership are T-scope, recall, and eye tracking. The T-scope and recall measures suffer from the limitations described earlier that include: a fixed viewing time, contamination by familiarity and, in many instances, shopper guessing. The eye tracking shows how shoppers read the package labeling. It quantifies the advantages of top of the package versus bottom. It shows the shoppers' discriminating process and, most importantly, it allows the shopper to ponder and thoroughly examine a package if he/she chooses.

Researching packaging attributes can be accomplished only through a comprehensive and well-thought-out questionnaire. Unfortunately, many researchers attempt to answer these questions through paired comparisons, i.e., showing two potential packaging alternatives side by side. This method is a simple approach for forcing a winner, because one package will test better than the other. However, in actuality, neither may meet marketing objectives, and the end result may be the best of the worst.

DESIGNING RESEARCH

With all the above in mind, let us consider a few of my do's and don'ts when designing packaging research.

1. Do not show different packaging alternatives side by side to a shopper. The shopper will never see two executions for the same package side by side in the store. His/her frame of reference is competition. Thus, each packaging execution should be tested against competition.
2. Never control the amount of time you let a shopper look at a package. Remember, a designer is trying to develop a package that is a stopper, a package that is involving, a package that a shopper will want to take a second or third look at. When a researcher controls the amount of time he/she lets the shopper look at a package, he/she can no longer measure involvement. Speed of communication is not the key. Effective communication is far more relevant.
3. Do not live by hard-and-fast rules. Packaging designers have demonstrated time and time again that being different can pay great dividends at the cash register. Who would have guessed years ago that an orange-juice company could use the color black as their primary packaging identifier? Yet Minute Maid has done it and has done so with enormous success.
4. Do not rely on traditional advertising research recall scores. Many researchers have a tendency to rely on that magical thing called recall. Yet, recall per se is irrelevant when it comes to packaging research. A package is not on the shelf to be recalled. A package is there to be seen, considered, and sold.
5. Do not tie the package designer's hands. Respect the creativity and excellence of the packaging design industry. They are creative, innovative, insightful, and most of all, approaching their task with a marketing frame of reference. To advise a package designer that certain colors or shapes or designs will not work within a category is short-sighted. Use their talents, allow them free rein, and explore all creative opportunities before accepting or rejecting an innovation in packaging.
6. Do not forget to look at competition. The shopper considers competition prior to making his/her purchase decision. The marketer should do the same. All too often, a tendency exists to "follow the leader." If he/she is using red, then we should use red. If his/her packaging is horizontal, then ours should be the same. Keep in mind, breaking through clutter and getting attention is the first step to a sale.

Effective packaging is an integral part of the marketing mixture. An effective package catches the consumer's eye and entices the shopper to give the product a try. Successful packaging leads to successful businesses. Do not underestimate the influence of packaging. The package represents the product. The package is equity. A major change in a package is a risk. Research the risk thoroughly and logically. Remember that the package is a product to the consumer at the point of sale.

CONTAINER INTEGRITY REGULATION, USA

Yoon S. Song
Process Engineering Branch,
Office of Food Safety (OFS),
United States Food and Drug
Administration, Summit-Argo,
Illinois

INTRODUCTION

"Canning" is defined as the process of preserving food wherein a food and its containers are rendered commercially sterile by the application of heat alone or in combination with pH and/or water activity or other chemicals (1). For "canned" foods, the container must be constructed in such a way that *Clostridium botulinum*, other pathogens, and spoilage bacteria can't enter the container after the thermal process. This is called container integrity. It is important to note that foods packaged in materials other than metal cans are also considered "canned" if the food undergoes the canning preservation process. Thus, today a canned food can be packaged in a number of other types of container, such as glass jars, paperboard cans, and plastics that can be formed into anything from pouches to soup bowls to serving trays. For traditional glass and metal canning, the food is placed in an airtight container and heated to destroy microorganisms. Foods with a naturally high acid content such as tomatoes, citrus juices, pears, and other fruits don't support the growth of spore-forming food poisoning bacteria. Therefore, foods that have a high acid content, do not receive as extreme a heat treatment as do low-acid foods. They are heated just sufficiently enough to destroy both pathogenic and spoilage bacteria, yeasts, and molds. Canners and food safety regulators are most concerned about foods with low acid content, such as mushrooms, green beans, corn, and meats, because the deadly *C. botulinum*, which causes botulism poisoning, produces a toxin in these foods during growth and their spores are highly heat-resistant.

The issue of container integrity has been recognized as critical for acid and low-acid foods since the canning industry, which dates back to the early 1900s, has experienced botulism and spoilage outbreaks related to commercial thermal processes and container closure operations. In particular, several incidents of botulism in the 1970s led to increased observation by the FDA and great awareness of quality control by container manufacturers and food processors to produce as perfect a container as possible under commercial operating conditions. According to many investigation reports, major causes for microbial spoilage in canned foods can generally be attributed to (a) underprocessing and (b) post-process contamination during container cooling process, storage, and distribution. Richardson (2) reported that microbial spoilage in Australian canned foods occurring from 1955 to 1968 resulted from underprocessing (46 cases) and postprocess contamination (64 cases). Davidson et al. (3) investigated 790 swollen cans collected from the U.S. local supermarkets over a two-year period. He reported that types and incidences of the microorganisms recovered were 7.9% pure cultures of spore-forming organisms traditionally associated with underprocessing and 91.6% typical postprocess leaker spoilage microorganisms. From a study of 154 incidents of food poisoning associated with postprocess contamination between 1921 and 1979 which occurred in Great Britan and Canada, Stersky et al. (4) also concluded that channel leaks during the cooling process were one of the major defects leading to bacterial spoilage. Therefore, thermal processes and sealing operations applied in commercial practice for canned foods must be properly monitored and regulated to prevent spoilage outbreaks and avoid potential health hazards.

REGULATORY OVERVIEW ON CONTAINER INTEGRITY

Container materials manufactured for use in contact with food in the United States, whether for home or commercial use, fall under the jurisdiction of the Federal Food, Drug, and Cosmetic Act (FFDCA, Title 21 United States Code 348) whenever they are intended to be marketed in interstate commerce. In general, there are two federal agencies that regulate canned food and container in the United States: the Food and Drug Administration (FDA) of the U.S. Department of Health and Human Services (DHHS) and the Food Safety Inspection Service (FSIS) of the U.S. Department of Agriculture (USDA). In general, the FSIS regulates red meat and poultry, and the FDA regulates all the rest including food with less than 3% raw or 2% cooked meat. The FDA regulations address container integrity in Part 113 (*Thermally Processed Low-Acid Food Packaged in Hermetically Sealed Containers*) and Part 114 (*Acidified Foods*) of Title 21 Code of Federal Regulations (CFR) (Government Printing Office, Pittsburgh, 2005). The FSIS has similar regulations covering low-acid canned meats and poultry as well as acidified meat and poultry in Part 318 (*USDA Canning Regulations*) of Title 9 CFR (5).

Both FDA and USDA-FSIS regulations are specific for thermally processed foods packaged in hermetically sealed containers. A hermetically sealed container is defined as a container that is designed and intended to be secure against the entry of microorganisms and thereby to maintain the commercial sterility of its contents after processing (Part 113.3 of Title 21 CFR). In particular, the regulations contain provisions (Part 113.10 and Part 114.10 of Title 21 CFR; Part 318.310 of 9 CFR) for training of personnel who supervise critical areas in thermal processing and packaging of canned foods. This implies that operators of thermal processing systems and container closure technicians must be under the direct supervision of persons who have successfully completed certified courses of study in canning technology. Currently, the Better Process Control Schools (BPCS) sponsored by the FDA provides an approved course of instruction.

RIGID CONTAINER REGULATIONS

The rigid container is defined as “a container that is neither affected by the enclosed contents nor deformed by external pressure up to 10 psig” (Part 318.300 (j) of Title 9 CFR). Examination of metal containers for defects and can double-seam measurements described in Part 113.60 (a) (1) of 21 CFR and in Part 318.301 (b) of 9 CFR are very specific, describing (i) the types of defects to look for (cutover or sharpness, skidding or deadheading, false seam, droop at the crossover or lap, and condition of inside of counter sink wall for evidence of broken chuck), (ii) the specific double-seam parameters to be examined (cover hook, body hook, tightness or wrinkle, thickness, width, overlap, and countersink), and (iii) and the specific measuring methods to be used (micrometer method, gauge method, and scope or projection method). For glass containers, the only specific procedure discussed is the cold water vacuum test. FDA regulations state that *it shall be done before actual filling operations and that the result shall be recorded*. Detailed procedures to conduct integrity tests for metal and glass containers have been well described in guidance documents, such as FDA’s Bacteriological Analytical Manual (BAM) (6, 7) and Food Processors Institute (FPI) manual (1).

Part 113.60 (a) of Title 21 CFR and Part 318.301 (b) of 9 CFR also require that regular observations shall be maintained during production runs for gross closure defects and any such defects shall be recorded along with the corrective action taken; that at intervals of sufficient frequency (at least once every 30 min recommended) a qualified person shall visually examine the top seam of a can randomly selected from each seaming head or the closure of any other type of container being used and shall record the observations made; and that additional visual closure inspections shall be made at the beginning of production, immediately following a closing machine jam or after machine adjustments. In addition to visual examinations, both FDA and USDA require teardown examinations to be performed and recorded by qualified individuals. Furthermore, regulations recommend that sample containers be tested at intervals not to exceed 4 h.

SEMIRIGID AND FLEXIBLE CONTAINER REGULATIONS

The semirigid and flexible container is one that is not affected by the enclosed contents but is deformed by external pressure of 10 psig or less (Part 318.300 (j) of Title 9 CFR). Unlike regulations for all rigid containers, the regulations for flexible and semirigid plastic packages are not clearly specified in CFRs other than the regular observations. The reason for this is that when these regulations were written, there was plenty of information concerning the procedures for testing metal cans and glass jars but very little for plastic containers. For instance, FDA regulations in Part 113.60 (a) (3) of 21 CFR only state that *for closures other than double seams and glass containers, appropriate inspections shall be conducted and tests be made by qualified personnel at intervals of sufficient frequency to ensure proper closure machine performance and consistently reliable hermetic seal production. Records of tests shall be maintained.*

The USDA-FSIS regulations described in Part 381.301 (d) (1) and Part 318.309 (d) of 9 CFR include more specific details on the evaluation of semirigid and flexible containers, such as visual test, physical test, and incubation test. The regulations require that heat seals and the entire container be visually inspected before and after thermal processing operation by a trained closure technician with sufficient frequency and that corrective actions be promptly recorded; that physical test be performed after thermal processing operation by a trained closure technician at sufficient frequency (at least once every 2 h recommended) and that corrective actions be promptly recorded; and that at least one finish container per batch be incubated for not less than 10 days at 95 ± 5°F. In addition, the USDA-FSIS requires that empty containers, closures, and container rollstock be inspected, stored, handled, and conveyed in a manner to ensure they are clean and free of defects that may affect the product or package integrity.

Processors who pack product in flexible pouches under military contract are also required to comply with specific U.S. military contract requirements (8, 9). A 100% visual inspection of the seals on every pouch produced may be required both before and after thermal processing. Other requirements are (a) destructive tests in which sample pouches must withstand internal pressure at 20 psig for 30 s (burst test), (b) residual gas tests ($<$10 mL), and (c) incubation tests after thermal processing for not less than 10 days at 80–95°F.

In response to requests by industry to evaluate containers and closures, the Food Products Association (FPA, the former NFPA), in joint efforts with FDA, USDA, and industry, developed guidance documents that (a) provided a classification of visual exterior defects of flexible and semirigid containers, (b) established the relative hazard of each defect to public health, and (c) defined sampling rates and action levels for the various defects in flexible and semirigid containers (10, 11). In addition, FDA published the *Bacteriological Analytical Manual* (BAM) that contains a chapter entitled, “Examination of Containers for Integrity” (12). This chapter describes procedures for the examination of paperboard packages, flexible pouches, plastic cups and trays with flexible lids, and plastic cans with double-seamed metal ends. Test procedures included are air leak testing, bio-testing, burst testing, chemical itching, compression testing, distribution test, dye penetration, electester, electrolytic, gas leak detection, incubation, light, machine vision, proximity tester, seam scope projection, sound, tensile testing, vacuum testing, and visual inspection. The manual, however, doesn’t reflect current advances in inspection techniques for container integrity.

SPECIAL CONSIDERATIONS FOR EMERGING INSPECTION TECHNOLOGIES

Inspection techniques for detecting package defects in the food industry have been moving toward nondestructive and online methods that test all packages. The applicability of these emerging inspection techniques to various food containers with different types and compositions has become of great interest to the industry. In spite of rapid advances in technologies, however, severe limitations of each inspection technique still have become apparent. This reality, coupled with the increased use of flexible and semirigid plastic packaging for acid and low-acid foods, made it necessary for the FDA to continue to investigate the integrity of plastic packages.

In the United States, the National Center for Food Safety and Technology (NCFST) in affiliation with the FDA has evaluated and reported several state-of-the-art techniques; these include pressure differentials, magnetic resonance imaging, ultrasonic immersion and airborne imaging, high-voltage leak detection, and thermal imaging techniques. However, there is still not sufficient information available on capabilities and limitations of the emerging techniques, in detecting various package defects and tampering, over traditional visual and destructive offline inspection methods. It is because validation of each technique is container-specific, and the detection sensitivity and online applicability of a technique depend upon targeting defect types, container shapes, and packaging materials. These evaluation studies should continue and will ultimately result in enhancing efficiency in removing different types of defective packages, reducing the risk of product recalls and subsequent outbreaks, and improving the overall safety of the food supply.

CONCLUSIONS

In summary, FDA’s major concern regarding container integrity centers on the postprocess contamination of acidified and low-acid canned foods. Requirements on all metal double-seamed cans are clearly stated in Codes of Federal Regulations, but the regulations for heat-sealed flexible and semirigid plastic packages are not clearly specified. It generally means that integrity tests for flexible and semirigid containers developed by industry, in the case of pouches, are reviewed by FDA, USDA, and/or the army for applicability and soundness. If acceptable, the tests are expected to be used. For many years, the emphasis on container integrity had been on rigid containers such as double-seamed metal cans because the container integrity issue started with processing of the metal cans, and metal cans are still the dominant container in the United States. However, FDA and USDA are just as concerned with the integrity of hermetically sealed, nonmetal containers and are monitoring them as closely as metal ones.

CONTROLLED RELEASE PACKAGING

KIT L. YAM
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

Controlled release packaging (CRP) is a technology for producing a new generation of packaging materials and final packages that can release beneficial active compounds such as antimicrobials, antioxidants, enzymes, flavors, nutraceuticals, anti-browning agents, and bioactive compounds in a controlled manner to enhance food quality and safety as well as extend shelf life. CRP may be considered as a form of active packaging (see Active packaging), in which the package is used as a delivery system to release active compounds to favorably modify the internal environment of the package. Currently, this technology is being developed in the laboratory and the industry, but it has the potential for commercial application in the future.

BASIC CONCEPT

Figure 1 compares the traditional method and CRP for adding active compounds to a food product. The traditional method is to add the active compounds directly into the initial food formulation as shown in Figure 1(a); however, once these compounds are consumed in reaction, protection ceases and food quality degradation may increase rapidly. Increasing the amounts of these compounds is sometimes not feasible as the levels in the food formulation are regulated by the U.S. Food and Drug Administration (FDA).

CRP can overcome this limitation by continuously replenishing the active compound via controlled release from the package, which is necessary for achieving long-term stability of the food. Different methods are available to incorporate active compounds into the package; for example, as shown in Figure 1(b), active compounds are incorporated into the food-contact layer of a package that is designed to allow the slow release and replenishment of active compounds to maintain an effective level during the shelf life of the product.

The benefits of controlled release of antimicrobials and antioxidant to retard microbial growth and lipid oxidation have been demonstrated in the laboratory. In some situations, the best results may be achieved by a combination of adding a portion of these compounds directly into the food formulation and then replenishing the remaining portion through CRP.

ACTIVE COMPOUNDS

Currently, the most commonly used active compounds for CRP research are antimicrobial and antioxidants. For example, antimicrobials include nisin, potassium sorbate, lysozyme, oregano, and garlic as well as antioxidants that include tocopherols, sesamol, BHT, and quercetin. The selection of active compounds depends on the application, activity of the active compounds, safety considerations, ability of the active compounds to be incorporated into the package, and cost. Natural active compounds are often preferred.

The volatility of active compound is also an important consideration. The applications of nonvolatile compounds are limited to products that have direct contact with the package, because direct contact is necessary for the migration of these compounds to the product. However, volatile compounds may be used for products that do not have direct contact with the package, because after being released from the package, these compounds may vaporize to the headspace and then condense onto the product.

ABILITY TO CONTROL RELEASE

A technical challenge is to achieve the ability of "controlled release." For example, how does one produce a CRP

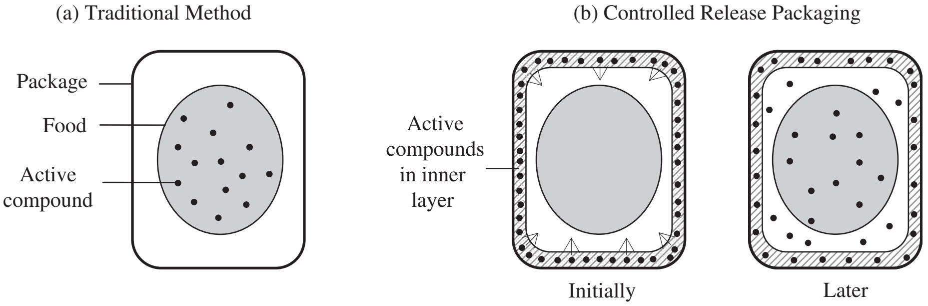

Figure 1. Traditional method versus controlled release packaging.

film that has a desired release property? In theory, it may be achieved by manipulating several factors that include the active compound or compounds to incorporate into the film, the polymer or polymers to make the film, and the film making processing method and conditions [1]. Those factors, along with the resulting structure or morphology of the film, will affect the diffusion of active compound in the film and the release of active compound from the film.

Another technical challenge is the determination of what release rate is suitable for a particular product. This decision requires an understanding of the stability of the product. For example, to reduce microbial growth or lipid oxidation of a food product, it is necessary to study the microbial and oxidative kinetics of the food product exposed to the condition caused by the release of active compound. This condition includes the concentration of active compound surrounding the product (which changes with time because the release of active compound from the film decreases with time) and temperature. The aim of the study is to determine the optimum condition and the target release rate required of the film.

Uncontrolled release may result in wastage of active compound. For example, lipid oxidation reactions have an inherent induction period in which the primary oxidation product remains constant. During this period, dumping antioxidant is not necessary and may also lead to pro-oxidation, and thus, the release of antioxidant should be kept at a low rate.

POTENTIAL APPLICATIONS

This technology is particularly useful for controlling food degradation reactions that are continuous and increase exponentially, such as microbial growth and lipid oxidation, because constant replenishment of inhibitory substances prevents runaway deterioration of safety and quality. Examples of potential applications are processed food products that require long-term inhibition of lipid oxidation and perishable food products such as fresh meat, which require short-term or intermediate-term inhibition of microorganisms.

CONVEYING

Paul J. Zepf
Zarpac, Inc.—Engineering,
Oakville, Ontario, Canada

DEFINITION

The Conveyor Equipment Manufacturers Association (CEMA) of the United States defines a conveyor as a horizontal, inclined, or vertical device for moving or transporting bulk materials (cereals, aggregate, powders, etc.) or objects (such as bottles, cases, cartons, products, etc.) in a path predetermined by the design of the device and having points of loading and discharge fixed, or selective; included are skip hoists, vertical tractors and trailers, tiering machines (truck type), cranes, monorail cranes, hoists, power and hand shovels, power scoops, bucket drag lines, any conveyor designed to carry people, and highway or rail vehicles.

Basically, a conveyor is made up of one or more sections that transfers (via an intermittent or continuous media) such items as inputs (bottles, bags, caps, cartons, product, etc), packages, cases, or pallets from one location or position to another. Each section may be driven independently at varying speeds or employ gravity as a method of transfer. The *conveyor speed* is the surface speed of the conveyor in feet per minute (fpm) or meters per minute (mpm), while “line speed” or more properly actual run speed is the transfer rate, given in pounds or kilograms per minute, parts per minute (ppm), or containers per hour (cph).

Two or more rows of containers carried side by side without internal divider rails on the same conveyor chain bed are collectively referred to as *mass flow*, while carrying only a single row is referred to as *single-lane* or *in-line* flow. For mass flow, the number of adjacent rows is referred to as the *line width* and is given as an integer, while *conveyor width* refers to the width of a section of moving conveyor element expressed in inches or meters. Pitch is defined as the center-to-center spacing of containers, given in inches or meters. The pitch in the direction of motion is referred to as the longitudinal pitch or travel distance, while the spacing across the width of the conveyor is the transverse pitch or sideways distance. The full width of the conveyor is called the “conveyor frame width.”

The integration of all packaging machinery with their conveyors is critical to produce a seamless transfer and assembly system that results in the consistent regular flowing movement of inputs, packages, or cases that enter into the packaging production process at specific points and are assembled, identified, verified, and distributed to fulfill customer needs. Integration of conveyors to conveyors or conveyors to packaging machinery should follow the principles as stated below in order for the packaging line to be successful.

Integration of conveyors with machinery should consider the following factors:

1. Selection and design of proper conveyor transfer type or types for the system to fulfill needs.
2. Design and installation of (a) *guiderails* and (b) *sensing and handling control components*.
3. Speeds, feeds, dynamics, and loads to achieve the required results.
4. Compatibility of *interconnecting machinery* and other conveyor types.
5. Installation and maintenance of conveyors and machinery.

There are many other components that can be attached to or are part of a conveyor system that perform special functions such as:

1. Quality inspection (vision, dud, low/hhigh/no fill, no/cocked cap, no/cocked label, count, etc.).
2. Coolers, freezers, conditioning ovens, cooker ovens.
3. All types of coding units (inkjet, laser, impression, stencil).
4. Staging or allowances for manual operations.
5. Hard and soft reject stations for off loading out of spec materials or sample selection.
6. In-process storage (buffers or sometimes called accumulators) areas.
7. Combiners, dividers, turners, orientors, fallen bottle removal, etc.

All of these devices require some form of conveyor or transfer equipment as the main critical element to manipulate or identify or test the products and/or inputs. Conveyors are therefore an integral part of the packaging process and are elements or machines that have their own reliability and maintenance issues.

DESIGN AND INSTALLATION OF CONVEYOR SYSTEMS

Traditionally, conveying systems were designed without paying much attention to drive dynamics, the forces imposed on the conveyor and product, or the effects of these forces on container stability. Design criteria were based on the average running-speed requirements and mechanical longevity. In fact, typical design formulas considered only rough estimates of the loading (forces) combined with factors that represent the number of startups and the amount of product slippage. Most present chain manufacturers are improving the nature and extent of engineering for their products. Chain manufacturers such as Rexnord, UniChain, and MCC have technical engineering data and software programs available to assist in designing effective conveying systems related to their products. Also, engineering services companies have developed their own specialized software programs for line design and conveyor systems integration.

In recent years, increasing demands, economics, and environmental concerns have placed enormous pressure on production facilities to increase operating speeds, reduce wastage, reduce rework, and cut manpower requirements. These changes have pushed traditional design methods to the limit of their effectiveness. In addition, the aesthetic appeal of complex input shapes (bottles, products, cartons, cases, etc.), the use of lightweight materials, the variety and nature of materials themselves, and input thin walling to reduce material weight (in film, corrugate, paper, plastic bottles and glass bottles) have resulted in a new generation of stability and control problems associated with the transport and manipulation of materials and containers by conveyor.

With current conveyor technology and the demand for high-productivity packaging lines, simple conveyors must be designed, built, and installed to run at a run utilization or availability of over 99.5% per month. Conveyors with attachments must be designed, built, and installed to run at a run utilization of over 99.0% per month (buffers, combiners, dividers, reject mechanisms, etc.).

For most cases, conveyors should be designed and run with minimum backpressures on the inputs or products in order to minimize part damage, maximize control, and maintain product conformity for optimum quality.

This article only *summarizes* the concerns and methods of container or input transport by conveyors.

CONVEYING SYSTEMS: OVERVIEW

There are many types of conveying systems in common use today. These conveyor designs are listed and described in the following pages.

Slat-Top Chain (Also Called Table top) Design (see Figure 1)

This style of conveyor comes in the following designs and materials (see Figure 1):

1. Magnetic hinged-joint chain conveyors or magnetic slat-top chains (also called tabletop) chain conveyors.
2. Steel or stainless-steel hinged-joint chain conveyors or steel or stainless-steel slat-top chains (also called tabletop) chain conveyors.
3. Plastic hinged-joint chain conveyors or plastic slat-top chains (also called tabletop or flat-top) chain conveyors.
4. Magnetic slat-top chains (also called tabletop or flat-top) roller chain conveyors.

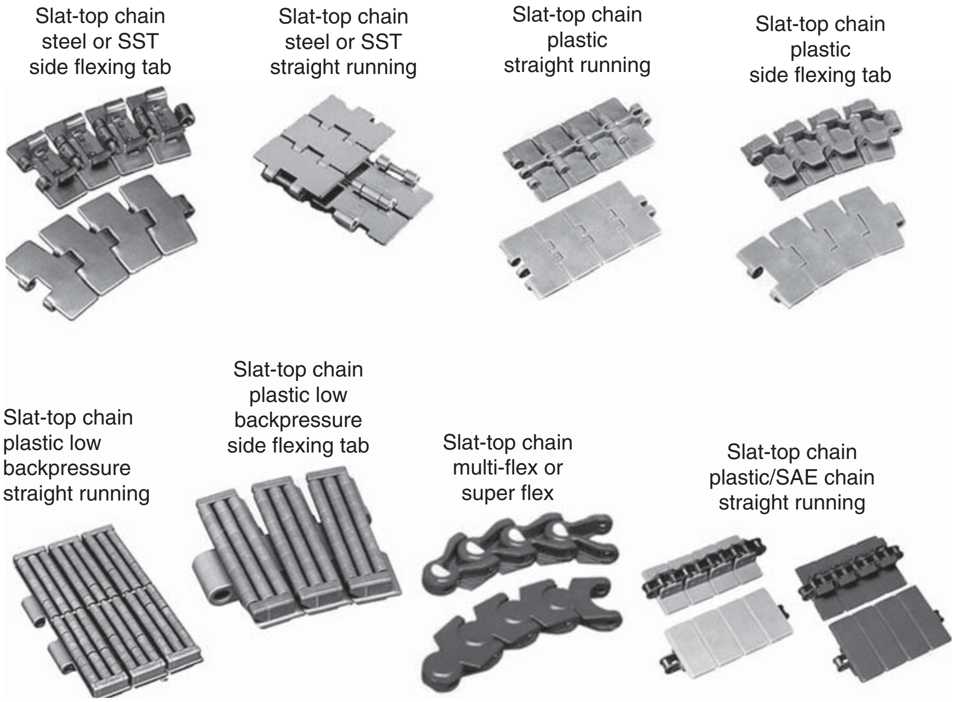

Figure 1. Types of slat-type or table-top chains.

5. Steel or stainless slat-top chains (also called table-top or flat-top) roller chain conveyors using SAE roller chain underneath to drive the slat top chain.
6. Plastic-top roller chain conveyors for low backpressure using SAE roller chain underneath to drive the slat-top chain.
7. Stainless-steel multiflex chain conveyors.
8. Plastic multiplex or super flex chain conveyors for small-curve-radius requirements.
9. Side-flex hinged chain conveyors or side-flex slat-top chains (also called tabletop or flat-top) chain conveyors.
10. Flex link™ hinged conveyors or flex link slat-top chains (also called tabletop or flat-top) chain conveyors.
11. Steel or stainless steel mesh belt chain that can have up to 20 ft of width.
12. Plastic or ceramic modular belts that can be mesh or mat style and widths varying from 12 in. (300 mm) to 120 in. (3000 mm).

Rex™ LBP Trademark of the Rexnord Company.
Flex link™ Trademark of SKF Flexlink conveyor systems.

Mesh-Top or Open-Top Modular Belt Chain Design (See Figure 2)

This consists of

- Metal (steel or stainless steel) straight mesh conveyors
- Metal (steel or stainless steel) curved mesh conveyors
- Plastic straight mesh conveyors

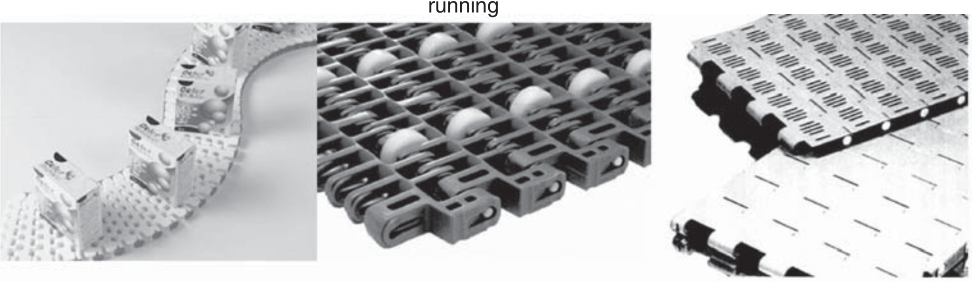
Mesh chains, like mat-top chains, form wide-running conveyors. They are constructed from steel or stainless-steel wire that is formed into interlocking loops or injection-molded plastic wide links connected together by stainless-steel or plastic long pins (pins are as wide as the chain). Mesh chains are manufactured in various mesh patterns. They are designed for slow mass transport of products such as bakery items, solid food products, small metal products, and some confectionary items where drainage or cooling is required. However, they are usually designed for the mass transport of stable inputs needing no orientation requirements. The metal mesh chains are excellent to use in hot and some corrosive environments. Mesh conveyors are connected together usually via a butt transfer or overlap in-line transfer. Curved or side-flexing configurations are possible.

New plastics and designs have now resulted in plastic mesh-type chains, giving low friction, reduced weight and torque requirements, wet capability, excellent drainage or fall through, better economy, and effectiveness for products where steel or stainless mesh or mats either cannot be used or are not economical. Mesh-type conveyors generally have less surface area in contact with the product due to the large percentage of holes or open space in the chain. Mat chains usually have more surface area in contact with the product.

Mat-Top™ or Modular Belt Chain Design (See Figure 2)

This consists of

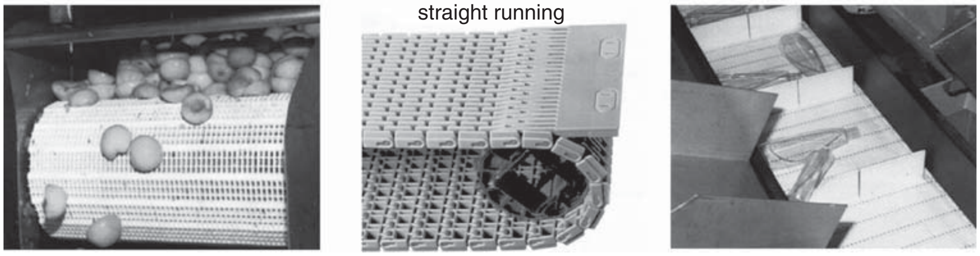
- Mat metal (steel or stainless steel) conveyors
- Mat-type plastic conveyors (see Figure 2).



Plastic modular belts side flexing type

Plastic modular belts low friction back mesh type pressure straight running

Plastic modular belts mat type straight running



Plastic modular belts mesh type straight running

Plastic modular belts mesh type w/comb transfer plate straight running

Plastic modular belts mat type w/flights straight running

Figure 2. Types of plastic modular belts.

Mat-top™ (Trademark of the Rexnord Company) chain, like belts, are wide-running conveyors. However, they are usually designed for the mass transport of stable inputs needing no orientation requirements. The chain is constructed using one wide link per longitudinal pitch as opposed to many adjacent narrow links. The wide links are connected by stainless-steel or plastic long pins so that two adjacent links resemble a "panel hinge" or "piano hinge." The links may have slots or holes for drainage. Mat conveyors are connected together usually via a butt transfer or overlap in-line transfer. Curved or side-flexing configurations are possible. These conveyors, although having flat running surfaces, are not considered flat-top chains.

New plastics and designs have now resulted in plastic mat-type chains, giving lower friction, reduced weight and torque requirements, wet capability, better economy, and effectiveness for products where steel or stainless-steel mats cannot be used or are not economical.

These conveyor types are composed of individually hinge-connected flat slats that form a smooth surface or plastic flat slats that are connected to a standard roller chain, usually number 60 chain. They function at any level, including substantial elevations, although the most common usage height is 36–42 in. (910–1070 mm) from the floor and usually transferring product in a horizontal plane.

Slat-Top Chain (Also Called Table top) Conveyors (See Figures 3 and 4)

These are sometimes called *flat-top conveyors*, can run at high speeds (generally up to 300 fpm or 100 mpm) and are widely used, for example, in the filling and packaging of bottles and cans, where production speed requirements constantly push the chain to their design limits. These chains are also used for many industrial conveying requirements, such as the manufacture and packaging of bearings, small mechanical components, blow-molded parts, and injection-molded parts. They can even interface effectively with robotic systems used in manufacturing and packaging. Slat-top chain conveyors use plastic or metal or a combination of the two materials in their construction (excluding the link pins, which usually are stainless-steel or ferritic tempered steel).

Plastic chain is usually made of predominantly three materials:

1. Acetal or delrin base chain for frictional requirements needing an approximate coefficient of friction 0.25–0.3 dry and 0.2–0.25 lubricated.
2. Low friction (LF) (about 18% Teflon) chain for frictional requirements needing an approximate coefficient of friction 0.15–0.2 dry and 0.1–0.15 lubricated.
3. High-performance (HP) (about 26% Teflon) chain for frictional requirements needing an approximate coefficient of friction 0.1–0.15 dry and 0.05–0.1 lubricated.

The proper plastic slat-top chain, which is dependent on friction, temperature, and speed requirements, is normally used for conveying plastic containers and other nonabrasive products that have a degree of stability.

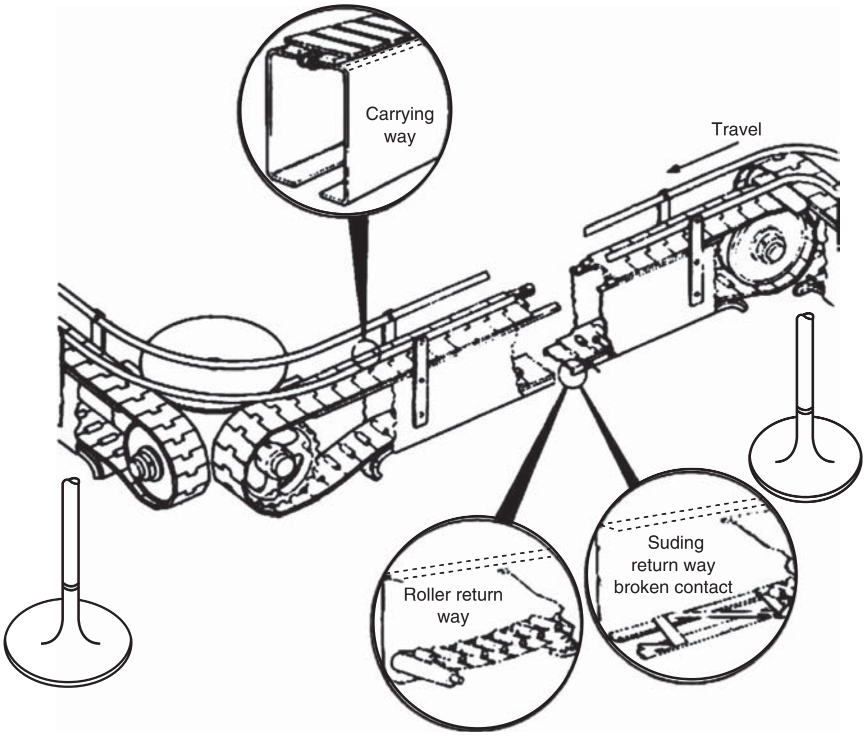


Figure 3. Typical straight-running slat-top-type conveyor design.

Lubrication of these chain types can take the form of a spray mist on the idle top side of the chain. The spray mist consists of soft water mixed with minute amounts of special liquid soaps specially formulated for either plastic or metal slat top chains.

Glass containers, steel cans, and abrasive-type products are generally conveyed on carbon or stainless-steel slat-top chains. Sometimes plastic slat-top chains can be used as an economy measure or noise reduction measure where its application is suitable.

Hinged slat-top chains or roller-driven slat top chains come in the following standard widths to fit the needs of the packaging process. All widths are narrow as compared to mat or mesh plastic modular chain. Standard widths are $3\frac{1}{4}, 4\frac{1}{2}$, 6 (not common) 7.5, 10, or 12 in. (89, 108, 152, 190, 254, and 305 mm) wide, and containers are carried at medium to high speed in single lane or mass flow. Speeds over 300 ft (90 m) per minute may be possible for specific chain materials and under certain conditions. Generally, speeds of under 300 fpm are for normal applications.

The chain or hinge runs in a “channel,” which is specially designed to support the chain or hinge on both sides and can carry both the loaded and return sections. The channel is fitted with wear strips to reduce friction and prevent long-term damage to the channel and slat top chains. The channel is designed to allow the hinged section to pull through on top, feed through the drive and idle sprockets, and return below the channel smoothly without hesitation. There is always a catenary or return chain slack at the drive end, and its profile affects conveyor torque.

Slat-top chains may be either straight-running or side-flexing. Straight-running chain is simple in design but requires special devices such as turntables or dead plates in order to move product through any type of turn. A side-flexing conveyor is more expensive but provides smooth, continuous turns and transfer of products. Side-flexing gives more control and flexibility than straight-running slat-top chains.

There is a fundamental problem with the use of side-flexing chain in that side forces are imposed on the chain, which can cause it to twist and lift out of the channel. There are four common designs of side-flexing chain: tab, wedge, magnetic, and super flex (or multi-flex).

Tab. Tab chain uses short lips on the underside of the links to hold the chain in the channel and keep it from lifting. Unfortunately, the tabs cause increased side loading and a longer maintenance time for chain repair or replacement.

Wedge. The body of the links are tapered, decreasing in width near the top surface of the chain. The channel has a mating taper that prevents the chain from twisting or lifting. Unfortunately, the wedge causes increased side loading but less than tabs and a longer maintenance time for chain repair or replacement.

Magnetic. Magnetic chain has permanent magnets located in either the chain or the channel. The magnetic attraction between the channel and the chain holds the chain into the channel. Plastic chain can be used in plastic channels with magnetic impregnated materials only if the link pins are of a ferrite material.

Super flex (Sometimes Called Multi-flex). Very tight radius side-flexing chain that can usually be easily lifted out for cleaning and inspection.

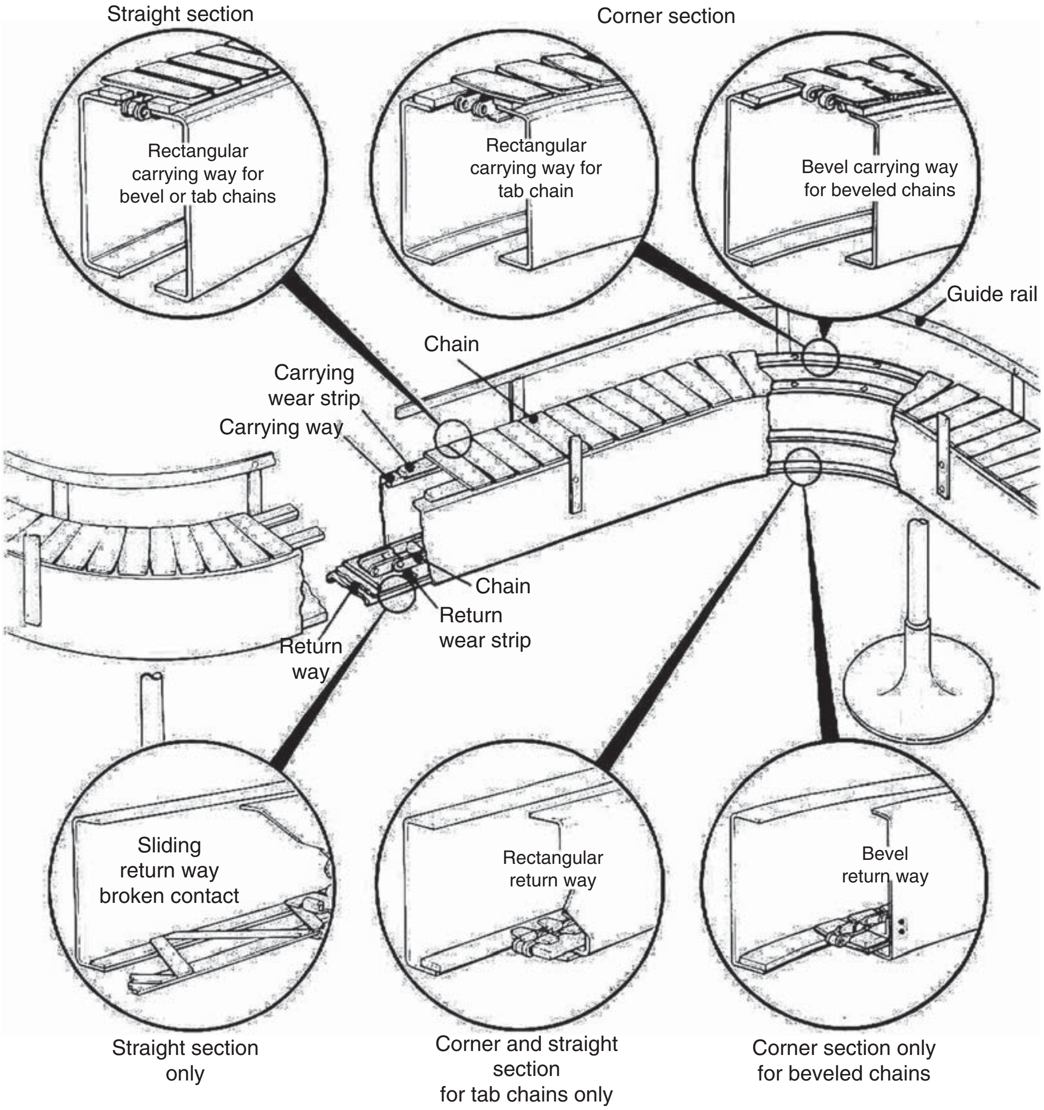

Figure 4. Typical Side-Flexing Slat-Top-Type Conveyor design.

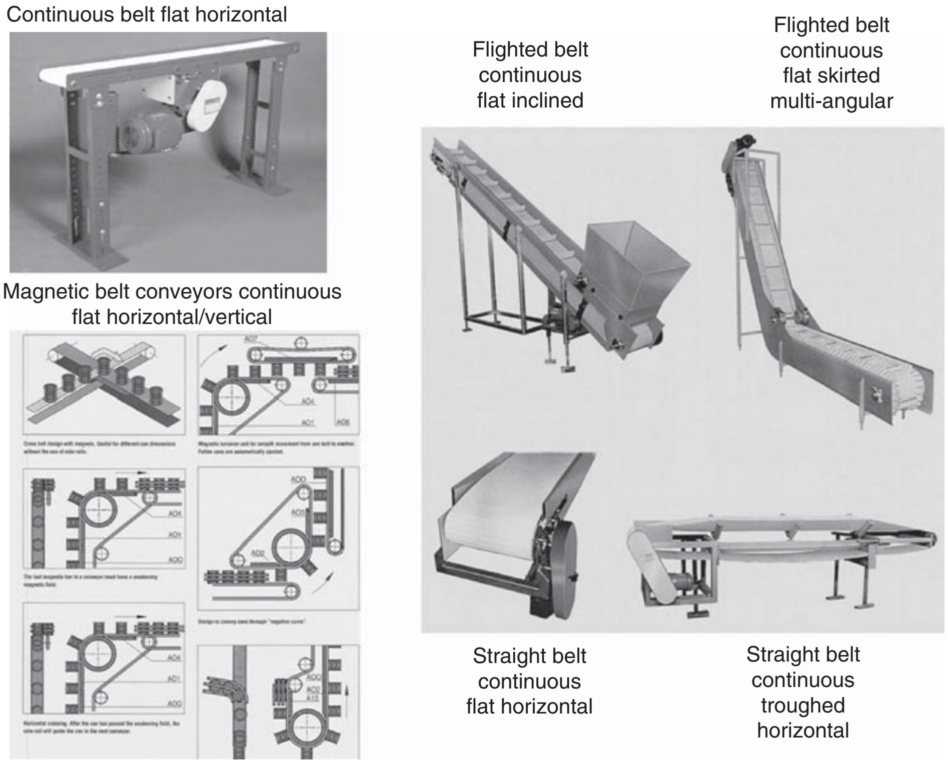
Cloth, Rubber, Synthetic, Reinforced, or Composite Belt Designs (See Figure 5)

This consists of

- Troughed belt conveyor for bulk granular transfers
- Spiral belt conveyors
- Flat straight belt conveyors
- Magnetic flat belt conveyors
- Retracking belt conveyors
- Magnetic spiral belt conveyors
- Flighted belt conveyors

A *belt conveyor* is defined as an endless fabric, rubber, plastic, leather, or metal belt operating over a suitable drive, tail end, and bend terminals. Most modern belts are reinforced with steel or Kevlar cords to increase strength and performance. In the case of handling bulk materials, packages, or objects placed directly on the belt, the belt is supported by and operates over belt idlers or a slider bed. Belt conveyors use a belt as a carrying medium for the controlled movement of a great variety of regular and irregular-shaped commodities, ranging from light and fragile to heavy and rugged, to granular, and to solid unit loads. The belt conveyor can be level or angled up or down. The angle of transfer is limited mainly by the stability of the commodity and strength of the product being moved. Belt conveyors are connected together usually via a butt transfer, or one belt is above or below the other and the product drops onto the downstream belt conveyor.

A belt conveyor consists of a flat belt wrapped around two end rollers (one powered, one idle) and supported along its length on both the loaded and return sections. The “loaded section” is the portion of the belt that carries



Continuous belt flat horizontal

Magnetic belt conveyors continuous flat horizontal/vertical

Flighted belt continuous flat inclined

Flighted belt continuous flat skirted multi-angular

Straight belt continuous flat horizontal

Straight belt continuous troughed horizontal

Figure 5. Belt conveyor types.

product (from idler roller to driver roller), while the return section runs from the driver back to the idler underneath the top section to form a closed loop. Belt conveyors can be driven at the drive or discharge end or at most locations on the return leg, generally near the discharge end. Common practice is to drive from the discharge end. Pushing by driving from the idler end is problematic, but could be used for very short lightly loaded belt conveyors.

Support for the top section may take the form of a fixed sheet or metal on which the belt slides or a series of equally spaced free-turning rollers or slider bars. Support for the return section takes the form of free-turning rollers or a stationary metal strip or horn. A special type of belt conveyor is the trough conveyor, which has troughing idlers that consist of two or more rollers arranged to turn up the edges of the belt to form it into a moving trough for usually granular or aggregate products.

Belt conveyors run at a variety of speeds and conditions. Belt conveyors can be used as follows:

1. To transport granular bulk, boxes, cartons, confectionery products, or randomly distributed containers.
2. To set the pace of assembly operations.
3. As a timing medium for integrated handling systems or subsequent machine operation.
4. For controlling and/or spacing products through the use of top and bottom or side-to-side grip belts.

Lug or bar chain design

This consists of

- Car-type conveyor
- Crossbar conveyor
- Drag chain conveyor
- Flight or bucket conveyor
- Floor chain conveyor
- Overhead trolley conveyor
- Pan or apron conveyors
- Pallet-type conveyor, indexing or continuous
- Pin-type slat conveyor
- Pocket conveyor
- Pusher bar conveyor
- Pusher chain conveyor
- Reciprocating-beam conveyor
- Rope and button conveyor
- Shuttle conveyor
- Sliding-chain conveyors
- Walking-beam conveyor
- Vertical elevator chain conveyor

Lug or bar chain conveyors transport items via hooks, brackets, or bars attached to the top or bottom sections of most types of chains at a predetermined pitch, which will pull or push the input or product with no slippage.

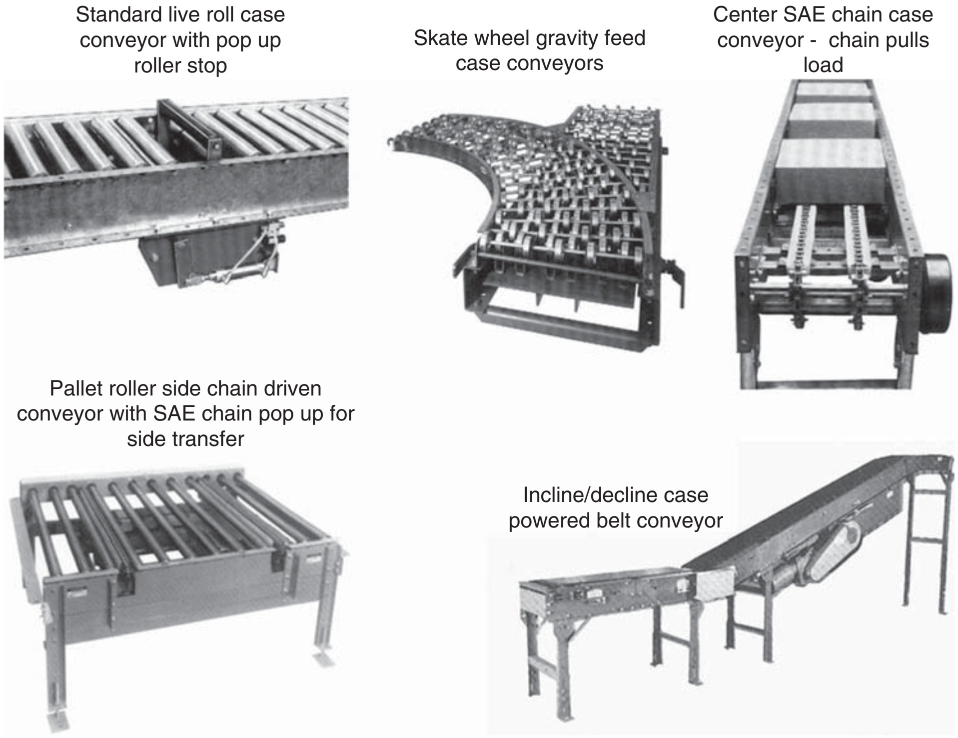


Figure 6. Case and pallet conveyor types.

Roller Design (See Figure 6)

This consists of

- Nonpowered roller or wheel conveyors or gravity roller or wheel conveyors
- Chain-driven live roller conveyors
- Roller spiral gravity conveyor
- Belt-driven live roller conveyor
- Line-shaft roller conveyor—straight, curved, and spiral
- Skate-wheel spiral conveyor—straight, curved, and spiral
- Skate-wheel conveyor

This type of conveyor system is used mainly for transporting large and/or heavy inputs or components such as large cartons (empty or full), cases, pallets, or unit loads.

Screw Design (See Figure 7)

This consists of

- Screw conveyors
- Ribbon flight screw conveyor
- Gravity chutes or spiral cage

Mostly granular or dough-type products are transported and/or mixed via screws that are fully or partly contained in a tube or trough.

Cable Design (See Figure 8)

This consists of

- Floor cable conveyors
- Overhead track with powered rollers
- Steel cable conveyors
- Steel-sheathed cable conveyors
- Urethane cable conveyors

Another basic conveyor design employs a cable as the transporting vehicle. The cable conveyor is used as an inexpensive method of moving lightweight containers, primarily empty cans and plastic bottles, in single-file mode only, at speeds of $\leq$800–1000 containers per minute. The method is also used in the food industry for handling full containers (usually cans) generally at speeds under 500 containers per minute. In operation, a $\frac{3}{8}$-in. (9.5-mm)-diameter, nylon-coated steel cable driven by a motor is supported on small-diameter sheaves along its length. The containers are seated on top of the cable and held in position by adjustable side guiderails made of stainless steel, aluminum, or plastic. The cable provides the drive and friction to move the container.

This method provides relatively low-cost conveying, notably for conditions where lengthy distances must be economically traversed in a plant environment. A capacity for long pulls and curves can minimize transfer points. Although about one-third the cost of flat-topped conveyors, the system can be used effectively for accumulating containers such as plastic bottles and metal cans.

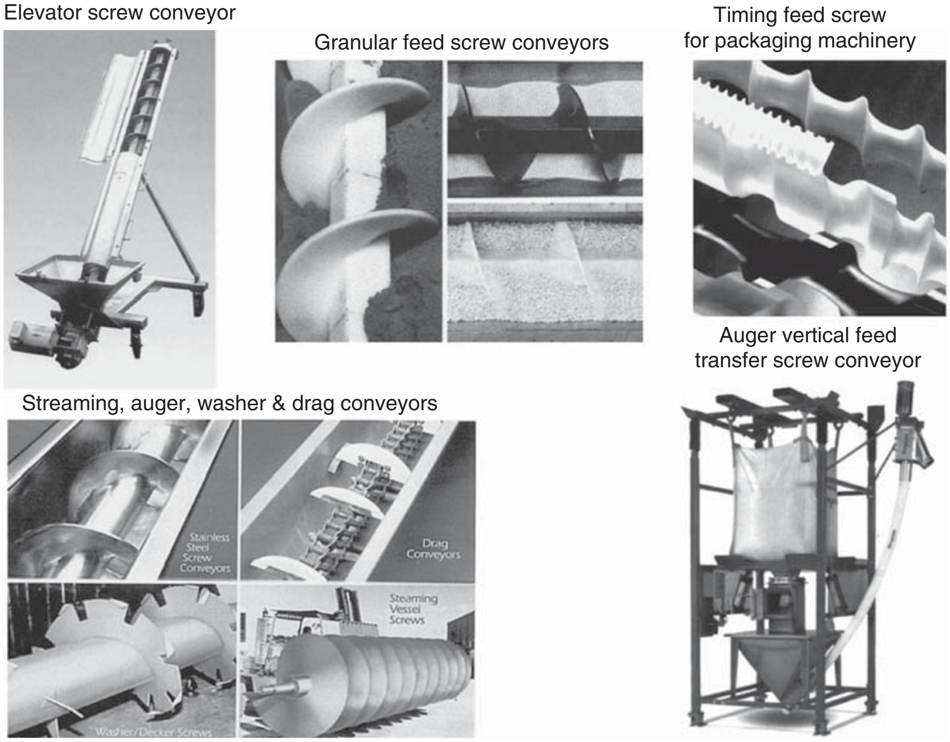

Figure 7. Screw transfer designs.

Also, urethane has made it possible to make short multiple cable transfer and positioning conveyors for a wide variety of products and inputs, especially cartons, pouches, and bags.

Air of Vacuum Design (See Figure 9)

This consists of

- Airveyor (air-driven conveyor)
- Vertical or angled air chutes
- Vacuum bulk-transfer tube conveyor
- Vacuum holddown conveyor
- Air-transfer tube conveyor for parts
- Pneumatic conveying

In the last few decades, packaging technology has developed new methods of stabilizing lightweight and/or some oddly shaped containers by drawing the product down onto flat-topped chain or belts through the use of a vacuum plenum. This permits conveying the containers at much higher speeds. The same concept can be applied to the operation of elevators and lowerators, but is not common. (See also Air conveying.)

Inputs or products can be very effectively moved in mass or single file on a thin film of air. Pressurized air is blown into a plenum, and small holes are drilled or punched out at an angle into a stationary plate. The containers are then supported by air pressure, with their motion over the plate induced by air coming out of the holes' raked angle. A major advantage of this low-friction system is the reduction in the number of moving parts and reduced maintenance. Disadvantages are the large blower requirements, which cause noise and power consumption issues as well as plant air contamination and pressures. Air transfer is effective for inputs or products that have light weight, low center of gravity, and a difficult shape, such as cartons, toilet tissue, and bags.

Pneumatic tubes are very common for the transfer of granular or powder products, and some solid objects can also be transferred effectively such as caps.

Vibratory Design (See Figure 10)

This consists of

- Vibrating spiral conveyors
- Vibrating straight transfer conveyors

Most vibratory designs are used to convey granular-type products over short and long distances. Cereal companies are common users of this type of conveyor.

POWER TRANSMISSION COMPONENTS

The following analyses are applicable to almost all types of conveyor designs. Each conveying system must have a "drive." The term "drive" refers to the apparatus that supplies motive power to the conveyor or is the energy source for the motive power. It usually consists of an electric motor (AC or DC), a gearbox, and possibly a mechanical drive train (shaft, chain, or belt). The most common configuration is still an AC electric motor, gearbox, and chain drive. Note also that the electric motor may be supplied by a VFO or variable frequency drive, which is becoming more of the standard method of control.

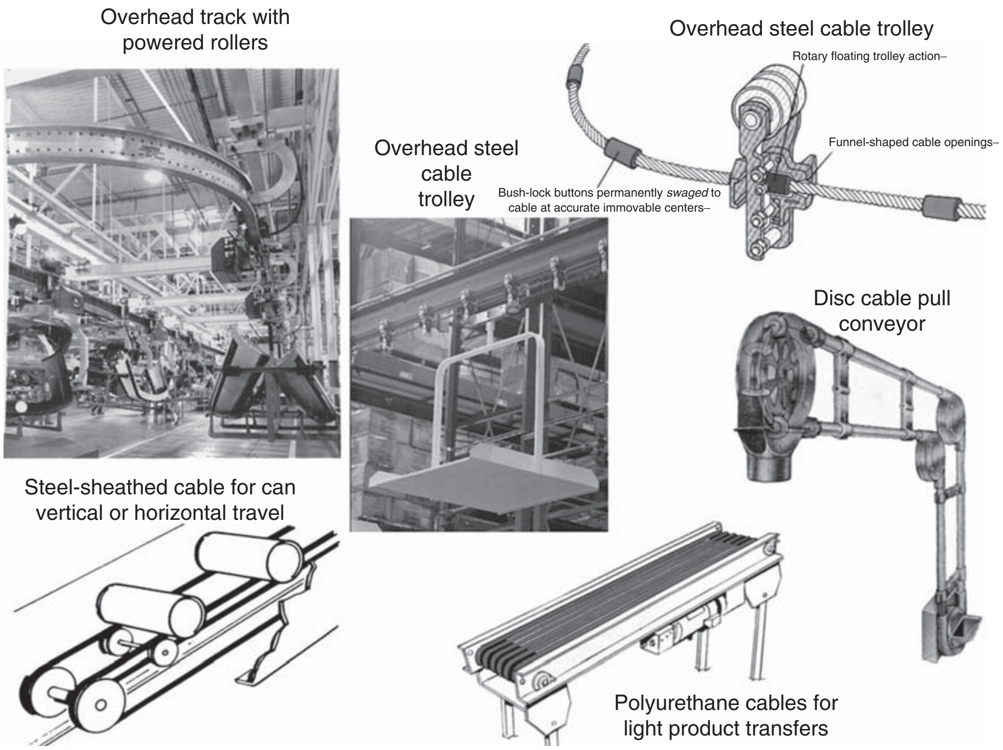

Figure 8. Cable and trolley conveyor types.

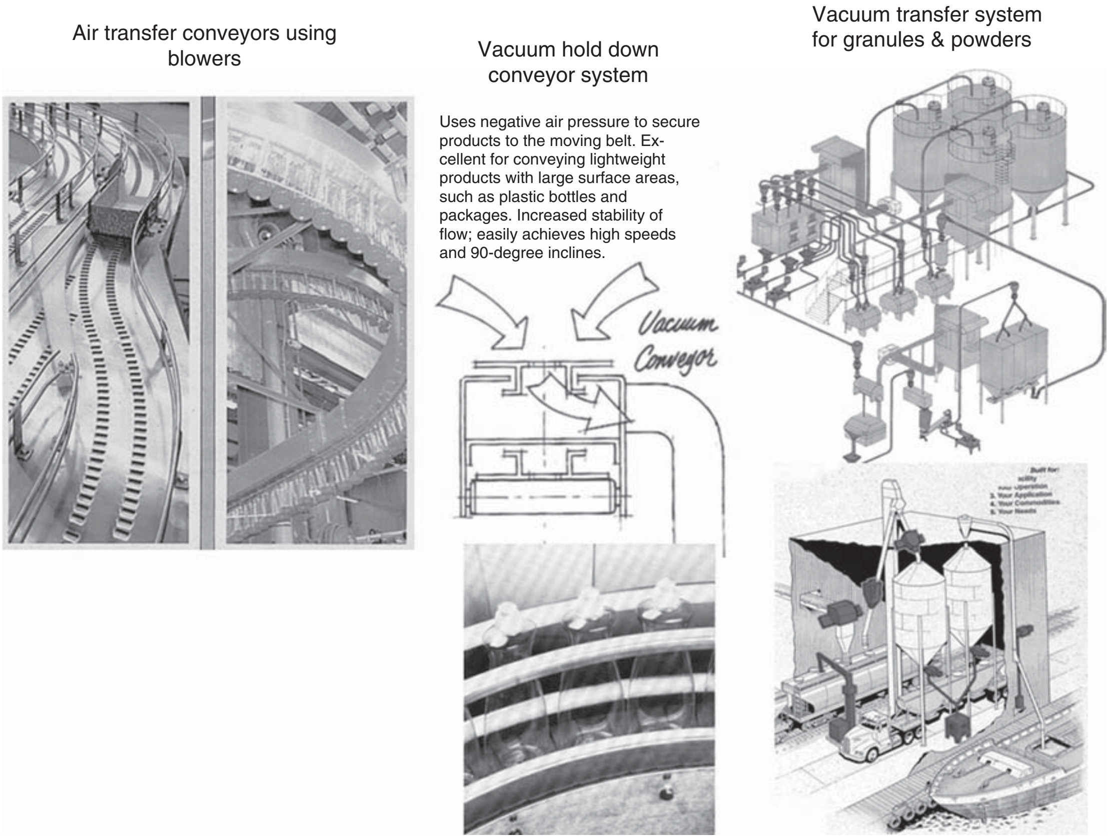
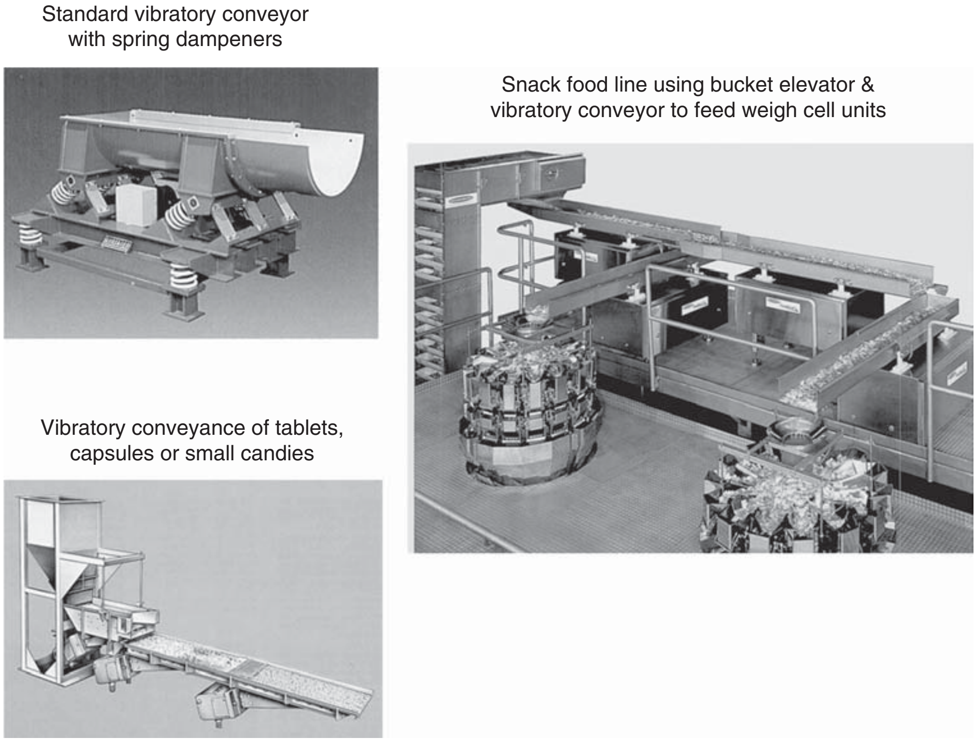


Uses negative air pressure to secure products to the moving belt. Excellent for conveying lightweight products with large surface areas, such as plastic bottles and packages. Increased stability of flow; easily achieves high speeds and 90-degree inclines.

Figure 9. Vacuum and air transfer systems.



Standard vibratory conveyor with spring dampeners

Snack food line using bucket elevator & vibratory conveyor to feed weigh cell units

Vibratory conveyance of tablets, capsules or small candies

Figure 10. Vibratory feeder conveyors.

Gearboxes

The purpose of a gearbox is to change the rotational speed and torque of a rotating shaft. Most gearboxes are *fixed-ratio* designs, where the ratio of input speed to output speed is constant. Fixed-ratio gearboxes are best with an AC inverter, and mechanically variable gearboxes should normally not be used with an AC inverter.

Belt-Pulley Power Transmission

A flexible connector (belt) is wrapped around two or more pulleys mounted on shafts. Power is transmitted from one pulley to another by a difference in tension in different sections of the belt.

There are two types of belt drives: positive (sometimes called timing belts) and nonpositive. In nonpositive belt arrangements, friction is relied on to transmit the peripheral force from the driving pulley to the belt and then to the driven pulley. This design permits a small amount of slippage between the belt and the pulleys. In positive belt drives, the peripheral force is transmitted by positive locking of "teeth" on the belt and pulleys. There is no slippage in this design. Examples of positive drives are gearbelts (standard or HTD). Gearbelts provide minimum noise levels and smooth operation. Care must be taken when high impact loading is required.

Chain–Sprocket Power Transmission

Chain drives are similar in concept to positive belt drives except that the connector is made from a number of rigid links that are connected by pins. The links rotate about the pins providing the flexibility necessary to wrap the chain around the sprocket. The pins engage the spaces between the teeth of the sprocket. The most common type of chain used is SAE roller number 40 and 50 steel chain.

TRANSFERS BETWEEN CONVEYORS USING SLAT-TOP CHAINS (SEE FIGURE 11)

The most common types of transfer as used in slat-top (also called table-top) hinged or *roller* chain conveyors and some special lug, mesh, and mat-top conveyors are

1. Butt end
2. Side transfer
3. S-inline transfer

In a *butt-end transfer*, two conveyors are literally put together inline or end to end in such a manner that one chain is short of touching the other chain by at least $\frac{1}{2}$ in. A dead plate or small rollers are placed between the gap to allow the product to run or be pushed across. Also, the upstream chain should be slightly higher by about 1/32 to 1/16 in. than the downstream chain. Therefore the inputs or product will fall or cascade onto the downstream conveyor. Belt, chain, slat-top chains (also called tabletop), mat, and mesh-type conveyors can all be butt-ended. Some mesh-type conveyors have comb transfer plates between end to end conveyors to reduce dead transfer and improve product flow stability.

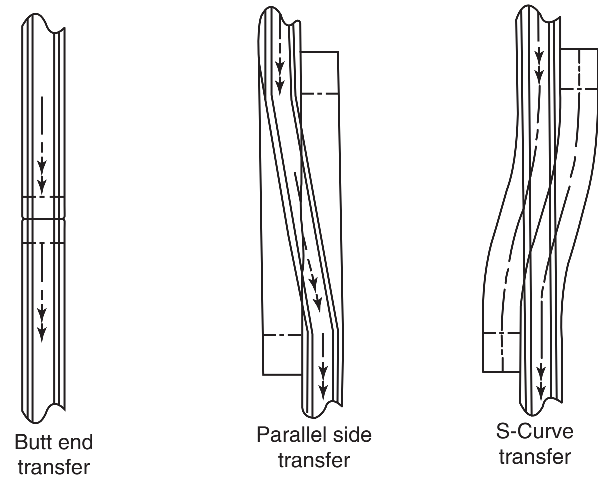


Figure 11. Type of slat-chain conveyor-to-conveyor transfer.

It is not advisable to use only a dead plate transfer for:

- Unstable packages with a difficult shape and/or high center of gravity or product that is open on the top and could allow spillover of the product bouncing across the dead plate or being pushed across by the next product.
- Conveyor speeds are above 150 ft/min.
- Package is shorter than the dead plate or transfer roller such that the package will hang up and wait for the next package to push it off.
- Packages have a base with sharp edges.

Twin side-driven belt conveyors can be used to grip most types of containers (especially with vertical side faces) and laterally carry them over the dead spot on the butt-end transfer. High-speed transfers can be accomplished under specific conditions.

In a *side transfer*, two conveyors are placed side by side so that the package is guided via angled guiderails from one conveyor onto the other. This ensures that the package will be controlled and powered from one conveyor onto the next.

The items one should consider when designing side transfers are

- The gap between chains should never exceed $\frac{1}{4}$ in. (6 mm); $\frac{1}{8}$ in. is optimum.
- The downstream conveyor should be about $\frac{1}{32}$–$\frac{1}{16}$ in. (1 mm) lower than the upstream conveyor for good transfer.
- The angle of cross transfer should not be greater than 15°. For difficult shapes or higher centers of gravity, less than 10° is advisable.
- Guiderail shape can be critical for difficult shapes.
- Conveyor speed differentials can be very critical.
- Because the transfer guiderails are angled to the conveyor pull direction, rotational forces on the container or input can be substantial.

In an *S-curve transfer*, two conveyors operate parallel together in an elongated S form so that the guiderails are straight and the conveyors flex at the transfer. This ensures that the package will be controlled and powered from one conveyor onto the next in line with minimal side forces and maximum control. Although this type of conveyor is more expensive than the traditional side transfer, the control for difficult shapes is superior and guiderail changeover to other sizes is quicker and more accurate. The items one should consider when designing S-transfers are as follows:

1. The gap between chains should never exceed $\frac{1}{4}$ in. (6 mm).
2. The downstream conveyor should be about $\frac{1}{32}$–$\frac{1}{16}$ in. (1 mm) lower than the upstream conveyor for good transfer.
3. Conveyor speed differentials are a minor consideration.
4. The side-flex radii should exceed minimum chain specifications. Only side-flex conveyor chains can be used.
5. The idle and drive ends should be straight sections for about 12 in.

In general, conveyors are critical elements in any packaging process and are grossly misunderstood and poorly manufactured. This is mainly due to nonpackaging people and some packaging people thinking that conveyors are non-value-added items that are as follows:

- Not a major item or consideration.
- The last thing considered in packaging line design and the last item purchased.
- Cheap units for moving inputs from machine to machine.
- One conveyor type is as good as another.

This thinking can be disastrous for many inputs and packages that have difficult or irregular shapes, sizes, and weights.

DESIGN AND INSTALLATION OF GUIDERAILS AND HANDLING CONTROL COMPONENTS

In general, guiderails are critical control parts attached to every conveyor system. They are very important parts in any packaging process and are grossly misunderstood, poorly manufactured, poorly set up, and usually not robust enough. This is mainly because most people think that guiderails are like the conveyors themselves, non-value-added items that are as follows:

- Not a major item or consideration.
- The last thing considered in line design and are poorly specified.
- Cheap units for just keeping inputs from falling over the conveyor.
- One guiderail is as good as another.

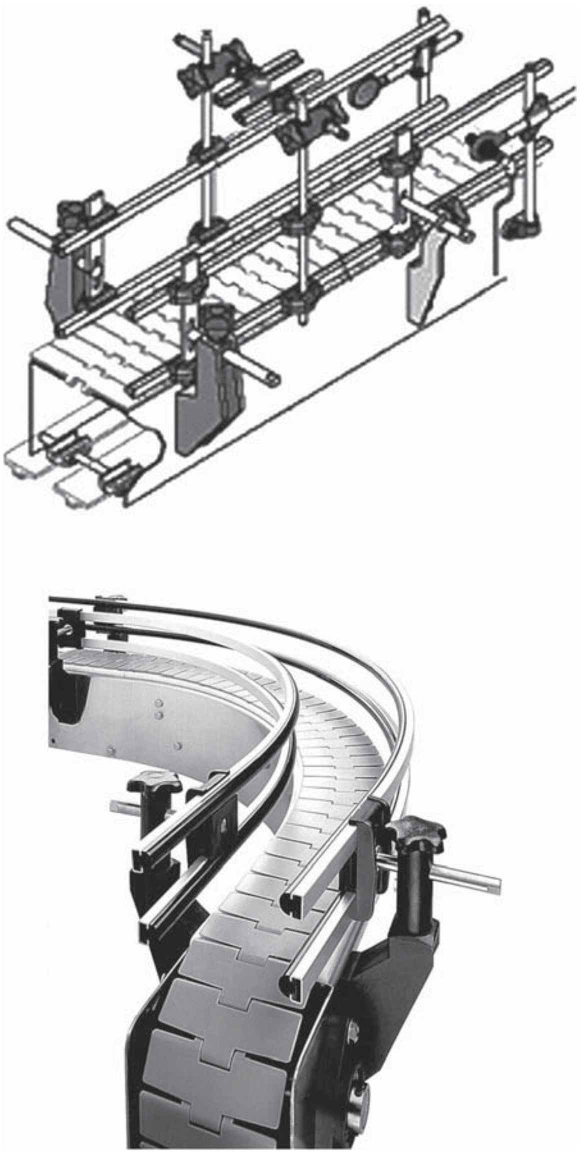

Figure 12. Typical guiderail configurations.

This thinking can be disastrous for many package shapes and sizes. Today, many packaging engineers require quick positive position guiderails that are robust in adjustment features. This is imperative on modern packaging lines that have multiple changeovers (Figure 12).

SPEEDS, FEEDS, DYNAMICS, AND LOADS FOR INTERCONNECTING MACHINERY

The common thread throughout all the operations described above is the use of conveyors to transport inputs from machine to machine, and finally to storage facilities or shipping positions. In general, each machine or staging point will have different requirements in terms of container spacing, linear infeed and outfeed speeds, method of infeed and input, or package or case orientation. For the packaging line to function smoothly, the conveying system must provide the required changes in pitch and speed and must also serve at times as a reservoir of inputs to help level out fluctuations in machine operation. In addition, the conveying system may also have to convert from single to multilane or mass flow and vice versa. All of these requirements must be met without tipping, spilling, jamming, or damaging the inputs, packages, cases, or pallet loads.

In the past, packages or case transfer rates were relatively low (e.g., ≤ 300 ppm or <20 cases per minute) and the packages were geometrically simple with low centers of gravity (e.g., short, round bottles). Recently, however, higher speed and performance requirements and more sophisticated machines have resulted in increased line rates (≤ 2000 bottles per minute in the case of breweries). Also, the aesthetic appeal of complex shapes and the use of lightweight materials and thin walling have resulted in a new generation of stability and quality problems associated with conveyance systems.

Traditionally, line speeds have been dictated by the operating capacity of the critical machine in the line such as the filling station. As a result of these changes, however, the performance of today's lines are limited not by the capabilities of the machinery employed but by the conveying systems used for package transport and manipulation.

CONVEYOR DESIGN

A packaging line should try to balance its machinery and conveyors with compatible function type. *Function type* means the method of operation, which can be either continuous or intermittent. Most low-speed lines generally have intermittent-motion machinery. High-speed lines usually have all continuous motion machinery. Medium-speed lines could be a mix of both. There usually are tremendous problems when a intermittent machine is coupled to a continuous-motion machine. The best way to solve the mix is to place a buffer between the two elements. These two motions are almost impossible to line-shaft mechanically but could be electronically line-shafted, but with great difficulty. It is possible to effectively run an intermittent motion on top of or within a continuous-motion machine or vice versa. These types of new high-technology machines require the correct selection of conveyor system for optimal results.

All packaging machines and equipment require some form of conveyance system to transport product or inputs from one machine to the next. Conveyors are therefore an integral part of the packaging process and are critical to the function of the packaging process.

The primary objective in the design or selection of the conveyor is that it function as efficiently and with as little maintenance as possible. Factors to consider are materials, load capacity, type of drive, speed range, and capability of the conveyor, not only with the objects being transported but also with the other equipment in the production line.

Many industries have developed specialized conveyors to suit particular needs. Often they travel at very slow speeds. Overhead trolley conveyors, for example, are used in heavy industrial applications, such as in automative plants and in other heavy manufacturing facilities. Drag-type chain conveyors connect under an automobile's chassis and intermittently and very slowly pull the vehicle along its manufacturing and assembly cycle.

Interfacing with feedscrews (feedscrews are sometimes called *scolls, timing screws, worms*) can be very critical. Normally, conveyors should run about 10% faster than the discharge feedscrew pitch.

CONVEYOR TECHNOLOGY RELATED TO SPEED

The beer–beverage industry is a prime example of reliance on advanced conveying and packaging technology to meet steadily increasing demands for greater speeds, production efficiencies, and marketing innovations. The developments in current high-speed conveyor systems are a response to this need. Today's state-of-the-art high-production conveyor systems can achieve smooth, damage-free travel of containers from delivery to final packaging. The design challenge is to sustain high production rates through the proper integration of the various conveyor types despite any temporary interruptions in container flow that may occur at any points.

High-speed can–bottle conveyor technology is a combination of up-to-date mechanical, electromechanical, and electrical/electronic techniques, resulting in production capabilities of up to 2000 cpm and plastic bottle rates of 200–1000 bottles per minute (bpm). The high production derives from container transport and accumulation techniques combined with microcircuit-controlled, start–stop, and speed modulation that compensates for intermittent container-flow variations.

Most high-speed container packaging lines have one or more critical machines in the line, such as the filling machine, which dictates the flow parameters for the remainder of the system. For smooth continuous production, all functions upstream and downstream of the critical machine(s) must be designed to assure an uninterrupted supply of inputs in and out of the critical machine(s). The conveyor system then must isolate discontinuities in input flow so that the critical machine(s) will be neither short of inputs from the upstream side nor slowed or shut down because of inputs that are backed up downstream. Continuous movement of the inputs in and out of the critical machine(s) is the best indication that the conveyor system is functioning properly, barring unreliability in upstream and downstream machines.

Backpressure is a multiple of the product weight times the coefficient of friction between the chain and product. Factors affecting chain pulls include the type of chain, container weight, and whether the process is dry or wet, depending on the product being handled. Smooth side transfers to and from the buffer areas and coordination of conveyor speeds with the number of lanes also are critical to the maintenance of the high production rates.

HANDLING LIGHTWEIGHT CONTAINERS

For delicate inputs or packages such as lightweight aluminum cans and thin-walled plastic bottles, confectionery goods, bakery goods, and medical and high-cost quality products, conveyors must handle the inputs gently, with as little contact and pressure as possible. This is accomplished by combining the buffer techniques and container traffic patterns with sensing and interlock devices that prevent jamming of containers and assure smooth, shock-free flow and minimal surging (which is critical for some types of plastic containers). Conveyor surfaces that reduce friction, techniques that maintain container-separation gaps, dimensional precision in fabrication of conveyor components to minimize binding and jerking, and interlocked motion controls are also a requirement for handling lightweight containers.

The container material, type, and shape are equally important factors in the design of a conveyor. Flow paths and buffer areas must be sensitive to the increased jamming potential of nonround shapes. Lightweight plastic bottles, particularly without base cups, are more likely to tip over. Usually nonround lightweight plastic container designs might function best with vacuum conveyors that stabilize the packages by pulling them and holding them onto conveyor surface for optimum control. Another method more commonly used is to use airveyors and convey plastic bottles via a designed in bottle neck ring.

STAGES IN CONVEYING

Today most production packaging lines receive a continuous supply of containers from single or multiple feed lines. The latest designs use a programmable controller that contains the electronic logic for operation of the solenoids, motors, clutches, brakes, and other control components to monitor the supply lines and determine the routing of inputs into and through the packaging line and the routing of finished goods to the truck or warehouse.

Sometimes, to prevent impact shocks downstream, notably at the critical machine, a comparatively slow, usually double or triple $7\frac{1}{2}$-in. (19-cm)-wide mass conveyor is used to spread the large volume of inputs, such as round stable containers, over a wider surface area. The high production rate can then be maintained, and the conveyor velocity is limited to up to 50 ft/min (15 m/min). Experience has shown this rate to be the maximum manageable at this stage of the production line to minimize package damage.

SINGLE FILING FROM MASS FLOW

Conventional methods of single filing containers have been limited to round units, with the volume of containers from multiple lanes or mass flow being directed into a single lane with the aid of converging guiderails (which have a shaker bar or use small plastic roller chain in the vertical position to facilitate merging and reducing friction or binding) mounted over multiple-speed combining conveyors.

With new computer-controlled, low-pressure techniques, however, nonround shapes can be conveyed at high speed by photoelectric monitoring of the gaps between the containers at the output end of the station. Chain speeds are adjusted automatically to maintain the desired gap between the containers and the optimum single-file exit rate. In addition to being much more tolerant of nonround container shapes, this method is significantly quieter and assures gentler handling of less-sturdy containers. Care must be taken in using this technique, because it will work only for a specific range of nonround containers.

SYSTEM DESIGN

The following factors affect the type and design of a conveyor system:

1. Input or package material, shape, size, weight, and center of gravity.
2. The conveyor system's speed of operation.
3. The space available and the production line layout and flow.
4. The best location for the major pieces of equipment and their interrelationships.
5. The location points of supply for the system.
6. The routing of finished products to warehouse and/or marketplace.
7. The production volume needed by the marketing department (present and future needs).
8. The cost justification for the system.
9. The probable return on the investment.
10. Locating points of labor needs and the most efficient use of the labor supply.
11. Access routes for primary and secondary packaging supplies, labeling, and maintenance.
12. The power, air, and/or hydraulic services that are available for systems operation.
13. The logic requirements of the electrical power and control system.
14. The systems basic pacing factors—whether the design is based on maximum process speed or on the projected sales volume.

Profits of successful consumer products companies are heavily influenced by the proper design and installation of conveyors in their packaging lines.

Special thanks to the following manufacturers for their input and materials. They have a wealth of knowledge, experience, and products.

CORRUGATED PLASTIC

Neal Ferguson
I.C.C. Primex Plastics Corporation
Updated by Staff

INTRODUCTION

Corrugated plastic refers to a wide range of extruded twin-wall plastic sheet products produced from high-impact polypropylene resin with a similar makeup to corrugated fiberboard. It is a lightweight, tough material that can be easily cut. Theoretically, almost any plastic material can be formed into a corrugated profile, but costs can be prohibitive. In the United States market, polypropylene copolymer (see Polypropylene) and high-density polyethylene (see Polyethylene, High-Density) are the materials in common use, although there is a small quantity of polycarbonate (see Polycarbonate) material imported for specialized outdoor applications. The board is marketed under the following trademarks: Coroplast, Correx, Corrulite, Corriflute, and Twinplast.

Correx and Coroplast are extruded profiles. Corrulite is laminated from three separate sheets and has the characteristic S-shaped flute of standard fiberboard. In all cases, the formability and mechanical properties are very similar, although the printability of the extruded sheet is superior. The plastic corrugated board has advantages over standard fiberboard, but certainly cannot be used as a substitute for all applications. The packaging designer should consider the following opposing criteria:

Advantages	**Disadvantages**
Long life	Cost
Chemical resistance	Formability
Insulation	Temperature resistance
Multiple color choice	Ultraviolet degradation
Strength: weight ratio	
Waterproofness	

PROPERTIES

Plastic corrugated board utilizes test data from both the fiber and plastics industries, and this can lead to confusion. Plastic corrugated's strength and durability have no direct relationship to corrugated fiberboard. Corrugated plastic sheet is inert. It is pH neutral. At regular temperatures most oils, solvents, and water have no effect. This allows good performance under adverse weather conditions or for a product exposed to harsh chemicals. When used in archival, pharmaceutical, and hospital applications, Coroplast may act as a carrier through a sterilization system (1). It can be wiped down with alcohol, autoclaved (check for extreme conditions), and treated with ethylene oxide gas. A single treatment by gamma radiation is not critical, but 4–5 exposures to the Standard AECL-2.5 mega rad dose will be sufficient to cause polymer breakdown. The rough handling capability of Coroplast compares well against fiberboard, and it has a significantly higher burst, puncture and edge, and flat crush properties than that of B flute fiberboard. Special products require additives that are needed for UV protection, antistatic properties, flame-retardant properties, custom colors, and anti-corrosion properties. For general performance comparisons of corrugated plastic and corrugated fiberboard, see Tables 1 and 2.

PRINTING TECHNIQUES

Plastic corrugated board is supplied in various base colors by blending pigment into the plastic resin. It can be printed by screen printing or flexography (see Decorating; Printing) if the extruded board is flat enough. The polyolefins are nonabsorbent and have poor adhesion surfaces unless they are corona-treated or flame–treated prior to printing (see Surface Modification). Minimum film thickness of ink is essential to expedite ink drying (see Inks). Therefore, ink viscosity should be approximately 10%

Table 1. Mechanical Properties Extruded Profile of Polypropylene Copolymer[a]

higher than normal. Squeegee pressure is normal with the squeegee medium sharp to sharp. Halftones and transparencies are possible using direct emulsion screens or indirect photo-films on a fine monofilament fabric (245–305 mesh). When force-drying, care should be taken to keep the oven temperature below 110°F (43°C) and to prevent sharp variations in air temperature. Corrugated plastic tends to be relatively rigid and, therefore, is best printed on flat–bed types of automatic and semiautomatic equipment.

One of the major uses for corrugated plastic is in signage, so high-quality printing and water resistance are important properties. Coroplast supplies a smooth polypropylene sheet for digital flat-bed printing (2).

FORMING METHODS

Standard boxmaking techniques can be used to fabricated corrugated plastic board. Generally, flat-bed presses using cam action or single stroke are used to die-cut, score, crease, or fold the material. Three-point or four-point, single-side bevel-edge rule is used for cutting. Six-point creasing is used for creasing parallel with the flutes, three-point for creasing across the flutes, to obtain a 90° bend. The packaging designer must bear in mind that the polyolefins have a “memory” and, unlike paperboard, will generally attempt to return to their previous shape. This characteristic calls for modified bending and creasing techniques, but difficulties can be overcome.

High-frequency welding has been the most successful method of joining the material. Because of the nature of the polymer, glues are not generally successful, but lap joints have been accomplished using corona-treated board with silicone-type or hot-melt adhesives (see Adhesives). Metal stitching can be used, but this creates a weak spot immediately surrounding the staple (see Staples).

Milseal 2 is a new, smooth plastic process that seals the edges of heavy duty sheets (3).

CONDUCTIVE CONTAINERS

Changes in the electronic industry resulted in a requirement for different packaging materials. Plastic resins have been formulated to prevent, or dissipate, a static-electricity charge that would normally build up in the material. In the past, a carbon-loaded film was printed onto the surface of corrugated paperboard, but this had a tendency to slough off easily. The sloughing rate can be reduced by dipping the entire material, but this is another area in which plastics have an advantage. If the carbon is introduced into a polymer before extrusion, the wear factor is sharply reduced and the board can be used in near-”clean-room” conditions. The electronic industry has requirements for conductive containers for dip tubes, kitting trays, stackable tote boxes, multitrip shipping containers, dividers, covers, and lids. Coro-Gard (Coroplast) is a conductive plastic sheet made to transport electronic materials and meets the Electronic Industries Association’s standard STD 15-5A, MILP 83668 (United States Air Force), and DOD-HBBK 263.

ENVIRONMENTAL CONCERNS

Twin-wall fluted structures produce strength and rigidity at lower weight, thus reducing the amount of material required for a product. Durability in all weather conditions means a longer life of the product. Polypropylene recycles in processing streams. Polypropylene copolymers are considered inert and nontoxic and safe for use in contact with food.

D

DATE CODING AND MARKING

Dale Voney
Markem-Imaje, Kennesaw,
Georgia

Date coding and marking serves many crucial purposes. Within a single date code or product label, one or many of the following functions can be filled: product marketing, product identification, traceability, date and/or time of product creation, expiration of product, product ingredient/chemical composition information, and product usage information. Depending on the type of product produced, where the product is produced, and where the product is sold, state and federal agencies may have specific requirements for the date code.

Most products will receive multiple date codes as they are created, packaged, and processed throughout a supply chain. In the different stages of a production cycle, various technologies are used to efficiently and accurately apply the proper marking. Depending on the objective of the date code and all of the variables involved in a particular application, one may choose from the following coding and marking technologies: continuous ink jet, drop-on-demand, laser, thermal transfer, direct thermal, and contact.

In this article, we will examine each of these technologies and discuss their proper application.

TECHNOLOGIES

Industrial printers used for marking and coding can use a variety of technologies. The most prevalent technologies are described in the following subsections.

CIJ (Continuous Ink Jet)

The principle of CIJ technology is to apply ink to the substrate by deflecting calibrated droplets from a continuously circulating stream. These droplets are distributed in a dot matrix pattern to form desired characters. The dot matrix pattern, or character, is made up of vertical dots controlled electronically. The horizontal placement of drops is achieved by the movement of the substrate under the print head. Ink is distributed from holding tank, through the printer, and into the print head. Droplets are created and dispensed to the substrate by the print head (see Figure 1). Droplets used in printing the message are selectively chosen by the equipment software.

6	Cannon
7	Charge electrode
8	Detection electrode
9	Deflector plates
10	Recovery gutter
11	Head cover
12	Gutter plug

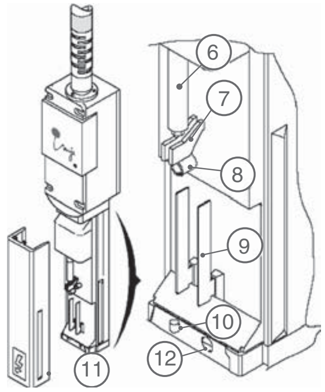

Figure 1. Continuous ink jet printhead.

Droplet creation, calibration, and consistency are crucial to this technology. Within the print head is an ink chamber that contains a small nozzle and a vibrating crystal, called a resonator. The pressurized ink flows through the chamber and toward the opening, called the cannon. During this journey, the resonator changes the characteristics of the ink stream from a continuous stream to a series of droplets that are marginally connected. As the ink stream leaves the cannon, marginally connected “teardrops” begin to form. Due to fluid dynamics, these teardrops eventually form individual, spherical droplets. The size of the drop varies and is dependent on the modulation of the resonator, cannon size, and ink pressure. The droplets continue down the print head and through a charge electrode. Since CIJ inks are conductive, the ink droplets can be selectively charged simply by changing the electrical current on the charge electrode. Only those droplets needed to form the desired matrix pattern or characters will be charged. Droplets then pass through two parallel plates, called deflection plates, whereby the charged droplets are deflected by applying voltage. The remaining uncharged droplets fall directly into a small vacuum tube at the bottom of the print head. The vacuum tube returns the ink to the ink reservoir.

For industrial packaging, CIJ technology is mainly used in **small-character ink jet printers (SCPs)**. Small-character printers are typically used to print directly onto products or primary packages. Depending on character height and dpi requirements, SCPs can also be used for secondary package printing. Here is a brief list of examples of SCP applications: lot identification for glass bottle printing, expiration information on metal cans containing vegetables, time of production on bags of bread, and kosher symbols on hot dog packaging. Due to the large variety of fluid chemistries that can be used in a continuous inkjet printer, it is a preferred printing technology for primary packaging applications.

DOD (Drop-On-Demand)

Drop-on-demand (DOD) ink jet technology uses the principle of applying ink to the substrate by ejecting drops though multiple openings. Each opening corresponds to a specific location on the vertical axis of the message to be printed. Drops are ejected from these openings based on message requirements and character locations relative to the print head (on-demand). DOD technology is mainly used in **Large-character ink jet printers (LCPs)**. There are different mechanisms used in DOD technology for ejecting drops.

Valve-Based. The principle is to supply ink under slight pressure to an array of valves that are all equipped with a drop-ejecting nozzle. By controlling the opening of the valves, the drops can be ejected to print characters or graphics. DOD-valve-based printers have coarse resolution. They are mainly used to print large alphanumeric characters onto shipping cartons (also called secondary packaging), hence their naming as large-character printers or **LCP-valve printers** (see Figure 2).

Piezoelectric-Based. Ink is supplied by a chamber to a print head. Each print head is comprised of an array of chambers that are all equipped with an ejecting nozzle. The principle is to activate a piezoelectric element attached to each chamber in order to deform the chamber. The change of volume of the chamber leads to the intermittent ejection of drops from the nozzle. Piezoelectric-based systems offer finer and more precise control, leading to high-resolution printing. The industry commonly refers to this equipment as “high-resolution printing systems” (see Figure 3).

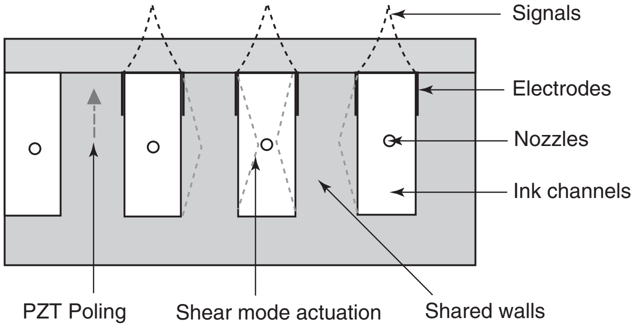

Figure 3. Drop-on-demand technology (piezoelectric-based).

Laser Marking

This technology uses a laser beam that interacts directly with the substrate material to create an indelible mark (see Figure 4). The laser beam can be of different wavelengths according to the laser source that is used. Different wavelengths are chosen in order to interact efficiently with the target substrate material. CO_2 (carbon dioxide) and YAG (yttrium aluminum garnett) laser mediums are the most common types used in the coding and marking industry. Of these two types, CO_2 lasers are used in the packaging industry. YAG lasers are used for marking metal surfaces.

In order to print characters or graphics, the laser beam(s) are directed to the correct location on the substrate. Different technologies are used to create the marking beam and control it:

Mask-Based. A mechanical mask (template) is used to create the pattern on the substrate. The laser marks the substrate according to the pattern placed in front of it. A different mask has to be used for each printed pattern.

Dot Matrix. A pulsed laser beam is formed into a column of dots. These dots are individually activated

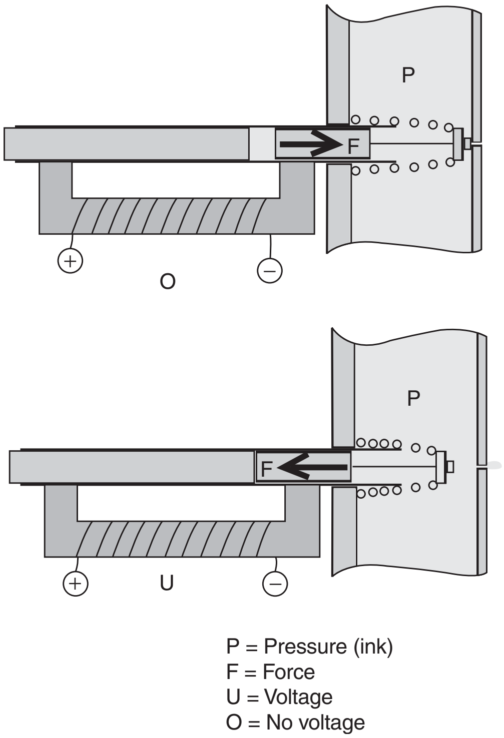

Figure 2. Drop-on-demand technology (valve-based).

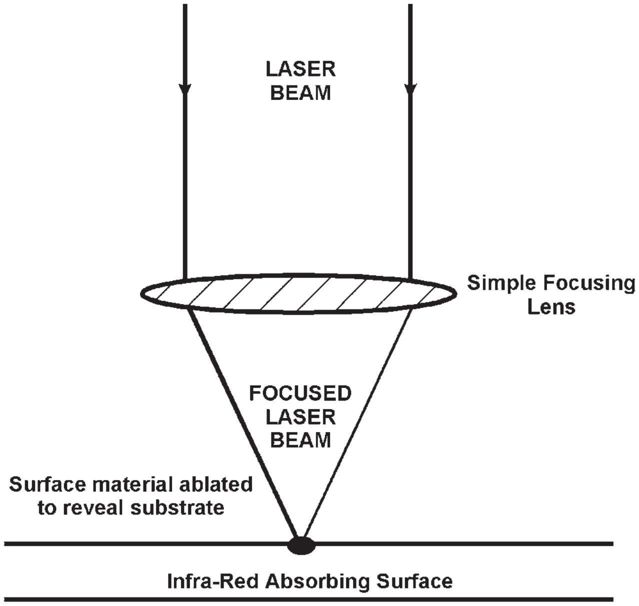

Figure 4. Laser technology.

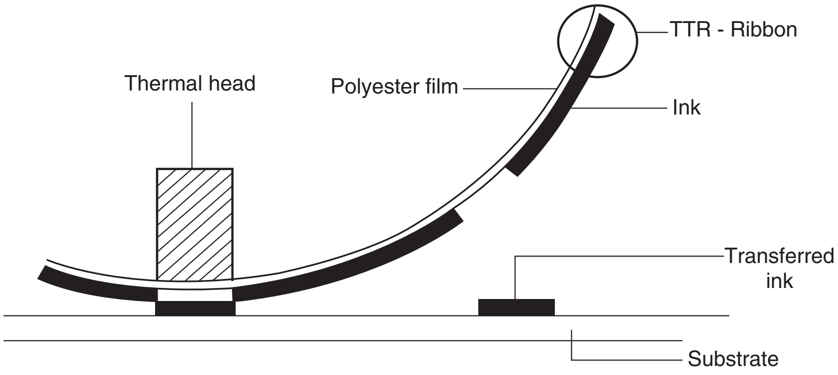

Figure 5. Thermal transfer technology.

for printing a matrix-based image from a repeat combination of columns.

Steered Beam. A pulsed laser beam is displaced along the *X–Y* axis by a set of electronically controlled mirrors.

Lasers used in the packaging industry range from 10 to 150 W of power. Various energies are required for creating legible marks on different substrates and speeds.

Thermal Transfer

This technology uses a thermal print head comprised of a dense array of thermal elements (or thermistors) that can be selectively activated. Printing is accomplished by bringing the thermal head in contact with an inked ribbon. The inked ribbon is pressed against the printable surface. The inked ribbon consists of a base polymer sheet material and a releasable coating made of fusible ink. By heating the ribbon with thermistors within the print head, small areas (dots) of ink are subsequently transferred by contact to the printed substrate (see Figure 5).

Thermal transfer technology can be used in three printing systems:

Thermal Transfer Online (TTO). This technology is used to print directly on packaging film.

Desktop Label. Thermal printheads transfer ink to adhesive labels. In these systems the labels need to be applied manually to the products.

Print and Apply Systems. Thermal printheads transfer ink to adhesive labels. An automated mechanism (applicator) then applies the label to the substrate.

Direct Thermal

This technology also uses thermal print heads, as above. The thermal elements of the printhead come in direct contact with specially treated labels. These labels are sensitive to heat and change color when in contact with an activated thermistor. This thermal technology does not require a thermal transfer ribbon. Two printing systems use direct thermal printing technology: **desktop label** and **print and apply systems**. The concepts of these systems are the same as listed above in the “Thermal Transfer” section (see Figure 6).

Contact Printing

Contact printing relies on mechanical methods to transfer print to a surface. The general principle of contact coding makes use of predefined forms (metal letters, engraved print wheels, rubber pads/stamps, etc.). These forms are pressed into the substrate. The image is transferred as the pressure is removed. Contact printing may or may not involve the use of ink or inked ribbon. Embosser, hot stamp, or roller printers are among these older contact technologies that are still in use today. These contact technologies are gradually being phased-out by electronically controlled printing technologies.

The technologies mentioned in the preceding paragraphs (except Mask Laser) utilize advances electronic technology to create and control character generation. These electronics give the capability of changing and printing variable information on the fly. This limits the amount of human intervention with the date coding equipment and allows for variable and unique messages generation from during production runs.

The latest date coding systems also contain communication capabilities that allow for the option of remote control, monitoring, and data collection. As quality control and regulation becomes more stringent, remote communication to date coding equipment will be more common.

APPLICATIONS

The horizontal segmentation of the packaging market is described below (see Figure 7).

Product/Primary Package Printing

These applications consist of printing: lot numbers, time and/or date of product creation, best before dates, or other product references directly onto the products and/or primary packaging in the manufacturing line. These applications are the fastest and highest-output packaging applications on the the production line, so speed and accuracy of date code placement are crucial. Four types of systems can be chosen:

- *Continuous Ink Jet Marking Systems*. This product is the workhorse for product and/or primary packaging printing applications. It generates marks onto

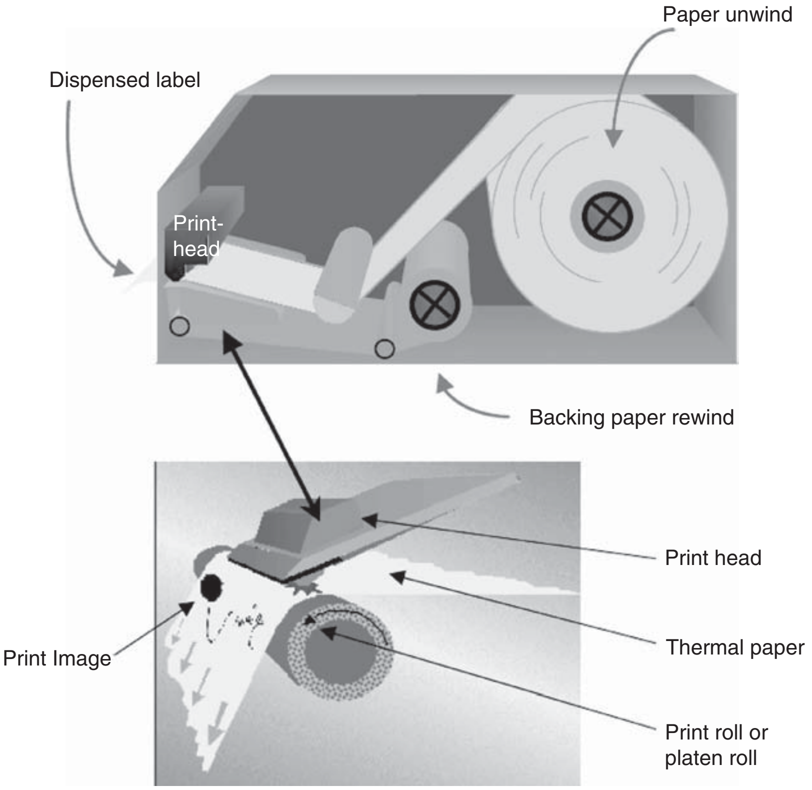

Figure 6. Direct thermal technology.

products without contact, at high speed, with large print distance, on most substrate materials (a wide range of ink chemistries are available). Its limitations are related to its moderate print quality, the limited printed width, and the necessity to use and handle liquid inks that maybe hazardous for fast drying chemistries. Common applications: bottle printing, retail chipboard box printing.

- *Laser Marking Systems*. Laser systems generate indelible marks on many (but not all) packaging substrate materials. They are preferred over ink jet because of their superior print quality, indelible marks, and the absence of consumables. Their main limitation is linked to the inability to mark all material types and colors.

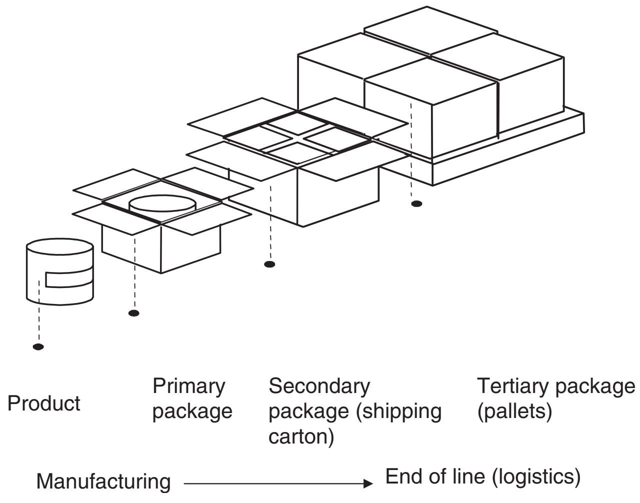

Figure 7. Packaging applications.

- *Thermal Transfer Online Printers (TTO)*. These printers print by contact on film materials. Their main advantage is in print quality. This enables them to print most industrial bar codes with good read rates. Also they do not use liquid consumables. This printing technology is primarily used in packaging film. Printing speeds can be a limitation.
- *Small-Character (DOD-Piezo) Ink Jet Systems*. These systems can be preferred to CIJ in applications where speed and print distance is not demanding. These systems can produce better print quality than CIJ systems.

Secondary Package (Shipping Cartons) and Tertiary Packages (Pallets) Printing

These applications consist of printing product information (product references, lot numbers) and shipping information (manufacturer, customer addresses, and order information). Three types of systems can be chosen:

Print and Apply Label Systems. These systems are the workhorse for these applications. They print high-quality labels that can be read automatically with high reliability with all scanning equipment. Their drawback is related to their limited speed and high cost of labels.

Large-Character Ink Jet Systems. Ink jet systems have the advantage of higher speed (noncontact printing) and better cost of ownership (there is no cost associated with labels).

Valve-Based (LCP Valve). These low-price systems print coarse resolution text or graphics directly onto most packaging substrates. They cannot print the shipping information that requires bar codes.

Piezo-DOD-Based (LCIJ). These systems use different technology variants and therefore come in models that can use either liquid ink (Markem-Imaje's High-Res) or solid ink (Markem-Imaje's HMIJ). They can print high-resolution text and graphics including shipping information that includes bar codes on most packaging materials. Their main limitation against labels is that they cannot meet the highest standards in bar code verification rates, and their output print quality/performance is substrate-dependent.

Desktop Label Printers. These systems are not integrated on packaging lines. The printed labels need to be applied manually to the products. Use of tabletop printers is therefore limited to low-throughput lines, or as backup to print and apply systems.

DECORATING: IN-MOLD LABELING

Ronald Schultz
RBS Technologies, Inc.,
Scottsdale, Arizona

In-mold labeling (IML) is a process for prelabeling plastic containers during the molding operation. IML differs from other prelabeling methods, such as pressure-sensitive and heat-transfer, in that the labeling mechanism is built into the molding machine. No additional labeling equipment or labor is required because the containers are ejected from the molding machine with the labels already in place. One of the most important advantages that IML offers packagers is cost reduction. Use of containers that come from the molder already labeled allows packagers to eliminate their labeling machines and flame treaters along with the labor, maintenance costs, utilities, and floor space for that equipment. Other advantages include labels with the highest-quality graphics, a plastic gram weight savings over post-mold-decorated containers, and, in the case of injection-molded containers, the ability to cover all five sides of a rectangular container with a single label in one operation.

Over the past several years, IML has evolved and grown into three related technologies: extrusion blow mold in-mold labeling (EB-IML), injection mold in-mold labeling (IM-IML), and thermoform in-mold labeling (T-IML).

BLOW MOLD IN-MOLD LABELING

Procter and Gamble recognized the advantages of EB-IML and was the first consumer products manufacturer in North America to use it on HDPE bottles in the late 1970s.

In-mold labeling requires some modifications to the conventional blow-molding procedure (see Blow Molding): (1) In-mold labels for EB-IML have a heat-activated adhesive on the backside; (2) the molds are fitted with vacuum ports or the labels are electrostatically charged to hold the labels in place on the mold wall during the blow-molding operation; (3) label magazines are added to hold stacks of die-cut labels, usually one for the front and one for the back of the container; and (4) a robotic pick-and-place device is added to transfer labels from the magazine into the mold cavity.

In a typical continuous-extrusion blow-molding (EB-IML) process, the robotic pick-and-place device takes a label from the magazine and places the printed side against the wall of the open mold, where it is held in place by the vacuum ports. As the mold closes, it pinches off a section of a molten plastic tube (the parison) as it comes out of the extruder. The closed mold then moves away from the extruder and high-pressure air is injected into the parison, inflating it like a balloon. When the hot plastic parison contacts the back of the label, it activates the adhesive and flows up and around the edges of the label. The label is flush with the surface of the container and becomes an integral part of it. A volume of plastic is displaced that is equal to the volume of the label (Figure 1). The air pressure in the mold is maintained until the container is cool enough to be ejected from the mold.

The largest numbers of EB-IML containers produced in North America are HDPE bottles made on rotary or "wheel" blow molding machines. These machines are used primarily for long runs of containers ranging in size from 8 oz to large, economy-size laundry detergent jugs of more than 300 oz. Volume of production is a function of container size and rotational speed of the wheel. Shorter runs of EB-IML containers are made on shuttle blow molding machines. These can be single- or double-sided with multiple mold cavities on each side. Recent developments in label insertion device technology have permitted retrofitting of older, non-IML shuttle machines to render them IML-capable. Lesser quantities

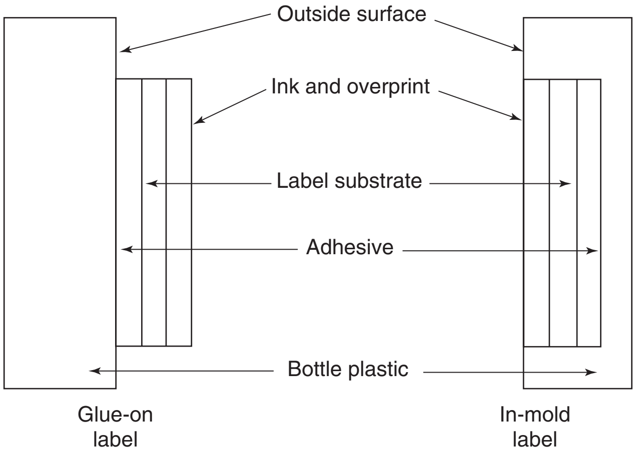

Figure 1. Diagram of in-mold versus glue-applied label.

of in-mold labeled PET and PP bottles are made by injection-stretch blow molding.

The greatest percentage of labels for EB-IML is still produced by integrated converters on large gravure presses, but polyolefin film is now the preferred substrate over 60-lb, coated two-side (C2S) paper litho stock. Film in-mold labels (FIML) are now used in the majority of EB-IML applications, and this trend is expected to continue for the foreseeable future.

Both paper and film labels for EB-IML require a heat-activated sealant layer on the backside. This sealant layer can be an ethylene–vinyl acetate heat seal coating applied on-press by the converter or a coextruded layer produced during the film manufacturing process by an independent substrate supplier. Regardless of the production method, the proper choice of adhesive is critical to the successful functioning of the label during the blow molding operation. Label defects such as blisters can result if the adhesive does not activate completely during blow molding. Once the labels are printed, they are die cut into stacks of individual labels by any one of several different methods including flat bed, rotary, or "high-die."

Gravure printed in-mold labels can have up to 10 colors and offer the highest quality graphics. Advances in print quality now make it feasible to successfully print in-mold labels by other methods such as sheet-fed offset, web offset, and a variety of narrow-web combination presses. These narrow-web presses can combine flexo, uv-flexo, rotary letterpress, and hot-foil stamping to create the type of highly unusual effects desired for labeling of personal care products. Narrow-web or sheet-offset printers use paper or film label stock that has been precoated with the heat-activated adhesive by another converter or an independent substrate supplier. Labels printed on narrow-web equipment can be rotary die cut inline or offline; those printed by sheet-fed offset presses are generally high-die cut.

The most successful film in-mold labels for EB-IML are polyolefin-based materials supplied in both white opaque and clear versions. Many of these are coextrusions of modified HDPE that incorporates a sealable layer and thus do not require application of a liquid adhesive during the converting process. Film in-mold labels offer many advantages over paper IML. These include improved moisture and product resistance, fewer label defects, easier recycling, and the ability to create a "no label" look. A film in-mold labeled container also has little or no label panel bulge typical of a paper IML application. However, film labels still cost at least 50% more than paper labels and are more difficult to print and handle because of static and other problems unique to thin, unsupported plastic substrates. Other disadvantages of the EB-IML process are higher tooling and setup costs, cycle time penalty for label placement and bottle cool-down, and the need to remove paper labels for recycling.

Film in-mold labels have captured a large share of the market and are now used extensively on laundry-product, household-cleaner, premium orange-juice, and motor-oil containers. They have replaced pressure-sensitive and heat-transfer labels in a number of health and beauty aid applications where the "no label" look is desired.

INJECTION IN-MOLD LABELING

Injection in-mold labeling (IM-IML) of open top containers, which has long predominated over EB-IML of bottles in Europe and Asia, is now showing significant growth in North America. The largest market for these containers is for dairy products such as butter, margarine, ice cream, and yogurt. Buckets for paint and cups for soft drinks are also rapidly growing markets. Injection molded in-mold labeled containers can be almost any shape and size from the smallest rectangular tub holding 100 g to large 10-L buckets.

Injection molding of plastic containers differs significantly from blow molding in several ways. Instead of a hot, taffy-like parison inflated by high pressure air into the confines of a hollow blow mold, the plastic used in injection molding is a viscose liquid injected under high temperature and pressure through ports or "gates" into the closed mold. The open space in the closed injection mold will become the container as defined by the male and female halves of the closed mold. The liquid plastic completely fills this space, forming the shape of the container. Once the plastic has solidified, the mold opens and the container is ejected.

Another difference is the labels used for IM-IML. Unlike EB-IML labels, IM-IML labels do not require a heat activated adhesive on the back side. These labels are thinner and are made of the same material as the container. The liquid plastic, injected at high temperature and pressure, fuses to the back of the label without the need for an adhesive. The most common container and label material is polypropylene. Injection molds are manufactured to very tight tolerances and so must the labels used for IM-IML. Die cutting precision required for IM-IML is about three times that of EB-IML.

As in EB-IML, the IM-IML process requires magazines to hold the labels, robotics to pick the labels from the magazine, and molds designed to accommodate the labels. The most common method of holding the label in the mold before the mold closes is electrostatic attraction. The label is given an electrostatic charge after it is picked up from the magazine by the robot.

If the label is for a rectangular container, an assisting device pushes it into the mold cavity. The charge on the label causes it to transfer to the inner surface of the mold. The mold closes and the molten plastic is injected into the mold, either through the male half (inside gating) or from the female side through a hole in the bottom of the label (outside gating). The plastic completely fills the space between the back of the label clinging to the mold cavity wall and the male half of the mold. A single label in the shape of a Maltese cross can cover the bottom and all four sides of a rectangular container in one operation. The "wings" of the label are carefully die cut to meet on the corners of the container (Figure 2).

Cylindrical containers are in-mold labeled in much the same way except that the charged label wraps around the

Figure 2. “Wings” of a container label.

core before the core is inserted into the mold cavity. Once inside the mold cavity, the static charge causes the label to transfer from the core to the inside surface of the mold. The injected molten plastic fills the space between the back of the label and the core.

THERMOFORM IN-MOLD LABELING

Labels similar in appearance to those used in IM-IML are given an electrostatic charge and inserted into the open mold cavity. These labels can be film or paper and have a heat-activated adhesive on the back side very much like those used in EB-IML. Once the labels are positioned in the mold cavity, plastic film or sheet is positioned over the open mold and heated to the point where it just begins to lose its structural integrity. A ram that matches the interior of the container forces the hot plastic film down into the mold cavity. The heat from the plastic film and the pressure from the ram activates the adhesive on the back of the label. The finished, labeled container is then ejected from the mold. T-IML containers can be polypropylene, polystyrene, or other suitable plastics.

Thermoforming machine manufacturers are working to improve both the quality of T-IML containers and the efficiency of the process to better compete against IM-IML.

IML has evolved from the simple blow-molded and injection-molded containers produced in the early days of the process into the sophisticated, even elegant products found in retail markets around the world. Further refinements in materials and processes can be expected to provide better containers at lower costs in the years ahead.

DIAGNOSTIC SENSORS IN PACKAGING AND IN SHELF-LIFE STUDIES

J. J .F. vanVeen and
W. D. van Dongen
TNO Quality of Life, Advanced
Food Analysis Group, Zeist,
The Netherlands

INTRODUCTION

Active and intelligent packaging may provide several benefits to the quality and safety of packed food. The active systems focus on the extension of the shelf life by keeping its quality for a longer period.

The intelligent systems monitor the quality of the food product or the storage conditions of the packed food. In the EU, “intelligent” packaging is defined as “packaging that monitors the internal and/or external conditions of a product through its life cycle.” However, a more suitable name would be diagnostic systems because their main function is to monitor the quality or the storage conditions of the food. A real intelligent system would be a package that takes an appropriate action after a deviation from the desired situation is measured. The value of a measured parameter will in that case act as a trigger for an active packaging system.

Degradation of food products may cause off-flavors or loss of nutritional value resulting in inferior product quality and consumer rejection. The mechanism of degradation and the reaction products highly depend on the type of product. Degradation of nutrients, flavour, and additives is mainly determined by light, pH, oxygen (oxidation), moisture, and other product matrix components.

Optimization of the composition and packaging of food products with respect to shelf life and sensory quality can be done with classical techniques such as high-performance liquid chromatography (LC) and gas chromatography (GC) and microbial testing.

However, noninvasive sensors provide an attractive alternative, because no sampling is required and the same package can be monitored in time under various conditions. This is in contrast to classical techniques where each measurement requires its own sample. In addition, if monitoring of each food package is required, these cheap noninvasive sensors are the only possible solution.

Apart from degradation, monitoring of contaminants such as pathogens or pesticides, in terms of quality control of food products, is also a useful application of noninvasive sensors in this field (1).

A useful classification of noninvasive sensors in packaging that can be used for diagnostic purposes and for shelf-life studies is:

- Time–temperature indicators (TTIs), monitoring the conditions during storage and transportation of the food products
- Leak indicators in modified atmospheric packaging (MAPs) monitoring the integrity of the food package

- Freshness or spoilage indicators monitoring the actual condition of the packed food product.
- Microbiological growth indicators monitoring the increase of the microbiological cell number or cfu.

All of these indicators, except for TTIs, are positioned inside the package and consequently they have to be considered as food contact materials (FCM).

In the United States, Japan, and Australia, smart packaging is already being successfully applied to extend the shelf-life food quality and safety. In Europe, the application of smart packaging systems is limited. The main reason for this is that until 2004, the legislative position of such food contact materials was uncertain.

One could raise the question, Who is waiting for these diagnostic sensors? Are they consumer-oriented or are they a desire of the retail or is it purely B2B (business-to-business)? Or is it purely meant for R&D purposes? The latter is certainly true as can be seen in the examples given in the following paragraphs. In our vision it is also clear that at this moment, B2B applications, like quality control in the food chain, will be the main application.

Because these diagnostic sensors in food packaging are at the moment not meant for checking the quality of the food product by the consumer, a visual detection of the sensor response is not strictly required. Therefore, the readout of the sensor could also be realized in an instrumental way, detecting features that cannot be observed by the human eye. This could be an optical scanner detecting optical changes in the sensor, such as fluorescence or absorption changes in the infrared region or the change in certain electrical properties.

Enabling technologies for discovery of markers and for (future) developments of diagnostic sensors in food packaging are advanced, comprehensive analysis for the discovery of food degradation markers, the integration with RFIDs (electronic version of noninvasive sensors), and the implementation of nanotechnology in new, innovative sensor concepts.

TIME–TEMPERATURE INDICATORS (TTIs)

These indicators or sensors are meant for those food products that easily deteriorates at higher temperature. The basic idea behind it is that they monitor the history of the temperatures at which the food product has been exposed. In fact they display an irreversible change, typically a color change, caused by both the time and the temperature.

In that way they should safeguard whether or not the food product has been exposed to high temperatures somewhere in the food chain, typically the cold chain. The “run-out” time of the sensor has to be correlated to the shelf life of each food product or groups of food products because the parameter time–temperature is only an indirect measure of the quality of the food product.

A major advantage of TTIs is that they can be attached to the outside of the package and as a consequence no food approvals are required here because they are not food contact materials.

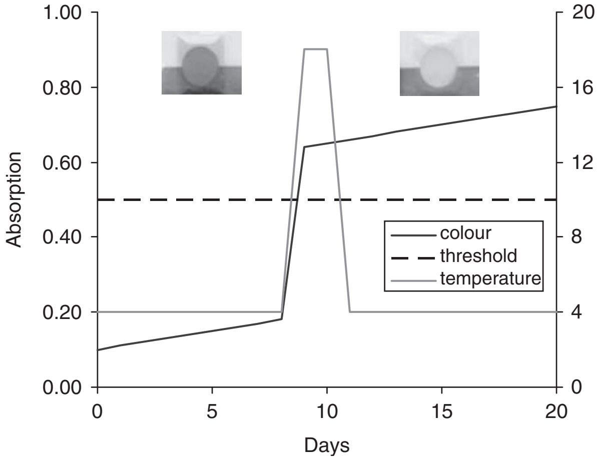

Figure 1. Schematic graph of the principle of operation of a TTI; color change from green (safe) to yellow (unsafe).

Principles used for this type of sensors are enzymatic reactions, polymerization reactions, and even microbiological responses. These irreversible reactions are, in general, coupled to a colorimetric change that accumulates in time and that can be detected visually (Figure 1). A number of companies are active in this field, such as Vitsab, Lifelines, Timestrip, and Cryolog.

Because these sensors behave in an accumulative way, the reagents have to be stored in separate chambers and the reaction has to be started or in other words the TTI has to be activated. This is typically done by means of a mechanical action.

Nowadays the introduction of RFID has raised the question, Can these electronic devices be used for monitoring the temperature history as well? Indeed, this is possible with so-called active RFIDs (RFID with internal power supply in the label) that are coupled to a temperature sensor. In contrast to the visual TTIs, they can tell us not only if the food product has been exposed to a high temperature, but also when this has happened because these devices log the temperature in time (at the moment with only a limited time resolution). A major drawback of these electronic devices, in particular active RFIDs, is that their cost price is still far too high to be applied in single food packaging.

LEAK INDICATORS

Nowadays, many packaging concepts are based on modified atmosphere packaging (MAP) that apply modified concentrations of oxygen, nitrogen, or carbon dioxide. Usually, low oxygen (O_2) or high carbon dioxide (CO_2) atmospheres are used to increase the shelf life of the food product of oxygen-sensitive products such as beer, meat, or pre-baked products. This clearly leads to a need for O_2 or CO_2 indicators that can be applied as noninvasive sensors inside the package.

These sensors could also be used for indicating microbial growth in the case of nonpermeable packaging

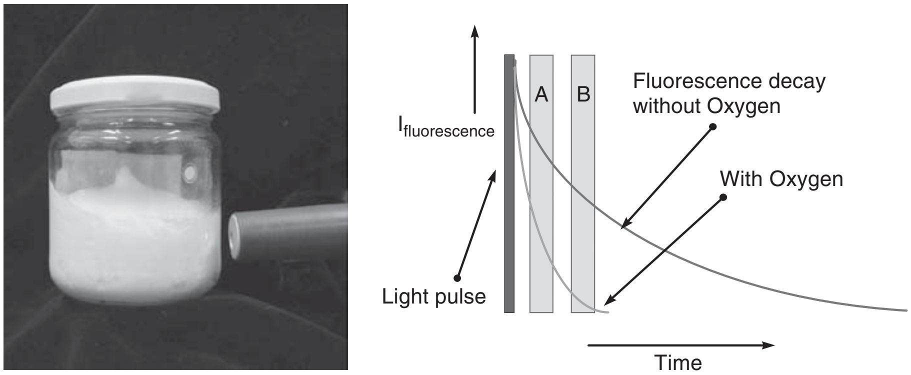

Figure 2. Sample with oxydot and reader pen (left), fluorescence decay curve (right).

material (e.g., glass). However, in flexible packaging the consumption or production of these metabolic gases will always be in competition with the ingress or losses through these materials.

Therefore the main application of O_2 or CO_2 indicators in packaging will be as leakage indicators to safeguard the integrity of the package (seal defects, pinholes) or to verify the efficiency of oxygen or carbon dioxide scavangers. The main application at the moment would be in B2B applications, in quality control at filling lines, and in R&D applications.

In the latter they could be used for gas permeation measurements, testing of packaging materials, or testing of packaging concepts (for instance, beer in plastic bottles). This could also be used in shelf-life studies or in studies measuring the rates of fat oxidation or of oxygen consumption by microorganisms.

TNO developed a noninvasive optical technique (2) that is based on the quenching of fluorescence of a dye embedded in a gas-permeable hydrophobic polymer by oxygen (Figure 2). This quenching also results in a change in the fluorescence lifetime of the dye. This effect can be recorded by an optical reader, also taking care of the illumination by means of a blue light-emitting diode.

The oxygen concentrations can be measured in liquids (e.g., dissolved oxygen) or in gas. Today this technique is being marketed as the Oxysense™ technique, enabling the detection of oxygen concentrations from ambient (21%) down to 0.01 mg/L in liquids or 0.02% by volume in gas. The sensor is independent of pH (2–12), is almost free of interference by other matrix components and the measurements itself does not consume oxygen.

Other noninvasive oxygen sensors, including those based on color or fluorescent intensity changes, have been described in literature. Commercially available systems for oxygen detection are currently provided by GSR/NCSR, Ocean Optics, PreSense, and Oxysense.

Noninvasive CO_2 indicators for food packaging, based on similar optical principles, are being developed at this moment in various research institutes. These are mainly sensors that make use of the permeation of carbon dioxide into a polymer with impregnated pH-sensitive dyes. These indicators can be color-based for visual detection or fluorescence based for instrumental detection (Figure 3).

DISCOVERY OF FOOD DEGRADATION MARKERS

For the development of smart packaging, which is able to monitor compounds correlating with freshness, quality, or safety, it is essential to have specific markers. A lack of specificity means that, for example, color changes indicating contamination can occur in products free from any significant deterioration. Therefore exact correlations appear necessary between target metabolites (indicators), product type, and (organoleptic) quality and safety. To find the appropriate marker, advanced analytical approaches in combination with food packaging research techniques allow obtaining insight in the key processes of food degradation. The combination of analytical techniques and food packaging research techniques such as gas permeability and optical oxygen measurements allow the selection of appropriate markers to avoid food degradation processes like lipid oxidation and growth of aerobic microorganisms.

To study more complex research issues such as off-flavor research, optimization and control of products, and aging or alteration of food during storage such as oxidation in complex food stuffs, more advanced analytical methods can be applied. The idea is to perform a comparative nonbiased determination of nearly all components in a broad range of polarity and molecular weight in a sample. This is in contrast to target analytical techniques as mentioned above, which aims at measuring a limited

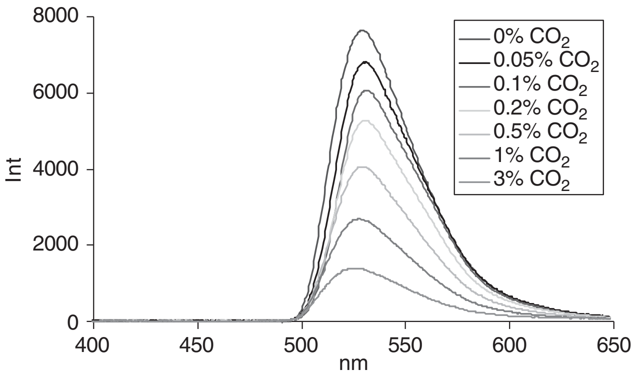

Figure 3. Spectra of the fluorescent intensity (green light) of a noninvasive carbon dioxide sensor excited by a blue polymer LED.

number of known parameters and/or compounds. Such comprehensive techniques are based on GC or LC coupled to mass spectrometry (MS). Next, data preprocessing tools and multivariate data analysis (MVA) are applied to find the relevant correlations between the analytical data with certain properties of interest (e.g., food degradation).

FRESHNESS OR SPOILAGE INDICATORS

Freshness indicators would be more ideal as, for instance, TTIs or leak indicators, because they also take into account the starting quality of the product as well as all "supply chain" mistakes. Real freshness indicators will indicate the actual freshness of the product instead of indirect measures of the freshness.

The freshness of a food product may express itself in certain metabolic products, gaseous or dissolved in the product. A freshness indicator that indicates if the product is not suitable for consumption anymore is referred to as a spoilage indicators. However, it is preferred if in an earlier stage an indication of the decrease of freshness is obtained. In that case we speak about a freshness indicator. Nearly all of the freshness or spoilage indicators are still in a development stage at universities, research institutes, or innovative companies. In general, it can be stated that gaseous metabolic products are less complicated to detect than dissolved metabolic products.

Issues that also play an important role here are microbiological quality and sensory quality.

EXAMPLES OF SPECIFIC PARAMETERS THAT CAN BE USED FOR FRESHNESS OR SPOILAGE INDICATORS

Specific Parameter/Marker	Food Product
Volatile amines	Fish
H_2S	Poultry
Ethanol, ethylene	Vegatables, fruit
Acetaldehyde	Yogurt, fruit
Hexanal, butyric acid	Salads (oils, fats)
ATP	Meat, fish
CO_2	Meat (salads)
Toxins	Meat (salads)

An important safety issue—in particular, in the case of (raw) meat products—is the monitoring of toxins or the pathogenic microorganisms such as *Salmonella* or *Campylobacter* that produce these toxins. Some attempts have been made to accomplish this, like the immunochemical detection principle for toxins by Toxin Alert.

The key challenge for toxin indicators is that pathogenic microorganisms generally exist in or on a food product at very low concentrations which can already be dangerous for humans. In addition, they are not homogeneously distributed throughout the whole food. Consequently, an indicator or sensor for toxins has to be extremely sensitive and needs to have a contact area with the food as large as possible. For all of these reasons, it is not likely that toxin indicators will become available in the near future.

Other, more realistic examples are, for instance, indicators for H_2S, volatile amines, ethanol, ethylene, or volatile carbonic acids.

A useful freshness indicator for poultry has been developed by VTT in Finland based on the color change of myoglobin from brown to green in the presence of the marker H_2S.

Ethylene is a useful indicator for the ripeness of most fruits. Colorimetric indicators for this parameter are under development by several institutes (e.g., RipeSense™).

Another good example is the freshness indicator of fresh-packed fish products (Figure 4). This indicator can be specifically based on the amount of trimethyl amine (TMA) formed by the bacterial reduction of trimethyl amine *N*-oxide (TMAO) or, less specifically, on the total volatile base concentration (sum of basic reduced nitrogen gases, including ammonia). These indicators have to be validated for specific type of fish products (e.g., fatty or nonfatty fishes) and they have to be sensitive enough to predict the shelf life on a reliable basis. The latter implies that they have to be able to monitor TMA or TVB (total volatile base) on a ppm level. TNO has developed such a sensor based on a visual detectable color change from green to blue of a few ppm of either ammonia or trimethyl amine.

Another indicator from TNO being in the same category as the volatile base indicator is the one based on the sum of volatile carbonic acids, as a measure of rancidity for fatty products such as salads, that change color from purple to blue.

A special kind of freshness indicator is a so-called microbial growth indicator, because this will display the freshness of the product by means of the number of microorganisms present in the food product in stead of specific (chemical) parameters formed in the product or in the headspace of the packaging. Such an indicator has to be nonspecific with respect to the type of microorganism, and it could be useful for monitoring the overall freshness of meat products.

Such a nonspecific sensor is under development at TNO (3). This development started for sterile products in closed, aseptic containers (for instance, in case of tissue engineering or clinical food) where the indicator only tells whether or not the product is (still) sterile (see Figure 5). In most food applications, however, sterility is not an issue and the indicator has to display the growth instead of the presence of microorganisms.

This particular indicator or sensor is based on the assumption that microorganisms will produce certain extracellular enzymes, such as proteases and amylases, which can be detected by means of a color change or by means of a chance in fluorescent properties of the indicator. Because the applied principle is cumulative, the indicator will not only be able to detect low levels of initial growth, but will also hold its value after the logarithmic growth phase of the microorganisms.

In the graph in Figure 6, it can be seen that the sensor, more or less independent of type of microorganism, will only depend on its growth rate and on its capability to produce external enzymes like, in this case, proteases.

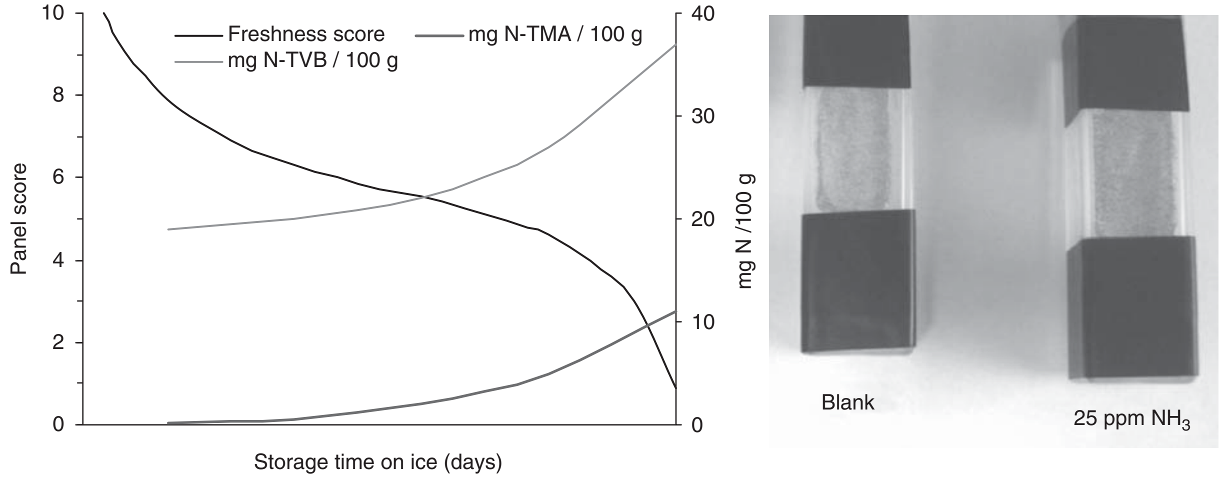

Figure 4. Freshness indicator for freshness of fish products based on total volatile base detection.

LEGISLATION

The EU is the only region in the world which has legislation specific for smart packaging substances. However, delays in drawing up the legislation have hampered the introduction of smart packaging (especially for releasing systems) in Western Europe food markets. A European Commission funded project [FAIR-project CT-98-4170 (4)] known by the acronym ACTIPAK came up with recommendations that were taken up in the drafting of amendments to the EU Framework Directive for food contact materials 89/109/EEC (5). This resulted in the adoption of a new framework Regulation (1935/2004) (6) in which provisions are made to allow the use of smart packaging systems. The new Regulation applies to smart packaging, containing deliberately added substances, provided that the packaging can be shown to enhance the safety, quality, or shelf life of the packaged foods or provides information on the conditions of the packaged food. A major provision is that the composition of food may be changed by the use of active packaging, provided that the final food complies with relevant rules on food and food additives. However, such changes should never result into the masking of spoilage or misleading the consumer. The Regulation (1935/2004 is valid in all EU Member States without a need for implementation in national laws) announces additional rules laid down in a specific measure. At the moment a specific regulation [EMB/973 Rev. 6B (7)] for smart packaging is being drafted and discussed with the Member States. The final regulation most likely will not differ significantly from the document now available. However, the extent of the authorization procedure is still open for discussion. It is clear that any authorization will only be related to the substance(s) that cause the smart function. Inert parts of a smart packaging (i.e., a sachet, box, foil) will remain the responsibility of the manufacturer. The inert part should comply with the rules for food contact materials valid at EU or national level [e.g., Directive 2002/72/EC (8)].

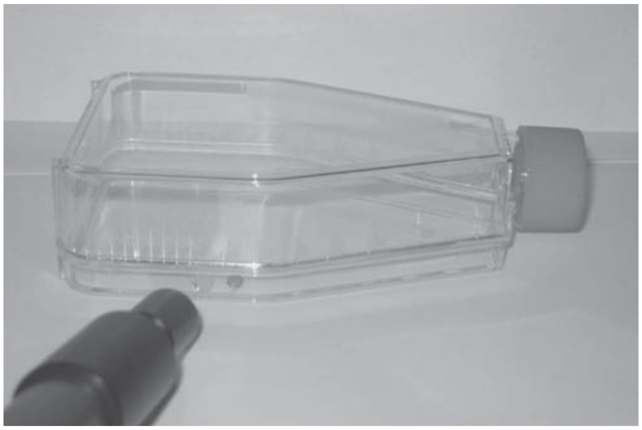

Figure 5. Photograph of a noninvasive sensor for sterile products with optical readout.

In addition, some of the systems are subject to regulations on food additives, labeling, environment/waste, food hygiene, and general safety. The EU system requires the opinion of the European Food Safety Authority (EFSA) before it can be inserted in any regulation. Therefore, the smart components need to be evaluated by the EFSA for its safety in food contact applications. EFSA guidelines are under preparation but may be adapted to the final specific regulation for smart packaging. The following issues will (most likely) be part of the guidelines:

- Toxicological evaluation of the smart components, taking into account the potential level of migration into the food.
- Demonstration of efficacy of smart materials is under discussion. Because this is not a safety issue, in many cases, the need for a demonstration of efficacy may be reduced or completely withdrawn. In those cases it is a up to the user to ensure that the smart packaging is efficious. However, the requirement in the Framework regulation that the consumer should not be misled may be a reason to check the efficacy even in the absence of a health risk

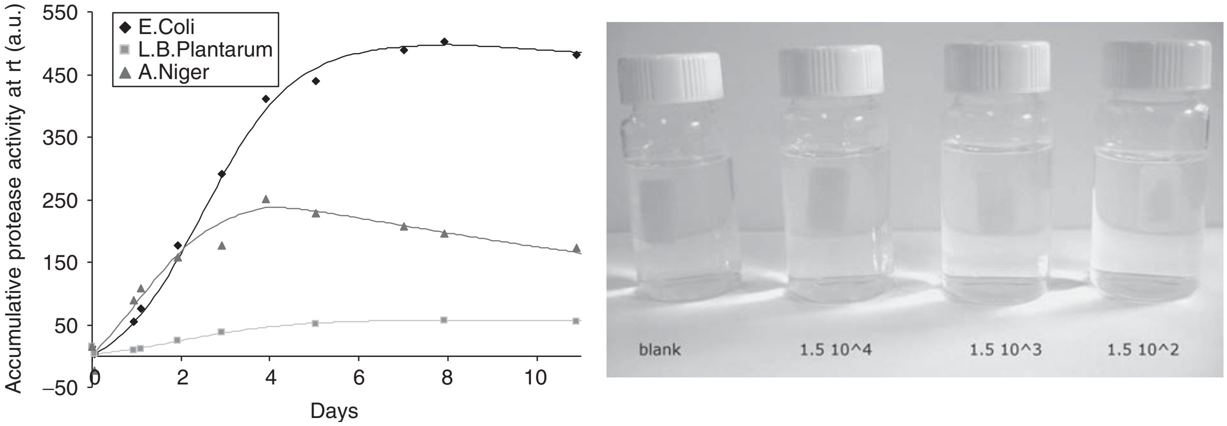

Figure 6. Proof-of-principle with a fluorescent indicator (left) for different microorganisms. Quantification of a color indicator (right) for various protease.

- Migration data regarding the smart component. Conventional migration methods may not be applicable, and dedicated migration methods may be required to demonstrate that migration of smart components does not endanger human health.
- Advise to the Commission for insert of the smart component in a list of authorized components.

Based on the outcome of that evaluation, the Commission (DG SANCO) will grant a petitioner, authorization for the submitted smart systems, which will be entered in the Regulation. The general requirements for food contact materials (1935/2004/EC (6)) also apply to smart packaging systems and, consequently, they shall not endanger human health. Labeling should comply with the food additive Directive89/107/EEC (9).

TRENDS

Presently, diagnostic sensors are mainly applied in the business-to-business (B2B) market in the form of TTI indicators to monitor the storage conditions of temperature-sensitive products. However, TTI is only an indirect measure of food quality and is not likely to replace the "best-before" dates.

The main drivers in packed food for the near future will be food safety and quality of fresh products. This implies that there will be a need for freshness, microbial growth, and toxin indicators. In this respect, it will be essential that the indicators provide a clear, unambiguous indication of product quality, safety, and shelf life. Probably all new diagnostic sensors will first be used in B2B applications with a some form of added value. It could be used as a quality indicator or shelf-life indicator, removed before presenting the products to the consumer, or invisible to the consumer. If the retail can guarantee that no pathogens are present in meat, this will give added value to the product. It would, for instance, allow the retailer to sell higher-value raw meat products. Or by improved selection and order picking directed by the shelf-life indicator, replacing the principle of "first-in first-out" by picking on remaining shelf life, the shelf life could be increased. An additional shelf-life day is absolutely a very interesting business driver for fresh products.

Nanotechnology will be more and more applied in the development of new freshness and toxin indicators, enabling more sophisticated and more selective sensor principles.

Also the combination with electronic devices, such as RFID and polymeric electronics, will expand the possibilities of diagnostic and intelligent packaging in future. A major demand for these devices will be the breakdown of cost price.

Currently, the market for diagnostic packaging is small compared to the more mature market of active packaging. However, we believe that the overall trend for diagnostic packaging will be a growth scenario.

DISTRIBUTION HAZARD MEASUREMENT

Dennis E. Young, CPP
School of Packaging, Michigan State University, East Lansing, Michigan

To be successful in the marketplace, products must be available to consumers. Most manufacturers produce products in one or several central locations, gaining the efficiency of larger scale operations. Markets and consumers, however, are far less concentrated and are located in widely separated areas, even thousands of miles away from the point of manufacture. This characteristic of most producers and consumers generates the need for physical distribution, which represents a key part of the supply chain system of any manufacturer. As global markets open and distribution channels grow in length and complexity, logistics takes on increasing importance.

Physical distribution in its simplest form combines three related logistic activities. Transportation moves products from point to point using a plethora of modes and equipment. Warehousing buffers the uncertainties of production and demand and helps ensure availability to satisfy demand. Handling connects the elements of the system, which include production to warehouse, warehouse to truck, truck to retail, and so on. Each element includes hazards to the safe passage of products and packages. In each case, the hazards are characteristic of the operations performed within that distribution element. All these activities also occur in an atmosphere that may change the results of the activities. Temperature and moisture, for example, can affect the characteristics of packaging materials, which compromises their protective ability.

Transportation requires vehicles, and vehicles produce vibration as a consequence of their motion. The discontinuities of transit media, such as road roughness, rail irregularities, water waves and air currents, are among the original sources of vibration. The vehicle reacts to these irregularities, amplifying some types and reducing other types. Vehicle suspension and structure play a role in vibration modification. The result is a complex mix of vibration frequencies and intensities, which change in response to immediate conditions. Figure 1 shows an example of actual vehicle vibration, demonstrating the change of vibration intensity over time. These transit vibrations may produce fatigue, abrasions, crumbling, separation, and other types of damage in products and packages.

Warehouses gain efficiency by the careful use of space. This usually involves stacking one product and package on another to fill the available storage cube of the building. Unit loads of products may be stacked several items high in floor loading warehouses. Even with storage that uses

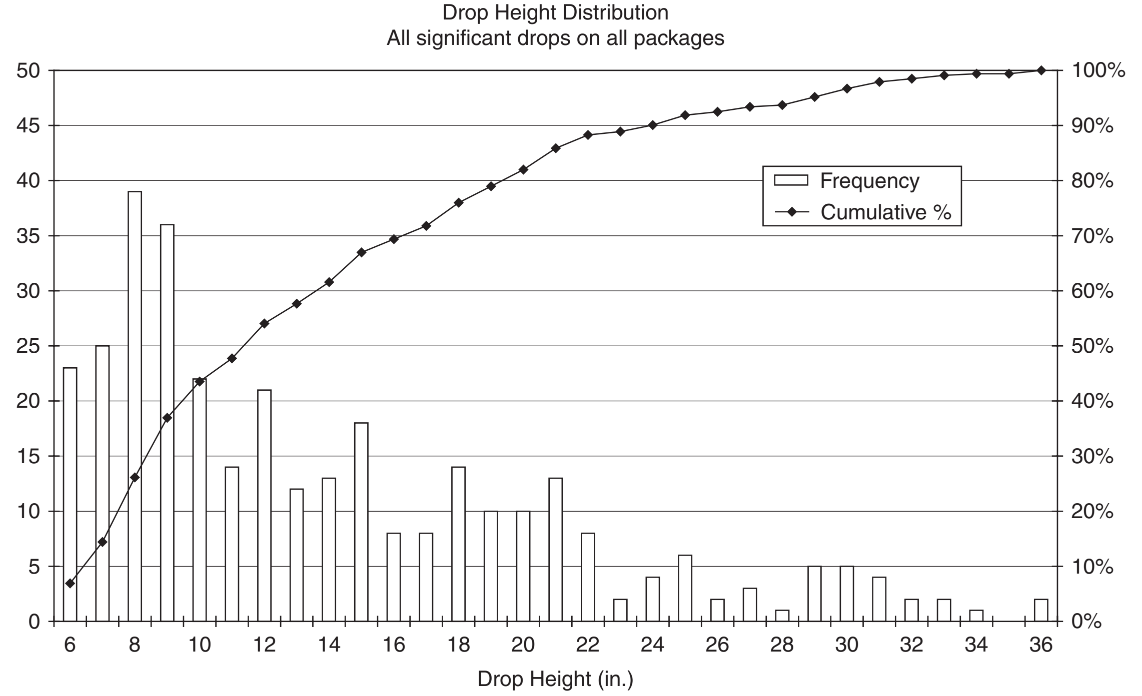

Figure 1. Example drop height distribution data.

racks to contain packages and unit loads, stacking often occurs, albeit with lower heights. The loads imposed on packages by the warehousing system can exist for weeks or even months. These warehouse loads may produce collapse, denting, buckling, bending, and other types of damage in products and packages.

Handling operations include the manual movement and placement of packaged products in sorting, transferring, and vehicle loading and unloading. Persons are often assisted by mechanical tools in this handling, including lift trucks, dollies, conveyors, and similar devices. Some handling operations are fully automated and use robotics or purpose-built devices to lift and place packages. Vehicles are also handled, and vehicle impacts such as railcar switching and truck docking may be hazardous. Inherent in handling is the possibility of accidental or purposeful drops, including severe mishandling. The shocks experienced by the product and package when dropped in handling may produce breakage, shatter, bending, misalignment, chipping, and other types of damage in products and packages.

Along with packaging material performance and product fragility, knowledge of the hazards of distribution is critical to successful protective packaging development. Data on package drops, vehicle vibration, compressive loads, and atmospheric conditions are central to determining the target performance of packages. If the general probability of occurrence of these hazards is known, then intelligent decisions on level of protection are possible.

Small, battery-powered instruments capable of accurate measurements and recording of transit hazards are available from several manufacturers. Instruments that can measure shock, drop, impact, and vibration usually employ accelerometers, or acceleration transducers. Likewise, instruments for detecting compressive loads would use some version of a load cell or weighing transducer. Temperature and humidity measurement requires appropriate sensors. In all cases, power from batteries and signal conditioning matched to the sensors are needed. Data are converted from the continuous or analog form into small, discrete steps by internal electronics. This analog-to-digital conversion (ADC) allows the data to be stored and understood by digital devices, including computers. Once detected, hazard data are stored in computer-compatible memory within the instrument, which is available for eventual transfer to a personal computer for analysis.

The process of measuring the hazards of distribution requires careful planning. The following steps are recommended:

- Observation
- Measurement
- Analysis
- Specification
- Validation

The first step to a quantitative understanding of supply change distribution hazards is qualitative. Observation of the distribution system details the elements of distribution, such as handling, transit, and warehousing, and it assists in understanding how these pieces fit together into a system. Attention should be paid to possible sources of handling drops or impacts. A block diagram of how a package travels from manufacture to consumption is a useful tool to develop. With these observations, targets for the measurement step may be selected. A certain handling operation, or a transportation mode or route, or an entire trip or system, may be selected. Independent variables, such as position in the vehicle or weight of package may be targeted at this stage. Much may be learned from observation alone. Although largely qualitative, the information gained is valuable to establish the order of events and the specific characteristics of equipment (vehicles, conveyors, etc.) and process (unloading, sorting, loading, etc.).

The measurement step concentrates on qualitative data collection. The location of the measurement system and transducers is critical at this point. Measurement needs to be taken at a point where eventual tests will be controlled. For example, if the goal is a vibration test, then the test system will be taking the place of the vehicle bed, as this is the point of input to packages transported in the vehicle. The test system will be programmed to simulate the motion of this vehicle. Accordingly, the measurement system must monitor the vehicle bed. Measurements taken of the response vibration, inside the packaging, will be interesting for package performance characterization but are not specifically useful for the development of test specifications.

Drop height data are collected by an instrument inside of the package that experiences the drop. Data on compressive load would also be taken by inside-package instruments. Shock and impact data-collection points depend on how the eventual test will be controlled. Temperature and humidity data may be taken at any point but with due consideration of the mitigating effects of the package.

All data types should be time stamped and date stamped when collected if possible. This allows the user to evaluate the location of each data event, which includes the truck terminal, warehouse, road or rail section, flight number, or loading dock. Small parcel tracking and vehicle global positioning system (GPS) information are tools to help interprete the data collected.

The analysis step focuses on converting raw data to information. Data from an electronic recorder are organized and stored by events as individual readings or packets of time. Slowly changing data, such as temperature, atmospheric pressure, or relative humidity, may be sampled by individual readings. Dynamic data, i.e., shock and vibration, need to be captured in time packets so that the rapidly changing nature of the original event may be observed. Drop heights may be estimated by the instrument software, and vibration data may be sorted for frequency content.

Data analysis should begin with a careful consideration of the goal of the measurement program. Temperature and relative humidity data help to define the exposure to extreme levels, the time of exposure, and how exposure changes over time and with the distribution situation.

These data can be used to develop laboratory tests or to assess the degree of hazard to product or package.

If the goal is the development of a random vibration test, then spectral analysis is the typical form. If data taken by a recorder inside a package are to be used to set up a drop test specification, then data analysis should include the number of drops, orientation of drops, and drop-height distribution. A useful form of data analysis for drop-height distribution is a drop-height histogram with cumulative percentages. Figure 1 shows an example from handling drop data collected in shipments by a parcel delivery mode (1). Similar results have been obtained in less-than-truckload (LTL) domestic shipments (2) and in many other studies.

Figure 2 shows a summary analysis of truck vibration in a truck distribution environment, in this example, a large semitrailer on intercity roads in China (3). In all these examples, the information should serve as illustrations of analysis form and content, not as definitions of these shipment conditions.

One key advantage of laboratory testing is the ability to compress time in the evaluation of package performance. A shipment that might take several days of elapsed time can be simulated in the laboratory in a matter of hours. The specific technique for time compression depends on the test being performed.

Time compression for drops is clear. The time between drops in actual shipment may range from minutes to days. In the laboratory simulation, drops are conducted with minimal waiting time, so the elapsed time is compressed. The time compression for top-load compression tests to simulate the effects of long term storage in a short test time is being developed by some users.

Time compression for vibration is more complex. In general, increased test amplitude intensity (G level) may be traded for reduced time. There are undoubtedly practical limits to such compression. A shipment of 20 h transit time probably cannot be effectively simulated in 10 min. Random vibration test durations of one to $\geqslant$6 h may prove successful in replicating field damage. Shorter or longer vibration test durations may be required to achieve desired results. The default vibration time of 3 h used by ASTM D4169 is suggested as an initial target International Safe Transit Association (ISTA) links test time and transportation distance using a similar relationship. The ISTA process relates test time to transportation distance. For example, a palletized load would be tested in one axis for *time = miles traveled/5*, with a maximum time of 240 min (5). There are several approaches to vibration time compression. Among these is the following generalized approach. Within limits, the trip time may be compressed to laboratory time using the following relationship, which was adopted from test equivalence formula (6):

$$L_2 = L_1\left(\frac{T_1}{T_2}\right)^a$$

where

L_2 = level of lab test vibration (overall G_{rms})
T_2 = time duration of lab test
L_1 = level of field measurement (overall G_{rms})
T_2 = time duration of field measurement
a = exponent, typically 0.3–0.5

Test specifications should also include consideration of the diversity of distribution environment hazard levels. For example, a series of drop heights should be constructed to

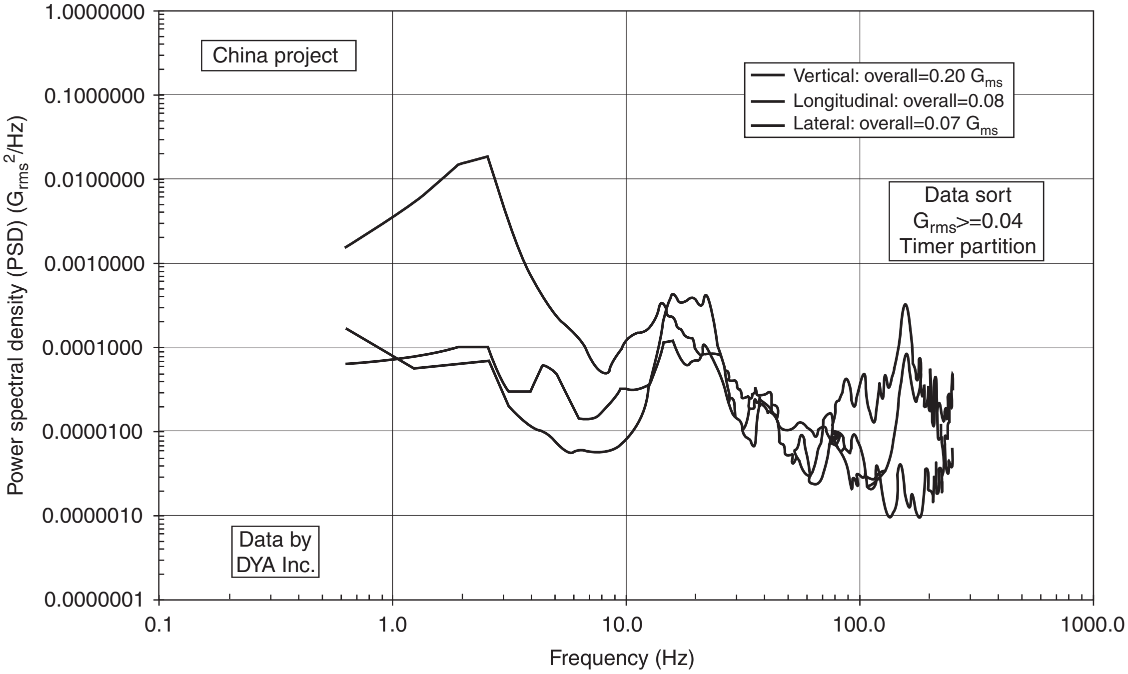

Figure 2. Example random vibration spectrum date.

reflect the actual occurrences measured in the field. Rather than a series of drops all at the same drop height, a series should be constructed with different drop heights, because that is how drops happen in actual handling. Such a series might include several low heights, a few midlevel drops, and one high drop. This is modeled on the actual hazard, where high drop heights occur seldom, and lower drops occur more often.

This level diversity technique is also valuable for vibration testing. Data may be sorted by event amplitude and grouped. The estimated actual time that vibration occurred at each group level is then calculated. One background level, which reflects most events recorded may be combined with one of more higher level tests of shorter durations. The time compression may be applied to some or all test segments that result. This multilevel test specification should provide a more robust simulation of the logistic environment hazard than a single-level test.

The validation step is a potentially time-consuming, but necessary, effort. During validation, the user compares actual field results with laboratory results and makes any required adjustments. This may include selected testing of products with known shipping histories. Of particular interest would be products that have exhibited repeatable, definable damage during transit. A laboratory test that produces similar results is the goal. If the test specification under development achieves this end, then it has demonstrated a degree of validity. A several such test cases will increase the validity and confidence in this specification. In general, exercise caution when using new test specifications that have not undergone validation, especially in the evaluation of new products and packages where no history is available.

All stages of the process, from observation through validation, should be documented carefully. In this way, future users may extend the development process to new logistical operations or assess the need for additional measurement and analysis efforts.

DRUMS, FIBER

Gerald A. Gordon
Sonoco Products Company,
Industrial Container Division,
Lombard, Illinois
Updated by Staff

INTRODUCTION

A fiber drum is a cylindrical container made with a sidewall made of paper or paperboard having ends and components made of similar or other materials such as metal, plastic, plywood, or composite materials. It is made by the convolute (not spiral) winding of multiple plies of paperboard into a tubular body, to which are attached headings that may be made from solid fiberboard, metal, plastic, natural wood, or plywood. No single ply of the sidewall may be less than 0.012 in. (0.30 mm) thick. The sidewall plies must be firmly glued together and may include protective layer(s) of metal foil, plastic, or other appropriate materials. The outer ply may be waterproofed, or, at the least, must be sized to resist the effect of casual water. Fiber drums provide high strength and low tare weight for the packaging of industrial commodities. A fiber drum intended for heavy-duty use may weigh as little as half that of a comparable steel drum.

Fiber drums are used globally and offer a strong, cost-effective means for the packaging of solid granular powder, paste, semiliquid, and liquid products. Fiber drums were originally introduced as an alternative to the metal drum and therefore had a circular cross section. In recent years, drums with a square cross section and rounded corners have become available. Fiber drums make up about 30% of the industrial containers used in the United States (1).

CONSTRUCTION

Sizes

Fiber drums are manufactured in a wide range of diameters and capacities: in diameter from about 8-in. (200 mm) to 23 in. (584 mm) in $1\frac{1}{2}$-in. (38-mm) increments, and in capacity from 0.75 gal (2.8 L) to 75 gal (285 L), with almost infinite variability, since capacity is controlled by the slit width of the tube, which can be adjusted in $\frac{1}{8}$-in. (3-mm) increments.

Stacking

The stacking strength of a fiber drum is determined by the number of plies of paperboard in the sidewall. This commonly varies from 4 plies for lightweight drums to 11 plies for large drums intended to carry heavy loads (these ply counts are for 0.012-in. board; the increasingly common use of heavier board requires fewer plies). The stacking strength is also a function of the moisture content of the paperboard; the higher the humidity, the lower the stacking strength. Taking these and other construction factors into account, the bottom drum in a stack of large, heavy-duty fiber drums might safely support as much as 2000 lb (900 kg).

Linings and Barriers

The basic structure of a drum may be modified by the insertion of a laminated barrier board (a sandwich made from aluminum foil and/or polyethylene between two plies of lightweight paperboard) into the sidewall to reduce the moisture vapor transmission rate (MVTR). Alternatively (or sometimes additionally), a laminated integral lining made of paperboard, plastic film, and sometimes aluminum foil may be used as the interior surface of the tube, to impart MVT resistance, oxygen transport resistance, and/or chemical resistance to the drum. The plastic part of such a laminated lining may include polyethylene (as barrier layer or as adhesive for a different barrier), polyester, poly(vinyl alcohol), silicone release lining, or a laminate of a special barrier polymer with polyethylene. A lightweight polyethylene lining or a loose polyethylene bag is also frequently used in the packaging of dry products to reduce MVTR. A “skin” (pigmented polyethylene-coated board) or label (decorated stock) may be wound as the outside ply of the drum, with the colored plastic or decorated stock to the outside, to provide protection from moisture or physical abuse, or to project information, using the drum surface as a “billboard.”

Table 1 shows that the MVTR of fiber drums may vary over a factor in excess of 300, depending on lining or barrier construction.

Adhesive

The adhesive most commonly used in the manufacture of fiber drums is sodium silicate, or water glass. Silicate adhesive has the advantages of low cost and general effectiveness, but the disadvantage of being water-soluble, and therefore producing drums with poor water resistance. Thus, a silicate drum subjected to a 5-day exposure in a water-spray test will lose about 90% of its stacking strength.

Table 1. Water-Vapor Transmission Rate of Chime-Style Fiber Drums[a]

Construction	Weight Increase
Silicate adhesive, no lining	10,000+ (est.)
Silicate adhesive, polyethylene barrier (0.7 mil)	600
Silicate adhesive, polyethylene lining (2 mils)	350
Flame activated polyethylene adhesive, no lining	175
Silicate adhesive, aluminum-foil barrier	125
Silicate adhesive, polyethylene/aluminum foil lining	30

[a] Total weight increase of a desiccant inside a 55-gal fiber drum with rubber gasketed steel cover, in grams of water per 30 days, with the drum exposed to 100°F and 90% RH. The values listed above are for comparative purposes only and should not be understood as absolute values that would be picked up by a specific product.

For drums requiring moisture proof capability, poly (vinyl acetate) (PVA) is used. There is also use of poly (vinyl alcohol) and dextrin. The main requirements for the adhesive are good wet tack and a quick setting speed. It is important to use an adhesive with high solids content to ensure that the amount of water added, as a consequence of using the adhesive, is kept to a minimum.

Lids

Fiber drums are known as open top drums. This means they have a lid that matches the diameter of the drum. The lid can be made of wood, plastic, steel, or fiberboard. The lid is held in place with a metal band, normally steel. Tight head drums have tops that are permanently fixed to the body. These drums are made only from plastic or steel. Steel lids are used in high performance specifications. Tight end drums are used for liquids and semiliquid products. Depending on the global manufacturer, there is a preference for the lid material. In the United Kingdom, the popular choice is plastic (polyethylene). In the United States the choice is split between plastic and fiberboard. In order to assist in the stacking of drums and in the stability of the stack of drums, it is usual for the lids to be designed in such a way that they locate within the base chimes of the drum on the next layer. For drums that require an airtight seal, a gasket is incorporated into the plastic or steel (1).

DRUM STYLES

Drums with Metal Chimes

Figure 1 shows the most common style of fiber drum, with metal chimes on the top and bottom of the drum. These chimes are mechanically formed during drum assembly to attach the bottom heading to the sidewall (bottom inset) and to provide an attachment site for a toggle-action locking band to hold the cover onto the drum (top inset). This drum style can provide the highest level of abuse resistance and product protection by a fiber drum. Many variations are commercially available for this versatile drum style.

Drums for Packaging Liquids

If made with an interior lining, caulking compound in the bottom juncture, and a gasketed steel or, preferably, plastic cover, a metal-chime drum can be used for the packaging of liquids, ranging from self-sealing latex adhesives to water-based chemical solutions, to solvent-based cleaners and fiberglass gelcoats. Such drums can also be provided with a spun-on locking band to produce a tight-head drum that provides an even better top seal. The use of fiber drums to package liquids has grown significantly with advancements in lining materials and manufacturing processes that have expanded the holding capabilities of the drums.

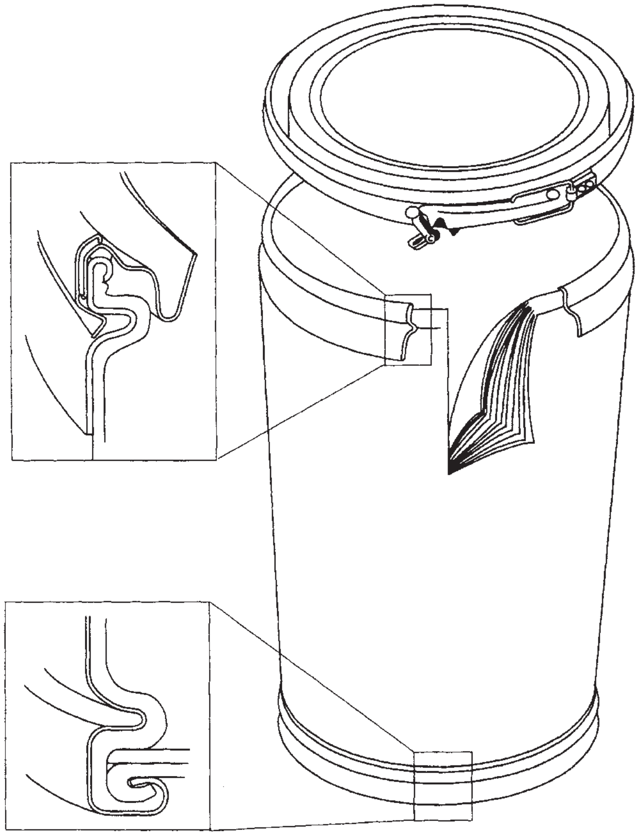

Figure 1. Drum with metal chimes.

Composite Fiber Drums

Figures 2 and 3, respectively, show open-head and tight-head composite fiber drums intended for the packaging of liquids. Some drums have a self-supporting plastic insert, or inner receptacle, inside each drum to contain the liquid. The inner receptacle is an integral part of the packaging and is filled, shipped, and emptied as such.

Straight-Sided Drums

Figure 4 shows the straight-sided chime of a drum intended for the packaging of hot-melt adhesives and other products that are dispensed by use of a platen pump. Since a close-fitting platen must slide into the drum to dispense the product, the inverted groove design typical of other drums with metal chimes cannot be used. Instead of reducing the diameter at the groove to provide purchase for a lock band as in the standard design, the chime and fiber tube of a straight-sided drum must be expanded outward by about 8%. Since paper typically can be elongated only about 3% before failure, the development of this drum style was not a simple task. This drum style may also be made with two tops (i.e., two removable headings) so that when the platen pump has removed as much product as it can reach, the drum may be inverted, the bottom removed, and the residual heel removed and placed on top of the next drum for dispensing.

Drums for Packaging Wire

Figure 5 shows a drawing of a drum designed for the packaging and dispensing of wire. The drum is made with a central core, around which the wire is coiled and from which it is dispensed.

Drums for the Aseptic Packaging of Foods

The aseptic packaging of foods at ambient temperatures requires a containment system that provides a good barrier to both oxygen and biological contaminants that might cause food spoilage. In this system the food is packaged in a high-strength polyester/polyethylene/aluminum-foil bag, which is then placed inside the drum. The drum itself is of heavy-ply construction, frequently using weatherproof adhesive, to allow outdoor storage. The drum functions to provide protection from mechanical abuse and moisture. The bag provides the barrier to chemical and/or biological degradation of the food (see also Aseptic Packaging).

Drums without Chimes

Figure 6 shows the simplest of drum designs: a fiber tube with steel or plastic headings attached by stitching, taping, adhesively bonding, or the use of mechanical clips. The top and bottom headings are designed to interlock to facilitate stacking. This inexpensive drum design, generally with an inner polyethylene bag, is commonly used for the packaging of such low-cost products as detergent and ice-melt compound in relatively small sizes.

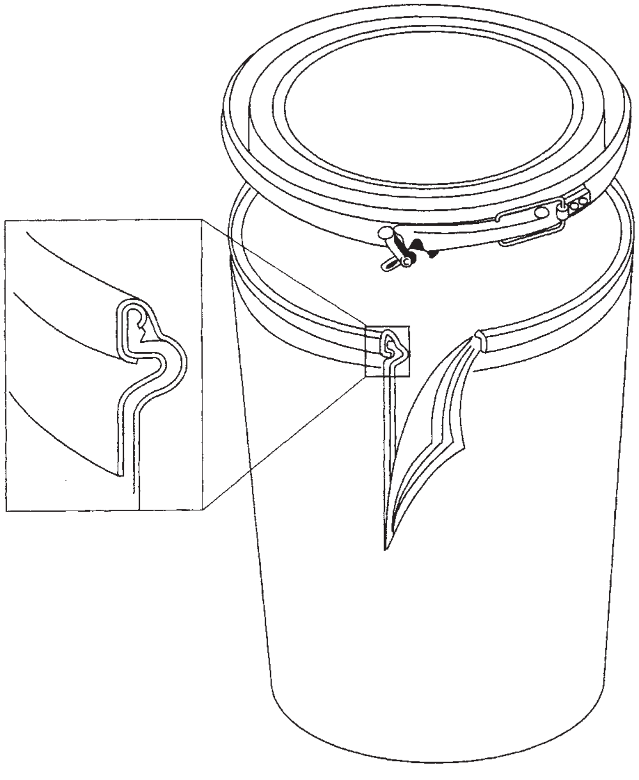

Figure 2. Open-head composite fiber drum.

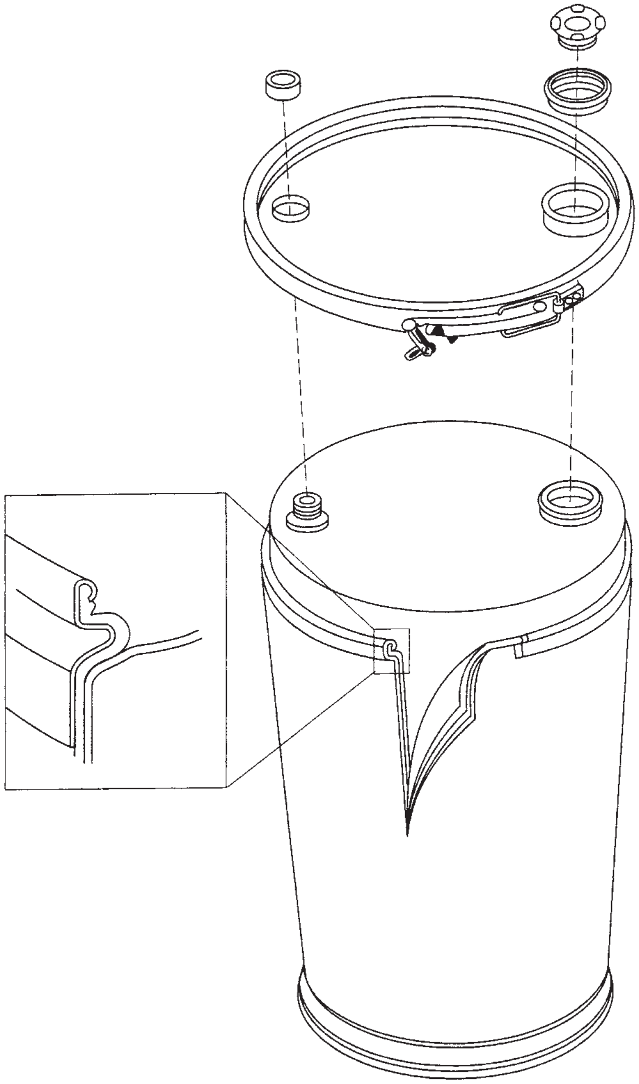

Figure 3. Tight-head composite fiber drum.

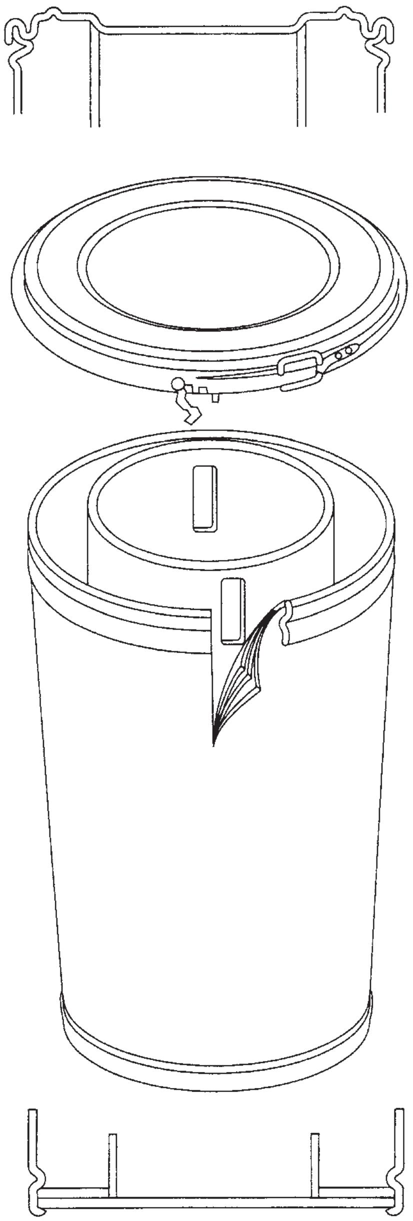

Figure 5. Drum for packaging wire.

Nestable Fiber Drums

A striking variation of this drum style is a nestable fiber drum. A frustroconical tube is made by the winding of precut sheets of paperboard, one for each ply. An integral polyethylene lining and plastic headings (adhesively bonded on the bottom, taped on the top) complete the structure. The advantage of this construction lies in the reduction of shipping cost and storage space for empty drums, but at the sacrifice of some stacking strength. This drum design was developed for the storage and transport of hazardous medical waste for incineration.

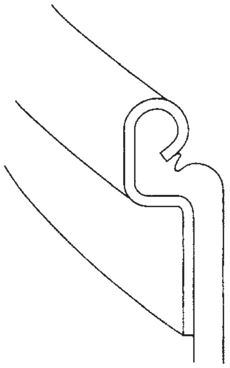

Figure 4. Crimp of straight-sided drum.

All-Fiber Constructions

Drums made only from fiberboard have somewhat greater structural integrity than do the chimeless drums described above. As shown in Figure 7, in the manufacture of such drums the bottom-end portion of a tube is notched and/or folded in and is then covered inside and out with fiber disks that are stitched and/or glued to produce a

Figure 6. Drum without chimes.

strong and secure heading. Covers, designed for slip fit, are made in the same way, but from a short piece of tube.

Drums of this style are available in several design variations. The simplest has a drum bottom with a cover of somewhat larger diameter, which slides over the drum, leaving a step or ridge at the juncture between cover and drum. The cover is often taped in place, but this may leave an unsightly ridge. This drum design can also be made with a tube and two covers, often used for the shipment of rolls of plastic or other materials that need protection to prevent damage to the roll edge.

In a somewhat stronger all-fiber design, the drum body is composed of two components (Figure 7): a tube that is glued into a somewhat shorter shell of somewhat larger diameter. The cover, having the same diameter as the shell, slides on over the exposed portion of the tube, leaving no ridge at its juncture with the shell. In a fourth variation of this style, the drum body is squared off to provide for more efficient use of storage space. The trade-off for this gain is some reduction in stacking strength as compared to the right circular cylindrical form of other drums. The primary application for all-fiber drums is for the packaging of dry powders, frequently with an inner polyethylene bag.

REGULATIONS

The manufacture and use of fiber drums are regulated by a wide variety of governmental and nongovernmental national and international agencies.

NMFC and UFC

The National Motor Freight Classification (NMFC) and the Uniform Freight Classification (UFC) are nongovernmental agencies concerned with the shipment of all commodities, hazardous or not, by common carrier by highway and rail, respectively, in the United States. As part of their function of setting freight rates for such shipments, these agencies also set construction specifications for the packaging to be used.

Other

The U.S. Department of Transportation (DOT), the International Maritime Organization (IMO), which publishes the International Maritime Dangerous Goods Code (IMDG), the International Civil Aviation Organization (ICAO), the International Air Transport Association (IATA), and RID/ADR, the organizations regulating international shipments of dangerous goods by road and rail in Europe have several things in common. First, they are all concerned only with the shipment of hazardous materials (the transport of dangerous goods). As far as these agencies are concerned, nonhazardous materials may be shipped in any packaging that the shipper desires to use. Second, they have all based their regulations, to a large extent, on the UN *Recommendations on the Transport of Dangerous Goods* (Orange Book). Fiber drums that conform with the UN Packaging Group I, II, or III Standards are often used to transport hazardous products in solid/dry form. Fiber drums cannot be used to transport hazardous liquids (1).

APPLICATIONS

Fiber drums are commonly used for the packaging of a broad range of products, from apple juice to zinc powder.

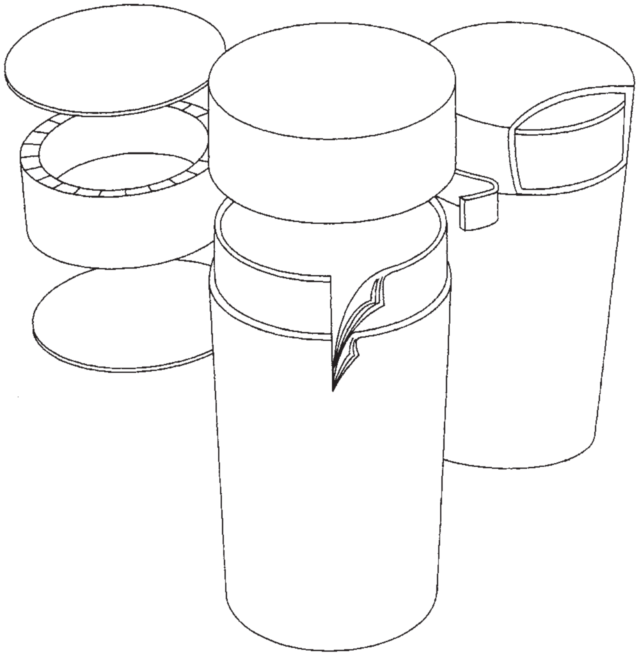

Figure 7. All-fiber drum.

Major markets include dry and solid chemicals, liquid and hot-melt adhesives, paints and coatings, liquid textile chemicals, such foods as tomato paste and dried onions, and rolls of plastic film and carpeting. Fiber drums are also used for the transport and dispensing of electrical wire and for the transport of hazardous wastes to incinerators and landfills.

RECYCLING

Fiber drums can be either reused, the component materials recovered and recycled, or disposed of in an energy-to-waste system. Internationally agreed identification code data and reycling logo can be applied to drum sidewalls and base that indicate their composition (2). This information is used as a guide to recycling. Fiber drum manufacturers can supply information and support on environmental and waste management issues.

DRUMS, PLASTIC

Bruno Poetz
Ernest Wurzer
Mauser Werke GmBH,
Düsseldorf, Germany

Chemicals and other industrial products are shipped mainly in pails and drums. In most parts of the world, 1- to 6-gal (4- to 23-L) open-top plastic containers, generally injection-molded (see Injection molding), are called pails (see Pails, plastic). In North America, 1- to 6-gal (4- to 23-L) closed-head (i.e., bung-type) blow-molded containers (see Blow molding) are called pails as well, or jerrycans. The term jerrycan is often used in other countries to describe bung-type containers in the 1- to 16-gal (4- to 61-L) size range. In general, however, the word drum applies to open- and closed-head containers larger than 6 gal (23 L). In North America, the standard drum sizes are 15, 20, 30, 35, 55, and 57 gal (57, 76, 114, 132, 208, 216 L). In Western Europe and most other parts of the world, standard drum sizes are 30, 60, 120, and 216 L (roughly 8, 16, 32, 55, and 57 gal).

Polyethylene liners for steel and fiber drums were blow-molded and rotationally molded in the United States and Western Europe in the 1950s, but there were no self-supporting plastic alternatives until the 1960s. In 1963, U.S. production of all-plastic 5-gal (19-L) pails and 16-gal (61-L) drums began. In western Europe, production of 16-gal open-top and bung-type drums started at about the same time, and a 32-gal (121-L) open-top drum soon followed. The introduction of all-plastic 55-gal (208-L) drums did not come until the early 1970s. The development of large all plastic drums took many years because they required special resins and processing equipment. Market acceptance has also required special designs.

Plastic containers have excellent performance characteristics. They are strong, lightweight, durable, corrosion-free, and weather-resistant and, in accordance with international transport regulations, are authorized to carry a great number of hazardous materials. Most plastic drums are used for chemicals, but they are also used in the food-processing industry for the shipment and storage of products that include concentrated fruit juice, vegetable pulps, and condiments.

RESINS

Self-supporting plastic drums are made of extra-high-molecular-weight (EHMW) high-density polyethylene (see Polyethylene, high-density). The molecular weight of these resins is so high that their flow rates cannot be expressed in terms of melt index (MI) as measured according to ASTM 1238, Condition E (44 psi or 303 kPa). The MI of relatively low-molecular-weight HDPE injection-molding resins ranges from 1 to 20 g/10 min; the MI of higher-molecular-weight blow-molding bottle resins is less than 1 g/10 min. Measuring the flow of EHMV resins requires higher pressure (Condition F, 440 psi or 3 MPa), and the values obtained are expressed in terms of high-load-melt index (HLMI). The HLMI of resins used for self-supporting drums range from 1.5 to 12 g/10 min. Design trends in plastic drums are related to the availability of EHMW resins. In the United States, 10 HLMI became the standard resin for drums with separate plastic- or metal-handling rings. The development of drums with integral handling rings required higher-molecular-weight resins (HLMI 1.5–3) that were available in Western Europe before they were produced in the United States.

All properties of polyethylene depend on three important factors: molecular weight (length of molecule chains), density (degree of crystallinity), and molecular weight distribution (distribution of longer and shorter chains). As molecular weight increases (and MI or HLMI decreases), toughness and resistance to stress cracking increases. The tradeoff for these improved properties is difficulty in processing. HDPE has crystallinity of 60–80% at density of 0.942–0.965 g/cm^3. (In contrast, LDPE has crystallinity of 40–50% at density of 0.918–0.930 g/cm^3.) As density increases, toughness and stress crack resistance decrease, but stiffness, hardness, and resistance to oils and chemicals improves. Molecular-weight distribution is related primarily to processing.

Chemical Resistance

Chemical resistance is particularly important in drum design. All 55-gal (208-L) drums use EHMW high-density resins, but there are variations within that category. Drums used for chemicals that are compatible with HDPE generally use relatively high-molecular-weight (e.g., HMLI 1–3) and relatively high-density (i.e., >0.95-g/cm^3) resins. Where stress cracking is a potential problem, relatively low-molecular-weight (e.g., HLMI 6–10) and relatively low-density (i.e., <0.95-g/cm^3) resins give better performance. Although no chemical dissolves polyethylene (particularly high-molecular-weight polyethylene), the effects of certain chemicals include strong swelling action by penetration into the container walls, stress cracking, oxidation, degradation by destruction of the macromolecules, or permeation through the container wall. Resistance tests should be made based on laboratory samples and on containers in use.

The resistance to stress cracking must be examined before using self-supporting plastic drums. The ESCR test prescribed in ASTM D1693 can be used for material selection, but tests must be performed on finished containers. This can be done by storing a drum filled with 5% surfactant for more than 3 months at temperatures higher than 40°C. Stress cracking may occur if there are stresses in the wall. Tensile and compressive stresses can be avoided by using an optimum wall-thickness distribution in production or in the design of the blow-molding tool. They may also occur when the products contain surface-active substances such as wetting agents at concentrations up to 20%. HDPE's resistance to stress cracking depends on the density and the molecular weight of the raw materials. As density increases, ESCR decreases. As molecular weight increases, ESCR increases. High-molecular-weight blow-molding resins with densities of 0.947–0.954 g/cm^3 have a high degree of stress-crack resistance and are ideal for drums (1).

HPDE drums can safely package a wide variety of chemicals. Uses within the chemical industry include dairy, agricultural, electronic, specialty, photographic, and oil-well applications, as well as those for organic and inorganic chemicals and natural flavorings.

Permeability

HDPE is susceptible to permeation by certain chemicals. Special attention should be paid to inorganic chlorinated hydrocarbons (e.g., per- and trichloroethylene) and aromatic hydrocarbons (e.g., benzene, toluene, and xylene). Normally, inorganic chlorinated or aromatic hydrocarbons cannot be packed in HDPE drums owing to permeation, but the permeation rate can be reduced by several methods of surface modification (see Surface modification). Within the HDPE family, high-molecular-weight grades have relatively high resistance to permeation. The risk is also reduced by using relatively thick walls.

UV Resistance

The service life of HDPE containers cannot be accurately predicted because it largely depends on climatic conditions. Different colorings (see Colorants), especially black (with carbon black), blue, green, white, and gray, increase resistance to weathering and protect the product from light. Depending on climatic conditions, additional UV stabilizers must be added.

DESIGN

Closed-Head Drums

Closed-head drums, also called tight-head drums, are available in different designs, with 2-in. (51-mm) and 3/4-in. (19-mm) bungs, in 15-, 30-, and 55-gal 57-, 114-, and 208-L) sizes. They are used where handling equipment is available to accommodate them. This is important because large self-supporting drums are designed to replace composite steel drums (steel with plastic liners or coatings), for which mechanical handling equipment is available worldwide. In the United States, plastic drums were initially designed with metal handling rings so that the drums could package heavy liquids (e.g., up to 1.8 g/cm^3 or 825 lb/55 gal) and still be handled by traditional steel-drum handling equipment, particularly the "parrot's beak."

A different approach was taken in Europe and other parts of the world, where the L-ring drum was 30- and 55-gal (114- and 208-L) capacities has become the standard. L-ring drums are produced by blow-molding the drum and integral rings in one step. The use of this configuration required the development of a wider parrot's beak, and at first it was approved only for liquids with densities less than 1.2 g/cm^3 or 550 lb/55 gal. The L-ring is now approved for heavier liquids.

Open-Top Drums

For general applications, open-top drums are provided in 8-, 15-, 30-, and 55-gal (30-, 51-, 114-, and 208-L) sizes. The advantages of the standard open-top drum are easy handling, absolute tightness, good stacking properties, and high radial rigidity. They are used most often for water-based products such as glues, softeners, and liquid soaps, as well as for foodstuffs. The standard open-top drum can be cleaned easily and reused.

SHIPMENT OF HAZARDOUS MATERIALS

International regulations for transport of dangerous goods (hazardous materials in the United States) are one of the central issues regarding the use of plastic drums because of heightened worldwide concern for environmental protection and the increasing number and volume of dangerous goods being shipped. HDPE is a safe and durable material for shipping dangerous goods.

United Nations Regulations

International regulations concerning packaging tests for hazardous materials are contained in the *United Nations Transport of Dangerous Goods* (2) and in the *International Maritime Dangerous Goods Code* (IMDG Code), which regulates substances shipped overseas. The recommendations do not specify how a package is to be made. They stipulate package-performance tests for each dangerous substance and modification of the test procedures based on the degree of hazard and some physical properties of the substance. They require a certification mark to show that the package has passed the tests. Self-supporting plastic drums can be used for a wide variety of dangerous substances. A typical drum marking under these regulations would be

$$\mathrm{UN} = 1\mathrm{H}1/\mathrm{Y}.1.8/150/84/\mathrm{D}/\mathrm{Mauser}\,824$$

where UN = United Nations; 1H1 = plastic drum, small opening; Y.1.8 = Group II products up to 1.8 g/cm^3; 150 = test pressure, kPa; 84 = year of production; D = FRG; Mauser = producer; and 824 = registration number.

U.S. Regulations

The Materials Transportation Bureau (MTB) of the Department of Transportation (DOT) has expanded Specification 34 (CFR, Title 49, Part 178.19) to include 55-gal (208-L) plastic drums (3). Previously, only drums of up to 30 gal were included, and 55-gal (208-L) drums needed special exemptions. The revision eliminates the need for those exemptions. They are now marked DOT-34-55. Some familiar commodities have been written into the regulations with no restrictions, but many of the chemical listings in Part 173.24(d) prescribe channel compatibility and permeation tests. Reference to specific types of polyethylene has been deleted from the most recent revision. Minimum wall thickness is specified, but this does not create significant differences between drum construction in the United States and other countries.

European Regulations

European regulations for rail and road transport of hazardous materials in plastic containers up to 250 L (66 gal) include testing procedures based on test data obtained with model liquids such as acetic acid, nitric acid, water, white spirit, surface-active agent, and *n*-butyl acetate. On the basis of the dangerous properties of these materials, all other dangerous substances can be approved and assimilated as long as their individual requirements are taken into account in testing. Plastic containers are included in the packaging regulations as follows: up to 15 gal (57 L) for Class-1 dangerous substances (very dangerous); up to 55 gal (208-L) for Classes 2 (dangerous) and 3 (less dangerous). Apart from the requirements concerning approval of the containers, quality assurance in production plays an important role in the safe transportation of dangerous goods.

Plastic drums will continue to gain importance, particularly if worldwide standardization occurs.

DRUMS/PAILS, STEEL

Richard B. Norment
Steel Shipping Container
Institute, Washington, DC

Despite centuries of innovation, no one has devised a more useful and adaptable medium-sized container for liquids and semisolids than a cylindrical container. Its shape, based on the circle, provides maximum strength; when fully laden, it can be tipped over and rolled. Early ocean shippers employed heavy, easily breakable clay and ceramics. They knew smelting and metalworking, but evidently could not produce metal containers much larger than pots and pans. From the Middle Ages until recent times, the standard container material was wood, usually oak, formed into metal-bound, stave-constructed barrels and kegs (see Barrels). The wooden barrel had no weight advantage but was far stronger and could be manufactured anywhere of materials widely available at low cost. Design differed little from the early jars, featuring the same bilged sides for maximum strength. In almost every trading nation, the wooden barrel reigned as the universal shipping container for liquids and semisolids until the late 19th century, when the first steel barrels appeared in Europe.

Impetus for the invention and development of the modern steel drum had begun years earlier with the Great Oil Rush of 1859. Oil-drilling technology improved so rapidly that by 1869, U.S. wells were producing 4,800,000 barrels ($7.6 \times 10^5\,\mathrm{m}^3$) a year. That introduced a much tougher problem: how to store and ship the oil. The only container available was the wooden barrel. Demand soon outstripped the production capacity of the cooperage firms, and oak became scarce and very expensive. The immediate solution was the development of pipelines, railroad tank cars, and the tank truck. But for smaller packages, oil-industry shippers still had to struggle along for another 40 years with the time-honored wooden barrel. Kerosene was the most important barreled product. The wooden barrel's chief problem was leakage. Designed to hold 50 gal ($0.189\,\mathrm{m}^3$), it commonly lost enough per trip to arrive at its destination containing only about 42 gal ($0.159\,\mathrm{m}^3$), a figure that has remained the standard "barrel" measurement of the oil industry.

A few years after their development in Europe, the first steel barrels were produced commercially in the United States by Standard Oil at Bayonne, NJ, in 1902. Constructed from 12 to 14-gauge terne steel, they were heavy, clumsy, bilged affairs with riveted or soldered side seams and were anything but leakproof. Extremely rugged, many of them lasted 20–30 years. They were also expensive compared with wooden barrels. Despite the need, steel barrels were slow to catch on; yet technical developments came rapidly. In about 1907, the welded side seam was introduced, which curtailed the leakage problems of riveted barrels and reduced costs. Shortly afterward, the first true 55-gal (208-L) drum was introduced, with its characteristic straight sides contrasting markedly with the bilged barrel. Rolling hoops were introduced soon thereafter, both expanded and attached, with the latter utilizing an I-bar section. The mechanical flange was invented after 1910. These improvements were far-reaching and gave the new container added advantages. Among them was lighter weight, which reduced shipping costs and reduced the amount of steel required. The new drum design permitted use of 16- and 18-gauge steels instead of the far heavier gauges used previously. These drum developments were followed in 1914 by the first true steel 5-gal (18.9-L) pail featuring the first lug cover.

The use of steel containers grew slowly before 1914, despite their cost, weight, and safety advantages over wooden containers. The advent of World War I marked the beginning of the end for the wooden barrel, along with the eventual dominance of the steel drum and pail. Wartime demand also spurred many improvements in manufacturing techniques and equipment. After the war, many innovations appeared, including pouring pails, agitator drums for paints, and new, colorful decorating techniques. Manufacturers began to use steel containers for products other than petroleum products and chemicals. Toward the end of the 1930s, the steel-container industry started gearing up for a second wartime effort. This time, however, the demands were far more stringent, requiring fuel containers for a highly mechanized war on more than one front. Innovation took a back seat to production considerations as war machines on the ground and in the air consumed vast amounts of fuel and chemicals. The 55-gal (208-L) 18- and 16-gauge drums were indispensable to the fuel supply of island bases and assaults in the Pacific, frontline mechanized operations in Europe, and to air and ground operations in East Asia. Apart from its ruggedness, the fact that a cylindrical drum could be rolled by one man was an important feature.

Although a downturn in steel drum and pail production occurred at the end of World War II, it was of short duration. Resumption of business created a demand from industry, agriculture, and consumers. The acceleration in chemical and pharmaceutical product development and output provided new markets for steel drums and pails. Demand for paints, lacquers and varnishes, adhesives, inks, foodstuffs, and other products made the steel shipping container industry one of the largest users of cold-rolled sheet steel (approximately 1 million tons in 1993). Despite the introduction of competitive containers made of other materials and of intermediate-bulk containers, U.S. production increased from 2.4 million drums in 1922 to 32.35 million drums in 1993.

Drums range in size from 13 to 110 gal (49 to 416 L), but the 55-gal drums account for 80% of annual production. Over 75% of all new drums are used for liquids, and the rest are used for viscous and dry products. About 70% of the market is accounted for by five broad product categories: chemicals (35%); petroleum products, including lubricants (15%); paints, coatings, and solvents (10%); food and pharmaceutical products (5%); and janitorial supplies, cleaning compounds, and soaps (5%).

As a result of increased environmental awareness, drum manufacturers, drum users, reconditioners, pail and drum recyclers, and steelmills have developed programs to collect, recondition, and/or recycle used steel drums and pails. In addition the recycled content of steel has surpassed an average of 25% per container. In fact, more steel is recycled than all other packaging materials combined (53 million tons of steel scrap in 1993) (1). Thus, choosing steel packaging conserves energy and natural resources and reduces waste. Each year over 40 million drums are reconditioned, thus prolonging the useful life of steel drums.

The industry's growing involvement in drum and pail reclamation is an important factor in purchasing agents' or packaging engineers' decisions to select the appropriate container for their company's products.

DRUM AND PAIL CONSTRUCTION

Steel drums [13–110 gal (49.2–416 L)] and pails [1–12 gal (3.8–45.4 L)] are generically fabricated from cold-rolled sheet steel in a range of thicknesses from 0.0946 in. (2.4 mm) (formerly 12-gauge) to 0.0115 in. (0.292 mm) (formerly 29-gauge). They consist of a cylindrical body with a welded side seam and top and bottom heads. The thickness of steel used in pails and small drums usually range from 0.0115 in. (0.3 mm) to 0.0269 in. (0.7 mm), while thicker steel [i.e., from 0.030 in. (0.8 mm) to 0.0533 in. (1.4 mm)] are used for larger, reconditionable drums (see Table 1).

Most drums are made of commercial-grade cold-rolled sheet steel, but stainless steel, nickel, and other alloys are used for special applications. Only about 45% of all new drums are lined with interior protective coatings, but the percentage is much higher (i.e., 80%) for drums used for chemicals. Over the years, the cost and weight of steel drums have been reduced owing to technological advances, such as the introduction of the triple-seam chime in the early 1980s. Improvements in cold-rolled steel chemistry, surface quality, and gauge control have also contributed to a reduction in cost and weight. Until the early 1960s, most tight-head drums were made of steel 0.0428 in. (1.1 mm) thick (formerly 18-gauge). There has since been a shift to a lighter-gauge drum with a steel thickness of 0.043 in. (1.1 mm) in the top and bottom heads and 0.030 in. (0.8 mm) in the body (formerly known as the 20/18 drum, now marked as 1.1/.8/1.1). Currently, 55-gal (208-L) drums of 0.0378-in. (1.0-mm) steel thickness are being manufactured to transport hazardous materials,

Table 1. Sheet Steel Thicknesses Versus Gauge No[a]

	Minimum Thickness		Nominal Thickness Marking[b]
Gauge No.	in.	mm	mm
12	0.0946	2.40	2.4
16	0.0533	1.35	1.4
18	0.0428	1.09	1.1
19	0.0378	0.960	1.0
20	0.0324	0.823	0.8
22	0.0269	0.683	0.7
24	0.0209	0.531	0.5
26	0.0159	0.404	0.4
28	0.0129	0.328	0.3
29	0.0115	0.292	0.3

[a] Sheet steel thickness is measured at any point no less than 3/8 in. (9.53 mm) from the edge. New DOT regulations that went into effect for new packaging manufacturers on October 1, 1994 no longer refer to steel thicknesses in gauges but rather in millimeters.

[b] Nominal thickness markings are those applied as part of the durable and permanent UN marks on the drum and pail (4). Consult ISO Standard 3574 for nominal thickness tolerances.

and 55-gal drums of 0.030-in. (0.8-mm) thickness or thinner are used for nonhazardous materials. Other popular sizes are 30 and 16 gal. In addition, the 85-gal drum, known as the “salvage drum,” is used to transport leaking or damaged packagings and debris from hazardous materials accidents. Each size can fit the non-bulk packaging needs of the drum user. [For a complete list of standard drum sizes and dimensions, consult *ANSI MH2-1991* (2).]

STYLES

Two basic styles of drums exist: the tighthead (or non-removable head), with permanently attached top and bottom heads, and the open head (or removable head), in which the removable top head or cover is secured by using a separate closing ring with either a bolted or lever-locking closure (see Figure 1).

Expanded rolling hoops, ie, swedges, in the drum body stiffen the cylinder and provide a low friction surface for rolling filled containers.

Tight-head drums (and pails) have their top and bottom heads mechanically rolled (seamed) in multiple layers to the body using a nonhardening seaming compound to form a joint (chime). Two openings, one 2 in. (51 mm) and the other 3/4 in. (19 mm), for filling and venting are usually provided in the top head, although side openings and other opening combinations and sizes are sometimes used. The openings are fitted with mechanically inserted threaded flanges conforming with American National Pipe thread standards. Threaded plugs for insertion in the flanges are made of steel or plastic and have resilient gaskets where appropriate. On full-removable-head drums, the top of the body sidewall is rolled outward to form a follow curl (false wire) to which the top head or cover is attached using a gasket of resilient material and a separate closing ring.

Steel pails are generally of the same configuration and style as the large-capacity steel drums, but are usually of thinner metal and may have only one expanded body hoop. A bail handle or carrying grip is often provided for handling purposes. A common closure for open-head pails is a lug cover that is crimped in place around the top curl and is removed by lifting the lugs (see Figure 1).

PROTECTION AND LININGS

Most steel pails and drums are fabricated from steel treated to resist rusting owing to moisture in the air. Steel is a nonpermeable, biodegradable material that is compatible with most chemicals and petroleum-based products.

Coatings are applied to the inside of drums (linings) and the outside (paint) to provide additional protection and decoration. State and federal environmental regulations control the amount of volatile organic compounds (VOCs) emitted during the application of the linings and the paint. Because conventional linings and paint contain some degree of organic solvent or heavy-metal pigments, these are being replaced by water-based or high-solids linings and nontoxic paint. In many instances, steel drum and pail manufacturers use after-burners to incinerate all vapors emitted in the paint booths, thereby reducing VOCs. Companies also recapture spray paint for remixing and reapplication on containers to conserve paint and protect the environment.

Interior

Linings are used for protection against acids, alkalies, and some organic chemicals. Phenolics provide protection against certain acids, and epoxies offer protection against alkalies. Linings consisting of varying percentages of epoxy and phenolic materials are most commonly used today. In some instances, the needed protection is supplied by a flexible or semirigid polyethylene liner insert.

Exterior

New steel containers can be painted, lithographed, or silk-screened to provide an attractively decorated and durable finish. Enamels are sprayed or roller-coated, baked, and oven-cured to give a scuff-resistant exterior coating. Black is generally the standard color, but other colors are available as well. Product and manufacturer information for merchandising or to satisfy transportation needs is applied by lithography, silk-screening, or stenciling.

STANDARDIZATION

National standards for steel pails and drums have been developed in the United States within the American National Standards Institute (ANSI) by a Committee on Steel Pails and Drums sponsored by the Steel Shipping Container Institute.

These dimensional standards have received international acceptance and have provided many advantages in

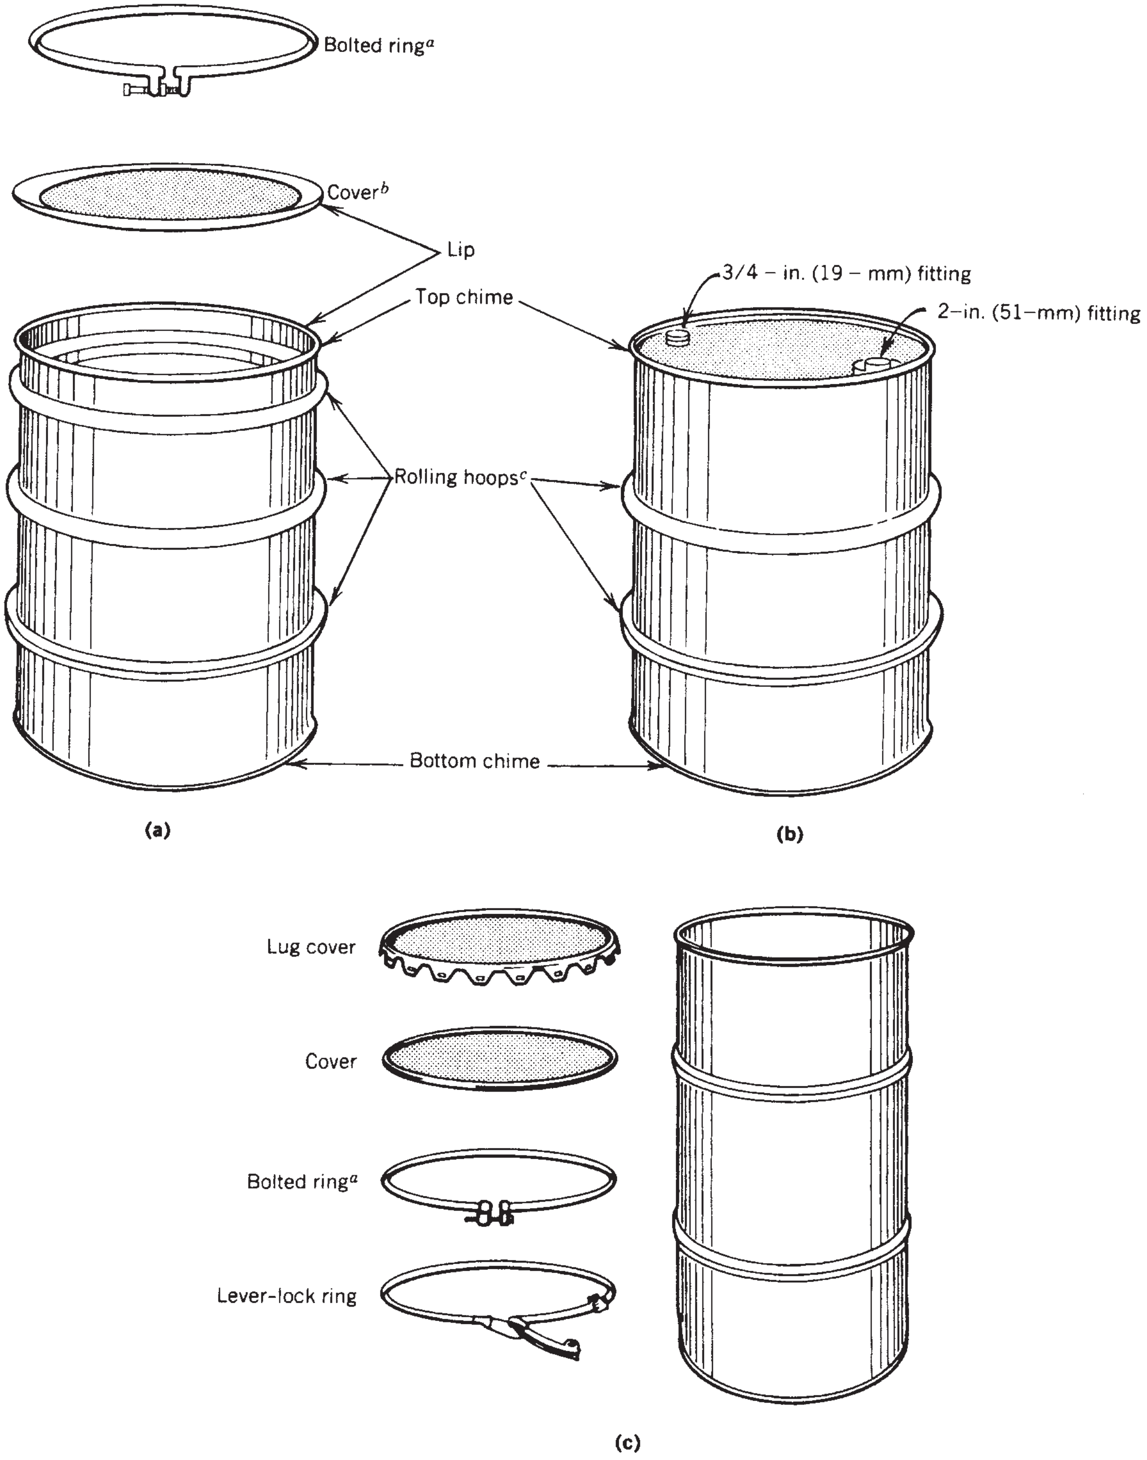

Figure 1. Steel drum designs: **(a)** open-head 55-gal (208-L) drum; **(b)** tight-head 55-gal (208-L) drum; **(c)** open-head 16-gal (606-L) drum. In part a, lever-lock ring may be used; in part b, lip of cover is turned down to fit over lip of drum; in part c, two or three rolling hoops may be used, depending on size and material packaged. Hoops are equally spaced horizontally. Actual drum dimensions may vary.

the areas of filling, handling, storage, and shipping. There are presently standards for the 55-, 30-, and 16-gal open-head and tight-head drums, as well as for the 20-L and 5-gal tight-head, nesting-lug cover, and straight-sided lug cover pails. The ANSI standard also includes a thorough glossary of terms related to packaging. The ANSI Committee is presently in the process of revising the current edition of the standard, *ANSI MH2-1991* (2), to incorporate the construction requirements set forth under the Department of Transportation's *Performance-Oriented Packaging Standards*, published in 1990 (see under "Regulations" below).

REGULATIONS

All-steel pails and drums used in the United States for the transport of hazardous materials must comply with the Department of Transportation's Hazardous Materials Regulations (DOT) (4). For nonhazardous products, these containers usually comply with the minimum requirements of the specifications set forth in the railroads' Uniform Classification Committee (UCC) (5) and the highway carriers' National Classification Committee (NCC) (6). Noncompliance with these latter two organizations' specifications, known respectively as the *Uniform Freight Classification* (UFC) (5) and the *National Motor Freight Classification* (NMFC) (6), may lead to higher insurance costs for the packager and/or shipper.

Significant regulatory changes have taken place at the DOT. Hazardous materials, governed by DOT, include flammable liquids, gases, and solids; oxidizing agents and organic peroxides; poisons; explosives; radioactive materials; corrosive materials; and certain marine pollutants and hazardous wastes. Decades-old DOT design specifications (such as the DOT-17E, -17 H, and -17C containers) have been replaced by new *Performance-Oriented Packaging Standards* (also known as HM-181 for its DOT docket number), based on the United Nations' *Recommendations on the Transport of Dangerous Goods*. The reasons for this shift were harmonization of packaging requirements with international regulations and development of package safety criteria based on the performance of the container rather than on its design. This has entailed a complete restructuring of the way packagings are specified. The SSCI's manual *Understanding HM-181 for Steel Drums* (3) summarizes the DOT regulations found in Title 49 of the *Code of Federal Regulations* (4) as they pertain to steel drums and pails.

Packagers must now provide their drum and pail suppliers with the following information: Packing Group, product vapor pressure (if liquid), net mass (if solid), and specific gravity (if liquid). The SSCI *Buyer's Guide* (7) provides a checklist for the packager. The steel drum and pail manufacturer marks the container, after having performed the following tests: drop, leakproofness, stacking, hydrostatic pressure (if liquid), and vibration. These tests are meant to minimize the risk of leakage that might result from normal handling, shipping, storage, and accidents.

A sample mark for an open-head steel drum of 1 mm thickness manufactured in 1994 by manufacturer M1234 and authorized to carry a Packing Group II or III solid with a gross mass of 300 kg (or less) is

UN 1A2/Y300/S/94/USA/M1234 1.0

where UN = United Nations, 1 = drum, A = steel, 2 = open head, Y = Packing Group II or III, 300 = maximum gross mass in kilograms (net mass of solid plus mass of drum), S = solid, 94 = year of manufacture, USA = country of manufacture, M1234 = manufacturer's number of symbol, and 1.0 = thickness in millimeters.

A tighthead drum with a nominal 1.1-mm-thick head and bottom and 0.8-mm body manufactured in 1994 and authorized to carry a Packing Group II or III liquid with a specific gravity of 1.8 or less and with a product vapor pressure of 230 kPa (or less) at 55°C is marked

UN 1A1/Y1.8/230/94/USA/M1234 1.1/.8/1.1

where UN = United Nations, 1 = drum, A = steel, 1 = tighthead, Y = Packing Group II or III, 1.8 = specific gravity (relative density of material to water), 230 = maximum hydrostatic pressure tested in kilopascals, 94 = year of manufacture, USA = country of manufacture, M1234 = manufacturer's number of symbol, and 1.1/.8/1.1 = thickness of top, body, and bottom in millimeters.

Steel drums of 1.0-mm thickness or more (also 1.1/.8/1.1) are permitted to be reconditioned and reused to transport hazardous materials, thereby extending the life of the container. Title 49 of the *Code of Federal Regulations* (CRF), Parts 100–199, gives the full details of DOT hazardous materials regulations. These regulations govern shipment by land, sea, and air. It is the responsibility of the shipper to ensure that they are using containers tested and marked in accordance with the minimum requirements for the material to be transported.

International

As stated above, the DOT's new POP standards are based on the *Recommendations of the United Nations Committee of Experts on the Transport of Dangerous Goods*, acting under the direction of the United Nations Economic and Social Council (8). Chapter 9 contains "General Recommendations on Packing," which details packaging requirements, types of packagings, and marking and testing requirements.

Members of the UN Committee are committed to adopt these recommendations into their respective nation's transportation regulations as closely as possible to the original, although differences are permitted. The UN recommendations are not regulations per se, but guidelines for regulations. Yet they are usually part of the law in the country of export or import, if not both. For example, Canada has adopted the UN recommendations into its Transportation of Dangerous Goods Act and Regulations and Related Performance Packaging Standards, while Mexico has nearly completed the process of writing the POP standards required under its hazardous materials transportation law of 1993.

Two international codes do have the force of law for member states: the International Maritime Organizations' (IMO) *International Maritime Dangerous Goods Code* (IMDG Code) governing hazardous materials transportation by water and the International Civil Aviation Organization's (ICAO) *Technical Instructions for the Safe Transport of Dangerous Goods by Air*. These two codes have adopted the UN recommendations.

As of January 1, 1995, European road and rail regulations (ADR and RID) conform to the most recent revisions of the UN recommendations.

STEEL PAILS

About 73 million new steel pails are currently produced in the United States each year; sizes range from 1 to 12 gal (3.8 to 45.4 L).

About 80% is accounted for by the popular 5-gal (18.9-L) pail. They are made in four basic configurations: full open-head, straight side, lug cover; full open-head, nesting, lug cover; tight-head, straight side; and tight-head dome top (see Figure 2). They are constructed of 0.0115-in. (0.3-mm) or thicker steel. Pail heights vary by volume, but diameters are 6 and 8 in. (15.2 and 20.3 cm, respectively) for 1 to 2.5-gal (3.8 to 9.5-L) sizes, 11.4 in. (28.6 cm) for 3–7 gal (11.4–26.5 L), and $13\frac{15}{16}$ in. (35.4 cm) for larger capacities. The two open-head designs account for about 75% of the total pail production.

Both types of open-head pails have a liquid-tight, welded side seam on the pail body and a bottom affixed by double seaming (see Can seamers). Two side "ears" are welded or riveted to the body, and a galvanized wire bail handle is attached. Handles are furnished with or without a grip, which can be wood or contoured plastic. The straight-sided pail normally has one strengthening body head (i.e., swedge), to add rigidity to the top of the

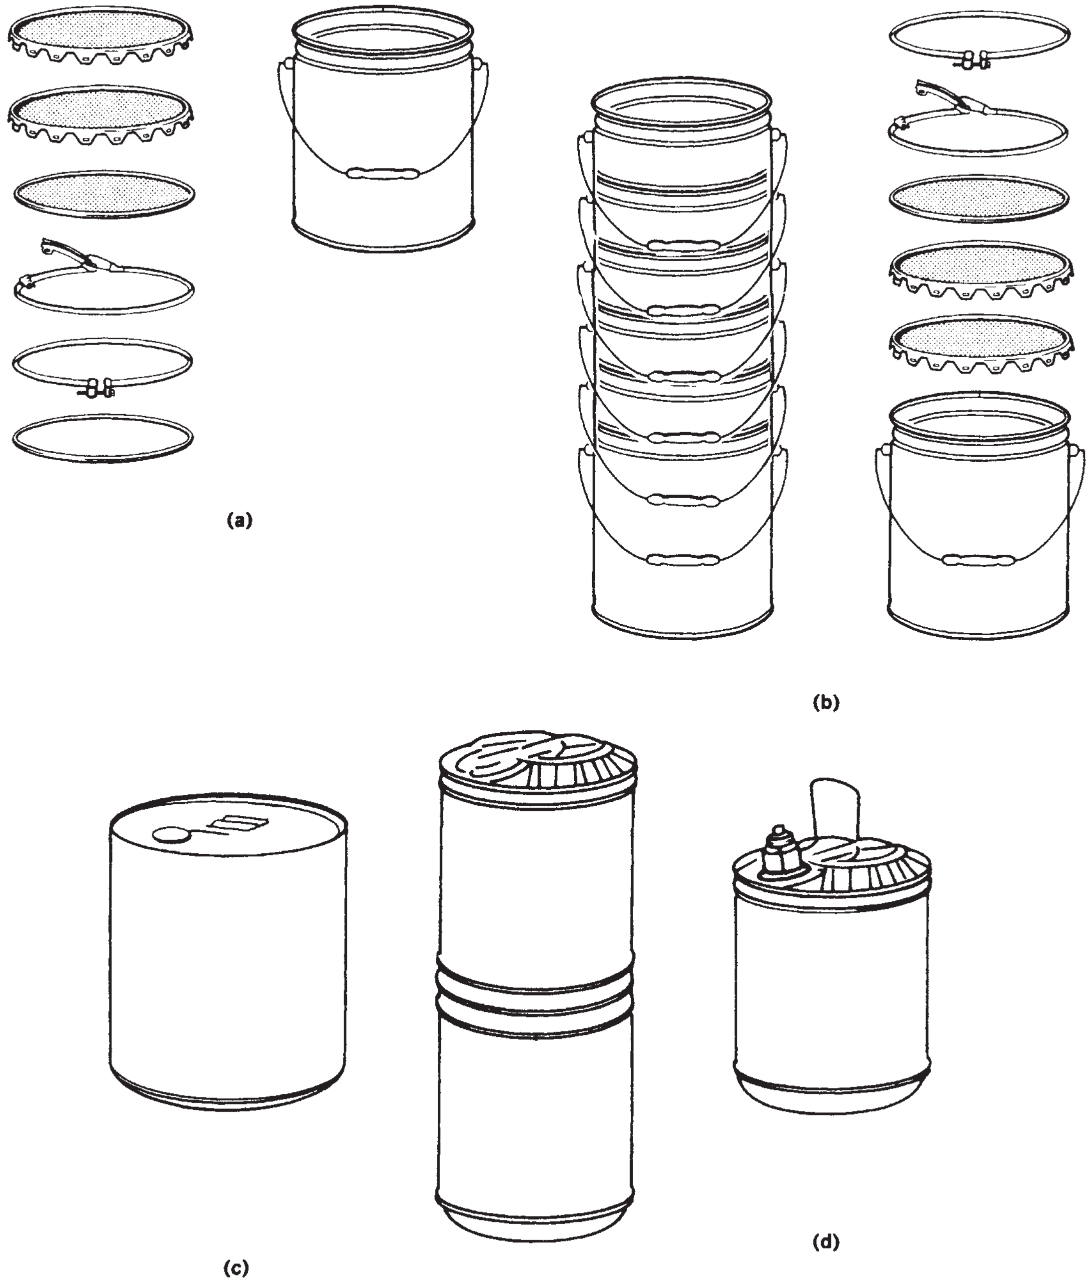

Figure 2. Designs for 5-gal (18.9-L) steel pails: (**a**) Open-head, straight side, lug cover; (**b**) open-head, nesting, lug cover; (**c**) tight-head, straight side; (**d**) tight-head dome top. (Courtesy of SSCI.)

cylinder. The tapered type usually has a second bead that, in nesting, rests on the top curl of the pail below and limits nesting depth.

The tight-head pail, accounting for some 25% of sales, is often used for the shipment of low viscosity or free-flowing liquids. It embodies a welded side seam, double-seamed top and bottom ends, and a carry handle, usually a D-ring, of galvanized wire spot-welded to the head. This container can be fitted with a variety of pouring and venting apparatus. An offshoot of the tight-head pail is a domed-top or utility pail, especially popular in $2\frac{1}{2}$- and 5-gal (9.5- and 18.9-L, respectively) sizes for petroleum products.

Pails are used for liquids, viscous products, powders, and solids. Pail markets include paint and printing inks; chemicals; adhesives, cements, and roofing materials; petroleum products; janitorial supplies (e.g., cleaners, and waxes); abrasives; cosmetics; fasteners and stamping; foods; insecticides; marine supplies; pharmaceuticals; powdered metals; and scores of other products and materials.

Because of their ability to withstand high temperatures, pails are the container of choice for the transportation and indoor storage of flammable and combustible liquids. The range of classes of flammable and combustible liquids allowed for warehousing and storage is greater than the range for like-sized containers made of plastic. See, for example, NFPA Code 30 on Flammable and Combustible Liquids (9).

In addition to varying capacities, steel thicknesses, and container construction, a host of options, fittings, and accessories are available to design a pail to a buyer's exact requirements.

Open-head pails can take two types of covers. The lug cover, usually incorporating 16 wide lugs around its circumference, can be applied at production-line speeds by automatic crimping equipment, although hand-operated and semiautomatic crimping tools are also available. The lug cover is opened with standard hand tools. The second cover, a ring seal, is best for resealing purposes. It consists of a formed disk that sits on the top curl of the container and is clamped to it either by a separate ring band or with rings that lock by lever action or bolt-tightening.

Another option is a combination of steel thicknesses. Cover and ends can be made of steel of different thickness than the body for different requirements of strength and economy. Lids and bottom ends can be strengthened by using embossed circumferential beads to provide increased rigidity.

On both tight-head and open-head pails, a wide range of opening sizes, pouring spouts, and cap closures is available. To cut costs, covers can have a simple, threaded pouring nozzle topped by a screw cap. Even simpler are pails furnished with just a dust cover over the pour opening to keep the interior clean, with the user clinching on or pressing in a pouring fitting after filling. Various metal and plastic pouring devices are offered, mostly of the pull-up style; these are covered by a cap during shipment. Some pour fittings incorporate vent openings that eliminate the need for a separate vent opening on the cover. Tamperproof seals, consisting of a steel cap clinched directly onto the pail fitting, are often used.

ECONOMICS OF PACKAGING

DIANA TWEDE
School of Packaging, Michigan
State University, East Lansing,
Michigan

PACKAGING MACROECONOMICS

U.S. industry shipments of packaging materials and containers in 2005 were nearly $103 billion, and sales of packaging machines were estimated to be $5.76 billion. Combined, these represent about 2.4% of all U.S. manufacturing shipments (see Table 1). But the economics of packaging go far beyond the simple cost of producing the materials and machines.

The total cost of the nation's packaging operations is easy to underestimate because it is embedded in the cost of producing everything, and data on packaging operation costs are not published. All products are packaged in some way, and their components and ingredients are repacked several times in the manufacturing operations of a supply chain. The fact that all products are packaged means that the packaging industry performance parallels the national economy's performance.

The packaging industries have almost every other kind of business as a customer, and so packaging affects the supply cost and demand of every product and factor of production, from food to building materials to auto parts. Retailing and distribution industry costs are also affected by packaging. And after use, packaging affects the social costs of disposal or recycling.

It is equally problematic to estimate the *value* of packaging. The values of protection and containment relate to the physical requirements of the product. Values of communication and differentiation relate to the marketing requirements that facilitate sale. Therefore, the amount of packaging materials used per product varies enormously. For example, the can represents a much larger proportion of the cost of a canned soft drink compared to the relative cost of a multiwall shipping sack for 50 lb of flour. Furthermore, packaging is a key way to differentiate products and add value to markets willing to pay higher prices.

Table 1. Gross Domestic Product 2000–2005 versus Packaging Expenditures (in millions of current U.S. dollars)

	2000	2005
Estimated U.S. value of all manufacturing shipments (1)	$4,209,000	$4,545,000
U.S. value of packaging shipments (2)	$92,617	$102,756
Percentage: packaging of all shipments	2.2%	2.26%
U.S. packaging machinery shipments (3)	$3,820	$5,760
Percentage (packaging material+machinery)	2.32%	2.39%

Consumer products use 80% of the packaging materials in the United States. The largest segment is the food and beverage industry, purchasing a little over half of all consumer packaging (35% for food and 19% for beverages). Other consumer products like health and beauty aids and household cleaners account for 8%, and a combination of tobacco, clothing, appliances, electronics, and furniture make up the rest (18% of consumer goods packaging). Packages for shipping (which includes shipping containers for consumer products) comprise 33% of the value of packaging (2).

Globally, the cost of packaging is variously estimated at between $390 billion (4) and $450 billion USD (5).

Developed market economies consume the most packaging. Pira International estimates that North America consumes 29% of the world's consumer packaging and Europe consumes 33%, compared to 4% by Latin America and 34% by the rest of the world (5). Datamonitor splits the worldwide consumption in thirds: the Americas at 34.2%, Europe at 33.2%, and Asia/Pacific at 32.5% (4). The U.S. per capita consumption of packaging for 2004 was estimated at slightly over $350 (5).

The expenditure on packaging is much lower in less developed countries, and packaging solutions tend to have lower cost. Materials and graphics are less sophisticated, the process to make and fill packages is more labor-intensive, and machinery is slower and less efficient than in industrialized countries. Food is not shipped long distances and is more likely to be purchased fresh rather than processed and packaged. There is less variety and much greater losses due to spoilage. But the packaging that is developed is generally economical, material recovery systems are efficient, and there are many creative packaging applications using indigenous materials and appropriate technology.

Packaging plays a significant role in a nation's economic development. Improvements in packaging can facilitate economic growth by increasing the efficiency of markets and by adding value to exports. Packaging can reduce the cost of food and increase its supply by preventing losses, which can be as much as 50% for food in developing countries.

The best way to add value to exports is to ship packaged products rather than shipping in bulk. There is a growing demand for more sophisticated packaging materials and methods to be used for export packaging. There is increasing realization by government authorities that investments in packaging technology can yield economic benefits, and organizations like the International Trade Centre have implemented programs to develop human resources in packaging and make information more easily accessible (6).

PACKAGING SUPPLY INDUSTRIES

Packing is produced by four manufacturing industries using very different raw materials and manufacturing processes. In the richly forested United States, the largest segment (40% of sales in 2005) is paperboard-based. Metal represents 16%, plastics is 26%, paper is 8%, and glass is 5%. Table 2 shows sales in the United States, by packaging material type, for an eighteen-year span, from 1992 to 2010 (estimated). It and most of the industry data which follows are drawn from *The Marketing Guide to the U.S. Packaging Industry*, used with permission (2).

The paper, glass, and metal packaging industries in the United States are mature. Their growth rate generally parallels, but is slower than, all manufacturing. The packaging industries' profitability varies, but is generally below the average for other manufacturing industries.

Commodity markets for metals, paperboard, and plastic resins used in packaging are characterized by low profit margins and high capital investments. Packaging conversion is, likewise, a low-profit sector. The degree of integration varies; paper and paperboard are the most vertically integrated, plastics is becoming less integrated as resin manufacturers have left the packaging business, and the big aluminum and steel producers no longer make cans.

However, unlike other mature industries, the packaging industry is not concentrated because packaging producers of various materials compete with each other due to the substitutability of container types. In 2005, only 26 companies had sales over $1 billion. The largest 50 packaging suppliers account for only 44% of total packaging shipments, with many companies supplying only one type of packaging material. Concentration is greater within each material's supply industry. Materials like molded pulp, beverage cartons, glass containers, and metal cans are made by industries in which the top four companies account for 65% of shipments (2).

Paperboard Packaging

Paperboard-based packaging is the largest segment of the packaging supply industry. It is also the most vertically integrated; companies producing 50% or more of their own paperboard account for 80% of the shipments of corrugated containers and folding boxboard cartons. Most of the large companies making paper-based flexible packaging also make their own paper (see also Paperboard).

Corrugated fiberboard accounts for almost 63% of the paperboard tonnage used in packaging. Since most products (in the United States, at least) are shipped in corrugated fiberboard boxes, the price is sensitive to the overall economy's performance. Periods of growth directly increase the demand for boxes by every industry, causing suppliers to reach full production capacity, which leads to higher prices. Similarly, the increase in imported goods from China has drawn demand away from the U.S. corrugated industry, and so the U.S. industry has cut its production in response, using the power of the integrated producers to orchestrate industry dynamics.

Paperboard packaging prices are also affected by the cost of wood (or recycled raw materials) and energy. Wood has always been relatively plentiful in the United States, and corrugated fiberboard boxes are one of the most highly recycled packaging materials. Energy is a large component of the production cost.

Metal Packaging

Tin-plated steel and aluminum cans make up most (70%) metal packaging. Packaging is a small portion (only 3.8%) of total steel production, but is 21% of total aluminum production. The metal can industry is one of the most concentrated of packaging industries in the United States, with the top 7 can producers accounting for 90% of the volume.

For many uses, steel and aluminum cans are interchangeable, and usage depends on relative prices. Aluminum is more expensive per pound than steel. But aluminum cans are lighter weight, and most innovations have emphasized further weight reductions. To reduce the cost of raw materials, the aluminum industry has facilitated recycling, and 50% of the aluminum cans used in 2003 (in the United States) were recycled. Since 1981, aluminum cans have outnumbered steel cans; aluminum is more popular for beverages, but steel still predominates for food (see Cans, aluminum; Cans, steel).

The largest use for metal cans (71%) is for carbonated beverages. The metal can is such a vital input to beer production that big breweries sometimes have their own captive can producing facilities. Food manufacturers use 26% of the cans produced.

The metal share of the packaging industry has been falling due to the substitution of plastics. Cans are being replaced by plastic bottles for beverages and by rigid plastic or retort pouches for food. Steel drums and pails have been replaced by lighter weight plastic drums and pails. The aluminum foil barrier in flexible packaging, bottle caps, and collapsible tubes has likewise been replaced by new high-barrier plastics.

Plastics Packaging

Plastics are the fastest-growing segment in packaging. Plastics have won market shares from all other packaging materials, converting glass bottle users to plastic bottles, paper bag users to plastic bags, fiberboard boxes to plastic wraps, and steel drums to plastic drums. Plastic packages generally use less material, are less costly to fabricate, and weigh less, thus reducing transport costs.

The largest-volume plastic used for packaging is low-density and linear low-density polyethylene used for film (LDPE and LLDPE = 30% of plastics packaging), followed by high-density polyethylene (HDPE = 26%), polyethylene terephthalate (PET = 18%), polypropylene (PP = 14%), polystyrene (PS = 8%), and polyvinyl chloride (PVC = 2%). The largest growth has been in PET for beverage bottles, including substitution for glass bottles and metal cans as well as the dramatic growth in the sale of bottled water.

The production of plastic resins is concentrated in oil-producing firms like Dow Chemical, ARCO, and DuPont. But the plastics converting industry is much more diverse, with few barriers to entry. Economical production scale is much smaller than that for converting paper, metal, or glass. Market leadership for a container type is often governed by proprietary technology that provides a special value. Since plastic forming is relatively easier than forming other packaging materials, there is more captive production by filling companies, especially for plastic bottles, thermoforms, and flexible packages that are produced in a form/fill/seal operation. (see Blow Molding and the articles on the individual plastics).

As the plastics industry has matured, it has developed more specialty applications. Lamination, coextrusion, and barrier coatings have improved barrier and strength properties, and thereby increased the market for plastic packaging. Furthermore, most composite packages (and even packages not normally thought of as composites, like coated cans and cartons) rely on an essential layer of plastic that adds strength, sealability, or barrier to other materials in the structure.

The flexible package converting industry is very dynamic. New materials and new combinations have been developed to improve manufacturing options and to increase the range of applications. Flexible packaging can now be used to package almost any kind of product, challenging every rigid packaging form with lower-cost options.

The flexible packaging industry is vital for developing countries without the resources or infrastructure needed for glass, metal, and paperboard industries. As a country develops its economy in the 21st century, improvements in low-cost flexible packaging can stimulate every sector, especially food industries.

Glass Packaging

Glass packaging is the smallest material segment in the U.S. packaging industry. Glass has suffered from declining sales as glass bottles and jars have been replaced by plastic, metal, and composite packages for many products. The 1980s was a period of consolidation and mergers, in an effort to make the industry more competitive with other materials. The top two producers now control 70% of the market.

The raw materials for glass are relatively inexpensive, but glass production requires a high amount of energy and has high labor costs. Very few bottle producers own the sources of raw materials, which account for 46% of the cost. The increase in recycling glass has reduced energy and material costs. Innovations in glassmaking have been focused on weight reduction, including improving the uniformity of glass distribution and plastic coatings, in order to reduce material and shipping costs. In addition, the efficiency of glassmaking has improved considerably (see also Glass container manufacturing).

The largest use for glass bottles is for beer (57% in 2004), followed by food (19%), beverages (9%), and liquor and wine (8%). However, in many cases, aluminum cans have displaced glass bottles for beer, and PET bottles have displaced glass for food, soft drinks, and liquor. Glass applications are growing only for food and drinks where its "prestige" image and high clarity are desired.

PACKAGING AFFECTS DEMAND FOR PRODUCTS

Packaging can increase the quantity demanded of a product by reducing its cost. For example, as developments in packaging technology have reduced the cost of protecting processed food, the market has grown to include more low-income consumers.

Packaging can also increase the absolute demand for a product by providing features that attract a new category of consumers. For example, the market for paint was increased by the introduction of "spray paint" to include consumers who had never painted before.

Packaging is used as a tool to differentiate products for market segmentation strategies. Buyers have unique needs and can be segmented into broad classes. For example, consumers with physical disabilities need easy-to-open packages. Some of the primary packaging benefits that are used to differentiate products are:

- The amount in the package, to match various consumption rates
- Low-cost minimal packaging for frugal shoppers
- Convenient package opening, reclosing, and dispensing features for a variety of consumer use behaviors
- Longer shelf life for consumers who want to store the product for future use, including packaging to reduce oxidation of fats and decay of fresh fruits and vegetables
- Special packaging for special occasions (gifts, holidays, etc.)
- Appeal to a consumer's psychographic image
- Fit with a lifestyle
- Package recyclability for environmentally conscious consumers

Of these benefits, the most universal demand is for low-cost improvements in package opening, reclosing, and dispensing features.

Packaging affects all stages of the buyer decision process—from problem recognition to postpurchase behavior—especially for routine purchases of low-involvement goods. Seeing a package can stimulate recognition of a problem that could be solved by the product. Package graphics can facilitate information search, evaluation of alternatives, and the purchase decision, by showing the attributes that differentiate the product inside. After the product is purchased, packaging shows how to use the product, and encourages a repeat purchase. Packaging can also play a role in purchases that require more extensive problem solving without the assistance of a salesperson.

PACKAGING COSTS

The cost of packaging per product, expressed as a percentage of selling price, varies widely, from 1% to 40%. For some products, like bottled drinks, perfumes, and aerosols, the package may cost more than the products' ingredients. These products depend on the package for their very existence. For other products such as durable goods, where the package is simply a means to facilitate distribution, the relative cost of the package is low.

Packaging costs depend on the materials and production methods employed. The choice of materials generally depends on the protection required and the marketing requirements. Protection and preservation needs depend on the nature of the product and its logistical system; fragile products and packages that will be roughly handled during distribution require more protection than do rugged products; and for perishable products to be stored, more preservation is required.

There is a growing recognition that package system development should begin early in the product development process. Packaging-related cost tradeoffs are much easier to optimize before the product is fully developed. For example, product modification to reduce fragility may be more economical than improving package protection.

Material Costs

Packaging materials include the primary package and its closure, the shipping container, and unitization materials. The cost of packaging materials depends on the cost of the raw materials (plastic, paper, wood, glass, and/or metal) plus the cost of conversion into packages to be filled. Most of the raw materials are competitively priced commodities. U.S. prices for raw materials can be found in publications such as *Plastics News* and *Official Board Markets*.

The percentage of the sales price represented by the raw material cost fluctuates, depending on commodity markets. In 2002, U.S. manufacturers of paperboard packaging spent, on average, 54% of the sales price on raw materials. It is highest for metal containers, 63%, and lowest for glass, 37% (2).

The more complex conversion processes, such as molding, coating, or laminating, add a greater percentage to the cost of converting the finished package. The conversion setup cost can also vary by container type. Conversion processes that require tooling, dies, or molds add fixed costs that are generally amortized over an initial production period.

The prices of packaging supplies are also affected by competition, vertical integration, and opportunities for intermaterial substitution. Prices are affected by general economic conditions such as recessions that result in oversupply, growth cycles that strain production capacity, and the cost of energy. The export demand for goods and for packaging materials also affects prices.

Packages can be purchased directly from the converters or from independent distributors. While a converter may offer a lower price for high-volume orders, it is rare to be able to purchase all packaging components from a single supplier. Bottles may be purchased from the bottle manufacturer, but caps, labels, shipping containers, pallets, and stretch-wrap will be purchased from other sources (although in the United States, glass bottles are often sold in corrugated fiberboard "reshipper" boxes). Independent distributors offer various components as well as entire packaging systems.

Most packaging is purchased competitively, especially when it is a standard commodity. For example, corrugated fiberboard regular slotted containers have standardized properties and are very similar when purchased from different suppliers. In order to ensure low cost, a purchaser may encourage competing firms to bid against one another. Packaging innovations, like light-weighting or material substitutions, are often introduced by one supplier competing against another.

At the same time, there is a countervailing trend to closer partnerships between packaging suppliers and purchasers. In exchange for a single-source contract, suppliers provide services such as design, quality guarantees, inventory reduction, just-in-time delivery, and customized logistics. Likewise, packages with special designs are more likely to be purchased from a single source. The supplier may work in partnership to design the package to the user's needs. For example, custom-molded bottles, trays, or plastic foam cushioning are available only from the supplier with the custom mold.

Packaging Machinery Costs

Packaging machines can be either purchased or leased. The purchase decision is evaluated like any other capital investment, judged on its net present value, by subtracting the initial investment from all cash flows from the machine's expected life of production, discounted for the time value of money. Expected income cash flows are forecast by a firm's marketing department, and the finance department crunches the numbers.

Selection of packaging machinery capacity and capability should match the expected production volume and lot sizes for the product's expected life cycle. Extremely high-volume filling operations have many dedicated single-purpose filling lines controlled by a single computer. But production plans can dramatically change in response to competitive conditions or packaging material substitutions. In order to reduce the risk of obsolescence, packaging machinery increasingly has the flexibility to run different materials and to change over quickly for different products with various lot sizes.

Package Filling Economics

Package filling operations are accounted for like any other factory operation, including inputs of direct labor, materials, energy, overhead, and shrinkage due to defects. Traditional approaches to cost reduction have focused on productivity (output/input) improvements, especially by reducing labor and energy inputs by increasing automation and by increasing machine efficiency and speed. Since successive packing machines are often linked together (e.g., filling, capping, labeling, cartooning, and palletizing), packaging line efficiency depends on a smooth flow of materials, often including master controls and a plan for accumulation to cover variation between adjacent machines.

New activity-based costing methods allow for the cost of specific operations to be more closely monitored, in order to compare alternative methods. They give packer/fillers the information needed to target productivity improvements and improve package and product quality. Planning economical production quantities, quick changeovers, and time phasing the delivery of materials can dramatically reduce costs. Improved quality control, using real-time statistical evaluation of data gathered by automated monitoring equipment on the packaging line, can reduce scrap and improve overall profitability.

In some cases it is less expensive to hire a contract packaging firm to fill packages. If production need is irregular, does not fit with current production, or is an uncertain test market, contract packaging may be more cost-efficient than filling packages in house (see also Contract packaging).

Logistical Packaging Economics

Packaging can dramatically affect the cost of distribution. For example, transportation costs are directly related to packaging cube and weight efficiency. Methods to reduce the size and weight of packaging include concentrating or nesting products, shipping products unassembled, lightweighting containers, improving the efficiency of stacking patterns in unit loads and vehicles, substituting slipsheets for pallets, and reducing the volume of cushioning materials by decreasing the fragility of products. Sometimes postponing packaging to a later time and place—for example, packing to order—can reduce packaging cube and investment dramatically.

Material-handling cost is also related to packaging; the productivity of operations like vehicle unloading and order picking depends on packaging configuration. If packages are individually handled, the cost will be much higher than if the packages are unitized in order quantities. The cost of the unitization materials is often offset by more economical mechanical handling.

Returnable packaging can often reduce distribution packaging costs if the shipping cycle is short in time and distance and if the shipper and consignee can work out the partnership details of ownership and cost sharing. Most returnable packages are initially more costly than single-trip packages, but the cost per trip can be lower. Potential returnable packaging investments should be evaluated on the basis of net present value to judge the investment's profitability. Factors to be evaluated when comparing returnable to expendable packaging include purchase cost, expendable packaging disposal cost, number of containers required for the logistical cycle, packaging management costs, and return sorting, cleaning, and transport costs (7).

The cost of distribution damage is directly related to packaging protection. But damage is not necessarily related to packaging cost. Often the cost of damage and packaging can be reduced simultaneously with a redesign that uses less materials or by substituting less expensive, yet more protective, materials. Sometimes it is more cost-effective to strengthen the product. Measurement and control of distribution damage costs is an important step in reducing packaging-related costs (see Logistical/distribution packaging).

Package Disposal Economics

It has been estimated that 76.7 million tons of packaging materials went into the U.S. waste stream in 2005, accounting for the largest component, 31%, of all municipal solid waste (MSW). MSW, generated from residences and commercial establishments, accounts for only 2.2% of the total solid waste generated; the other 97.8% includes waste from agricultural production, mining, demolition, hazardous materials and so on. More packaging is recycled than any other category of MSW: 40% of packaging was recycled in the United States in 2005 (8).

In the United States, disposal costs of MSW are paid by local governments, consumers, and businesses. Businesses pay the direct cost for disposal, and as a result they have a higher rate of recycling and more reusable packaging than do consumers. There is a trend to making consumer disposal costs more explicit, rather than hiding them in the general tax base, in an effort to encourage trash reduction and recycling. There are also "external" social costs, especially for landfilling and incineration, including possible pollution and the fact that many communities will not permit landfills or incinerators to be sited nearby. The site problem resulted in skyrocketing disposal costs; landfill tipping fees doubled in the period from 1987 to 1991, especially in highly populated areas in the Northeast. As a result, recycling of packaging materials has become more widespread. Recycling can be economically viable, but only when the reuse value of recycled material and the disposal avoidance cost exceeds the cost for collection, sorting, transporting, and reprocessing. Governments in Europe and Japan have implemented a packaging tax to help cover recycling costs.

CONCLUSION

Packaging affects every part of our market economy. There is a growing awareness at the financial level in major processing–packaging corporations that packaging represents a significant proportion of the cost of doing business. Even at 5–10% of the retail price, packaging costs can amount to hundreds of millions of dollars for a multi-billion-dollar food or beverage firm. It should be recognized that packaging costs must be analyzed in a systems approach, where the basic component purchase price is only one factor among many. Other costs include labor, machinery, distribution, development, impact of one component's cost on others', and research.

Furthermore it is increasingly recognized that packaging is more than a cost center. Packaging also directly impacts sales and profitability. A packaging innovation may have a higher purchase price than the container it replaces but can increase profits by adding value, increasing product quality, reducing damage, and improving efficiency of production and distribution.

ELECTROSTATIC DISCHARGE PROTECTIVE PACKAGING

Steve Fowler
Fowler Associates Inc., Duncan, South Carolina

Marvin Havens
Cryovac/Sealed Air Corporation, Duncan, South Carolina

INTRODUCTION

Contact and separation of any material from another generates electrical charges that, if separated quickly enough or isolated by sufficient resistance, result in what is known as *static electricity*. Indeed, the root word for electricity is *elektron*, Greek for "amber," because the Greeks originally found static electricity after rubbing amber with fur or cloth. This experiment is still repeated in school science demonstrations. Thus, static electricity can be considered to be an old and reliable scientific observation. However, protecting materials from the influence of static electricity did not become a seriously studied area until the advent of modern microelectronics.

Historically, static electricity has been a serious fire and explosion hazard for many industries from milling grain to manufacturing explosives. Dust control, choice of materials, and simple procedures were adequate solutions for these industries. Early electronics were large and robust enough to be immune to static electricity damage. However, with smaller and more dense solid-state devices, even subtle static electricity problems could destroy an entire device. Military reliability and economic losses estimated as high as $15 billion (1–3) have driven the technical understanding and development in the area now known as *electrostatic Discharge* (ESD) protective packaging.

HISTORY

People have seen static electricity for millennia. Lightning, the most spectacular example, results when charges are generated by contact and separation between air and water droplets and where water carries one charge away. When sufficient field strength accumulates for the separated charges to neutralize each other, lightning strikes. This is the same basic effect observed by walking across a carpet in the winter with rubber-soled shoes and reaching for the doorknob. In the dry air, a spark will often be observed and felt at about 10,000 V. In humid air, the voltages are less and not often felt.

Early electrical components, like resistors, capacitors, inductors, and vacuum tubes, were simple and robust enough to be virtually immune to physical damage from static electricity. The first transistors were also relatively insensitive to static because of their physical size. However, as solid-state components became smaller and faster, static sensitivity became a minor but increasing problem. Early static-control methods such as good grounding, choices of clothing materials, relative humidity control, and air ionizers were sufficient for a while. As solid-state technology progressed to ever-smaller, more complex circuits with metal oxide semiconductor technology (like CMOS and TMOS) or field-effect devices such as field-effect transistors (FETs), static became recognized as a serious problem in both manufacturing and operation. Some MOSFETs are known to be susceptible to electrostatic discharge damage at voltage thresholds as low as 150–250 V, values well below human sensitivity to static (4). While it is possible to design some static electricity protection into a chip, the best static-safe solutions for manufacturing, shipping, and storage of electrical components include electrostatic discharge protective packaging.

The military and NASA were the first to technically define and quantify static electricity problems related to electrical and electronic parts. Not only was static electricity a problem with electronics reliability, there were some unfortunate accidents believed to be caused by static, such as several missile explosions and, perhaps, the 1967 Apollo command module fire. The Department of Defense issued the original MIL Specifications that set the basis for further investigation and understanding of electrostatic discharge protective packaging (5).

CLASSIFICATION OF TYPES

Based on the type of protection required and the materials available, the original MIL Specifications divided electrostatic protective packaging into two types. In later recognition of performance differences between foils and metalized films, Type I was subdivided for a total of three types. Although MIL-Spec nomenclature and tests for electrostatic protective packaging are being phased out in favor of industry standards, they are still widely recognized.

Type I. This uses a metal or foil as a moisture barrier layer within a multilayer plastic pouch. Their electrical function is to form a metallic Faraday cage around the components to provide protection against high-voltage fields (e.g., static) and attenuate at least 25 dB or essentially all RF (radio-frequency) interference. Although the metal forms a Faraday cage, commercial Type I materials are multilayer composites of metal foils, usually aluminum, sandwiched between films with Type II surface resistivity and heat-sealing properties. This metal within this structure provides good Faraday cage protection, and the Type II film provides antistatic isolation between the electronic components and the metal foil. Type I materials are commonly referred to today as *electrostatic barrier materials*.

Type II. This uses a plastic film with a strong antistatic agent either compounded within or coated onto it. The antistatic agent must have an appropriate hydroscopic nature so that it will absorb and hold a trace of atmospheric moisture that actually provides the electrostatic dissipation layer. These materials are now called *static-dissipative materials*.

Type III. This uses a metalized layer, often vapor deposited nickel or aluminum on a polyester film, to provide a Faraday cage effect. However, because the vapor-deposited metal is thin enough to have limited transparency, the RF attenuation is limited to >10 dB.This difference in RF attenuation is the major difference between Type I and III. As with Type I packaging, commercial Type III materials are multilayer sandwiches with surface properties of Type II films. In recognition of their lesser attenuation than Type I or electrostatic barrier films, Type III films are called *static discharge shielding materials*.

TERMS AND TEST METHODS

Triboelectricity

The Greek word *tribein*, meaning “to rub,” combined with *elektron*, Greek for “amber,” defines the phenomenon we know as triboelectricity. Although the phenomena is ancient, it has been difficult to quantify and is better explained in relative terms. Table 1 is a triboelectric series of materials arranged from positive to negative, based on their charge polarities after being rubbed together. In general, when two materials on the list are rubbed together, the upper one will take the positive charge; the lower, the negative charge. Except for illustration, the triboelectric series is of little practical value since materials near each other can switch relative charge position and since the amount of charge between the two materials can vary widely (6).

However, the major point of the list is to show that common semiconductor materials and packaging materials are very low in the triboelectric series with metals higher and humans being much higher. Thus it is easy to see how a printed wiring circuit board with metal conductors, components, and connectors, all loosely held in a plastic bag and handled by human hands, can produce static electricity with possible electrostatic damage to the electronics.

Triboelectricity and its measurement has been discussed at length by the ESD Association (7). Most of the measurement techniques use a rolling or sliding test specimen that drops into a Faraday cup where the accumulated charge is measured in nanocoulombs. One method uses large (1 in. × 1 in.) cylinders of either PTFE or quartz, and another uses smaller (1/2 × 1 in.) cylinders of PTFE, quartz, or polished brass that are rolled down an inclined plane into a Faraday cup. Another method uses chips in rail magazines that are slid into the Faraday cup.

Table 1. Triboelectric Series (29)

Positive	Human hands
+	Rabbit fur
	Glass
	Mica
	Human hair
	Nylon
	Wool
	Fur
	Lead
	Silk
	Aluminum
	Paper
	Cotton
	Steel
	Wood
	Amber
	Sealing wax
	Hard rubber
	Nickel, copper
	Brass, silver
	Gold, platinum
	Sulfur
	Rayon
	Polyester
	Celluloid
	Polyurethane
	Polyethylene
	Polypropylene
	PVC
	KEL F
–	Silicon
Negative	Teflon

Other tests pull cards from bags or rub materials in a programmed way and measure the field strength developed as volts. As expected, all these tests are done with controlled humidity and temperature conditions.

Surface Resistivity

Surface resistivity is the resistance in ohms measured between two parallel electrodes on opposite sides of a square. The geometry in Figure 1 illustrates why the common units of surface resistivity are ohm/square for a measurement that is otherwise physically dimensionless. Some commercial surface resistivity measuring devices use concentric circles with a calculated “area factor” as seen in Figure 2. In either case, a given applied voltage allows a current to be measured that calculates the surface resistivity. Although test voltages are not spelled out in the specifications, relatively low voltages (50–100 V) are used, which, for the lower limits of the measurement correspond to picoampere current measurements (8).

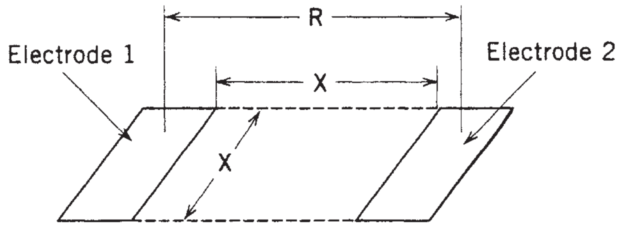

Figure 1. Surface resistivity geometry with parallel electrodes.

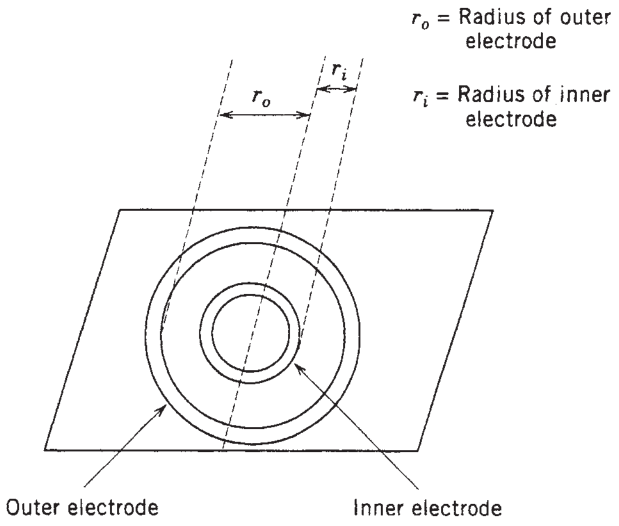

Figure 2. Alternative geometry for surface resistivity using concentric ring electrodes.

Surface resistivity can be used to broadly classify materials as conductors such as metals, insulators such as most ordinary plastics, or semiconductors as illustrated in Figure 3. Materials with surface resistivity values of $<10^5$ Ω/square are classified as conductors, those with values and above 10^{12} Ω/square are classified as insulators. Static dissipative materials are defined as having surface resistivity values between 10^5 and 10^{12} Ω/square.

There has been some discussion that surface resistivity is too simple a measurement for several factors such as the effect of film thickness and the use of multiple layers of differing resistivity values. For example, a more conductive layer below a less conductive layer can suppress the measured charges. This has resulted in a recent test method for surface resistance.

Triboelectricity and Surface Resistivity

While triboelectricity and surface resistivity have some relationship for the generation and separation of electrical charges, no good overall experimental correlation between the two has been found. One paper took an extensive variety of materials and test conditions and found no

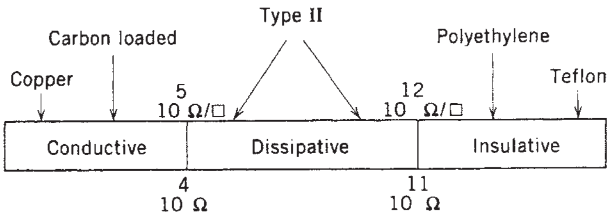

Figure 3. Surface resistivity and surface resistance ranking of common materials.

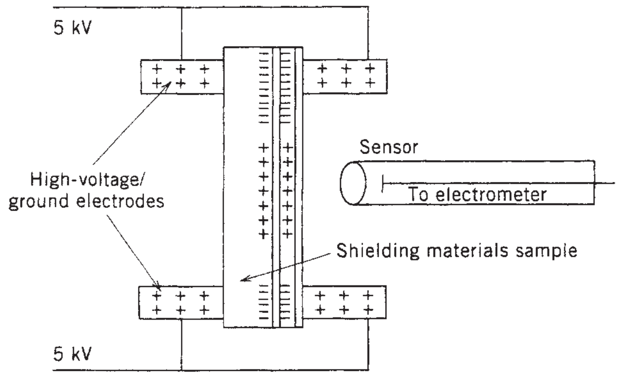

Figure 4. Static decay time fixture (5).

direct correlation (6). As stated in EIA-541-1998 and these data, it may be best to associate triboelectricity with the generation of static electricity and surface resistivity with its dissipation.

Static Decay Time. Static decay time is the time for a charge impressed on a film sample to decay to a nominal lower value. This is most often measured as the time for 5000 V to decay to 1%, or 50 V. Commercial instruments often use the fixture geometry illustration in Figure 4. They usually operate where the voltage cuts off the timer. One static decay-time measurement variant uses a digital oscilloscope to take voltage versus time values, which are then fed through an exponential decay curve-fit program that calculates the static decay time with a minimum error (9).

Surface Resistivity Versus Static Decay Time

While surface resistivity and static decay-time measurements are simple and straightforward lab procedures, there have been comparisons and discussions about their relative merit. One relatively extensive work showed data that, for homogeneous bulk additive-loaded Type II films, indicated a reasonable correlation between the surface resistivity and static decay time as illustrated in Figure 5. However, this correlation does not hold for any films with more than a single layer. Such films include the Types I and III structures with metal foils or metalized layers for RF attenuation or multilayer and coated Type II film materials (10).

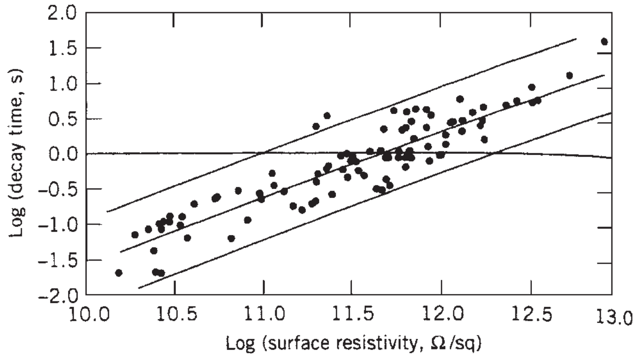

Figure 5. Correlation of surface resistivity and static decay for monolayer materials Only (10).

Surface Resistance

Because of concerns that surface resistivity was oversimplified, the ESD association prepared a new test method for surface resistance, ANSI/ESD Association STM11.11, which uses a fixed annular geometry and a fixed 100 V to measure resistance across the surface of the material to calculate resistance in ohms. This method separates the test result from any inherent resistive properties of the film. In special cases, it is possible to convert this test fixture geometry to a loose estimation of surface resistivity by

$$\text{Surface resistance } (\Omega) \times 10 = \text{surface resistivity } (\Omega/\text{square})$$

However, surface resistance is increasingly the preferred term over surface resistivity.

Volume Resistivity. Volume resistivity is the resistance of current passing through a section of film. However, even for simple homogeneous composition monolayer materials, like early Type II films, the static dissipative properties are based on atmospheric moisture absorbed on the surface, not a bulk material property. Also, because most advanced electrostatic discharge protection materials are of multilayer construction, all Types I and III plus many Type II films, *volume resistivity* is now an essentially meaningless term for these types of materials.

Static Shielding

Static shielding measures the energy that penetrates the test bag relative to the source energy. With an impressed 1000 V onto the outside of a bag containing a capacitive sensor, the current and time are plotted with a fast digital oscilloscope. The current and time are then used to calculate the energy transferred inside as nanojoules (11).

Effect of Relative Humidity

Most additives achieve either low surface resistivity or static decay-time function by attracting low levels of moisture to the film surface. For this reason, it was quickly apparent that the electrical properties would be related to relative humidity (12). In addition, moisture is quickly absorbed and slowly desorbed by strongly hydrophilic antistatic agents. Both of these were addressed by the test methods that specify the use of 10 ± 3% rh (relative humidity) at 72°F and holding the samples in a controlled environment chamber for 48 h before measuring surface resistivity or surface resistance and static decay time.

Effect of Accelerated Aging

Early Type II materials based on bulk loading of an antistatic additive into a monolayer film were found to have diminished electrostatic protection over time. This was due to the low but finite volatility of the additives used. Because fresh films would perform well, but older films would fail, an accelerated aging test procedure was needed to simulate field use. MIL Specs were developed that used held samples at 160°F for 3 days before the surface resistivity and static decay-time measurements were done. For monolayer bulk additive loaded Type II films, it is estimated that this accelerated aging test predicts performance for films between 6 and 12 months old. While other methods of achieving good surface resistivity films are less susceptible to activity loss with time, the test method has remained (28).

Corrosion

Because antistatic additives function by absorbing atmospheric moisture and weakly ionizing it, corrosion can be a problem with many metals used with electronics (14, 15). The MIL Spec considered seven metals to be important: low carbon steel, 2024 aluminum alloy, copper, silver-plated copper, SN63 solder-coated copper, 314 stainless steel, and Kovar. The test methods check for corrosion and/or surface discoloration when test films are in contact with clean coupons of these metals for 72 h at 120°F and 65% rh (5).

Polycarbonate Compatibility

Field service people from a major electronics equipment manufacturer found that polycarbonate components, like circuit board connectors, would "craze" and then crack (16). After a costly worldwide recall, the problem was traced to a Type II bag additive that could attack polycarbonate. EIA-564 standard for polycarbonate compatibility had the effect of nearly eliminating certain antistatic additives from the market films (17).

CURRENT STANDARDS

Standards generally are changed over time as additional information accumulates. On the basis of this information and the three different types of materials discussed above, the current accepted standard properties are listed in Table 2. Besides the electrical, corrosion, and polycarbonate standards, there are many more including those that cover heat seals and optical transmission for reading product codes inside a bag.

Figure 6. Antistatic additive molecules showing dual characteristics.

TECHNICAL SOLUTIONS

Early Type II Additives and Mechanism

Because Type II properties and materials are used either by themselves or as the inner or outer layers in other types of electrostatic protective packaging for good antistatic performance, they will be discussed as the base technology.

The original static-dissipative materials were based on then-current additive technologies for antifog and antistatic properties in plastic films. These additives are generally characterized as relatively long molecules with two distinctive molecular ends that can be considered "heads" and "tails" as illustrated in Figure 6. Most of the molecule's length is the tail, which is a chain of roughly 10–18 carbon atoms surrounded by hydrogen. This tail part of the molecule is nonpolar and is considered hydrophobic or polymerphilic because it prefers to "dissolve" in the polymer. The other "head" end is polar and hydrophilic and wants to diffuse out of the nonpolar polymer to the surface or "bloom." On the surface, the polar end is capable of absorbing atmospheric moisture and weakly ionizing it to create the modestly conductive electrical path necessary for static dissipation as in Figure 7. While these films use additives that were homogeneously compounded into the plastic and then extruded as a single layer, even simple "homogeneous" composition films function with distinct layers because of additive blooming to the surface.

Because the first MIL Specs required a visually distinct identification for these materials, a pink tint was added, which is why these early Type II materials are often called "pink poly."

There were some problems with the early materials. Some of these problems, like limited lifetime and water solubility of the additive, have been noted in the discussion of terms. The limited effective lifetime problem is related to a combination of blooming and the nature of additive "reservoirs" within the bulk film. As long as there is sufficient additive concentration within the film, additive diffusion to the surface will maintain a surface

Table 2. Electrical Standards for Types I–III Materials

Property	Surface Resistivity (Ω/square)	Surface Resistance (Ω)	Static Decay Time (sec)	RF Attenuation, EIA (dB)	Static Shielding, ESD-STM11.31 (nanojoules)
Type I	$<10^{12}$	$<10^{11}$	<2	>25	<5
Type II	$<10^{12}$	$<10^{11}$	<2	—	—
Type III	$<10^{12}$	$<10^{11}$	<2	>10	<50

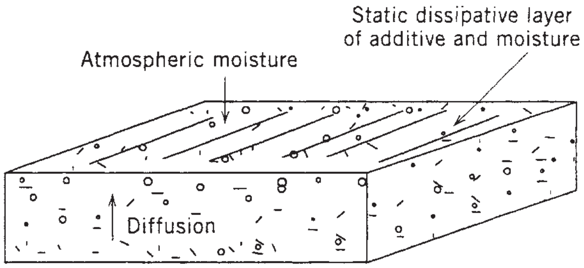

Figure 7. TYPE II film (18).

concentration sufficient for good surface resistivity. However, when the interior reservoir becomes depleted, diffusion to the surface cannot maintain the necessary surface concentration and therefore results in the loss of surface electrical properties as illustrated in Figure 8, 9. It was found that static dissipation required a higher additive concentration than for an antifog property, which made some pioneer films feel greasy. Refinement of the additives has improved this situation (18, 19).

Multilayer Type II ESD Protective Films

After recognizing that the static dissipative properties of even simple Type II films were based on distinct layers, it was inevitable that coextrusion and/or coated films would be adapted to ESD protective films to maximize the properties.

To deal with the diffusion-related limitations of the early Type II films, coated or topical antistatic films were developed. The first ones used quaternary amines (or quats), which are excellent antistatic agents but, because they are nearly incompatible with nonpolar polymers, must be topically applied. These quats were added to a compatible polar acrylate polymer that was cured with an electron beam to form a static-dissipative surface matrix (20–22). While this cured coating solved some problems with diffusion and evaporation of the additive, it was found that any contact with water would leach out the antistatic additive and, thus reduce the static-dissipative electrical property. There are some current materials that have improved compatibility between the additive and the coating matrix that resist leaching with modest water exposure.

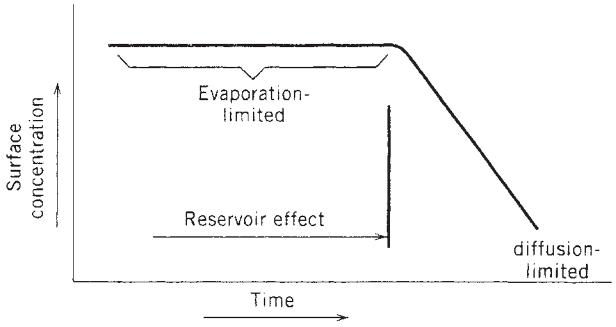

Figure 8. Reservoir effect.

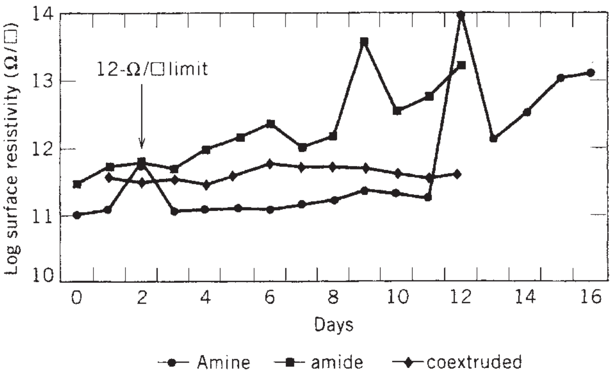

Figure 9. Log of surface resistivity versus time—reservoir effect is seen the loss of surface resistivity when the film interior becomes depleted of additive (18).

The next materials evolution utilized coextrusion of multiple layers in which different static-dissipative properties could be incorporated. One of the first of this type used high-density polyethylene (HDPE) skins over a quat-loaded polar polymer matrix blended into less polar polymers as illustrated in Figure 10. This structure buried the static-dissipative layer behind insulating layers. This material had static decay times that met the then-current MIL Spec, which required that a Type II film have either static decay time of <2 s or surface resistivity between 10^5 and 10^{12} Ω/square. This structure of insulators over static-dissipative layers was a major advantage because the film surface was virtually free of contamination. This same coextrusion technology was used to make low-surface-resistivity film shown in Figure 11 (18).

Additive Chemistry and Polycarbonate Compatibility

As discussed previously, some expensive problems related to additives crazing polycarbonate were encountered. In these, ethoxylated amines were found to be the worst for their effect on polycarbonate. Polymers, like other chemistry, follows the rule "like dissolves like." While amines can begin to dissolve into polycarbonate, the polycarbonate is so rigid that it cannot swell to accept the amine molecule; instead, it forms a surface crack or "craze." These surface cracks can expand until the polycarbonate piece breaks. Fortunately, ethoxylated amides and

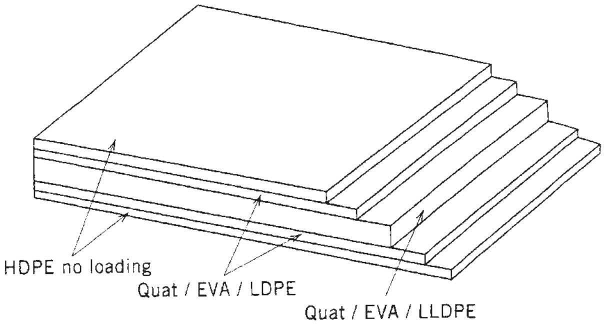

Figure 10. Multiple-ply static dissipative film with clean skins.

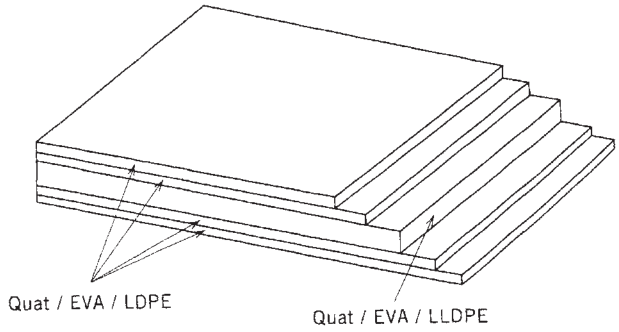

Figure 11. Multiple-ply static dissipative film with low surface resistivity skins.

quaternary amines were found to be more polycarbonate compatible as well as have good antistatic properties. Typical chemical structures are shown in Figure 12. The polycarbonate compatibility is illustrated in Table 3 (18).

Types I and III Mechanism via Faraday Cage. Types I and III materials have a common MIL Spec heritage that is differentiated only by the degree to which they attenuate RF interference. They function by creating a Faraday cage effect where electrical charges repel each other to the maximum extent possible—that is, on an exterior surface. The electrical field inside the package is essentially nil. The foil is a barrier to EMI and moisture as well as static. With Type III, the vapor-deposited metal is controlled to a thickness that is somewhat transparent but achieves static discharge shielding and EMI shielding of at least 10 dB.This allows one to read some label or bar-code information through the bag without opening it and still have a high level of ESD protection. The polyester substrate film also often provides more physical protection than a foil in a polyethylene-based film sandwich (23).

Because foils and metalized films are relatively fragile against printed circuit boards with many edges and devices and because their metallic nature can help transmit some charges into the contents, commercial Types I and III materials are laminated with Type II films. This provides physical protection and a modestly conductive static-dissipative layer between the electronics components and the shielding metal layer as illustrated in Figure 13 (24). Some Type I and III bags are laminated with extruded Type II films; others use static-dissipative coatings on regular films.

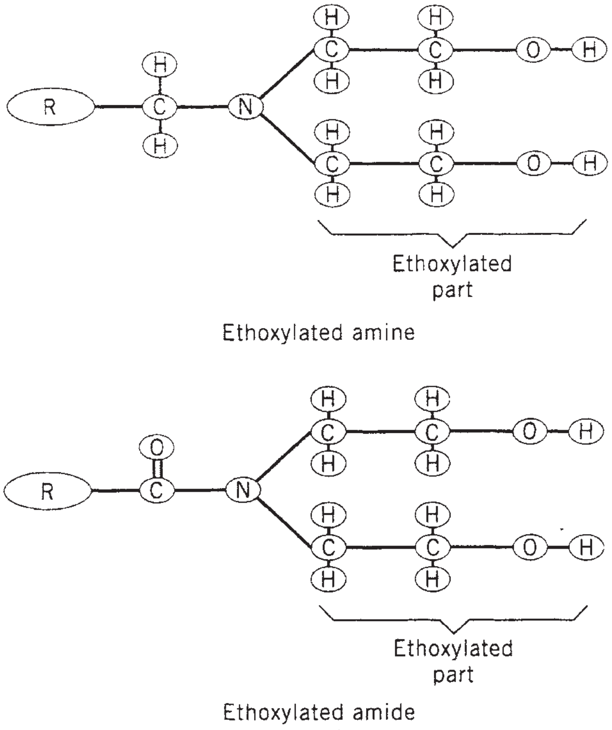

Figure 12. Typical antistatic additive molecules.

Heat-Shrinkable ESD Protective Packaging

Most ESD protective packages are loose-fitting bags that function by surface static dissipation but offer no mechanism to minimize static generation by friction within the bag. To address this need, static-dissipative chemistry and structures have been adapted to heat-shrink films that, when heat-shrunk tight onto the electronics, essentially eliminate motion within the package. The exterior is then protected by the static-dissipative surface of the shrink film. Electrostatic discharge protective heat-shrink films have not been possible using metals or metallized materials and are therefore all Type II in their performance.

The first antistatic shrink films were based on multiple-ply coextrusion, which encapsulates the additive containing layer within two “clean” skin layers. This trapped the additive and effectively eliminated corrosion and polycarbonate compatibility problems but is not currently on the market (4, 25). It has been replaced, in part, by straightforward commercial shrink films that are coated with special antistatic additives.

Table 3. Polycarbonated Compatibility (17): Highest Compatible Stress Level (psi)

	Temperature			
Material	73°F	120°F	158°F	185°F
Ethoxylated amine	2500	1700	<1000	<1000
Ethoxylated amine	3400	2500	1700	1000
Quaternary amine	3400	3400	2500	2000
Control (air)	3400	3400	2500	2000

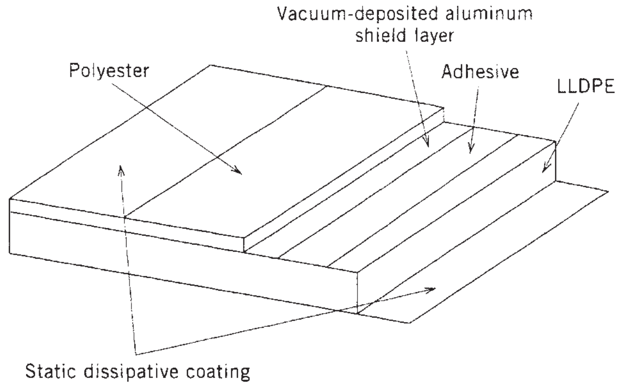

Figure 13. Typical Type III metallized bag laminated construction.

Inherently Static-Dissipative Polymers for ESD Protective Packaging

Several classes of inherently antistatic polymer have been utilized experimentally in electrostatic discharge protective packaging (26–28). While the most public attention is given to inherently conductive polymers, like polyacetylene, these polymers are often so rigid or insoluble that their packaging applications are limited. Also, in the case of polyacetylenes, these often need to be doped with some other material like iodine to achieve their conductivity. Most dopants like these are also inherently corrosive and therefore unacceptable.

One class of inherently static dissipative materials that was found to have workable properties is poly(amide ethylene oxide) block copolymers. On the molecular level, these polymers incorporate hydrophilic poly(ethylene oxide) (PEO) block segments into a polyamide (nylon) structure. The polyethylene oxide absorbs and holds a sufficient amount of water to achieve static dissipation. The PEO segment length and choice of nylon are important to balance the moisture absorption for surface resistivity versus moisture that blocks heat seals (28).

In all cases discussed so far, the major drawback to the inherently static-dissipative polymers has been cost. Few materials can compete effectively with combinations of additives compounded into or coated onto inexpensive resins like polyethylene and metalized polyesters or foils that are sandwiched with static-dissipative polyethylene.

Polymer Systems with Conductive Fillers

Conductive fillers in conventional polymers were considered a means of achieving high conductivity for static dissipation. These fillers have included aluminum flakes, carbon powders, carbon flakes, nickel-coated carbon fibers, nickel-coated mica flakes, and stainless-steel fibers, to name a few. In general, once a conductive filler is added in sufficient quantity to physically connect particle to particle, the resin matrix becomes essentially metallic in electrical conductivity. The practical problems have been numerous and include opacity, reliable extrusions, electrical properties, and relative cost. In general, these systems are applicable to injection or compression molding but have limited use with films. A carbon-loaded film was successfully marketed for a while with a modest surface resistivity. However, it fell into disfavor when it was noticed that the black bag would leave pencil-like black streaks that were conductive. Conductive fillers have not been satisfactory solutions for flexible packaging materials.

ORGANIZATIONS CONCERNED WITH ESD PROTECTIVE PACKAGING AND APPROPRIATE STANDARDS

Given the safety and economic issues behind EMI and electrostatic discharge shielding, static dissipative, and antistatic protective packaging, it was not surprising that a group of organizations have participated in opening communications and formulating standards. The four groups listed below have issued pertinent standards for the industry.

ENVIRONMENTAL REGULATIONS, NORTH AMERICA

MICHELLE RAYMOND
Raymond Communications,
Inc., Silver Spring, Maryland
Updated by Staff

INTRODUCTION

Environmentalists started the trend toward recycling mandates on packaging because of the "Stop Styro" campaign, originating in Berkeley, California in 1987. The greens used the McDonald's foam clamshell as a

---

[†] ESD Association (aka Electrical Overstress/Electrostatic Discharge Association or EOS/ESD Association). Address: 7900 Turin Road, Bld 3, Rome, NY 13440-2069. http://www.esda.org

"symbol," something consumers could easily identify. They told consumers to stop using polystyrene foam (often misidentified as *styrofoam*, a Dow Chemical trade name). Thus, eschewing PS foam became a simple way consumers could do their part to save the earth.

The original rationale for banning foam was that it was not degradable in landfills, was not made of a renewable resource, used toxic chemicals in manufacture, killed sea life when ingested (allegedly styrene leaches into food from the containers), and uses harmful CFCs. The plastics industry formed a new group (Council for Solid Waste Solutions) to lobby plastics waste issues in general. CSWS (Now American Plastics Council) had to hire lobbyists throughout the country to combat the new wave of PS foam bans.

Since this historical event, environmental regulations have expanded into all forms of commerce and regulations have increased many-fold. Environmental regulations involving recycling and solid waste management affect the packaging industry most.

The United States Environmental Agency's official statement on packaging states that in most parts of the developed world, packaging constitutes as much as one-third of the nonindustrial waste stream. As more countries are raising their standards of living, more countries are seeing significant growth in packaging waste. At least 28 countries have laws designed to encourage recycling and reduced packaging. Many countries require manufacturers to take back packaging discards or pay for their recycling.

There are no federal package mandates of a similar nature in the United States. States and local governments concern about waste continues to grow. New containers emerge that complicate recycling. Demand for secondary materials from abroad have put increased pressure on recyclers who are competing for limited feedstock.

Packaging can be made more sustainable by applying the principles of product stewardship: eliminating toxic constitutents; using less material; making packaging more reusable; using more recycled content; and making it more readily recyclable (1).

All of the 50 states plus 12 of the Canadian provinces have environmental agencies and regulations that cover state, local, and municipal laws. Basically, they all follow the mandate; for example, New Hampshire Title X-Chapt 149-M states that waste management rules are in place to to protect human health, preserve the natural environment, and conserve dwindiling resources through proper management of waste. The reader is advised to check the web sites for the individual states of interest. Examples of rules from some states are given in the following discussion.

WASTE MANAGEMENT/RECYCLING

The individual United States and provinces of Canada have laws on the books that reflect the product stewardship principles of the U.S. EPA. New York State's Solid Waste Management Act of 1988 sets out the principles of reduce, recycle, and reuse. The California Beverage Container Recycling and Litter Reduction Act, effective as of September 1986 and amended in January 2008, sets out the law for efficient and large scale bottle and container recycling. Sections 14500–14501 declare that California's intent is to gather manufacturers, distributors, and consumers to join in a large-scale redemption and recycling of beverage containers. The recycling goal was set out as 80%; and when any one type of container falls below 65%, an increased refund value is increased. (This may be eliminated by a new law presented to the California Legislature in 2008.) The Legislature also urged cities and counties to make redemption and recycling centers available to the public. The responsibilty to provide redemption opportunities rest jointly with manufacturers, distributors, dealers, recyclers, processors, and the Department of Conservation. It established this act to significantly reduce beverage container litter in the state.

In addition, industry has accepted recycling. Coca Cola wants to set a goal of 100% recycling of its cans. Coca Cola will recycle more than 100 million pounds each of PET and aluminum (2).

RECYCLED CONTENT MANDATE

Some states have minimum recycled content standards for plastics (CA, OR, WI), glass containers (CA, OR), and trash bags (CA).

California Beverage Container Recycling and Litter Reduction Act Section 14549 states that every glass container manufacturer shall report to the California Department of Conservation the amount of total tons of new glass food, drink, and beverage containers and the tons of California postfilled glass used in manufacturing these containers. Each glass manufacturer shall use a minimum of 35% postfilled glass in the manufacture of glass beverage and food containers measured on an annual basis; but if a glass manufacturer demonstrates that its use of postfilled glass during the annual period is made up of at least 50% mixed color cullet, then the manufacturer may use a minimum of 25% postfilled glass. A new law in California (AB 2449) covers the recycling of plastic bags.

Oregon's Rigid Container Recycling law (Or Rev St 459A.650-655) required that by 1995 all rigid containers must contain 25% recycled plastics or plastic resins that are recycled at a rate of 25% or must be reused at least five times.

Wisconsin has a law that requires 10% recycled content in rigid plastic containers eight ounces and over.

LANDFILL BANS

All states have landfill bans. They cover a whole spectrum of waste from batteries, appliances, and yard waste to newspaper and packaging materials. Wisconsin is one of the first states to enact sweeping landfill bans. Laws were enacted to manage waste reuse and recycling (Adminstrative code NR542-549). In the 1990s when The Waste Reduction and Recycling Law was passed, 17% of waste was recycled. By the end of 2004, when laws on landfill bans and recycling were fully implemented, recycling rose to 32%.

In 1995, Wisconsin's law was amended to include packaging materials. Forbidden in landfills are aluminum and steel containers, glass containers, corrugated cardboard, plastic containers, polystyrene foam packaging, and bi-metal containers, Plastics #3–7 can be landfilled or incinerated. If a market will exist for recycling of these plastics, they will be banned from landfills.

North Carolina was the benchmark state for local landfill bans. A total of 32 communities at first had some sort of local landfill bans in this #2 manufacturing state. Some just banned corrugated containers (OCC), others banned all kinds of recyclables. The bans forced businesses to recycle and push haulers to either set up routes or pull out OCC at landfills when the price was right.

DEPOSITS/BOTTLE BILLS

The term “bottle bill” refers to a container deposit law; that is, a refundable deposit is paid on a beer, soft drink, or other beverage container at time of purchase.

In 1971, Oregon passed the first bottle bill in the United States (3). The law covered all beer and soft drink containers. By 1986, ten states enacted some form of bottle bill. Some of these states cover water, juice, and other beverages not included in the Oregon bill. In 2009, Oregon will make its first change to its original bill by covering bottle water and flavored bottled water (4)

In 2008, eleven states and twelve Canadian provinces have a deposit law. Several states and provinces have expanded their laws to cover beverages such as juice and sports drinks, tea, and bottled water; beverages that did not exist when most bottle bills were passed. The eleven U.S. states are California, Connecticut, Delaware, Hawaii, Iowa, Maine, Michigan, Massachusetts, New York, Oregon, and Vermont

These bills were intended to reduce beverage container litter. Now the protection of natural resources through recycling and reduction of solid waste going to landfills are the goals. Seven states reported a reduction in beverage container litter ranging from 73% to 83%.

Unclaimed or unredeemed deposits have been determined to be the property of the distributors and the bottle bill states. These containers are considered abandoned by the public and involve millions of dollars a year.

There are still areas where food packagers have been successful in defeating proposed bottle bills such as in Columbia, Missouri in 2007. Also, there have been complaints that redemption rates are declining because deposits are not keeping up with inflation. However, Senator Ed Markey of Massachusetts has introduced an amendment to the Solid Wastes Disposal Act to require a refund value for certain beverage containers (of metal, glass, or plastic or in combination) and resources would go to the state for pollution prevention and recycling. This Bottle Recycling Climate Protection Act (introduced November 5, 2007) would apply to all of the United States. States with high recycling rates would be exempt (5).

HEAVY METALS BANS

The model Toxics in Packaging Bill, developed by the Coalition of Northeastern Governors (CONEG), is law in 18 states. In 1995, six states moved to amend the law in an effort to clean up some loose ends (6).

The model bill states that no package may be sold if any packaging component (including inks, dyes, pigments, adhesives, stabilizers, or other additives) contains lead, cadmium, mercury, or hexavalent chromium intentionally introduced during manufacture or distribution. The law usually gives manufacturers two years to phase down to 600 ppm; then 250 ppm, with 100 ppm after four years. The model law allows state regulators to later institute bans on other heavy metals if they are found to be a threat.

GREEN AND ECO-LABELING

Laws are on the books in many states to guard against false claims of environmental value. An ecolabel identifies overall environmental preference of a product within a product category based on life-cycle considerations. In contrast to self-styled labels, these labels are awarded by an impartial third party. Ecolabeling is a worldwide effort. It is, however, only one type of environmental label and gives the consumer information about the relative environmental quality of a product In North America, the Global Ecolabelling Network Secretariat is located in Ottawa, Ontario, Canada (7) The International Organization for Standardization has undertaken efforts to attempt to standardize three major voluntary environmental labeling types. Type 1: environmental labels; Type 2: self-declaration claims; and Type 3: environmental declarations, for example, report cards and information labels. ISO 14020 guiding principles for labeling, including ecolabels, are accuracy, avoiding unecessary trade barriers, scientific basis, provision of information on methodology, life-cycle approach, allowance of innovation, minimal adminstrative burden; open consensual process; and provision of information on products. Companies that want to participate in an ecolabeling program make application and submit products for third-party testing. If approved, the companies pay licensing fees for permission to use the program’s label for a specified period. Ecolabeling is a voluntary policy instrument. An increase in certified products indicates that producers or providers see an advantage is displaying the label. Consumer surveys indicate that there is a preference for products perceived as environmentally positive. The willingness of consumers to pay for green products has been regularly confirmed. However, surveys show that superior environmental performance generally only becomes a key competitive factor once product performance, quality, and value have become established.

Green Seal, Inc., is a third-party certification organization in the United States. One of their certifications involves paper products used in food preparation (8).

RESIN CODING

The resin identification code developed by the Society of the Plastics Industry in 1989 was intended to assist plastic recyclers in sorting bottles by resin type. Even though there are thousands of different resin grades used by

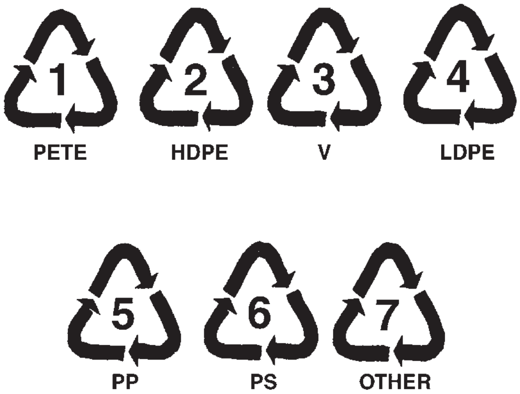

Figure 1. Identifications and abbreviations for seven types of resin grades.

industry, a committee decided on some basic identification numbers and abbreviations for seven types as shown in Figure 1.

Some of the states objected to the codes at first because of a concern that the code would be used as a recycling symbol, and not all resins are welcome in curbside bins. Nevertheless, the SPI model bill was pushed and passed in 39 states. While there still is much confusion, industry and consumer/government interests have been unable to agree on an acceptable change in the code.

Many companies inappropriately use the SPI code as a green claim on bags, nonretail bottles, and clamshells, which are unwelcome in curbside bins. Even though two states technically require the code on plastic clamshells, legal experts say there have never been any enforcement actions against companies not using the code.

If companies are using blends of polymers or multilayer bottles that recycle, then experts say it is generally acceptable to put that resin number (e.g., PET) on the bottle. Many large companies have in practice.

NAFTA/MEXICO

The North American Free Trade Agreement (NAFTA) came into effect January 1, 1994. The agreement sets out rules for trade among Canada, the United States, and Mexico. Mexico faces severe environmental degradation. Mexico's principal environmental law is the General Law of Ecological Balance and Environmental Protection, in effect since 1988.

Mexico generates about 80,000 t of municipal waste every day. About 70% of this is collected every day, but only a fraction is adequately transported or deposited in a sanitary landfill. Mexico is serious about solving its severe environmental problems. It is believed that there is an extraordinary opportunity for U.S. environmental firms to export solutions to Mexico. ACCESS-MEXICO is a low-cost program and source of Mexico's environmental laws in English. It is considered to be a key element in reducing barriers between the United States and Mexico and is a source of information for anyone wishing to do business in Mexico (9).

ENVIRONMENTAL IMPACT OF PACKAGING

Susan Selke
School of Packaging, Michigan
State University, East Lansing,
Michigan

The term *environment* subsumes many concepts related to how packages and packaging systems function in the broader context of our planet, its people, and its ecosystems. Increasingly, packaging designers, manufacturers, and users are paying attention to the environmental impacts of packaging. This is being driven by a combination of (a) pressure from consumers and from regulators and (b) the desire of business and industry to engage in responsible corporate citizenship. In this article, we discuss the broad topic of environmental impacts of packaging and provide an overview of some of the major current environmental concerns impacting packaging. We will examine the solid waste impacts of packaging and the topic of sustainability in greater detail.

LIFE CYCLE ASSESSMENT

In discussing the environmental impacts of packages and packaging systems, a key concept is the need to take an approach that looks at systems and that encompasses the entire life cycle. For example, if we were to determine whether glass bottles or steel cans were environmentally preferable based on the energy use in filling alone, we would obviously be neglecting a vast array of considerations that are also important. Similarly, if we were to attempt to decide whether packaging juice in pouches was environmentally preferable to packaging it in bottles, we might reach an inappropriate conclusion if we failed to consider the requirements for the associated distribution packaging (not to mention other aspects of the transport and delivery system).

Therefore, there is general agreement that the appropriate framework for evaluating environmental impacts must include (a) the whole system and (b) the entire life of the item being evaluated, from "cradle to grave." This approach is known as *life cycle assessment* or *life cycle analysis* (LCA) and is the analysis of the environmental impacts of product or process systems, including packaging, with the goal of selecting those that have the least overall adverse environmental impacts, or of modifying systems to diminish those impacts.

While actually performing an LCA is fraught with complications and can be extremely sensitive to the assumptions and data used, not to mention the difficulty in making decisions from the complex sets of information generated, there is general agreement that this is the correct philosophical approach to use. We will not discuss LCA in detail, but rather will use the concept as an organizing principle for this discussion.

A wealth of information is available on LCA, and extensive efforts are underway to further develop this methodology. One of the primary sources of information is the Life Cycle Initiative developed by the United Nations Environmental Program (UNEP) in cooperation with the Society for Environmental Toxicology and Chemistry (SETAC) (1). There are also a variety of LCA studies of particular materials and systems. Unfortunately, some of these reach contradictory conclusions. Increasingly, computer-based systems are available to calculate LCAs, but they too often fail to provide adequate information about the underlying data and assumptions used. Because of the complexity of doing full-fledged LCAs, there is also considerable interest in and development of modified LCAs, which are more limited in their approach and provide data in a form that is much easier to use for decision making, even though it is less complete. The Wal-Mart "Scorecard" can be regarded as one of these (2).

RESOURCE DEPLETION AND CONSERVATION

Depletion of natural resources may occur when nonrenewable resources are utilized in the production of packaging materials. For example, the manufacture of aluminum cans may consume aluminum ore, which is a finite resource. (On the other hand, ore is not consumed if the cans are made from 100% recycled aluminum.) Whether this is a serious concern is dependent in large part on the relative scarcity or abundance of the resource in question, as well as on the amount that is used for packaging. For example, large amounts of sand and sandstone are used in the production of glass bottles, but the earth's supply of this resource is abundant, so resource depletion is not a serious concern. In contrast, the earth's supply of chromium is rather small, but only relatively tiny amounts of chromium are used in the manufacture of tin-free steel for packaging, so while the overall global depletion of chromium might be a concern, packaging does not play a significant role in such depletion. In principle, use of renewable resources is less of a concern than use of nonrenewable resources since renewable resources, by definition, can be replenished. The major raw materials used for all the major packaging materials (wood, paper, aluminum, steel, glass, and plastics) are, fortunately, relatively abundant at this time, at least to the extent that serious shortages are not likely to arise in the near future, given current and projected patterns of use. Future availability of petroleum and natural gas for plastics is likely the most serious concern. However, manufacture of plastics packaging is responsible for much less than 5% of petrochemical resource use; and when life cycle energy is included, plastics often use less total petrochemicals than do competitive materials.

Of course, recycling of materials can extend their availability by reducing demands on the resource base.

ENERGY

In addition to material resources, packaging is also a consumer of energy resources. The typical mix of energy resources used differs by material. In the production of paper, renewable biomass (wood) is a major energy source, as well as being the primary raw material. On the other hand, in production of paper from recycled fiber, petroleum products are the primary energy source. For plastics, petroleum and natural gas are both raw materials and energy sources. The aluminum industry is heavily dependent on electrical power, and production of aluminum metal from ore is highly energy-intensive. The glass industry relies primarily on natural gas and electricity as energy sources. The manufacture of steel from ore uses coal as the primary energy source. Transporting of packaging materials of all types uses primarily petroleum-based energy. All packaging materials use electricity at various points in their manufacture. Electricity is not a primary energy source and depends on a mix of energy technologies, including hydroelectric and nuclear power, but in the United States is most heavily dependent on coal. Modification of packaging processes to make them more energy-efficient can result in significant cost savings as well as environmental benefits. Beginning in the late 1970s and early 1980s, increasing fuel prices and consequent interest in energy efficiency led to a number of studies comparing the energy use of various alternative packaging systems for products (3–5). These are the forerunners of more recent life-cycle assessment studies.

Waste-to-energy incineration can recover valuable embedded energy from combustible packaging materials and thus diminish dependence on other fuel sources.

POLLUTION

Emission of air and water pollutants during the manufacture, distribution, and disposal of packaging also impacts the environment. Different packaging materials are associated with different types of pollution concerns. Manufacture of paper, for instance, produces water effluents with a high load of organic materials, producing a significant biological oxygen demand (BOD). In the manufacture of plastics, on the other hand, air emissions of volatile organics are generally a more serious concern than water emissions. For all types of packaging materials, proper control and treatment of effluent streams is important for protection of the environment, and is mandated by government regulations. This is true not only for manufacture of packaging materials but also for the converting processes that change these materials into packages. The practice of waste minimization (defined as reduction of the production of toxic materials), commonly practiced in the chemical industry, can also have benefits for the packaging industry in dealing with requirements for proper treatment of effluent streams. Simply put, if a toxic material is not used or produced, it will not be present in effluent streams and thus will not require treatment for its removal. An example that is commonplace in packaging is the substitution of water-based inks and adhesives for solvent-based systems in a variety of printing and converting operations. This substitution enabled many converters to avoid the necessity of installing expensive air pollution control systems to collect volatile organics when new air emission regulations were enacted. Three particular types of pollution concerns have been regarded as of particular importance in recent years.

Ozone Depletion

In the mid-1980s, it was discovered that an “ozone hole” was formed over Antarctica in the spring, and a vast body of scientific evidence has since accumulated linking the destruction of stratospheric ozone throughout the globe with chlorofluorocarbons (CFCs) and similar compounds. As a result, there has been a global phase-out of ozone-depleting substances (ODS). There is no longer any manufacture of CFCs in industrialized countries. This is essentially now a non-issue for packaging, because the necessary changes in aerosol propellants and foams are for the most part complete, worldwide. Nevertheless, it will still be a number of years before the ozone layer returns to its normal condition. The 2006 international report on ozone depletion predicts that ozone levels in Antarctica will return to pre-1980 levels by about 2060–2075 (6).

Global Warming

In the late 1980s, a number of scientists became increasingly concerned about the possibility that increases in the atmospheric concentration of carbon dioxide and other “greenhouse gases” were acting to increase average global temperatures. Potential consequences of such temperature rise were believed to include an increase in ocean levels and consequent flooding, changes in rainfall patterns, change in ecosystems with adverse effects on animal and plant populations, and a variety of other effects, including increases in the number and severity of tropical storms.

Subsequent developments have increased the evidence base that global temperatures are in fact increasing, and better understanding of the mechanisms behind global climate has led to a clear scientific consensus that anthropogenic greenhouse gases are leading to increasing global temperatures and rising sea levels. In 2007, the Intergovernmental Panel on Climate Change (IPCC) released its 4th Assessment Report (7).

Among the IPCC findings are that global temperatures have increased by about 0.6°C (1.1°F) over the last 100 years, that this increase is due to human effects on the climate, specifically increases in concentrations of greenhouse gases, and that the rate of increase has increased to about 1.8°C (3.2°F) per century over the last 25–30 years. This higher rate is expected to be sustained over the next century. Carbon dioxide concentrations increased from the preindustrial level of about 280 ppmv (parts per million by volume) to 358 ppmv by 1994, and by 2005 they were about 379 ppmv. Current carbon dioxide concentrations are higher than they have been at any time in at least the last 420,000 years. The last time the earth had CO_2 levels as high as they are today was likely 10–20 million years ago (7).

Sea levels have increased around the world by about 17 cm (6.7 in.) over the last 100 years. The rate of increase was about 1.8 mm per year between 1961 and 2003, increasing to about 3.1 mm per year from 1993 to 2003. IPCC is not sure whether this faster rate is due to natural variability, or to an increase in the long-term trend. The primary cause of sea level rise is the combination of (a) thermal expansion in response to increased ocean temperatures and (b) increased volume of water in the oceans due to melting of ice (7).

The fourth IPCC assessment says the most likely temperature scenario for the future is a warming of 2–4.5°C (3.6–8.1°F) this century, reflecting a continuing warming rate of about 0.2°C per decade. This rate of warming is unprecedented in at least the last 10,000 years. IPCC says it cannot rule out values substantially higher than 4.5°C, but feels an increase of less than 1.5°C is very unlikely (7). For sea level, the current projections are for increases of 0.18–0.59 m (7–23 inches) this century. These projections do not include the full effects of changes in the Greenland and Antarctic ice sheets—which could increase the estimates by 0.1–0.2 m, or perhaps even more. IPCC felt that these phenomena are not yet well enough understood to be incorporated in the predictions. Moreover, ocean levels will continue to increase long after 2100, even if greenhouse gas concentrations have stabilized, and may have reached only half their eventual total even by 500 years from now (7). Collapse of the West Antarctic ice sheet could raise sea levels by as much as 5 m. Only a few years ago, this was thought to be highly unlikely at least for several millennia, but some scientists now think it is not nearly so far-fetched. Melting of the ice sheet in Greenland is considered much more likely, and this alone could increase sea levels by as much as 7 m (8).

Use of fossil fuels for energy is the primary cause of increased carbon dioxide concentrations in the atmosphere.

Chlorine, Chlorinated Organics, and Plasticizers

In recent years, there has been increasing concern about the effects of chlorine, and in particular of chlorinated organic compounds, as well as other chemicals that can interfere with action of natural hormones or that have hormone-mimicking effects (endocrine disruptors and similar compounds).

Initial attention focused largely on dioxins. Considerable concern was expressed about incineration of polyvinyl chloride (PVC) because of fear that presence of PVC in incinerators would lead to increased dioxin production. Despite evidence that PVC is at most a minor factor in dioxin production in incinerators, with combustion and emission-control system conditions being much more significant, opponents of incineration often have raised this as a major issue. Concern has also been raised about possible hormonal disruption effects associated with a variety of other chlorinated organic compounds. PVC again is often targeted as a contributor to these problems. Organizations such as Greenpeace have even called for elimination of chlorine-based chemical production processes.

While attacks on chlorine have diminished somewhat, a current target is a variety of phthalate plasticizers. A recent U.S. study found high levels of plasticizers in a significant fraction of water samples (9). The Canadian government has listed plasticizers as one of the sources of endocrine disrupting substances (10). The Center for Bioenvironmental Research at Tulane and Xavier Universities is one of many other sources about such effects (11).

Concern about these chemicals was refueled in part by the publication of *Our Stolen Future* (12) in 1996. The organization by this name continues to provide updated information about endocrine disruption (13).

SOLID WASTE ISSUES

Much of the criticism of packaging in recent years has been related to its disposal. During the 1980s, a number of municipalities in the United States, particularly on the East Coast, began to encounter significant problems with lack of availability of disposal facilities for municipal solid waste (MSW). Packaging accounts for approximately one-third of the MSW stream by weight, a fraction that has been relatively constant for several decades, so it became a natural target for efforts to decrease the amount of MSW requiring disposal. At the same time, there was a change in the general philosophy about solid waste management techniques from heavy reliance on landfilling to use of a more complex mixture of options.

In the United States, this was expressed, by the EPA and others, as the philosophy of integrated solid waste management, incorporating the solid waste management hierarchy. This hierarchy placed waste reduction at the top, as the most desirable option, followed by recycling and composting, next incineration, and finally landfilling at the bottom. The goal was to manage waste materials as far up the hierarchy as was practical.

Waste reduction

Waste reduction, or source reduction, is an action that prevents generation of waste. Using less material in a package means that less will be disposed at the end of the package life. Furthermore, it results in savings in production, processing, and transportation of materials. Of course, this must be balanced against the function of the package. Elimination of packaging would mean the elimination of many of the products we enjoy, as well. Similarly, underpackaging can lead to significant product damage, thus increasing waste. The packaging industry has a long tradition of source reduction, accomplished for the most part with the goal of saving money by using less material for packages. Glass bottles, plastic bottles, metal cans, and many other package forms have become thinner and lighter over the years.

Reuse of packages is another form of waste reduction. While some types of reusable packaging, such as refillable beverage bottles, have decreased in use, in the distribution packaging segment, reuse has enjoyed some revival in the last decade or so. Some industries have switched from corrugated boxes to plastic or metal crates or bins. One-way wood pallets have been replaced by reusable plastic pallets in a number of applications. There have been efforts to combine source reduction and reuse by providing no-frills refill packages for consumer products such as laundry detergent, but with limited success.

The U.S. Environmental Protection Agency, in its series of reports on MSW, now also includes discussion and quantification (to the extent possible) of source reduction (14).

Recycling

Much of the attention related to reducing packaging waste going to disposal has focused on recycling, including both (a) designing packages for easier recyclability and (b) using recycled materials in manufacture of packages. There are significant differences between packaging materials in average recycling rates and in the potential for incorporation of recycled content.

Aluminum beverage cans used to boast the highest recycling rate for any packaging material, but their rate has fallen from its historic high of 65% in 1992, while the rates for other packaging materials have increased. In 2005, the recycling rate was only 44.8% (Figure 1) (14, 15). It should be noted that the Aluminum Association cites higher rates, but includes imported used beverage cans in calculating the rate (15), a practice that is not accepted by EPA.

A substantial portion of the aluminum beverage cans recycled come from the 11 states with deposit systems for carbonated beverage containers (and in some cases on other beverages; one of these states exempts aluminum cans from the deposit). The aluminum industry set up a network of buyback centers in many nondeposit states, but these have decreased in relative significance as collection of cans and other recyclables at curbside has increased. Aluminum cans remain one of the most valuable materials collected in such programs. New aluminum cans are an important end market for recycled aluminum. Using recycled aluminum is economically attractive due to the high cost of virgin raw materials (bauxite) and to the large energy savings associated with making aluminum sheet from recycled aluminum rather than from bauxite (95% energy savings).

The recycling rate for steel cans has actually exceeded the rate for aluminum cans for the last several years. The rate reached a historical high of 62.9% in 2005 (Figure 1) (14, 16). While steel cans are also commonly collected in curbside recycling programs, recovery of steel from garbage going to waste-to-energy incineration facilities is another important source. This is possible because of the magnetic nature of steel, which allows it to be fairly easily separated from the mixed waste, either prior to or after incineration. While steel cans generally contain about 25% recycled content, most collected cans are used in nonpackaging applications. Used cans are now recognized as a valuable source of high-quality steel scrap.

The recycling rate for glass containers is considerably lower than for aluminum and steel, about 25.3% in 2005 (not including refilling), and has been relatively stable for the last decade (14). In contrast to aluminum, raw materials for glassmaking are relatively low in cost. While energy savings do accrue from using recycled glass (cullet) in making new containers, they are significantly more modest than with aluminum. The energy required to process the cullet and transport it to the glass-making facility may consume a significant amount of this savings. An additional problem with glass recycling is the requirement for separation of the glass by color. While automated sorting equipment does exist, this is often still a hand-sorting operation and is restricted to unbroken containers. Facilities for sorting commingled recyclables (material recovery facilities, MRFs) typically lose a substantial fraction of their incoming glass stream to breakage. Container manufacturing is the major market for recycled glass and can accommodate very little color contamination. Uses for mixed-color cullet can be found in construction and related industries, where recycled glass can substitute for some of the aggregate in concrete and asphalt, for instance, but these are low-value uses that are often uneconomical. The major sources of collection of glass containers for recycling are deposit systems for beverage containers and curbside recycling programs. A significant number of curbside programs have stopped collecting green glass because of lack of markets, and some have stopped collecting glass containers all together, primarily because of contamination of paper with broken glass in single-stream collection systems.

Recycling of paper and paperboard packaging materials is heavily dependent on the particular form of packaging involved. Corrugated has the highest recycling rate of all packaging materials, 71.5% according to EPA (Figure 2) (14) and 76.6% according to the Paper Industry Association Council (PIAC) (17). Most of this material originates in the business sector, rather than from individual consumers. Retail stores, factories, and so on, can generally achieve savings in their waste disposal bills by participating in programs to source-separate corrugated boxes for recycling. In addition, some garbage collection operations divert selected loads of waste, known to contain a high percentage of corrugated, to sorting facilities where hand sorting is used to recover this material. An additional source of material is dropoff collection sites. Curbside collection of corrugated is less available, though it does appear to be growing. Major end-use markets for corrugated containers include manufacture of new corrugated, boxboard, and kraft paper for grocery sacks. While, in general, paper fibers are shortened and weakened by the processing required to repulp and clean the fibers, it is possible to make recycled grades of board with properties

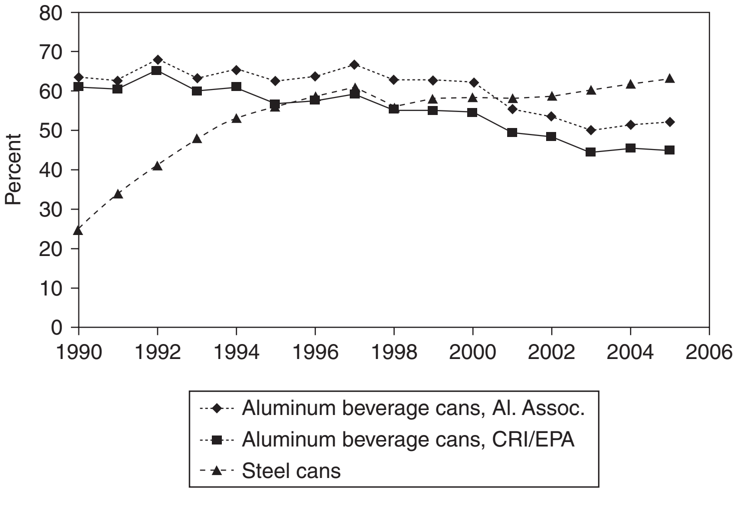

Figure 1. Aluminum beverage can and steel can recycling rates (14–16).

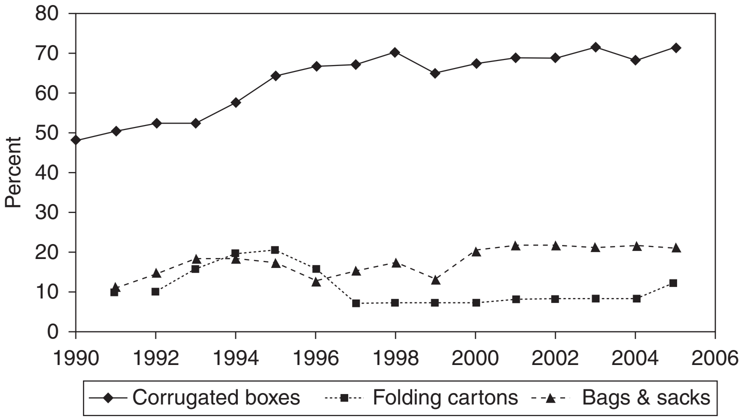

Figure 2. Corrugated, folding carton, and paper bag recycling rates (14).

near those of virgin materials, especially when the recycled content is blended with virgin fiber. Kraft bags and sacks had a recycling rate of about 21% in 2005, considerably lower than the rate for corrugated. Some of this is collected through drop-off sites or curbside collection, often along with corrugated or newspapers. Recycling of folding cartons was almost unheard of before 1990, but reached a rate of 11.9% in 2005. Efforts have been made to recycle milk cartons and aseptic "juice boxes," but they have not had much success, and recycling rates for these materials remain negligible. The overall recycling rate for paper and paperboard packaging was 58.8% in 2005 (14). In addition to domestic uses, export of recovered paper is significant.

Recycling of plastic packaging differs considerably by resin and container type. For a long time, the "star" of plastics recycling was polyethylene terephthalate (PET) soft drink bottles, which reached a recycling rate of 53.3% in 1994, according to EPA (Figure 3) (18). However, the recycling rate has fallen substantially since then, and in 2005 was only 34.1% (14). The 11 deposit states provide a major source of this material. As PET has spread into the "custom" bottle market, curbside collection has become increasingly important as a source of recyclable materials. The growing use of single-serve beverage bottles and, in particular, the rapid growth in bottled water have contributed to the declining PET bottle recycling rate. These bottles are often consumed away from home and, except in Maine and California, are not covered by deposits. The PET industry has worked on establishing convenient drop-off sites for bottles, especially at special events, but this has not been sufficient to reverse the decline. Other types of PET packages have a lower recycling rate than bottles. The overall PET container recycling rate in 2005 was 26.5%; the overall PET packaging recycling rate was 25.2% (14). The major use of recycled PET is fiber applications such as fiberfill, carpet, and clothing. Other major uses include containers, automotive parts, strapping, and other products (19). Recycled PET is acceptable for direct food contact in certain circumstances. First, some such applications, such as use in egg cartons or vegetable trays, provide limited potential for migration. Second, some applications use a layer of virgin plastic to provide a functional barrier between potential contaminants in recycled PET and the product. Third, some mechanical recycling processes have received letters of nonobjection from FDA after demonstrating their ability to remove potential contaminants. Finally, some systems use tertiary recycling processes (methanolysis or glycolysis) to chemically break down the polymer into monomers, purify them, and use them as feedstocks for production of PET that is identical to virgin resin.

Currently the most widely recycled plastic packaging material is natural high-density polyethylene (HDPE) bottles, such as those for milk and water, which were recycled at a rate of 28.8% in 2005 (Figure 3) (14). The major source of these bottles is curbside collection programs. The high-quality unpigmented homopolymer is suitable for a variety of uses, including applications in packaging, housewares, toys, pipe, and traffic cones. Significant packaging applications include motor-oil bottles (blended with virgin resin), household chemical bottles (as a buried inner layer), and bins and pallets. Some recycled HDPE is also used in film form, primarily for shopping bags. Recovery of pigmented HDPE bottles is somewhat lower than for unpigmented bottles, 26.0% in 2005 compared to 28.3% for unpigmented bottles, according to the American Chemistry Council (20), and its uses are more limited because of the complications caused by the mixtures of colors. Motor-oil bottles and agricultural pipe are two major markets. The demand for recycled HDPE, as for other recycled materials, tends to be strongly influenced by ups and downs in the supply and cost of virgin materials.

A significant amount of plastic film is recycled from two major sources, stretch wrap and bags. Pallet stretch wrap is widely collected for recycling, although precise recycling rates are not readily available. It is collected in the same way as most corrugated—through commercial sources. It used to be common for grocery and other retail stores to have drop-off bins for collection of plastic merchandise bags, but many such programs have disappeared, and recycling of bags has fallen. EPA reports a "bags and sacks" recycling rate of 3.2% in 1990, but only 0.6% for 2005 (14). Two major markets for recycled plastic film and bags are plastic lumber and trash bags. Other markets include housewares, agricultural film, and merchandise bags.

In the 1980s and early 1990s, the National Polystyrene Recycling Company engaged in an effort to recycle

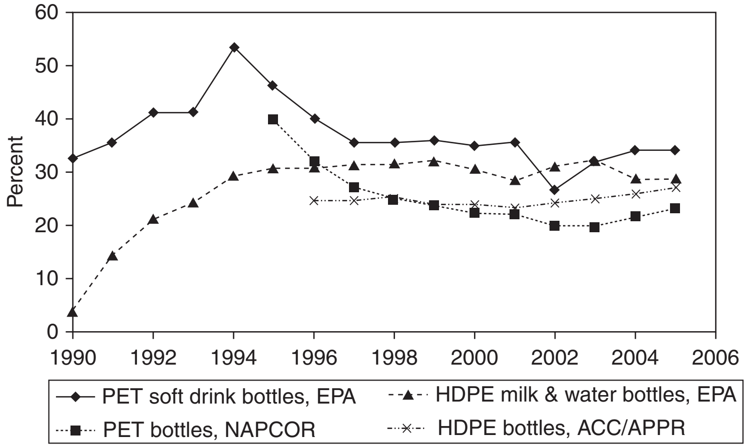

Figure 3. PET and HDPE bottle recycling rates (14, 19, 20).

expanded polystyrene from food-service applications. These efforts have largely disappeared. Most current polystyrene recycling is limited to foam cushioning materials, primarily (in the United States) through the efforts of the Alliance of Foam Packaging Recyclers (21).

Some recycling of polypropylene (PP) bottles takes place in communities with "all plastic bottles" collection programs. The "rule of thumb" is that about 5% of PP can be included in HDPE recycling without adversely affecting the performance of the recycled material. Of course, it must be noted that the caps and fitments that may be included on the collected HDPE bottles are usually PP and contribute to this total. Most specific recycling of PP packaging is caps on PET bottles. The density-based separation systems that are a routine part of PET recycling are quite good at separating PP and PET.

Little recycling of other plastic packaging materials is occurring in the United States. PVC is recycled to an appreciable extent in Europe, but not much in the United States Some recycling of comingled plastics occurs; the major products are substitutes for wood or concrete, often for outdoor use. However, such systems are rare and their economic success has been marginal at best.

As can be seen above, the most desirable way to collect materials for recycling is significantly influenced by the type of material to be collected and by where it is most available. For corrugated boxes and stretch wrap, collection efforts focus on the commercial sources that discard most of these materials. For beverage bottles, deposit legislation, originally passed primarily as a litter-prevention measure, has been proven to be a very effective method of collection, in terms of recovery rate. In Michigan, the only state with a 10-cent deposit on all covered containers, recovery rates are over 97% (22). For understandable reasons, retailers generally oppose expansion of deposit systems. Nevertheless, both Maine and California have expanded deposits to cover most beverage containers with the explicit goal of increasing recycling. Efforts are underway in other states to do the same. Curbside collection programs generally offer significantly higher diversion rates than drop-off collection, due to the greater convenience that they provide. The variety of materials accepted obviously influences the proportion of materials diverted from disposal. Other important variables are the amount of effort the consumer is expected to go to in preparing the materials, the logistics of the system (is a container or cart provided, is collection weekly or less often, etc.), is participation in recycling less or more expensive than simply putting the materials in the garbage (pay-as-you-throw plans), is recycling voluntary or mandatory, how much effort is devoted in a community to educating and motivating residents to participate, and so on.

Composting

Composting is the managed biodegradation of waste materials. It has grown substantially as a disposal option for yard waste, but is still very limited, in the United States, as an organized system for disposal of MSW. Obviously, only the biodegradable fraction of MSW can be handled by composting. In principle, this includes most paper and wood packaging, as well as those plastics that are truly biodegradable. In practice, some composting systems are limited to food and yard wastes, not accepting any packaging materials, and others accept packaging materials only if they are paper. Difficulties in getting compostable plastics accepted in such systems include the limited use of these materials, the difficulty in differentiating compostable from noncompostable plastics, and concern on the part of operators that the materials will cause problems in the proper functioning of their systems or adversely affect their markets.

Incineration

The next step down the solid waste management hierarchy is incineration. As practiced in the United States today, it is virtually always coupled with energy recovery, and therefore offers not only a reduction in the volume of solid waste requiring landfilling but also the generation of energy, which can displace some combustion, usually of coal. To avoid unacceptable air pollution, sophisticated and expensive pollution control equipment is required. The ash generated from the noncombustible residues combined with that from the air pollution control systems may contain levels of heavy metals high enough to require disposal as a hazardous waste. The recommended practice is to dispose of these materials in ash monofills. While in the mid-1980s EPA called for significantly increased use of incineration and it did grow substantially, it has remained relatively stagnant since the mid-1990s. Reasons include public opposition and high cost.

The growth in incineration was instrumental in the development of U.S. state legislation prohibiting the deliberate introduction of lead, cadmium, mercury, and hexavalent chromium into packaging materials (except in narrowly defined circumstances) and in limiting their inadvertent presence. These laws, based on model legislation promulgated by CONEG, the Coalition of Northeastern Governors, are commonly referred to as Toxics in Packaging legislation and as of 2007 had been passed in 19 states (23).

Landfill

Landfilling is at the bottom of the solid waste management hierarchy, seen as the least desirable option, but nonetheless one that is always necessary for residual materials that cannot be effectively handled by options higher in the hierarchy. The major drawbacks of landfilling are the space that it uses and its potential for groundwater contamination. On the positive side, landfills are often the least expensive option for handling many types of waste and can serve as a source of methane for use as a fuel.

OTHER ENVIRONMENTAL IMPACTS

In addition to the effects discussed above, packaging can be associated with a variety of other environmental impacts, such as destruction of natural habitats, loss of scenic beauty, and noise pollution. For the most part, packaging plays only a minor role in such impacts. For instance, use of paper, including packaging, is often cited as a prime factor in destruction of tropical rainforests. However, slash-and-burn agriculture is a much more significant factor. Little rainforest destruction can be attributed primarily to harvesting of wood for manufacture of wood or paper packaging.

LEGISLATION

No discussion of packaging and the environment would be complete without a mention of legislation, which has been, in many cases, the primary driving force behind the increased attention given to environmental impacts. The mid-1990s have brought a slowing in the pace of legislative demands for packaging changes, but they remain an important factor. In the United States, legislation at the state level remains more significant than federal legislation. In Europe, both EEU (European Economic Union) and individual country legislation are significant. Extended producer responsibility (EPR) is the guiding framework. In Canada, both Ontario and Quebec have fee systems for manufacturers based on the amount of packaging, to help support recycling programs. Extended product responsibility, also denoted EPR but sharing the responsibility among producers, consumers, and government, guides policy there. A variety of other efforts could be cited around the world.

Recently, plastic merchandise bags have been identified as a particular concern in many localities. Several countries or other political units have enacted use fees to increase the cost of such bags. Others have banned their use outright.

GREEN MARKETING

The environmental attributes of a package are increasingly being used as a marketing tool. In several cases, enforcement activities have been undertaken against companies making such claims without proper justification. It is extremely important for any business contemplating environmental claims on a package to ensure that the claims are in compliance with relevant guidelines and regulations in the countries or states in which they will be sold.

SUSTAINABILITY

Increasingly, the concept of *sustainability* is being seen as providing useful guidance for decision-making in packaging as well as in other areas. While sustainability has been defined in a number of ways, the basic idea is to operate in ways that meet current needs without adversely impacting the ability of future generations to meet their own needs (24).

Adverse environmental impacts associated with a product or process will generally negatively impact its sustainability. Therefore, life cycle analysis can be a useful tool in evaluating sustainability.

Another concept with a close connection to sustainability is the idea of cradle-to-cradle design. In this type of design, waste streams associated with production, use, or disposal of a product become feedstocks for production of either the same type of product or some other product. This idea was popularized by McDonough and Braungart in the book *Cradle to Cradle* (25). Minimizing waste of materials is one approach to enhancing sustainability.

The Sustainable Packaging Coalition is a leading proponent of the selection and use of packaging systems that are sustainable. SPC defines sustainable packaging as packaging that (26):

> Is beneficial, safe & healthy for individuals and communities throughout its life cycle
> Meets market criteria for performance and cost
> Is sourced, manufactured, transported, and recycled using renewable energy
> Maximizes the use of renewable or recycled source materials
> Is manufactured using clean production technologies and best practices
> Is made from materials healthy in all probable end-of-life scenarios
> Is physically designed to optimize materials and energy
> Is effectively recovered and utilized in biological and/or industrial cradle to cradle cycles

Evaluating the environmental impact or sustainability of packaging systems is often very complex. Specific results generally depend on what assumptions are made, where the boundaries of the system being evaluated are drawn, and on what value judgments are made. While this can lead to considerable controversy about specific comparisons (what package is “best”), this does not mean that there is no point in trying to do so. In many cases, opportunities can be identified to make changes that clearly reduce the environmental impact of packaging systems.

ENVIRONMENTAL MANAGEMENT SYSTEM

JOE CASCIO
BOOZ ALLEN HAMILTON
Ex-Chair, US Technical
Advisory Group

PRINCIPLES OF ENVIRONMENTAL MANAGEMENT

The overarching purpose of an environmental management system (EMS) is to formalize environmental management and to instill the environmental ethic in organizations. This is done primarily through formal procedures, programs, and process management controls that are applied to the organization’s operations. To achieve these ends, over 150,000 organizations in countries around the world have implemented EMSs that are based on the ISO 14001 international standard. Provisions in the standard assist implementing organizations in structuring procedures, programs, and processes into formal systems. The standard is prescriptive only with regard to organizational actions and structural arrangements but contains no performance requirements and is only moderately reliant on broad principles of environmental care and behavior. The few “principles” that are invoked include those dealing with employee involvement, management visibility, process consistency, pollution prevention, continual improvement, and system integration. It is instructive to consider each one of these separately, if only in brief:

Employee Involvement

Organizational success in environmental performance often depends on employee involvement that can only be achieved through employee commitment. In fact, where environmental care is relegated exclusively to a specialized staff, employees are less likely to acquire the habits of thought and manner that raise the environmental performance of the organization. With this in mind, the authors of ISO 14001 shifted many of the responsibilities for environmental care from the environmental staff to the organization's employees. The standard prescribes that key requirements of the EMS be implemented at "each relevant function and level" of the organization. This places the primary mandate for action on the employees in those functions and levels. For example, the standard expects that employees know the environmental objectives and targets, the applicable legal requirements, the elements of environmental management programs, and the operational controls that apply, as well as the importance of conformance to the environmental policy, the significant environmental impacts of their work, and their specific roles and responsibilities. Under the traditional approach, awareness and responsibility for these items would have been allocated almost entirely to members of the environmental function.

Management Visibility

A successful EMS also requires management visibility and leadership to bring it into being and to ensure its success. The authors of the ISO 14001 standard reasoned that any attempt to change an organization's culture without strong leadership from the top would likely end in failure. Employees are not easily fooled when management is not genuinely interested. An EMS requires that top management articulate a vision for environmental protection and that it play an active role to ensure the effectiveness of the management system and its continual improvement over time.

Prevention of Pollution

The authors of the ISO 14001 standard recognized the challenge of getting organizations to think proactively about the environmental consequences of the new products or processes they design. If engineers and product developers can be made to think about this while they are designing the new product or process, then significant gains toward environmental protection may be realized. To that end, ISO 14001 promotes preemptive environmental design either to avoid the creation of pollutants or to enlist other techniques to avoid the improper treatment or disposal of wastes.

Continual Improvement

When implemented, an ISO 14001 EMS establishes a framework that relies on the continual improvement of the various components of the system. A tacit tenet of ISO 14001—strongly articulated for quality management in the ISO 9001 standard—calls for process consistency and reliability. These two attributes provide confidence to the organization that the desired outcome will be achieved consistently. Continual improvement complements these traits by working to ensure that processes do not stagnate—that is, ensure that they remain fresh, vigorous, and relevant and become ever better in their consistency and reliability. If they do not become better, they will surely become worse. Continual improvement expects that processes be kept under frequent review and updated by the organization so that they are less likely to become neglected and ineffective over time.

Integration

Finally, it is useful to view an EMS as a subsystem of the organization's total management system. The ISO 14001 standard has been written to be applied flexibly and compatibly, capable of being integrated within existing organizational systems. Organizations have in fact found it easy to integrate their ISO 14001 EMSs with their quality management subsystems and with other subsystems including those for occupational health and safety. In this view, the EMS is simply a component, a subsystem of an organization's full, overarching management system.

THE RELATIONSHIP BETWEEN ISO 14001 AND SUSTAINABLE DEVELOPMENT

The concept of sustainable development (SD) gained popularity in 1987 with the publication of a UN-sponsored report prepared by a group of eminent international environmental experts led by Madame Gro Harlam Brundtland of Norway. The main thesis of SD is that human enterprise today should not rob future generations of their heritage—either of the ecology or of natural resources.

The 1987 *Report* spawned a series of national and international studies, commissions, and conferences on SD, culminating in the 1992 Rio Conference on Environment and Development (UNCED). Despite all the attention and time lapse, many organizations today continue to search for pragmatic ways to implement the principles of SD. Arguably, the ISO 14000 series of standards for environmental management and analysis provide the very tools needed to effectively implement the concept of SD. Provisions in the various standards of the series can lead organizations to focus their environmental protection efforts in ways they may never have done before. Principal among these is the behavioral changes that can be made to instill the environmental ethic in the organization's employees. Inducing such cultural changes in organizations can produce more efficient, reliable, and consistent environmental protection from operations and from decisions

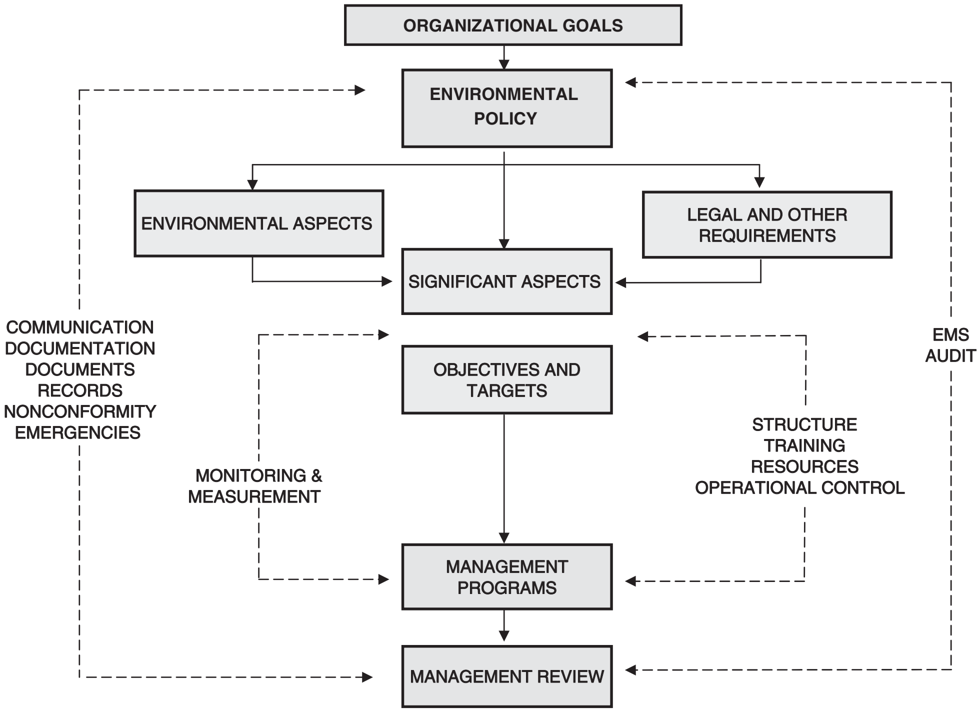

Figure 1. Interrelationship of ISO 14001 elements.

and actions on new products, processes, and investments. The ability to make these business decisions with a caring, environmentally sensitive attitude, understanding, and commitment is fundamental to the achievement of the SD goals.

THE ISO 14001 ELEMENTS

The ISO 14001 standard consists of a number of required elements that are interrelated to form a system. The elements and their gross interrelationships are shown in Figure 1. The paragraphs below provide a brief description of each of the relevant elements in the standard:

Organizational Goals

Every organization has its own goals that stem from the vision and aspirations of its founders and leaders. These may span the gamut from reaching specific financial goals to providing social services to ensuring the national defense. The possibilities, considering the vast number of existing organizations, are virtually unlimited. ISO 14001 takes the existence of the organization's fundamental goals as a fact, as a preexisting condition upon which the organization then expresses its desire and makes an additional management commitment to be an environmentally responsible organization. That commitment helps to give shape to the organization's environmental vision, which is then transformed into a public statement. The commitment must be expressed in a written, publicly available environmental policy if the organization wishes to obtain recognition for implementing an ISO 14001 conforming EMS.

Environmental Policy

The organization's Environmental Policy verbalizes management's commitment to run an environmentally responsible enterprise. The content of the environmental policy is meant to inspire—reflecting the commitment from top management and serving as a beacon to guide the behavior and actions of all members of the organization. These commitments also serve to set the objectives and targets for the EMS.

Environmental Aspects

The organization must identify its environmental aspects to begin the effort to build an EMS and to give substance to its commitment to be environmentally responsible. The common approach to environmental care, prior to EMS, was to review the environmental laws and regulations and then set controls in place to avoid excursions from requirements. The concept was to match legal requirements to the organization's activities and implement control programs to maintain compliance with the law. This based the entire focus of environmental protection on maintaining compliance, not on identifying potentially harmful activities, and gave rise to specialized organizational competencies strictly devoted to maintaining compliance. In contrast, an EMS works to place the emphasis on identifying the potentially harmful activities irrespective of legal and regulatory requirements. The environmental interactions of these activities are designated as environmental aspects in an EMS, and only after they are identified do we analyze the applicability of legal requirements. An EMS is structured to manage the organization's significant environmental aspects with the aim of preventing them from occurring and causing harmful environmental impacts.

Legal and Other Requirements

Having identified all of the organization's environmental aspects, we next need to select those that are most significant. The creators of ISO 14001 recognized that any organization might identify hundreds, perhaps thousands, of environmental aspects, but that only some of those might pose a significant threat to the environment. Among those that do pose such potential danger are those aspects that have regulatory requirements. Regulatory authorities have defined many substances, materials, and activities that present significant environmental hazards. It is prudent for the organization, therefore, to compare its list of environmental aspects against legal requirements to find those that have a match. The chances are that those that have regulatory requirements pose significant threats and should therefore be designated as significant environmental aspects.

Significant Environmental Aspects

Regulation is not the only criterion for designating significant environmental aspects; other factors may also be used to establish significance. These include the aspect's potential to cause environmental impacts, to pose health and safety risks, and to create business exposures. The point here, though, is to recognize that significance determines the design and scope of virtually every element of the EMS. An EMS focuses the organization primarily on managing those aspects that are significant; the remaining aspects are addressed through employee awareness, involvement, and commitment as the environmental ethic slowly takes hold throughout the organization. Among other ways, the EMS focuses on significant environmental aspects as follows:

- The organization must consider significant environmental aspects when setting its objectives and targets.
- Environmental management programs (EMPs) are designed to achieve the objectives and targets for significant environmental aspects.
- Employees whose work may create significant impacts must have received specific training and must be adjudged competent on the basis of appropriate education, training, and/or experience.
- The organization needs to consider external communication of its significant environmental aspects.
- The organization needs to put in place operational controls for operations and activities associated with significant environmental aspects.
- The organization needs to have procedures for the significant environmental aspects of goods and services it receives from external sources.
- The organization must have procedures for monitoring and measuring the key characteristics of its operations and activities that can have a significant impact on the environment.

Objectives and Targets

Objectives and targets should be set before drafting that portion of the policy that addresses the nature, scale, and impacts of the organization's activities, products, and services. This ensures that policy language is consistent with and reflects the organization's objectives and targets. Within the EMS, the objectives and targets determine the shape and content of the environmental management programs (EMPs).

Environmental Management Programs (EMPs)

While EMPs are primarily structured around the resources and timelines to achieve objectives and targets, they can also be used to consolidate other elements required in an EMS. Operational controls, for example, are needed to maintain control of operations and activities associated with significant environmental aspects. One can hardly expect to achieve objectives and targets if operations and activities are subject to being out of control. This is also important for regulatory compliance, since maintaining control is usually essential to staying in compliance. There are significant reasons, therefore, to incorporate operational controls within the EMPs. This same reasoning can be applied to other requirements of ISO 14001 such as training, roles, and responsibilities, as well as monitoring and measurement. All of these necessary elements of an EMS can be included in the full documentation of the EMPs.

Communication, Documentation, Document Control, Records Management, Nonconformity, and Corrective and Preventive Action

These elements of an EMS apply across the system and should be integrated with the organization's existing subsystems with similar functions. They act as lubricants in the EMS, to keep it working smoothly through information flow and self-corrective mechanisms. They should be designed to fit naturally with the culture and structure of the organization and its traditional approach to these areas. They are not dependent on the number or type of significant environmental aspects identified for the EMS. Nonetheless, they are important parts of the system. Document control, for example, ensures that only the latest authorized version of procedures are being followed by employees. The subsystem for records management ensures that generated records are maintained, safeguarded, and retained appropriately in the system. Communication ensures that information flows to the various functions and levels of the organization to enable the system to maintain its relevancy and functionality. Nonconformity, along with corrective and preventive action, provides the self-corrective mechanism that keeps the EMS working as it was intended to work.

EMS Audits

EMS audits test whether the system has been implemented and maintained as designed. Importantly, system audits are not compliance audits. The reason to look at compliance data during an EMS audit, for example, is not to test the organization's regulatory posture, but rather to test whether the programs (EMPs) that have been implemented are actually working as they were intended to work to achieve and maintain compliance. So, while EMS audits look at all elements of the system, they have a unique role in testing whether EMPs are actually achieving the ends for which they were designed—that is, whether they are effectively working to achieve the objectives and targets.

Management Review

ISO 14001 reserves a special role for top management, as well it should. Not only must they formulate and articulate the environmental commitments of the organization in the environmental policy, but periodically they must also render judgment on whether the EMS continues to be suitable, adequate, and effective.

Suitability addresses the issue of fit. Does the EMS fit the nature and character of this organization? An EMS that is designed for a municipal utility is not likely to be suitable for an oil refinery.

Adequacy addresses the issue of resources and commitment. Have proper and sufficient resources been allocated to ensure that the objectives and targets can be reached? Have all significant environmental aspects been identified and addressed to avoid environmental incidents?

Effectiveness relates to whether the system, as designed and implemented, can live up to the aspirations, goals, and commitments in the environmental policy. Here, it's not just a question of the right level of resources, but whether, as structured, the EMS can fulfill the policy commitments. In a very broad sense this is also a determination of whether the EMS has the capacity to bring the organization to its goal of becoming an environmentally responsible organization.

ENVIRONMENTAL REGULATIONS, INTERNATIONAL

Michele Raymond
Raymond Communications,
Inc., Riverdale, Maryland
Updated by staff

INTRODUCTION

The global community's interest in environmental sustainabilty has risen considerably since the second edition of the *Encyclopedia* was published. Many countries around the world have implemented environmental packaging requirements to allocate and distribute waste, to manage costs, and to to shift responsibility on the packaging manufacturer. The regulations differ greatly outside of the United States, but these regulations impact U.S. products. However, the U.S. must be aware of the global regulations in order to remain competitive. International fees and design requirements impact greatly on U.S. goods sold abroad.

Environmental concerns over resource use, pollution, and waste management, along with the idea that packaging businesses should share some of these concerns, have been the driving force behind packaging legislation. In many countries, the polluter pays principle and the Extended Producer Responsibility (EPR) are at the core of these regulations. The EPR has grown in popularity especially in Central and Eastern Europe. Asia is also involved in regulatory activity and has achieved complex packaging design requirements. Packaging engineers will need to keep control over the design of their products and be aware of fee requirements worldwide. This article gives only a brief description of where focus must be placed for any producer of packaging materials doing business outside of the United States.

FEES

Traditionally, packaging waste has been managed through government-backed disposal and recycling, The cost of waste management is not reflected in the price of the product. Charging companies a fee on the packaging they put out in the marketplace ensures that they share some of the economic burden.

Fee programs around the world are all quite different. Each country has a unique method for allocating recovery costs by setting fees and defining categories. Most countries place responsibility for ensuring packaging collection and recycling on the packer/filler or importer. Industry associations have established collective systems to manage compliance of the companies involved. Usually, costs are distributed among the members. In some countries, the government continues to provide collection and recycling services and charges a tax to industry based on the quantities of packaging material involved. Fees must be paid by the importer of goods. Fees are determined by the packaging weight and the type of material used.

Individual market types have a major impact on packaging fees. Other countries have broader requirements. Material definitions are not uniform and depend on the specific materials involved. If a product is made up of various materials, the component would fall into several categories. For example, a paper (70%) and aluminum (30%) product would fall into two material categories. In France, Japan, Taiwan, Sweden, and the United Kingdom, this example would be considered paper and the paper fee would apply. In Austria, Germany, and South Korea, the product would be considered a composite. This would represent a higher fee than the paper category. Belgium and Luxembourg do not have a designated category, and the product would go to the "other" category. What designates a packaging material that requires fees is also different for many countries. Some programs cover all packaging (sales, consolidation, and transport packaging) whereas others focus only on sales packaging. Austria, Belgium, the Czech Republic, Greece, Ireland, Italy, and Hungary, for example, have fees for all types of packaging including transport packaging. Variations in the fee schedules make it hard to analyze cost. The general trend is as follows: If a material is more difficult to recycle, then the fee is higher. An example of a fee schedule from Germany in 2004 was $0.19 for paper, $1.37 for plastic, and $0.98 for a composite (1).

EUROPE

European lawmakers have a different approach to ensure recycling than those in the United States. Unlike U.S. legislatures that have created hundreds of laws to encourage companies to use recycled material, those in Europe apparently believe that it makes more sense to force manufacturers to take more of a direct responsibility for packaging waste.

The assumptions are that the less environmentally sound containers will cost more to manage, consumers will choose the better materials, and manufacturers will supposedly use the materials in their new products.

The European Directive

The European Directive on Packaging was first passed in 1994 and amended in 2004. It contains some of the most comprehensive requirements focused on reducing packaging waste. All companies who sell products in the European Union (EU) must comply with the following: (a) *Source reduction*: Companies must demonstrate that they have reducd their packaging as much as possible and then identify the critical area that prevents further reduction in weight or volume of the packaging component. (b) *Recovery standards*: Packaging components must be recoverable by at least three recovery routes (energy, organic, or material recovery). (c) *Reuse*: Optional but must meet the requirements of the reuse standard if it is claimed as reusable. (d) *Heavy metal content*: Sets a concentration limit for lead, cadmium, mercury, and hexavalent chromium. (e) *Hazardous substances reduction*: Noxious substances must be minimized if they could be released in emissions, ash, or leachate when the packaging is landfilled or burned.

All packaging placed on the EU market must be in compliance with ERP or may be removed from the market. U.S. companies must incorporate the ERPs into their packaging design, and they must document how each standard of the Directive considered.

One of the problems with the Directive is that each country can set up its own "economic instruments" (i.e., taxes, deposits, industry collection fees, or a combination), and each country can stress different types of packaging from different sources. However, the European Parliamnent has adopted binding targets for the recycling of waste for its 27 member countries. The plan should be formed by 2014 for full use by 2020. Countries that fail to comply will be faced with full legal action (2)

All Packaging Affected

The Directive applies to all packaging. There are no specific exemptions for institutional, commercial, or other packaging that may be difficult to recycle. Every company supplying companies within the EU with raw materials for packaging, finished packaging, packaging components, or packaged goods are affected by the Directive, as will distributors of packaged goods and companies engaged in the collection, sorting, recovery, or disposal of packaging waste.

The Directive also covers disposable cups, plates, and cutlery used in the food service sector, but does not include the large road, rail, ship, and air containers. In principle, the Directive covers all packaging placed on the market within the EU and all packaging waste, whether disposed of at industrial or commercial sites or in private homes.

The Directive is binding on national governments, not on individual companies. Companies will simply be responsible for complying with whatever legal requirements are laid down at the national level.

National governments must ensure that systems are set up for the return or collection of used packaging, to ensure that it is effectively reused or recovered. For packaging that ends up in the home, recovery organizations are already in full operation in Germany and Austria.

The legal basis for these operations varies: They can be "Take back," which obliges a company to take back directly or contract with third party; "Give back," where companies are legally obliged to ensure that the used packaging material in their possession is either "valorized" (which means either recycled, composted, or sent for incineration with energy recovery) or passed to an organization that will take responsibility for valorizing it; or "Join up," companies are legally obliged to join (and pay a fee) to an approved recovery organization, which is responsible for meeting mandated targets.

Member states must ensure that packaging complies with certain essential requirements. These include minimization of packaging weight and volume to the amount needed for safety, hygiene, and consumer acceptance of the packed product; minimization of noxious or hazardous constituents; and suitability for reuse, material recycling, energy recovery, or composting.

The Directive contains certain "optional extras." Member states *may* (but do not have to) encourage environmentally sound reuse systems, provided that these conform with the EU Treaty; and where appropriate, member states are to encourage the use of materials recovered from recycled packaging waste in the production of new packaging and other products.

The EU member states have been considering applying reduced VAT rates on environmentally friendly producers. EUROPEN is the voice of industry for packaging and the environment in Europe. EUROPEN believes that any attempt to favor some types of packaging over others would be disproportionate to any real environmental difference and would distort competition (3).

Germany

Germany enacted the world's most stringent and well-known packaging ordinance in 1991. It forced a direct take-back obligation on the entire packaging chain (manufacturers and distributors, including wholesalers and distributors).

Quantified targets only apply to sales packaging within the DSD system. Manufacturers and distributors taking part in a "Dual System" which collects, sorts, and passes on used sales packaging for recycling are exempted from the general take-back requirement, provided that the Dual System meets the targets laid down. The DSD does *not* cover transport packaging or industrial packaging, where the absolute take-back requirement applies.

DSD is a monopoly, so there are no competitive pressures to keep costs down.

Pioneer disadvantage is that Germany was unable to learn from experience elsewhere.

The Green Dot symbol (Figure 1) is the license symbol of a network of industry-funded system for recycling the packaging material of consumer goods. The Green Dot means that a company has paid its DSD license fees and has become well known in Europe. The Green Dot signifies that a manufacturer contributes to the cost of recovery and recycling. If a company does not join the Green Dot scheme, they must collect recyclable materials themselves, and this sometimes is almost impossible for mass products. Thirty-two countries use the scheme. Companies are not required to use the dot on their products except for companies in France, Turkey, Spain, Portugal, and Bulgaria which must use the logo.

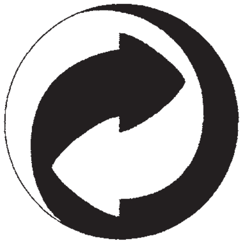

Figure 1. Germany's "Green Dot." It is not to be confused with a recycling logo.

The confusing issue for exporters is that use of the symbol on signifies payment of appropriate fees in *each country* where required. There is no pan-European program. Most European countries have transposed the Packaging and Waste Directive into national law. It is important for an exporter to join for each country to ensure compliance. Using the symbol without payment of fees can bring lawsuits for fraud.

Many countries will move in the direction of shared responsibility rather than full manufacturers responsibility as in Germany.

Refillables

Refillable containers are popular for beer and other beverages in some European countries. Germany has a refillables "quota" that has been challenged by the EU on trade grounds. Portugal recently enacted a refillables quota in its packaging law. Critics charge that these quotas are designed to protect the market share of local beverage makers, not protect the environment. Meanwhile, the patchwork of deposits, voluntary and mandatory, are pushing soft drink makers to use refillable plastic bottles.

PACIFIC RIM/EAST ASIA

Japan

Japan's Environmental Agency is now the Ministery of the Environment. Japan has a Fundamental Law for Establishing a Sound Material Cycle, meant to reduce waste, recycle waste, and appropriate disposal for the final use. The Ministry of International Trade and Industry has spent millions on research for plastics-to-fuel technologies, and it is pushing Japanese governments to purchase items with recycled content.

Hong Kong, Singapore, and Korea

All have active recycling systems, though they do not yet have direct "take-backs" for packaging. Malaysia is considering the idea, because its government has consulted with Germany's Minister of the Environment.

China

China has placed greater concern on environmental issues early in the 21st century. Problems are significant and involve soil, water, and air pollution. China's laws are among the strictest in the world, but enforcing them has been difficult. There is an eco-labeling law that apparently restricts companies from making green claims without government sanction.

As of June 1, 2008, all supermarkets and stores cannot give out plastic bags. Stores must clearly mark the price of plastic bags and are banned from tacking the price onto products. Ultrathin (less than 0.025 mm) bags are also banned (4).

Australia

Australia maintains one of the strictest regimes of environmental regulation. The only non-European nation to outrank it is New Zealand. The New South Wales government administers environmental protection legislation covering all facets of concern including waste disposal, and avoidance, resource recovery, recycling, and waste. Environmental regulations cover houshold, industry and government agencies (5).

New Zealand

New Zealand payback accord is made up of manufacturers and suppliers who use packaging, recyclers, and service providers. In 2003, the New Zealand Sustainability initiative set 2008 reycling targets. Rates are paper, 70%; aluminum, 65%; glass, 55%; plastics, 23%; and steel, 13% (6).

DESIGN

Material Restriction

South Korea currently bans packaging that is press-packed, coated, or shrink-wrapped in PVC. Several countries are expected to charge more for PVC packaging. Expanded polystyrene is forbidden in South Korea for packaging toys and composite materials. Phase-outs apply to packaging of electrical, office, and audio–visual products. An increasing number of countries (Denmark, Sweden, Norway, and Japan) have restrictions on the use of phthalates used in food packaging and toys. Many retailers, especially in Asia and Europe, refuse to accept packaging made of PVC. France and Denmark provide a fee reduction of certain materials that contain more than 50% recycled material.

Packaging Reduction

Several countries have implemented restrictions of empty space and the permissible number of layers in a packaging product. South Korea has a limit of no more that 10–35% empty space or 25–40% for a set product (a gift containing several packaged products). Austalia has limits that range from 25% to 40%. There is a 40% limit in Japan for cosmetic products. New Zealand has regulations that forbid deceptive packaging. Many countries, such as Australia, Belgium, the Netherlands, Greece, Slovakia, Spain, and South Korea, require companies to submit a detailed packaging reduction plam. The EU may make packaging reduction part of its reporting requirement. Reduction plans vary. Belgium, Greece, and the Netherlands require a company to develop a plan only if the goods are manufactured in that country. Spain and Slovakia require a plan if the quantity of packaging placed in the market exceeds a certain tonnage.

ECO-LABELING

An eco-label is a label that identifies overall environmental preference of a product (i.e., goods or services) within a product category based on life-cycle considerations, is in contrast to a self-styled symbol or claim statement developed by a manufacturer or service provider. An eco-label is awarded by an impartial third party that meets established environmental leadership. The Global Eco-labeling Network is a nonprofit association of third-party environmental performance labeling organizations founded in 1994 to improve, promote, and develop eco-labeling (7).

Programs

The United States Environmental Protection Agency researches international eco-labeling programs in order to identify common themes and connections with the International Community. Eco-labeling is voluntary, but the European Union has implemented eco-labeling regulation legislation. The EPA has identified 22 different eco-labling programs worldwide. Five of the most developed programs that have completed some form of evaluation are listed below.

The EU Flower. The EU flower was introduced in 1992 (see Figure 2). It is run by by the European Commission and is adminstered by Competent Bodies, which are representative organizations chosen within the EU member states. The flower logo is intended to promote design, product, marketing, and the use of products that have a reduced environmental impact during their life cycle. Packaging awards have gone to rubbish bags and converted paper products. The implementation of the EU's eco-labeling critria has been slow and has met with resistance from manufacturers and distributors (8).

Germany's Blue Angel. This program was implemented in 1977, making Germany the first country to implement a national eco-labeling program. The entire program is administered and financially managed by the German Institute for Quality Assurance and Certification (a private institution). It is considered more successful than the EU flower program. Packaging awards have gone to return bottles, recycled plastic and paper, and crates for food.

The Nordic Swan. The Nordic Swan was introduced in 1989 as a voluntary seal of approval (Figure 3). Currently, Norway, Sweden, Finland, Iceland, and Denmark participate. The Nordic Council of Minsters oversees the program. A listing for packaging guidelines has been approved.

Figure 2. European Union's ecolabel symbol.

Figure 3. The Nordic Swan.

Japan's Eco Mark. This is the second oldest eco-labeling program after the Blue Angel. It was introduced in 1989 as a seal of approval program to promote environmentally friendly products. It is implemented by the Japan Environment Association, a nongovernmental organization that acts under the guidance of the Environment Agency. Awards have been made for refillable containers, packaging material from recycled pulp, and recycled paper for packaging.

Taiwan's Green Mark. This program was launched in 1992 by Taiwan's Environmental Protection Administration and is administered by the Environment and Development Foundation, a private institution.

The United Nations Environment Program. This U.N. program reviews eco-lableling as an environmental policy tool and potential trade barrier.

Standards

The ISO standards for eco-labeling were set by dozens of countries working throughout the 1990s to develop standards for sustainable environmental management. ISO 14020 lists a set of principles by a practioner of environmental labeling. ISO 14024 specifies the procedures and principles that third-party certifiers must follow. ISO 14020 guiding principles for eco-labeling include: accuracy; avoiding unnessary trade barriers; scientific basis; provision of information on methodology; life-cycle approach; allowance of innovation; minimal adminstrative burden; open, consentual process; and provision of information on products.

ESTIMATION OF SHELF LIVES OF OXYGEN SENSITIVE PACKAGED PRODUCTS

Kit L. Yam
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

This article introduces a simple model equation (Equation (3), described later) and its application to estimate the shelf lives of oxygen sensitive foods in packages. A similar form of this equation also may be used for moisture sensitive products. The equation is useful to design packages for protecting products that are sensitive to the oxygen and moisture in air.

The accuracy of the estimations depends on whether the situation being considered satisfies the assumptions of the equation. The equation assumes the following: (1) the shelf life of a product is controlled by the oxygen permeation through the package, (2) the maximum allowable oxygen of the product may be defined and is known, (3) the package is made of a plastic material with uniform thickness, (4) the package has complete integrity (no leaks), and hence permeation is the only means of oxygen transfer, and (5) the oxygen concentration driving force (i.e., $P_e - P_i$ in Equation (3)) is constant. Because these assumptions are not always satisfied, experimental shelf life studies are usually recommended to validate the estimations of the equation.

Assumption (1) may be further explained using Figure 1, which shows that oxygen from outside the package can cause deterioration in the product by a series of steps as follows: (a) permeation through the package wall into the package headspace, (b) diffusion through the headspace to the food product surface, and (c) reaction with the food product until the extent of deterioration is no longer acceptable. The shelf life of the product is, thus, equal to the total time required for these steps to complete. In most situations, the diffusion step may be ignored, because the package headspace is usually small and diffusion of oxygen occurs quite quickly in the headspace. Therefore, the assumption that the shelf life is controlled by the permeation step is valid only in situation in which the

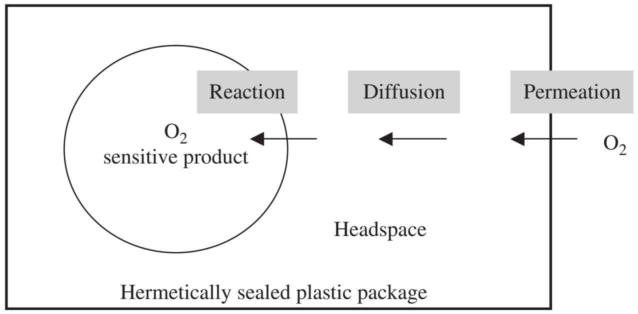

Figure 1. Permeation through package and reaction with product.

time required for reaction step is small or negligible. In practice, this assumption is satisfied if the package has good oxygen barrier; for poor oxygen barrier packages, the equation is not applicable because the reaction step controls shelf life.

In Assumption (2), the maximum allowable oxygen is the maximum amount of oxygen that a product can tolerate before becoming unacceptable. Table 1 shows the maximum oxygen and water tolerant limits for some food products, which can be converted into the maximum allowable values by multiplying the product weights. Note that these limits may serve only as general references, because experiments usually are required to obtain more accurate values.

Equation (3) has the advantage that it is simple and can provide useful estimations, although more sophisticated equations are available for situations in which higher accuracy is required (1).

MODEL EQUATION

The oxygen transmission rate (OTR) through a permeable package (e.g., a plastic pouch) may be calculated using the equation

$$\mathrm{OTR} = \frac{\overline{\mathrm{P}}\mathrm{A}}{\mathrm{L}}(\mathrm{P_e} - \mathrm{P_i}) \qquad (1)$$

Table 1. Maximum tolerant limits for some food products

Food	Maximum H_2O (%)	Maximum O_2 (ppm)
Beer, wine	3, loss	1–5
UHT milk	3, loss	1–8
Soups, sauces	3, loss	1–5
Fruits juices, soft drinks	3, loss	10–40
Preserves, jams, pickles	3, loss	50–200
Dried foods	1, gain	5–15
Snack foods, nuts	5, gain	5–15
Instant coffee, tea	1, gain	15–50
Oils and fats, dressings	10, gain	50–200

where

OTR = oxygen transmission rate, cc O_2/day
A = surface area of package, in^2
L = thickness of package, mil
$\overline{\mathrm{P}}$ = oxygen permeability, $(\mathrm{cc\ O_2 \cdot mil})/(100\ \mathrm{in}^2 \cdot \mathrm{day} \cdot \mathrm{atm})$
$\mathrm{P_e}$ = oxygen partial pressure in external environment, atm
$\mathrm{P_i}$ = oxygen partial pressure in headspace, atm

If the assumptions stated earlier are satisfied, the shelf life ($\mathrm{t_s}$) can be estimated as

$$\mathrm{t_s} = \frac{\mathrm{O_{2,\,max}}}{\mathrm{OTR}} \qquad (2)$$

where

$\mathrm{t_s}$ = shelf life, day
$\mathrm{O_{2,max}}$ = maximum allowable oxygen, cc O_2

As a reminder, Equation (2) assumes that the O_2 permeation through the package is the controlling factor of shelf life. Substituting Equation (1) into Equation (2) yields

$$\mathrm{t_s} = \frac{\mathrm{O_{2,\,max}L}}{\overline{\mathrm{P}}\mathrm{A}(\mathrm{P_e} - \mathrm{P_i})} \qquad (3)$$

This equation is useful for evaluating many what-if scenarios, as illustrated in the following two examples.

APPLICATIONS OF MODEL EQUATION

Example 1. Assume an oxygen sensitive package food has a shelf life of 12 months. If the package thickness is decreased by 20% and the surface area is decreased by 30%, what is the new shelf life?

Equation (3) may be use to obtain

$$\frac{\mathrm{t_{s2}}}{\mathrm{t_{s1}}} = \left[\frac{\mathrm{O_{2,\,max}L_2}}{\mathrm{PA_2}}\right] \Big/ \left[\frac{\mathrm{O_{2,\,max}L_1}}{\overline{\mathrm{P}}\mathrm{A_1}}\right] = \frac{\mathrm{L_2A_1}}{\mathrm{L_1A_2}}$$

The subscripts 1 and 2 denote the changes before and after, respectively. Since $\mathrm{t_{s1}} = 12$ months, $\mathrm{L_2} = 0.8\ \mathrm{L_1}$ and $\mathrm{A_2} = 0.7\ \mathrm{A_1}$, the new shelf life is estimated to be

$$\mathrm{t_{s2}} = 12\frac{(0.8\mathrm{L_1})\mathrm{A_1}}{\mathrm{L_1}(0.7\mathrm{A_1})} = 12\left(\frac{0.8}{0.7}\right) = 13.7\,\mathrm{months}$$

Example 2. A 100 g oxygen sensitive food is vacuumed packed into a multi-layer plastic pouch, which has a thickness of 10 mil, a surface area of 80 in^2, and oxygen permeability of 0.12 (cc mil)/(100 in^2 day atm). What is the estimated shelf life if the oxygen tolerant limit of the product is 5 ppm?

Multiplying the tolerant limit and product weight to obtain

$$\text{Maximum allowable } O_2 = (5 \times 10^{-6})\,(100) = 5 \times 10^{-4}\,\text{g},$$

which is the amount of O_2 allowed to enter into the package before the product becomes unacceptable. Because the molecular weight of $O_2 = 32$ and 1 g mole of $O_2 = 22400$ cc, the unit of maximum allowable value may be converted from weight to volume

$$\begin{aligned}\text{Maximum allowable } O_2 &= (5 \times 10^{-4})\,(22400)/32\\ &= 0.35\,\text{cc}\end{aligned}$$

P_i may be assumed to be zero since the product is vacuum packed. P_e may be assumed to be 0.21 atm, the normal partial pressure of O_2 in air. Therefore, the shelf life may be estimated by Equation (3) as

$$\begin{aligned}t_s &= \frac{O_{2,\max}L}{\overline{P}A(P_e - P_i)} = \frac{(0.35)(10)}{(0.12/100)(80)(0.21-0)}\\ &= 174\ \text{days}.\end{aligned}$$

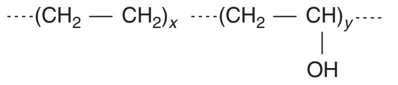
ETHYLENE–VINYL ALCOHOL COPOLYMERS

Ronald H. Foster
EVAL Americas, Houston,
Texas

Ethylene–vinyl alcohol copolymers are hydrolyzed copolymers of ethylene and vinyl alcohol. The polymer poly(vinyl alcohol) has exceptionally high barrier properties to various gases, solvents, and chemicals, but it is water-soluble and difficult to process. By copolymerizing vinyl alcohol with ethylene, the high barrier properties are retained and improvements are achieved in moisture resistance (EVOH is not water-soluble) and processability.

The resulting EVOH copolymer has the following molecular structure:



$$\cdots(CH_2 - CH_2)_x \cdots(CH_2 - \underset{\displaystyle OH}{\underset{|}{CH}})_y\cdots$$

Ethylene unit Vinyl alcohol unit

There are currently two global suppliers of EVOH copolymers. Kuraray Company Ltd. (EVAL™ resins) and Nippon Gohsei (Soarnol resins) are both Japanese companies with manufacturing facilities in Japan, Europe, and the United States. Chang Chun Group of Taipei, Taiwan has recently announced the startup of an EVOH production facility in Taiwan and is reportedly in the process of providing initial product samples to the market. Manufacturing capacity for EVOH resins worldwide is approximately 220 million lb annually. Table 1 lists the range of EVOH resins available.

Table 1. Range of EVOH Resins

Property	Range
Melt index (g/10 min)	0.7–20
Density (g/mL)	1.12–1.22
Ethylene content (mol%)	24–48
Melting point (°C)	156–196

EVOH copolymer resins first became commercially available in 1972 in Japan. However, widespread use of these resins did not occur until 1983 when U.S. food producers started using the resin for all-plastic, squeezable bottles.

The primary use of these resins is still food packaging, where the excellent gas-barrier properties are utilized to prevent oxygen degradation of food products. This has ultimately led to the replacement of many metal and glass food packages with the benefit of reduced weight and improved ease of use. In addition, usage has broadened due to EVOH's superior resistance to solvents, chemicals, and hydrocarbons, expanding into nonpackaging industrial applications such as the agricultural chemical, automotive, appliance, and protective-clothing areas.

EVOH copolymers are highly crystalline in nature, and their properties are dependent on the relative concentration of the comonomers. Figure 1 shows the relationship between comonomer concentration and moisture and gas transmission barrier properties, and Figure 2 shows the relationship between relative humidity and oxygen transmission rate.

It is this combination of exceptional barrier properties that permit the use of thin layers of these materials in multilayer packaging and nonpackaging structures.

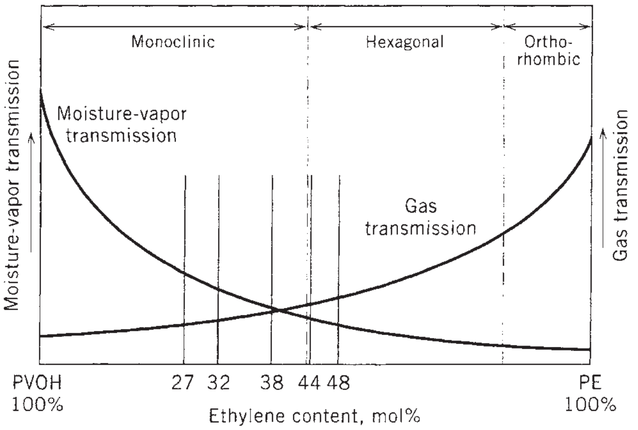


Figure 1. Comonomer concentration vs barrier properties.

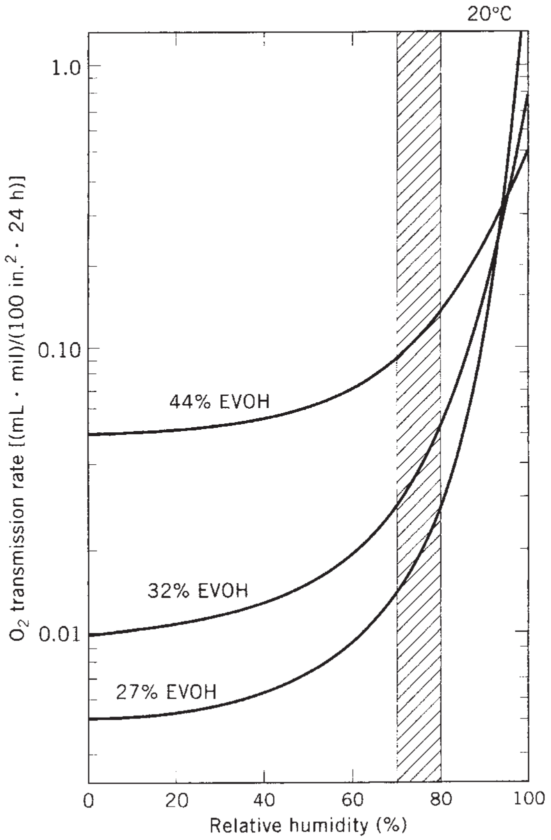

Figure 2. Oxygen transmission rate versus relative humidity.

EVOH COPOLYMER PROPERTIES

The general characteristics of EVOH copolymer resins are discussed in the following paragraphs.

Gas-Barrier Properties

EVOH resins are best known for their outstanding barrier to the permeation of gases such as oxygen, carbon dioxide, nitrogen, and helium. The use of EVOH copolymers in a packaging structure enhances flavor and quality retention by preventing oxygen from penetrating the package. For packages utilizing modified-atmosphere packaging (MAP) technology, EVOH resins effectively retain the carbon dioxide, oxygen, or nitrogen used to enhance the product. (See also Barrier polymers.)

Table 2 compares the gas transmission properties of EVOH copolymers with other commonly used packaging materials.

Hydrocarbon and Solvent Resistance

EVOH resins have a very high resistance to hydrocarbons and organic solvents. The weight-percent (wt%) increase in EVOH resins after immersion for 1 year at 20°C in various solvents is 0% for solvents such as cyclohexane, xylene, petroleum ether, benzene, and acetone; 2.3% for ethanol; and 12.2% for methanol.

Table 3 shows the performance of protective gloves containing an EVOH layer, and Table 4 reflects the resistance of EVOH to various fuels. These properties make EVOH resins an excellent choice for the packaging of oily foods, edible oils, agriculture pesticides, organic solvents, and other industrial applications.

Flavor, Fragrance, and Odor Protection

Protecting food products has become increasingly important, especially with the current trend away from product additives and the move toward smaller portion-size packaging. Protection can mean different things in different situations. One of the areas receiving increased attention in food packaging is the flavor–aroma barrier (see Aroma Barrier Testing).

The food industry is becoming increasingly aware of the importance of flavor barriers in containing natural flavors and preventing extraneous flavors from contaminating the product. Some food products are notorious for their ability to absorb extraneous flavor or aromas. Another important flavor consideration is commonly called "flavor scalping," in which some plastics, such as polyolefins, selectively absorb certain flavor constituents from the product.

EVOH resins provide excellent protection to the migration of flavors and the absorption of D-limonine, which is the primary flavor constituent in citrus juices, as can be seen in Table 5 and Figure 3.

Where food products are concerned, aroma barrier is somewhat analogous to flavor barrier. Food products must be protected from outside aromas in the distribution chain, grocery store, and home. Other food and nonfood products such as garlic, agricultural chemicals, pesticides, insecticides, or perfumes can be highly aromatic. In this

case, the desire is to retain the aroma in the package and not let it escape into the surrounding environment.

As shown in Table 6, EVOH can provide protection to aroma migration.

Mechanical and Optical Properties

Although not intended for use as structural resins, EVOH resins have high mechanical strength, elasticity, and surface hardness, and excellent weatherability. These films are highly antistatic in nature, preventing the buildup of dust and/or static charges. EVOH films have a very high gloss and low haze, resulting in outstanding clarity characteristics. Table 7 compares the mechanical and other properties of EVOH resins.

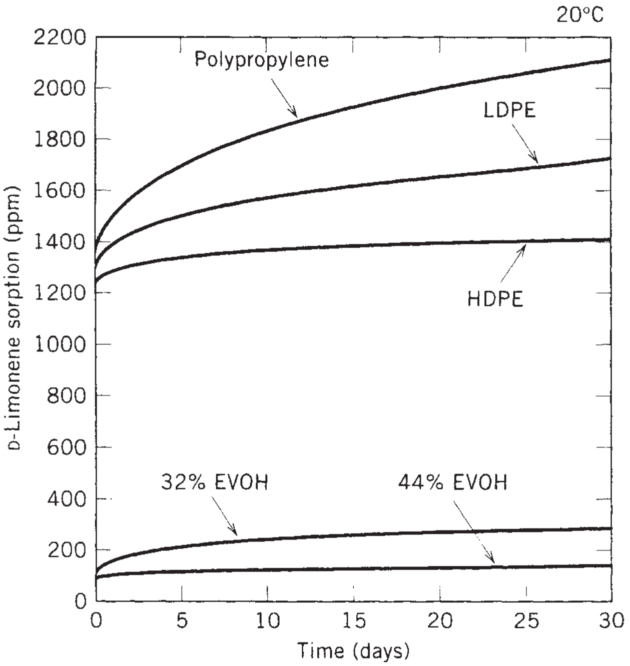

Figure 3. D-Limonene sorption.

Processability

EVOH resins are thermoplastic polymers easily processed on conventional fabrication equipment without special modifications. Using commercially available equipment, EVOH resins, in conjunction with other resins, are suitable for use in the following processes:

- Blow film
- Cast film
- Sheet extrusion
- Blow molding
- Profile extrusion
- Extrusion coating

Depending on the requirements, EVOH resins can be coextruded with all types of polyolefins, nylon, polystyrene, polyvinyl chloride, and polyester. Downstream processing such as thermoforming, vacuum forming, and printing is easily accomplished with EVOH resin- or film-containing structures.

Regulatory Approvals

Depending on the resin grade, EVOH resins and films have FDA approval for direct food contact as specified in the code of Federal Regulations, Title 21, Section 177.1360. EVOH resins and films can also be used in high-temperature laminates (retortable applications), provided that a functional barrier layer is used to separate the EVOH layer from the food product.

Various other approvals related to the use of EVOH resins and films in meat and cheese products and in other countries such as Latin America, Canada, and Europe have been granted by the appropriate regulatory agencies.

EVOH resins are considered nontoxic according to the USP Class VI test protocol.

PACKAGING STRUCTURES

Throughout the world today, the primary use for EVOH resins and films is food packaging. All plastic multilayer structures containing EVOH provide a cost-effective alternative to traditional forms of packaging such as glass or metal. In addition, they also offer other advantages such as convenience of use and source reduction of packaging materials.

Rigid and semirigid containers such as bottles, trays, bowls and tubes, flexible films, and paperboard cartons containing EVOH as the functional barrier layer are commercially available today. These structures utilize the multilayer concept to protect the barrier layer (EVOH) from the effects of moisture. This concept is also used to produce an economical structure by using relatively inexpensive materials, such as polyolefins, as the bulk of the structure. Most multilayer structures used today have five to nine layers. Multilayer structures can be produced by either coextrusion and lamination technology.

When using EVOH in multilayer structures, it is necessary to use an adhesive layer to gain adequate bonding strength to the other polymers. Commercially available adhesive resin such as Admer (Mitsui Petrochemical Industries Ltd.), Plexar (Equistar), Tymor (Morton Chemical), or Bynel (DuPont Company) are suitable for use with EVOH resins.

Rigid and Semirigid Containers

The most common methods of producing these containers are thermoforming, blow molding, and profile extrusion. Most thermoformed containers are produced in a two-step process. First a coextruded multilayer sheet is produced. This sheet, containing a barrier layer (EVOH), is then formed into the final container using either melt-phase or solid-phase thermoforming technology. There are two

Table 7. Mechanical Properties of EVOH Resins

Property	Unit	EVOH Resin Grades

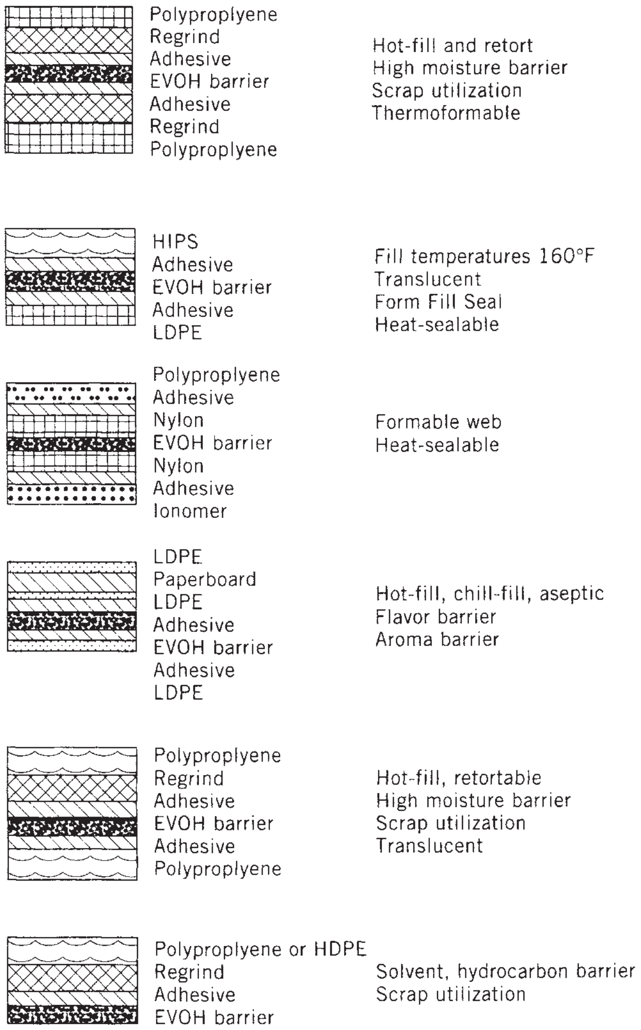

Figure 4. Barrier constructions.

exceptions to the two-step process: the use of rotary thermoforming and the "omni" process originated by American National Can, which is a variation of the injection blow-molding process.

Multilayer bottles are produced using either extrusion blow-molding or injection blow-molding technology. Likewise, tubes can be produced using direct-profile coextrusion, heat sealing of extruded sheet, or blow-molding coextrusion processes.

Figure 4 shows typical multilayer structures used for rigid and semirigid containers.

Flexible Films

Flexible films consume the largest volume of EVOH of any package structure. Flexible films are produced by several methods. These include solution coating, laminating coextrusion coating, and coextruding either tubular or flat (cast) films. Converting operations such as vacuum forming, printing, form, fill, seal, and heat sealing are used to fabricate packaging structures from these films. Figure 4 shows typical multilayer flexible-film constructions. Monolayer EVOH films, either biaxially oriented or nonoriented, can be used in conjunction with the laminating or coextrusion coating process to also produce flexible films.

Paperboard Containers

In recent years, the use of EVOH to replace aluminum foil as the barrier layer in paperboard cartons has grown rapidly. These containers, used primarily for juice products but also for nonfood products, utilize the EVOH in several ways. Besides serving as an oxygen barrier, the EVOH layer can also be used to prevent "flavor scalping" (fresh juice) or as an aroma barrier (laundry products). Coextrusion coating onto paperboard is the primary

Table 8. EVOH Film Properties

Property		Unit	EVAL™ EVOH Grades EF-XL	EF-F	EF-E	Oriented Polyamide	PVDC-Coated Polypropylene
Thickness		mils	0.6	0.6	0.8	0.6	0.9

Note: Tie layers are used between any layers of EVOH and either PE or PP. These are omitted from the table for clarity.

process for producing these containers. Typical structures may be seen in Figure 4.

EVOH FILMS

In addition to EVOH resins, monolayer EVOH films are also available. These films, either biaxially oriented or nonoriented, provide a unique balance of attractive appearance of toughness, dimensional stability, barrier properties, and economics. When combined with other types of polymeric films in a laminating or laminating–coating process, the resulting structure provides properties similar to those of a coextruded structure. Table 8 lists the properties of several monolayer EVOH films.

APPLICATIONS

Since the introduction of EVOH resins and films in Japan during the 1970s and in the United States and Europe in the 1980s, the use of these materials has continued to grow. Table 9 shows a portion of the commercial applications utilizing EVOH as a barrier layer.

Economics

To determine the most economical barrier polymer, the price of obtaining the barrier needed for a given application at a given set of use conditions and a given packaging structure must be compared. Factors such as price per pound of the polymer, polymer yield, oxygen transmission rate, and the use of recycled scrap must be considered.

When the low barrier cost of EVOH resins is combined with their recyclability and the new developments in coextrusion technology, the packaging specialists has available a means to design a packaging structure that will not only compete with glass and metal containers on a performance basis but also provide a definite economic advantage.

EUROPEAN PACKAGING LEGISLATION

Luigi Rossi
European Commission; and
Strategic Advisor for Keller and
Heckman LLP

At the end of the 1950s, following the issue of U.S. Food and Drug Administration (FDA) Act on food contact materials (FCM, 1958), some European countries began adopting the first regulations and recommendations. All these new European rules were designed to avoid excessive release into foodstuffs of the substances contained in the materials, especially in plastics, and above all to rule out the possibility of a health hazard to the consumer as a result of the toxicity of some of the substances used to manufacture these materials.

In the European Union (EU) the differences in the provisions adopted at national level were sources of problems for packaging companies, which were forced to adjust production to the country of destination and apply for authorization to use a new material. This led to a growing need to approximate ("harmonize") the various laws and thereby remove legal barriers to community trade in packaged food which, with the abolition of customs duty and the new systems of sales (supermarkets) and lifestyles (pre-packaged food), were developed extensively.

In 1960 the Council of Europe (CoE) takes the initiative to harmonize the rules on plastics (see later). In 1972 the European Commission (EC) drew up a broad program of action designed to harmonize all existing national laws in the field of FCM (plastics, paper, ceramics, rubber, etc.). Because this attempt is not yet finished, depending by the material considered, rules derived from EU or national authorities or CoE exist in Europe, making the description of European Packaging Legislation extremely difficult. Therefore this note describes briefly the main aspects of current legal situation in Europe summarizing the rules on the basis of the material and the origin.

EU LEGISLATION

The legal binding acts (= laws) are called "measures" and can be adopted under a directive or regulation[*]. These measures can be divided into three categories:

- Measures applicable to all materials and articles
- Measures applicable to one category of materials and articles
- Measures relating to individual or groups of substances

All the measures adopted and mentioned here may be found in all EU official languages in EC website[†] and summarized in Figure 1.

Measures Applicable to All FCM

Framework Legislation. The Framework measure, Regulation (EC) 1935/2004, adopted in 2004 replaces those adopted in 1976 and 1989. It establishes for all FCM:

- The definition of the scope
- The obligation to manufacturing the FCM following the "good manufacturing practice"
- The interdiction of an "unsafe" migration of the constituents of the materials or articles (safety clause)
- The prevention of any unacceptable contamination of the foods even if this contamination does not imply health problems (inertness clause)
- The prevention of any deterioration in the organoleptic characteristics of foods (i.e., taste, odor, or texture of the foods)
- The information, through an appropriate labeling ("for food contact") or a symbol (🍷🍴) to the consumer or food industry of the suitability of the materials and articles to come in contact with food (labeling clause)
- The obligation for the business operators to trace FCM i.e. to identify the businesses from which, and to which, the FCM are supplied (traceability clause)
- The procedures for the authorization of substances and materials
- The obligation to consult the European Food Safety Authority (EFSA) if the specific measure deals with aspects having an impact on the consumer health
- The safeguard measures to be taken in certain dangerous situations
- The public access to the technical dossier made available by the business operator when the authorization of a substance is required
- The right of the business operator to require a certain confidentiality on the management by EC or EFSA of certain data, the disclosure of which may significantly harm its competitive position
- The possibility to share data of the technical dossier needed to obtain the authorization of a substance to avoid
- The obligation to have declaration of compliance for materials and articles covered by specific legislation
- The obligation for the MS to check the conformity of FCM to the related laws (control clause)
- The establishment of a Community Reference Laboratory (CRL) for food contact materials (see later)

Regulation on Good Manufacturing Practice (GMP). The obligation to apply the rules of GMP is included in general terms in the framework regulation. To ensure a

---

[*] Directives are binding acts that require the transposition in the national laws. Regulations are directly applicable legal acts.

[†] http://ec.europa.eu/food/food/chemicalsafety/foodcontact/legisl_list_en.htm

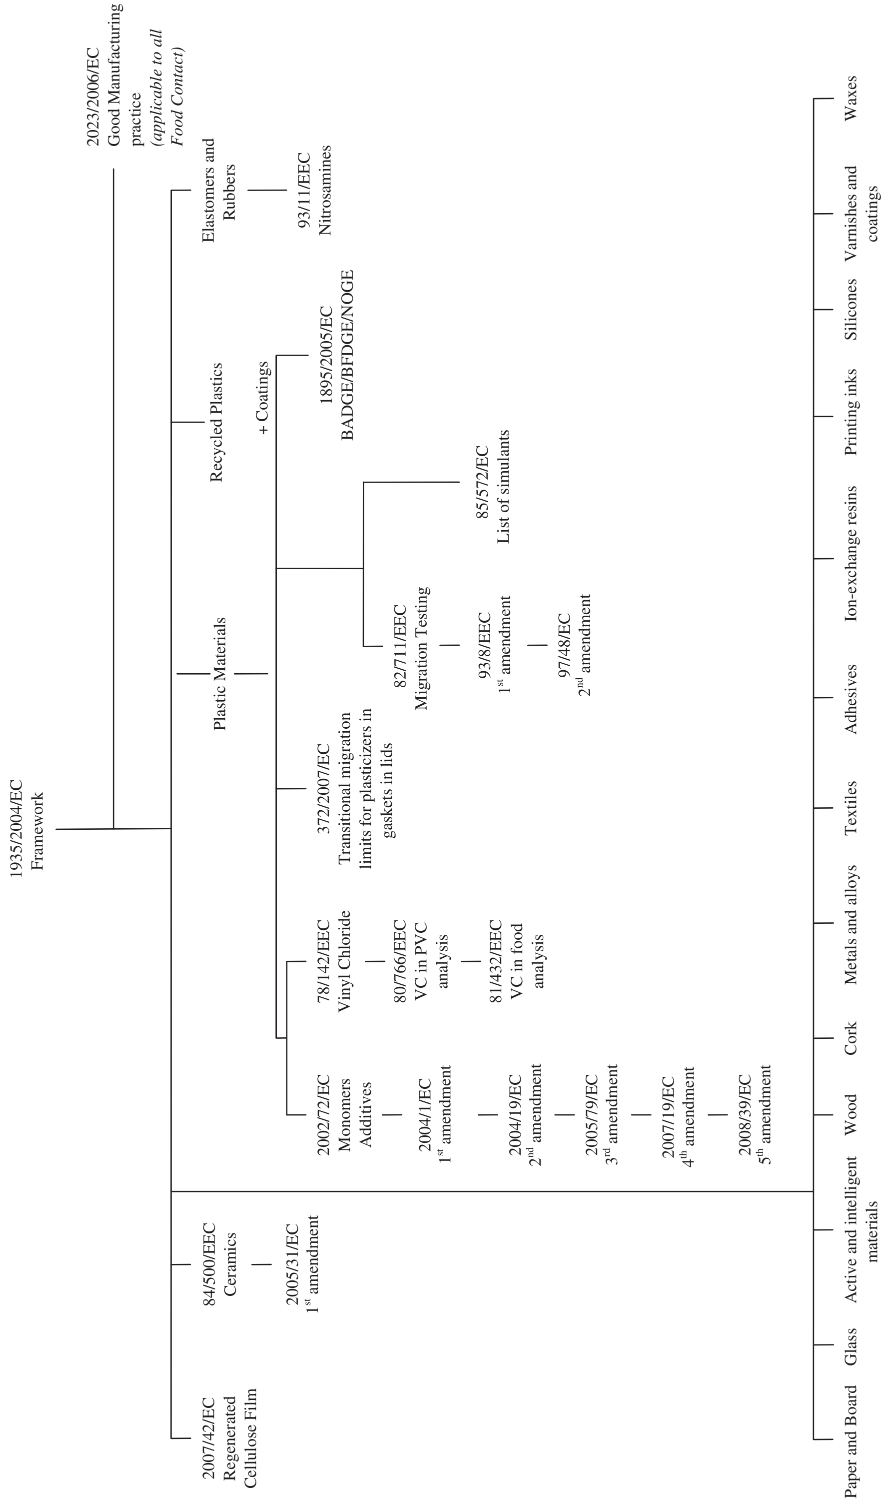

Figure 1. Overview of community legislation.

harmonized application of GMP throughout the EU and throughout the different business sectors, the basic principles of GMP are detailed in Regulation (EC) No. 2023/2006. These requirements, applicable as of August 1, 2008, have to be applied at all stages of production of FCM and in all sectors. All aspects of the GMP need to be adequately documented, and the documentation should be available to control authorities. Imports from third countries should also apply adequate GMP systems in their production. For two materials, GMP requirements have been further detailed— that is, for printing inks and for recycled plastics.

Specific Measures on A FCM

Measures on specific materials deal with the groups of FCM mentioned in Table 1. Until now, only four groups of materials have been regulated by EU measures: regenerated cellulose films, ceramics, plastics, and recycled plastics. Some general rules exist also for active and intelligent materials.

Directive on Regenerated Cellulose Film (RCF). Directive 93/10/EEC, which codified two previous directives, regulated the regenerated cellulose film. It establishes (a) a list of authorized substances and (b) the restrictions on the composition of the material.

In 2004 a new amendment, Directive 2004/14/EC, authorized a new type of regenerated cellulose film with a coating consisting of plastics, which is compostable and biodegradable in accordance with the requirement of packaging waste Directives.

Ceramics. Directive 84/500/EEC sets out migration limits for lead and cadmium and the method of analysis. Moreover, it specifies the requirement of the declaration of compliance as well as the supporting documentation to be made available to the national competent authorities on request. This documentation shall contain the results of the analysis carried out, the test conditions and the name and the address of the laboratory that performed the testing.

Table 1. Groups of Materials Including Recycled Materials which May Require an EU Legislation

Active and intelligent materials and articles
Adhesives
Ceramics
Cork
Rubbers
Glass
Ion-exchange resins
Metals and alloys
Paper and board
Plastics
Printing inks
Regenerated cellulose
Silicones
Textiles
Varnishes and coatings
Waxes
Wood

Directive on Plastics Materials. Finally, the Commission began to draw up rules for plastic materials. Due to the wide divergence of national regulations, their poor scientific basis and the need to reach a large agreement between Member States, the Commission was obliged to take a very cautious, step-by-step approach toward harmonization. Therefore the main provisions are dispersed in numerous directives and amendments. They are mainly regulated by three measures:

- Directive 2002/72/EC, which set out the main provisions
- Directives 82/711/EEC and 85/572/EEC, which set out the basic rules to checking the compliance with the quantitative restrictions and specifications inserted in the Directive 2002/72/EC

Their main provisions are related to:

- The overall migration limit (OML), which for all the plastics have the same value, that is, 60 mg/kg (of food/food simulant) or 10 mg/dm^2 (of surface area in contact with food)
- The positive lists of monomers and additives (for additives as of January 1, 2010), which collect all the substances authorized and then prevent the use of monomers and additives not listed
- The quantitative restrictions or specifications applicable to the substance(s) (e.g., SML, QM and QMA)
- The functional barrier (FB), which is a layer permitting the use of nonauthorized substances in the layer(s) not in direct contact with food, provided that (a) their migration in food or food simulant does not exceeds 0.01 mg/kg (of food/food stimulant) and (b) the substances are not classified in EU as proved or suspect “carcinogenic” “mutagenic” or “toxic to reproduction”
- Certain more restrictive provisions for young children
- The rules on the choice of food simulants in relation to food in contact and the conditions of contact (duration and temperatures) in the conventional, standardized migration testing

The field of application is quite limited because it applies only to materials and articles made up of one or more layers exclusively of plastics material. The multi layers consisting of at least one layer other than plastic are excluded even if the material in contact with food is made of plastic.

Recycled Plastics. Regulation (EC) No. 2008/1016, which applies to mechanical recycling of plastics, foresees the individual authorization of the recycling process at the community level based on the safety evaluation of the recycling process performed by EFSA. Because the recycling processes are unique based on technology applied, individual authorization dedicated to the applicant will be issued. All recycling processes shall be accompanied by an adequate quality assurance system that should be audited by member states. Recycled plastic as well as the materials and articles containing recycled plastics need to be accompanied by a declaration of compliance.

Directives Concerning Individual or Groups of Substances

While legislating on a broad scale (i.e., in relation to various sectors of production), the Commission has also been obliged to lay down rules for individual substances that have been the cause of considerable public concern. This applies to the individual measures related to vinyl chloride monomer used in PVC, mono- (MEG) and diethylene glycol (DEG) used in regenerated cellulose film, *N*-nitrosamines and *N*-nitrosatable substances from rubber teats and soothers, certain epoxy derivatives in plastics, azodicarbonamide in plastics, and some plasticizers in gaskets in lids.

NATIONAL LAWS

The national laws are not yet fully harmonized at the EU level, whereas, additional national laws remain in place. In these cases a possible option to avoid technical obstacles to the trade in the EU is given by the application of the so-called Principle of mutual recognition, set out in Articles 28 and 30 of the Treaty. It states that any product lawfully produced and marketed in one member state must be admitted to the market of any other member state. Therefore it is important to know the additional national laws in force in member states. Due the complexity of this issue, it is necessary to consult directly national legislations. Useful references can be found in the SANCO website* and on the Internet.†

COUNCIL OF EUROPE (COE)

In the absence of national laws or also, sometimes in their presence, the resolutions of the CoE may be useful to export in EU or in the marketing between member states. CoE is a European international institution that was created before the EU and is independent from it. CoE adopts resolutions, guidelines, and technical documents (TD) on FCM not covered by EU law. These documents are not binding texts unless the countries transpose (partially or totally) them into national law. Numerous resolutions, guidelines, and TD regarding various types of materials such as paper, inks, coatings, rubber, silicones, ions resin exchange, cork, and metals have been adopted. Some have been recently transposed into national legislation of some EU countries. All CoE adopted texts are reported in the CoE website.‡

OTHER (CEN, JRC)

Other European organizations set out not binding guidelines in the field of the method.

The Commission Agency, Joint Research Center (JRC), was selected as CRL. Its activity is described in its website.§

The European Committee for Standardization ('CEN') produces harmonized standards to develop and validate test methods. It established several validated method of analysis for the determination of overall and specific migration limits. All the methods adopted by CEN are described in the CEN website.¶

FINAL CONCLUSIONS

Harmonization of legislation at the community level is moving forward quite slowly for various reasons. However, the harmonization continues and will continue as necessary to remove the technical barriers to the exchange and ensure more safety in the use of FCM.

EXPORT PACKAGING

Frank W. Green
Point O'View

Export shipments have been a major business for thousands of years. Even today, export cargo is carried by surface ships in the holds and on decks. Since the worldwide acceptance of containerization, a large percentage of exports is moved in cargo containers. A smaller, but growing, quantity of high-value and high-priority items is shipped by air as break bulk or in air containers.

There are no standards, rules or regulations, codes, references, or guidelines for the export packaging of specific products. In a sense, every item, destination, and form of shipment dictates the requirements. When packaging for export, every detail must be carefully considered. The products and packages will be completely out of the control of the shipper, and they may be "somewhere out there" for weeks. Export shipping is the test. The package fails at its weakest point. It is almost impossible to overpack. Export shipments must arrive in good order. They may have taken months to arrange and to produce. They cannot be easily replaced or repaired at destination.

HAZARDS OF EXPORT SHIPMENTS

The packaging engineer must understand and meet the requirements and hazards of various forms of shipments (see the Distribution hazards article).

1. Break bulk cargo in the holds and on the docks of oceangoing surface vessels of many types, sizes, flags, and ages.

§ http://crl-fcm.jrc.it/

¶ http://www.cen.eu/catweb/67.250.htm

2. Unitized loads in the holds of surface ships.
3. Containerized loads on container ships, on the decks and in the holds of cargo vessels.
4. Transport by lighters and barges; on open boats through surf to sandy beaches.
5. Rollon, rolloff (Ro-Ro).
6. Containerized air shipments plus ground handling and transportation.
7. Individual packages and unitized loads shipped by air freighters and in the holds of passenger planes.
8. Miscellaneous combinations of modes of transportation, handling, and intermittent storage in foreign places and unknown conditions.

Export packaging encounters at least two domestic movements that involve the usual hazards of handling, loading, dropping, compression, and moisture, plus the hazards of transportation. One major exposure is during the movement to the seaport or the gateway airport. The second involves the customs procedures and storage of the country of debarkation, multiple handling, unforeseen conditions of transshipment, and eventual delivery. Products must be packed for the toughest part of the journey and survive all of the exposures.

Only about 30% of the cargo losses can be classed as fortuitous losses resulting from sinking, stranding, fire, collision, seawater, or heavy weather. One ship is lost, somewhere in the world, almost every day. Approximately 70% of the losses may be preventable:

10% Water damage—freshwater, sweat, condensation, and saltwater.

20% Theft, pilferage, and nondelivery

40% Handling and stowage—container damage, breakage, leakage, crushing, contact with oil and other cargo, contamination, and failure of refrigeration or other equipment

During transit, cargo must withstand the conditions of rough seas, turbulent air, and substandard roads.

At sea, a ship may move in six different directions at the same time. A top-loaded container may travel 70 ft (~20 m) in each direction with each 40° roll as often as eight or nine times per minute. Figures 1 and 2 diagram the movements involved. The center point is least subject to these movements, but the shipper does not control the location and stowage of the cargo or of individual containers.

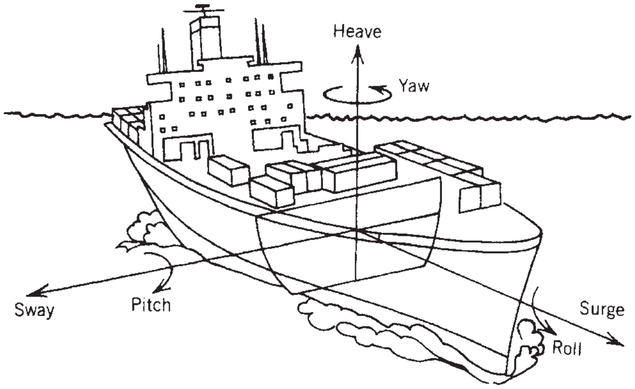

Figure 1. The six directions of motion of a ship at sea.

SPECIFIC CONDITIONS

With the above as a brief introduction to the hazards of international cargo movements, the packaging engineer should further study this subject and the conditions that may exist at the ports of embarkation and debarkation.

Brief descriptions of port conditions and equipment are provided in *Ports of the World* (1, 2) and similar publications. Information can be obtained from the cargo carriers regarding their equipment, methods of handling, routes, stops, trans shipment, and other details. They can also provide some information about local conditions at the port facilities. Some marine underwriters may have constructive suggestions. The consular staffs and the commercial development departments of each country are well informed. Foreign sales agents can provide details about the customers and their facilities, needs, and preferences. Too often the shipper is uninformed and relies on gossip rather than acquiring a realistic understanding of this complex subject.

PRODUCT ANALYSIS

Every facet of the products to be exported must be analyzed, and the potential problems, even marginal ones, must be identified. Export handling and shipping expose the weaknesses if they are overlooked.

Corrosion and Mildew. All metals must be protected against water and moisture for surface transportation and even for air shipment from or to humid and tropical areas. All natural materials (e.g., leather, cotton, wool, and paper) must be protected against moisture, fungus, and mildew.
