
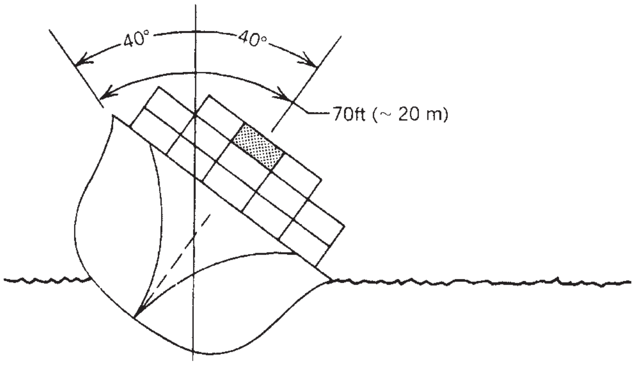

Figure 2. The distance (~20 m) traversed by a top-loaded container in a 40° roll.

Problems can begin because the products are not thoroughly cleaned for fingerprints, cutting or cooling oils, dirt, and foreign matter, or because of unnoticed rust, mildew, or local moisture in the packages. In transit and in storage, the moisture and mildew, condensation, or sweat may find the weak point in the packaging and cause irreversible damage. If the product surface is critical or if the item is expensive or choice, the damage may be total.

When the problems are identified, corrosion inhibitors (special oils and petrolatums) or properly used vapor-phase inhibitors and waterproof wrapping are applied. For electronic equipment and critical metal surfaces or hidden areas, desiccants with sealed moisture-vapor barriers are used. If possible, the critical sections or elements are removed from the larger units and packaged separately (inside the larger box or a sheathed crate). A small vapor-phase inhibitor or moisture-vapor barrier package provides better protection more economically than a thorough package for an entire unit. Containerization does not assure protection against water damage or moisture. Air shipment does not offer full protection because of entrapped atmosphere, and the cargo is on the ground more than in the air.

Pilferage and Nondelivery. It is essential to recognize that the exported products may stay days or weeks in conditions where pilferage is easy. Therefore, the packages should not identify the contents as worth pilfering for private use or resale. Identification of the product on the outside of the package by brand name, manufacturer's name, or the shape and size of the box is an open invitation to steal. A damaged package exposes the contents for pilferage.

Cigarettes, liquor, cameras, stereos, jewelry, furs, small appliances, and many other items are ideal targets for pilferage. Many consignees use code identification because their names on the packages would encourage pilferage. Some even have the items delivered to a "front" to avoid identification.

With the potential problem of pilferage identified, steps should be taken to assure special handling and accountability. Packages should be stored in separate locked areas and on board in lockers or safes.

Nondelivery occurs when the packages are stolen, destroyed, lost, unloaded and left at the wrong destination, or misdelivered. Adequate, permanent, and prominent markings help to avoid some of these problems. Unitizing or using master overpacks is also helpful.

Breakage. The internal weaknesses of electronic products equal the fragile construction, design, or materials of many products; any part that extends; and any item that is not in balance are all subject to breakage or physical damage. It may be necessary to protect the package from the product because of a dense weight load or severe imbalance.

Any product that is hard to handle, tends to fall over, or is especially awkward for any reason must be given special consideration. Often, production equipment requires special handling, and provision must be made in the package. Skids and other devices may help to keep the equipment on its base and handled properly.

Cushioning, blocking, and bracing are all essential (see the Cushioning design article). Built-in lifting eyes or other devices, special skids and pallets, and guide marks for the stevedores are helpful. On large items, the balance and the lifting points should be marked. Occasionally, an experienced exporter includes special instructions and photographs with the documentation and on the outside of the packages or crates.

Contamination. Some products can be spoiled or damaged because they can absorb the odors or fumes from the other items that may be in the same container or nearby in the holds or warehouses. Often the people who work with these items ignore or forget these problems.

Precaution can be taken to specifically request the carriers not to expose the items to adverse conditions. Sealed moisture-vapor barriers may give further assurance. Packages should be marked to indicate that they should not be stowed with potentially harmful cargo.

If photographic supplies and other sensitive items are exposed to excess heat, light, or moisture, then damage can result. This type of problem must be identified, the product shielded in the packages, and full instructions provided to the carriers.

Hazardous Materials. The shipper must identify any hazardous materials. These should be separated and given special documentation and packing under strict rules and specifications. It is essential that each hazardous material is classified and properly identified on the packages, with the correct and legal labels.

It cannot be assumed that compliance with domestic regulations will assure foreign acceptance of the shipments. This requires special study. Improperly labeled cargo may not be shipped and can cause great confusion (see the Standards and practices article).

MARKS AND SYMBOLS

It is essential that proper markings and symbols be used. Even a poor package, adequately closed and marked, has a good chance of being delivered in reasonable order. An excellent package that is not adequately marked may never reach its destination.

Only those markings that are essential and appropriate should be used. Any other markings, or too many, can be confusing and serve no purpose. New, clean packages with no advertising or other printing should be used. The selected markings can be printed by the manufacturer of the packages or stenciled permanently. Crayon, chalk, marking pens, tags, and cards should not be depended on.

Code marks for the name of the consignee and of the shipper (if used) are best for products that might be pilfered (see the Code marking and imprinting article). These and port marks should be large, clear, and applied on the side, end, and top of each package (Figure 3). Required weight and dimension information should be clear.

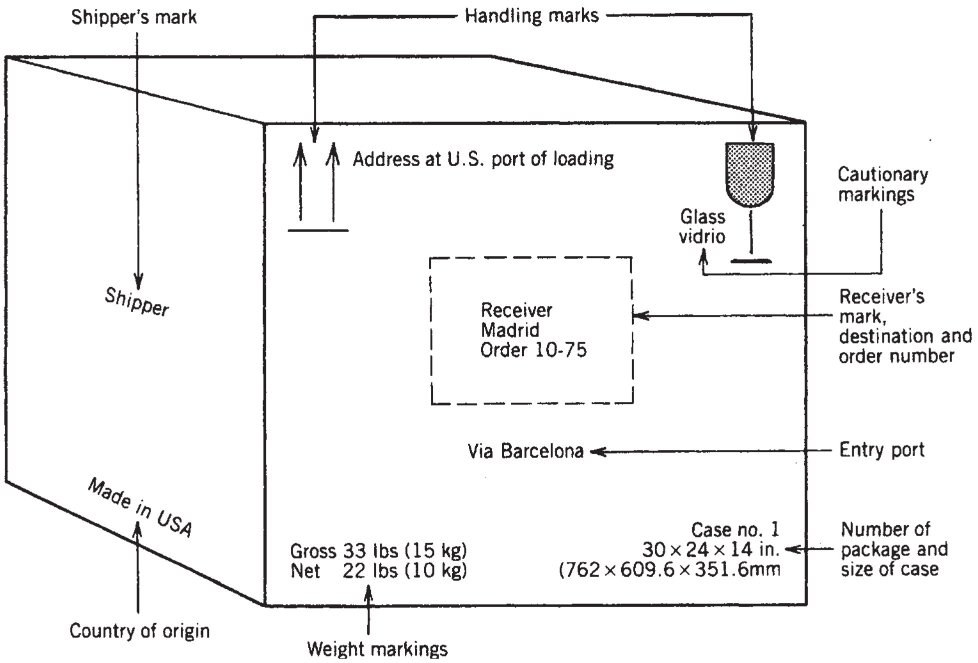

Figure 3. Assignment of codemarks for shipping.

Handling precautionary instructions should be printed or stenciled on the outside in the language of the destination country (Figure 4). Many times the cargo handlers cannot read the language of the country in which they are working. Pictorial precautionary markings may be the most helpful (Figure 5). In general use, they are recognized and have replaced a wide variety of symbols used in the past. Regardless of the markings, it is essential to package adequately and protect the products being shipped because the precautionary marks are frequently ignored.

When a large number of units are being moved in a single shipment, it helps to corner-code mark them with a distinctive symbol or to color code the opposite top corners with triangles or stripes. If a series of shipments is being sent to the same destination to be collected and staged for further inland shipment, the same method of coding should be used. This helps to reduce the number of stray packages.

When a number of packages are being shipped together, they should be numbered on the packages with the same numbers as the documentation. If there are 18 packages in a shipment, they should be numbered on the packages as 1/18, 2/18, 3/18, …, 18/18. Thus, if a package is missing, it can be checked on the documents for size, weight, and contents.

PACKAGING FOR EXPORT

Some exporters use their domestic packages for export. This is not good practice, but it may be economical. Preparation of domestic packages for export includes the following:

1. Waterproofing by liners, overwrapping, or overbagging.
2. Master packing small to medium size packages.
3. Unitizing a quantity of packages with suitable strapping, adequate pallets, and shrink or stretch films.

Unless conditions are thoroughly understood, this applies even for air shipments because of ground handling, storage, and trans-shipment.

Packaging for Break Bulk. This is the traditional form of shipment for small and large items stowed in holds or on the decks of surface ships. The individual packages are handled by the ship's gear individually or on stevedore pallets. They are pushed or moved manually, or sometimes by roller conveyor or lift truck, out of the square of the hatch to wings. They are stacked with other cargo and used to help brace the loads against movement as the vessel rolls and pitches. There is a loading plan specifying that the lightweight items should go on top of the heavier and more rugged cargo and that special classes of products should be given special treatment. The plan must also consider late cargo and the sequence of discharge at ports of call. Packages must withstand a static load of similar material 20 ft (6.1 m) high without distortion or rupture throughout the intended voyage. This applies in the lateral as well as the vertical direction. Problems of shock and vibration may be 50 times those normally experienced in domestic transit. Moisture is usually encountered during a sea voyage at deckside, in customs, and in lighters. Wooden boxes, sheathed crates, and cleated "export" plywood are appropriate for break bulk shipments when properly constructed, packed, and secured.

Figure 4. Precautionary handling instructions.

Unitized Loads. In addition to the details already covered, it is necessary to note that the outside boxes in unit loads may be chaffed by other cargo during the ship's movement. The 20-ft (6.1-m) static load rule applies. It may be necessary to provide a wood or heavy-duty cover to distribute the superimposed weight and to protect the individual packages.

Containerized Loads. Cargo containers provide physical protection so the 20-ft (6.1-m) guideline does not apply. The moisture problem can sometimes be intensified because of minimum air circulation. Containers should be secured and loaded evenly from end to end. Containers should be thoroughly cleaned and inspected before use. There are special containers for unusual loads and conditions. The packages may be removed at portside and then face another domestic shipment to the consignees. Customs inspectors in some foreign ports do not restuff containers the way they were shipped. They sometimes repack with the larger and heavier items on top of the smaller items, for example.

Lighters, Barges, and Open Boats. Some modern barges may be similar to large containers. Lighters and open boats may provide the most difficult tests of the trips. The handling is doubled and may be crude or rough, partly because of greater exposure to sea water, fog, mist, and spray. Sound packaging is required.

Rollon, Rolloff (Ro-Ro). In this method of shipment, highway trailers and other units on wheels can be loaded and secured in the vessel for relatively short voyages. These modern ships offer good conditions, and the handling is minimized; however, the loading, unloading, customs, and storage are portside.

Containerized Air Shipments. If the containers are properly loaded and precautions are taken against moisture in the packages and on the ground, this method of shipment may be the safest. Domestic packaging can often be used if the delivery is known to be normal.

Individual Units by Air. Unit loads by air freighters and individual packages unitized by the airlines for shipment on air freighters may be moved automatically and have little or no handling or moisture problems. Individual packages in the holds of passenger planes, however, may experience many rough handlings. In the cargo space, the

handler usually cannot stand up straight and often resorts to crude methods of moving packages. The small items may be rolled or thrown and will not be thoroughly secured.

Miscellaneous Modes. Packages shipped to inland points may experience a good deal of rough handling, storage under unexpected conditions, and exposure to pilferage and corrosion.

GUIDELINES

If shipments can be fully controlled by the shipper and the consignee by containerization, documentation, representation at both ends, and complete understanding by all parties, there can still be serious trouble unless adequate packaging is used and properly implemented. It is almost impossible to design and develop packaging that is too good for export shipment.

EXTRUSION

J. A. Gibbons
Egan Machinery Company

INTRODUCTION

Extruders are the most common machines in the plastics processing industry. They are used not only in extrusion, but in most molding operations Molding and extrusion are the basic techniques of forming polymers into useful shapes. The molding process, which is normally intermittent, can fix three dimensions (height, width, length) of an object. The continuous extrusion process through a die can fix only two (height, width). These two processes are usually complementary rather than competitive and produce a wide variety of products as diverse as pigmented pellets, threaded closures, and refrigerator liners (1).

The extrusion process in which an Archimedean screw rotates within a cylindrical barrel is probably the most important polymer processing technique used today. It is used to manufacture continuous profiles such as fibers, tubing, hose, and pipe; to apply insulation to wire; and to coat or laminate paper or other webs (see Extrusion coating). This article, however, deals primarily with single-screw extruders for compounding polymers and producing pellets, for producing rigid or foam sheet, and for making blown or cast films.

The extrusion principle was first employed about 1795 for the continuous production of lead pipe. The first patents on an Archimedean screw extrusion machine were granted to Gray in England (2) and Royle in the United States (3). During the nineteenth century the machinery became refined for manufacturing rubber, gutta-percha, cellulose nitrate, and casein products. Modern extrusion technology as applied to synthetic thermoplastic polymers began in about 1925 with work on PVC (see Poly(vinyl chloride)). The first screw extruder designed specifically for thermoplastic materials appears to have been made by Paul Troester in Germany in 1935 (4).

SINGLE-SCREW EXTRUDERS

Modern single-screw extruders designed to process thermoplastic resins normally are <1 in. to 12 in. in diameter, although larger extruders have been built. The most common diameters for production-sized machines are 2–8 in. (51–203 mm). Figure 1 shows an 8-in. vented extruder with a barrel length of 32 diameter, and a 600-hp (447.4 kW) drive. The main features of an extruder are shown cross-sectionally in Figure 2.

The solid polymer fed to the extruder may be in the shape of powder, beads, flakes, pellets, or combinations of these forms. The extruder conveys, melts, mixes, and pumps the polymer at high temperature and pressure through a specially shaped die. The die's configuration and the solidifying or cooling process determine the shape of the product.

All extruders consist of a barrel, a screw, a drive mechanism, and controls. The heart of the extrusion process is the screw. It is fashioned with a helical thread or threads, along with varying channel depth. The function of the screw is to convey material and generate pressure in order to produce pellets or other shapes. In the case of a solids-fed screw the function is expanded to include solids conveying, compression, and melting. Rotation of the screw accomplishes all these functions.

Successful operation of an extruder depends on the design of the screw. The depth and length of each zone of the screw is determined by the product to be run. Barrier flights and/or mixing sections are sometimes built into the screw to improve its efficiency in melting and delivering a homogeneous polymer to the die at the proper temperature and pressure. The profile of the melting process in a mixing screw is shown in Figure 3.

An extruder interior schematic is shown in Figure 4. Here the solid resin is introduced into the hopper and, through the action of the rotating screw, is conveyed into

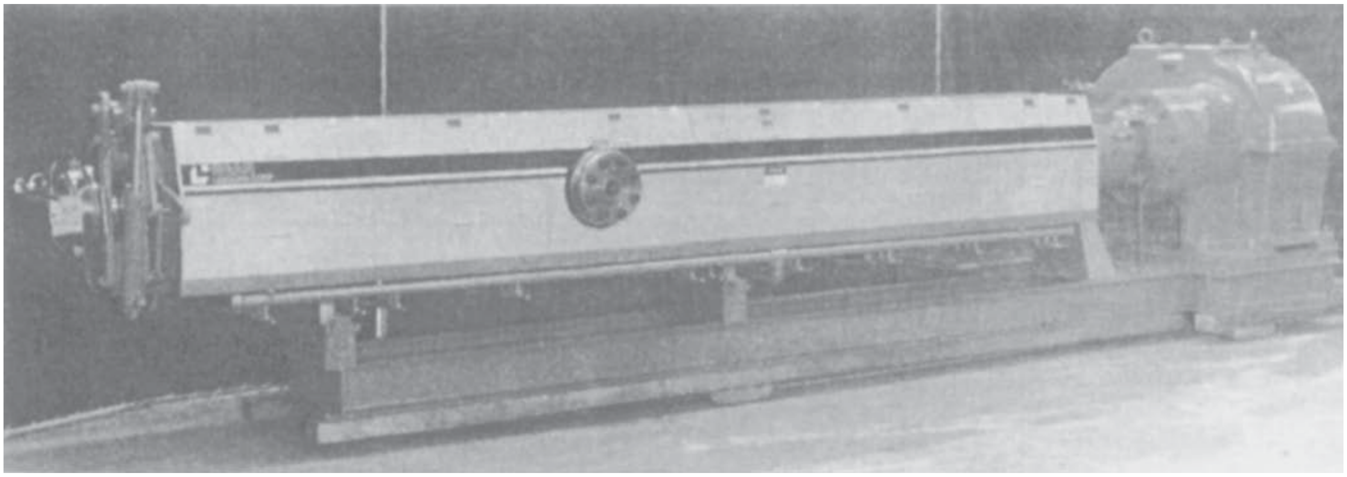

Figure 1. An 8-in. (203-mm) 32:1 L/D vented extruder.

the heated barrel. The screw in this section is feeding or conveying the solids and hence is quite deep. The geometry of the screw is such that the depth decreases in the transition zone, and the solids start to melt. Melting results from the shearing action of the screw as motor horsepower is converted into frictional heat. Barrel heaters are used for start-up and to supplement the melting process. The melt continues to be pumped toward the discharge, or die end, of the extruder through the metering section of the screw. (Metering is pumping at a given rate in a uniform manner, within close temperature and pressure tolerances.) The die then forms the polymer in the desired shape. Downstream cooling equipment solidifies and maintains that shape.

Screws are cut from alloy steel. The tops of the conveying flights are hardened or surfaced with special alloys for extended life. The clearance between screw and barrel is close. In operation, the screw floats in the barrel on a layer of melted polymer.

The barrel, or hollow cylinder in which the screw rotates, is manufactured from machined steel and built to withstand pressures of 7500–10,000 psi (51.7–68.9 MPa). Barrels are also lined with special alloys or hard-surfaced to extend life. The length of a barrel is defined as a multiple of its diameter (i.e., *L:D* ratio of 32:1 = a barrel:screw 32 diameter long). The length of an extruder barrel is determined by the polymer and process involved.

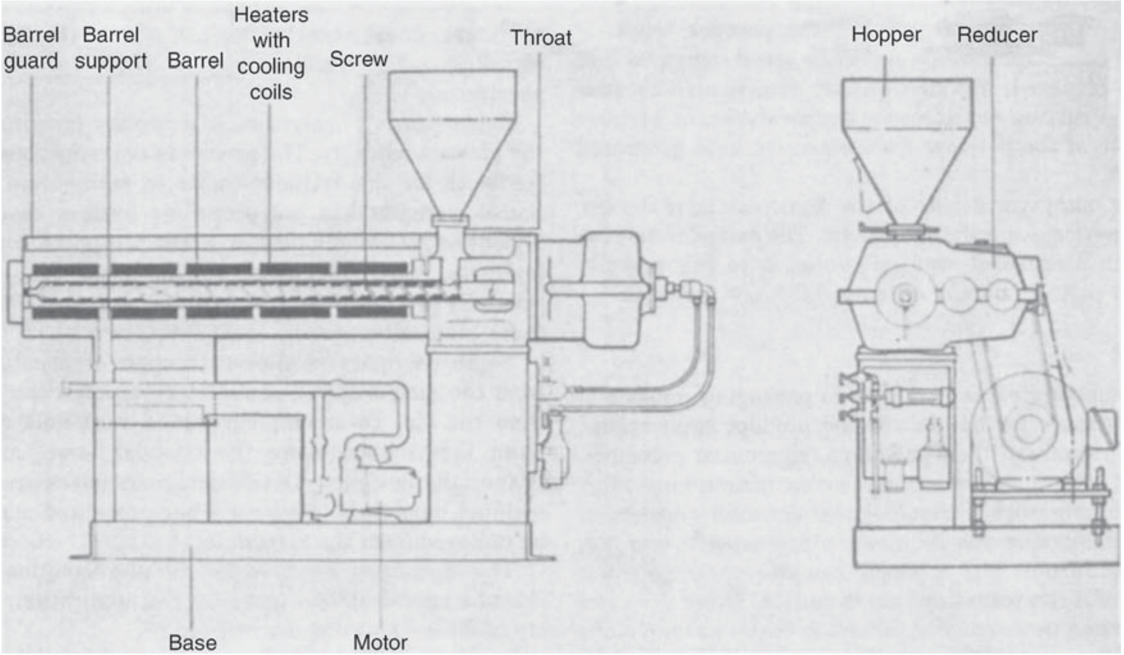

Figure 2. A cross section of an extruder.

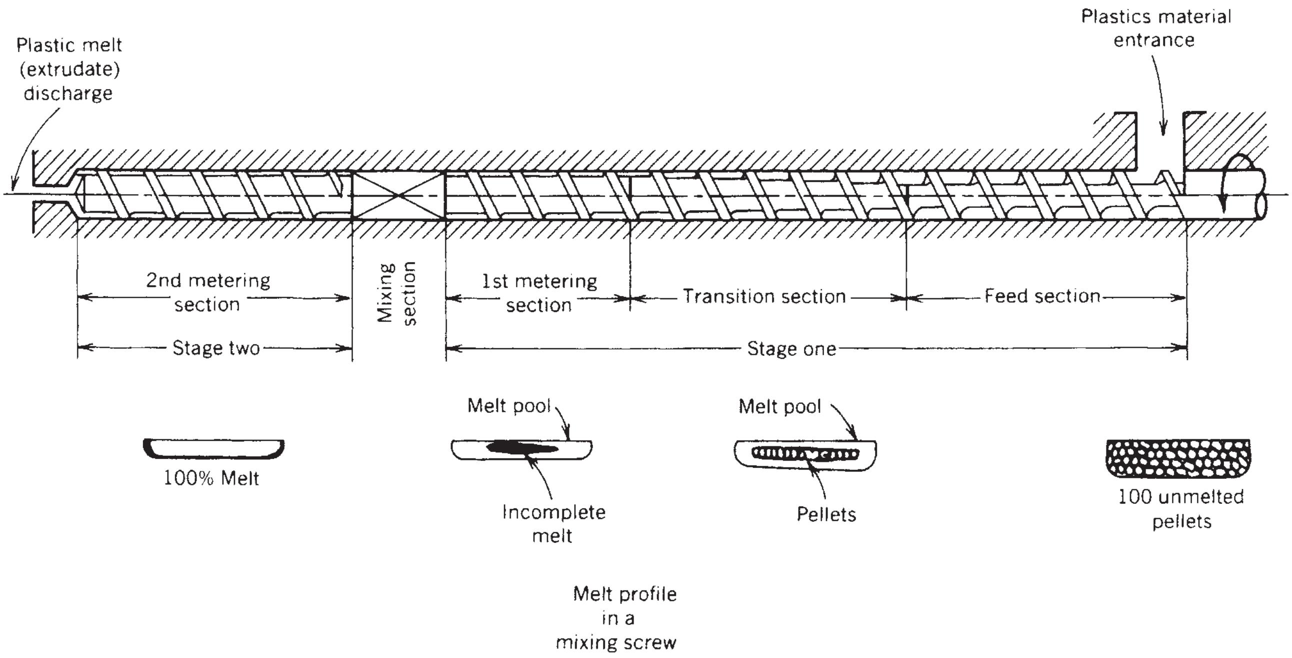

Figure 3. Melt profile in a mixing screw.

Extruders must be heated and cooled. Electrical heating or fluid heating can be used on the barrel. In electrical heating, resistance heating elements in various forms surround the barrel. Tubes for cooling fluid, cast in aluminum, also contain heating elements. Some barrels are built with jackets through which heating and cooling fluid can be circulated. Extruder barrels are usually divided into zones of specific lengths, each of which can

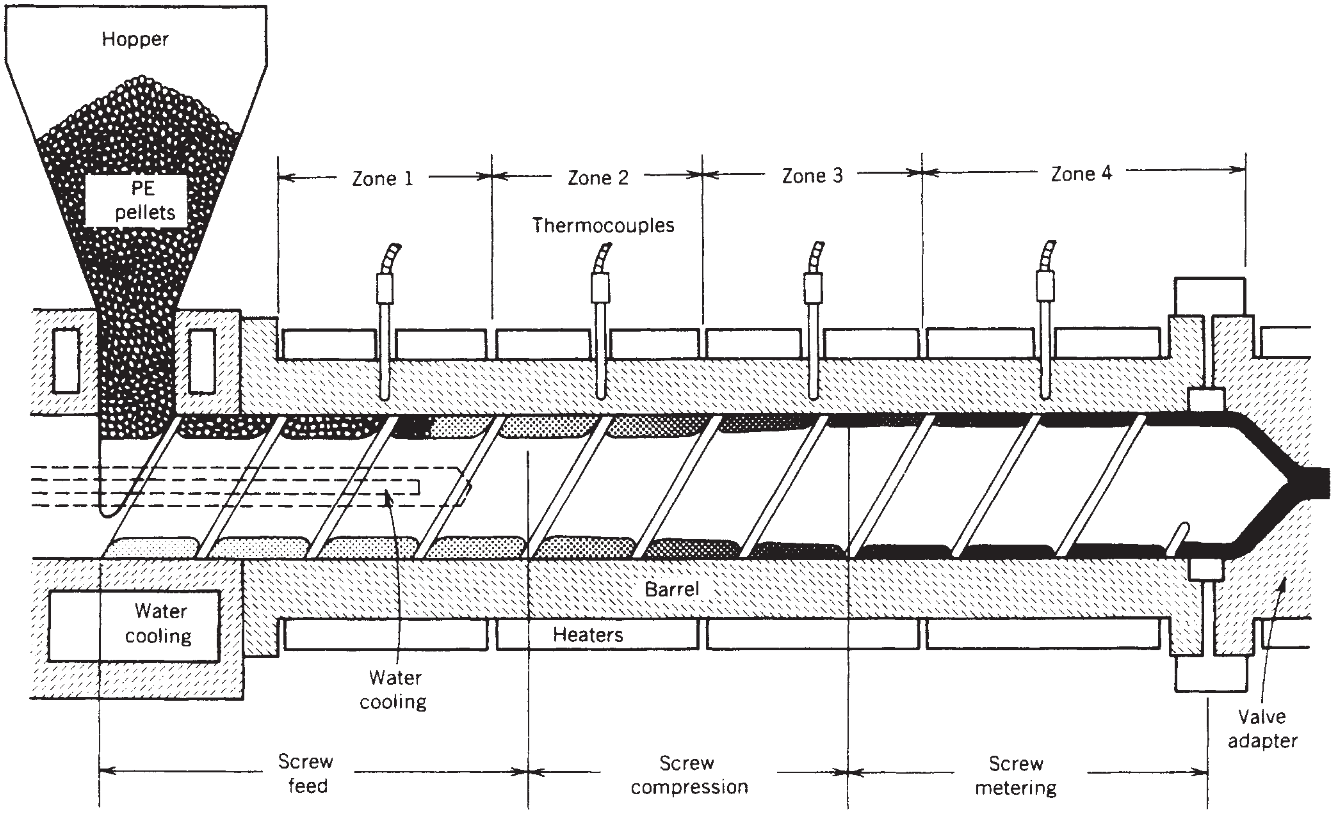

Figure 4. Schematic of the interior of an extruder.

be set at a desired temperature. The zones are controlled by instruments or by microprocessors. Thermocouples are normally used to sense temperature and to signal the action of the controller (see Instrumentation).

The drive mechanism consists of a motor and a gear reducer. The motor is usually a variable-speed dc drive system with the ability to run a speed range of slow to fast in a ratio of approximately 1:20. The gear reducer is used to lower the speed of the motor output shaft (e.g., 1750–2000 rpm top speed) to the desired screw rotation speed. Most extruders operate in a variable screw speed range of up to 200 rpm, but speeds considerably lower are used with certain polymers, especially on very large machines. The screw rotation speed depends on the diameter of the extruder, the polymer to be extruded, and the production rate desired. The limiting factor in a given-size extruder is quality of the product, which is dependent on the melt quality. As screw speed increases and more rate is achieved, the melt quality deteriorates because of nonuniform mixing or excessive temperatures, or because of degradation of the polymer from excessive heat generated by high shear.

COMPOUNDING

Extrusion compounding as it relates to packaging consists of preparing polymers for use in specific product applications. Mixtures of polymers, filled polymers, pigmented polymers, and a host of other polymer additives constitute a huge market. Compounding with a single-screw extruder consists of mixing and dispersing one or more minor constituents (e.g., pigments, stabilizers) into a major constituent, a polymer. The product of a compounding line is pellets. These are used by the converting industry. Converting is the process of melting the pellets and producing extruded sheet, film, injection-molded parts, and so on.

Compounding can be separated by functions: resin-plant extruding, blending, reclaim, and devolatization.

Resin-plant extruders take the products from a polymerization operation and make pellets. The feed to these machines can be powder, granules, other irregular shapes, or even a melt. A melt extruder has a molten feedstock and only generates pressure, whereas a plasticating extruder has the job of turning solids into a molten mass and then generating pressure. During pelletizing, stabilizers and processing aids are combined with the polymer (see Additives, plastic).

A blending extruder is used to mix feedstocks of compatible polymers, or different viscosities of the same polymer. The blending operation tailors the physical properties to meet a specific end use.

Reclamation

Reclamation of polymers is an important segment of the plastics industry. Film producers are satisfying sustainability calls and reducing costs by replacing virgin plastic with reclaim. Edge trimming is necessary when it comes to cast films. The trims are recycled by means of a special extruder, fed back in-line, and used for the encapsulation of the film edges. For blown film, recycled material can be used in the center layer of the film structure, and virgin layers prevent recycled material from contacting packaged food. Edge encapsulation prevents barrier material from making it to the edge of the film, which would preclude that scap from reintoduction (5).

The problems of reclamatiom are numerous because the feedstock for the extruder comes in many sizes and shapes. Some examples are polypropylene battery cases, polyester X-ray film, soft-drink bottles, bread wrappers, unusable foam products, fibers, filaments, and off-grade film of all kinds. Specially designed extruders must be used for processing these materials.

Some polymers require extraction of moisture or gases from the melt before a satisfactory product can be produced from the die. To accomplish this, a vent hole with vacuum pump is introduced along the extruder barrel, and the screw is specially designed. Devolatizing extruders are used where residual monomer, water, or other unwanted materials must be removed from the extrudate.

The machinery required for the aforementioned processes must be specifically designed for the application. A wide variety of design features are utilized.

Specially designed extruders are used for the addition of short fibers to thermoplastic polymers (6). This is done to improve the physical, mechanical, and structural properties of the virgin plastic. Cost-per-unit volume can also be improved. The extruder uses a three-stage screw. The polymer is melted in the first stage. The short fiber, usually chopped fiberglass, is screw conveyed into the side of the extruder barrel. The glass and polymer are mixed in the second stage. The third stage allows venting and pressure generation for the die at the exit. A cross-sectional view of a side-fed extrusion system is shown in Figure 5.

Another unique design is used for reclaiming. Because the bulk density of most of the scrap-plastic items is low, use of a dual-diameter extruder has become prevalent. The feed end of the screw has a larger diameter, so there is a greater volume for the entering light fluffy feedstock. This facilitates high production rates.

Vertical extruders meet special needs such as limited floor space, or other plant layout requirements.

BLOWN AND CAST FILM

Film is a relatively thin [usually $\leqslant 10$ mil ($\leqslant 254\,\mu$m)] flexible web made from one or more polymers, either blended or coextruded (see Coextrusion, flat; Coextrusion, tubular) but not to be confused with a fabricated extrusion-coated or laminated web (see Laminating; Multilayer flexible packaging).

Films are used in flexible packaging (for overwraps, bags) as industrial wraps (stretch and shrink films), in medical and health care products (disposable diapers, backings, hospital bed liners), in agriculture (mulch films), for sacks (drum liners, garbage bags), and as laminates (aseptic container stock). (Some packaging overwrap films are produced by casting a solvent solution of PVC resin on a stainless steel belt and evaporating the solvent as the belt

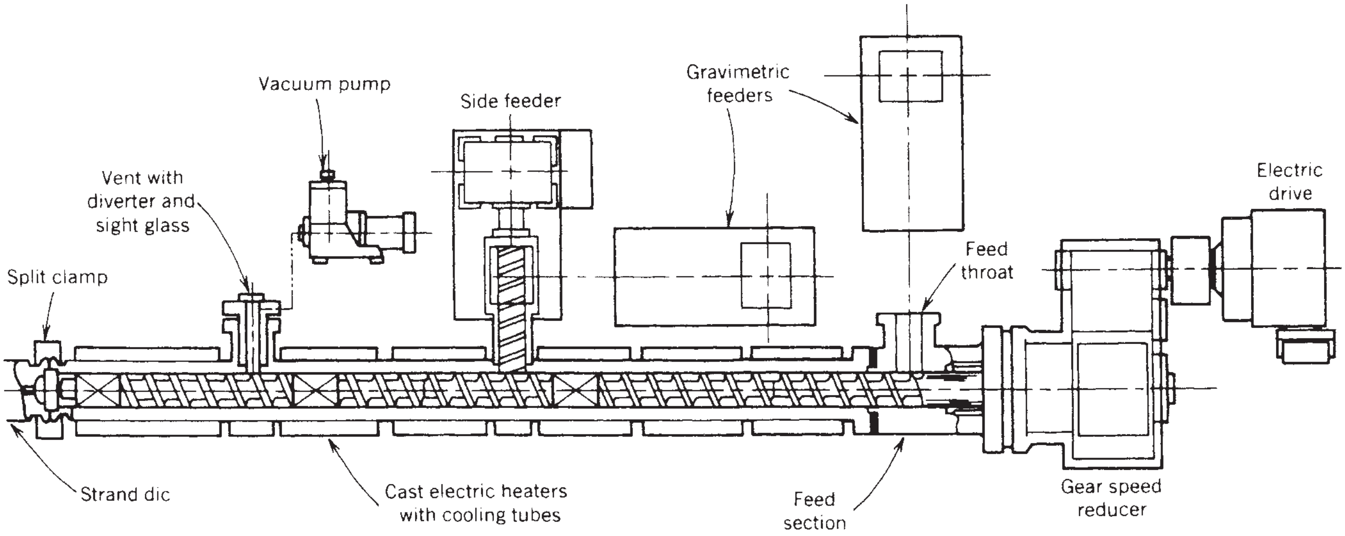

Figure 5. Cross section of a side-fed extrusion system.

travels through a heated chamber. This process normally uses a pump to distribute the solution through the die. Solvent casting is beyond the scope of this discussion.)

The same basic extrusion processes are used for producing both blown and cast film. The first two steps, melting and metering, are part of the extrusion process described above.

Forming

In the forming process, the polymer is squeezed through a die as it leaves the extruder, to form a thin uniform web. The cast-film process produces a flat web. In the blown-film process the die shapes the polymer into a tube. This latter process is more versatile because it can produce not only tubular products (bags), but flat film as well, simply by slitting open the tube. Key to the success of both processes is the die, which must distribute the polymer uniformly.

Orientation

In the orienting stage of the blown-film process, the tube is blown up into a bubble that thins out, or “draws down” the relatively thick tube to the required product gauge (thickness). In certain blown-film processes, the polymer is blown downward to produce films with special properties. The ratio of the diameter of the blown bubble to the diameter of the die is called the *blowup ratio*. Most LDPE (see Polyethylene, low density)-blown films used in packaging are made using blowup ratios of 2.0:1–2.5:1. The blowup ratio is changed depending on the characteristics of the resin being extruded and the properties desired in the film. In cast film, the molten polymer is also drawn down to the desired finished gauge. Drawdown ratios between 20:1 and 40:1 are typical. (If a polymer exits a die at 40 mils (1 mm) thick and finishes up 1 mil (25 μm) thick, the overall drawdown ratio is 40:1.) In the orientation process the long molecules of the polymer line up in the stretching direction, which improves the film’s strength in that direction. A key difference between the two filmmaking methods lies in the manner of orientation.

Because both edges are free in cast film, it is drawn down only in the direction the material exits the die (machine direction). Because cast film is drawn in one direction only, it usually exhibits excellent physical properties in the machine direction, and poor properties in the cross-machine direction. The cast-film process is shown in Figure 6. In the blown-film process, the extruded tube is stretched in two directions: as it is blown into a bubble and as it is drawn from the die in the machine direction by the adjustable speed drive system. This results in strength properties that are more uniform and can be balanced depending on the blowup ratio and the takeoff speed. Figure 7 illustrates the blown-film process.

Certain films can be biaxially oriented to enhance properties for specific packaging uses such as shrink films (see Films, shrink) or overwrap. The blown process produces a thick tube that is then reheated and blown out while increasing the take-away speed to maximize orientation in both directions. The cast process extrudes a thick, flat sheet that is chilled, then reheated and stretched in the machine direction and then reheated and stretched across its width by means of a tenter frame. The most common plastic materials to be biaxially oriented are polystyrene (see Polystyrene), homopolymers and copolymers of polypropylene, usually coextruded (see Film, oriented polypropylene); and polyester (see Film, oriented polyester). These films are then coated to enhance heat-seal or barrier properties.

Quenching

After the polymer has been extruded, it must be solidified into finished film. In blown film the quenching (or cooling) process is achieved by convection, by blowing air on the outside and sometimes on the inside of the bubble. Air rings at the die exit direct and distribute air uniformly to the bubble. In cast film the web leaves the die and is

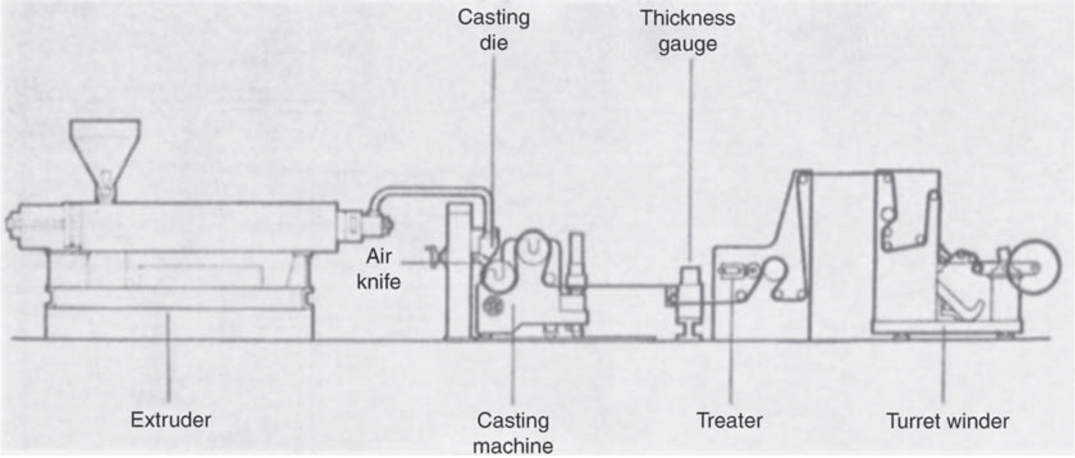

Figure 6. Cast-film line.

deposited on the surface of a driven cooled roll. There are usually several rolls in series (normally called "chill rolls"), arranged to cool the polymer by conduction, or direct contact.

Conduction cooling is quicker than convection cooling, and this has an effect on the clarity of the film. Because convection cooling (quenching of blown films) is relatively slow, more and larger crystals form in the film, as compared to those formed in the casting method. Because interfaces between crystals scatter light, blown film tends to be more hazy than cast film. This "haze factor" normally rules out use of blown film where clarity is very important, such as food overwrap applications. Because conduction cooling is more uniform and rapid than convection cooling, cast film has less gauge variation than blown film. This superior flatness means the film can be handled better in subsequent converting operations such as multicolor printing and laminating. These operations are performed at high speeds and cast film is preferred to minimize scrap.

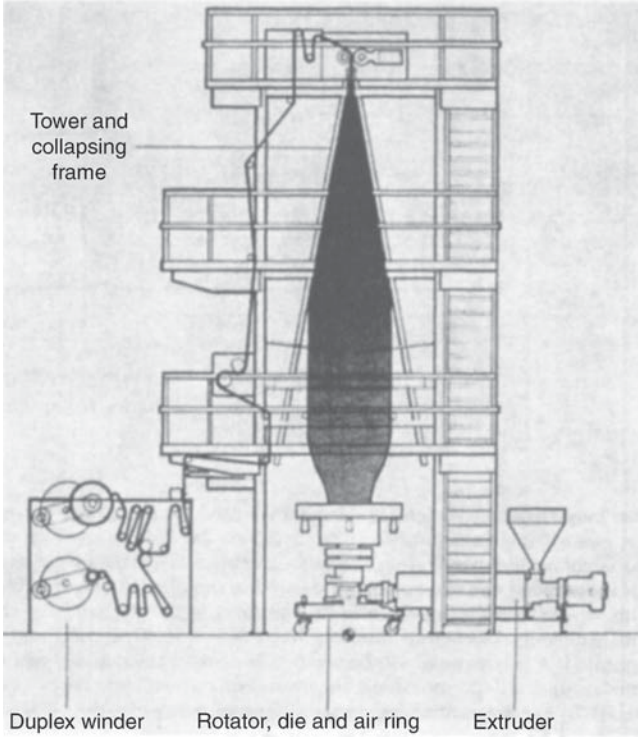

Figure 7. Blown-film line.

Gauge Randomization

In practice, perfectly flat film cannot be made, due to die geometry and machine tool constraints. Blown-film thickness variations of ±7% and cast-film thickness variations of ±3% are typical. Variations in thickness are frequently evidenced by gauge bands. If relatively small variations become significant at the film winder or at a later converting process (printing, laminating), adjustments must be made to distribute them. In the blown method, variations in the film are usually randomized by rotating or oscillating the die to distribute the gauge variations over the finished web. In cast film, because a flat web with two free edges is produced, the downstream winder with edge trim slitters is normally oscillated across the film, winding only a portion of the cast web (see Slitting and rewinding). This generates waste film that must be recycled or scrapped.

It is common to measure sheet and flat-film thickness automatically after the die, compute and average thickness, and use the signal to control screw speed and thus control thickness in the linear direction. Special casting and sheet dies that operate in conjunction with a computer and a thickness-measuring gauge automatically control the film thickness across the width of the die as well.

Wider lines and thinner layers are the current interest in film extrusion. Dies are becoming wider and layers are shrinking as film extruders look to optimize properties and output as economically as possible. Extrusion Dies Industries (EDI) report that 3.1 m dies have grown to 4.7 m and even 5.3 m. It is hoped that cast prolypropylene films could then compete with biaxially oriented polypropylene (BOPP). For the clarity that is achieved with BOPP, the film used must be quenched rapidly. This is achieved by running the chill roll slowly. At EDI, the Multiplier feed block makes films with hundreds of layers possible. Kiefel says customers are looking past dies to its Perfect Cool system in order to produce more layers. Most of the bulk equipment used at present is still three layers (5).

RIGID SHEET EXTRUSION

Film thicker than 0.010 in. (0.25 mm) is normally defined as sheet (see Films, plastic). It is thermoformed (see Thermoforming) into objects that hold their shape, a property that film does not possess. Extruded sheet is thermoformed into cups, lids, containers, packaging blisters, automotive panels, signs, and windows. The machinery required for the manufacture of sheet usually extrudes the polymer horizontally into a nip formed by two hardened cooling rolls that define the final product thickness and surface. Additional rolls and a conveyor for more cooling and pull rolls and a winder or shear complete the sheet extrusion line (see Figure 8). The extruder is often vented to remove low levels of moisture from polystyrene and ABS. Sheet is traditionally extruded horizontally from a die similar to a flat-film die, but with specially designed interior flow surfaces to suit the particular polymer. Restrictor bars are usually used for added gauge uniformity (see Figure 9). Sheet dies are often more massive, to minimize distortion.

The takeoff unit for extrusion of sheet usually consists of a cooling and polishing unit (C & P unit) having three driven, highly polished, chrome-plated rolls; a roller conveyor; and a pair of driven rubber-covered pulloff rolls. The C & P unit serves three functions: cooling, polishing, and gauge control. In some cases, one or two of the chrome-plated rolls are embossed to yield a sheet with specific surface qualities. Roll diameter is contingent on the output of the extruder, the linear speed of the equipment, and the level of heat transfer required. High-capacity multiple-zone temperature control units are often built into the C & P unit, which must be of rugged construction to eliminate vibration. Sheets up to approximately 0.050 in. (1.3 mm) thick can be wound onto rolls; thicker sheet is cut to desired lengths. In some cases the sheet is pulled directly into a thermoforming machine, providing an in-line, pellet-to-part operation.

FOAM SHEET EXTRUSION

Extruded polystyrene foam (see Foam, extruded polystyrene) sheet material used for making egg cartons, meat and vegetables trays for fast-food packaging, and similar applications continues to find new uses, ranging from decorated picnic ware to coated and laminated sheets. Polyolefin foams are used for packaging materials (see Foam cushioning), insulation, and wire coverings. Most of the world's extruded foam is produced on tandem-extrusion equipment. Although the extrusion process is relatively straightforward, special equipment and controls are needed.

The first extruder has a long barrel and is used to mix a nucleating agent uniformly throughout the melt of a base polymer. The nucleator, typically a selected filler, controls foam cell quality. In effect, it creates imperfections in the polymer melt, forming nucleation centers for cells to originate.

About two-thirds down the primary extruder barrel, the gas blowing agent is introduced. At this point the melt is homogeneous and at a pressure of 3500–4000 psi (24.1–27.6 MPa). Fluorocarbons are the usual agents, often blended with hydrocarbons, such as butane or isopentane, to reduce costs (6). Carbon dioxide blended up to 35% with either fluorocarbons or hydrocarbons reduces material costs still further.

The product mix is fed through a screen changer for filtering. Then the mix, still under pressure, is fed into a larger extruder that cools and discharges the product under conditions to allow extrusion through the annular die. This is achieved through use of a low-speed screw rotating in a barrel cooled by high flow rates of water. Foaming occurs only outside the die lips.

The foamed tube is expanded to 3.5–4 times its diameter and extruded horizontally over an internal cooling and sizing mandrel that cools and orients the foam and supports the tube as it leaves the die. After the tube passes

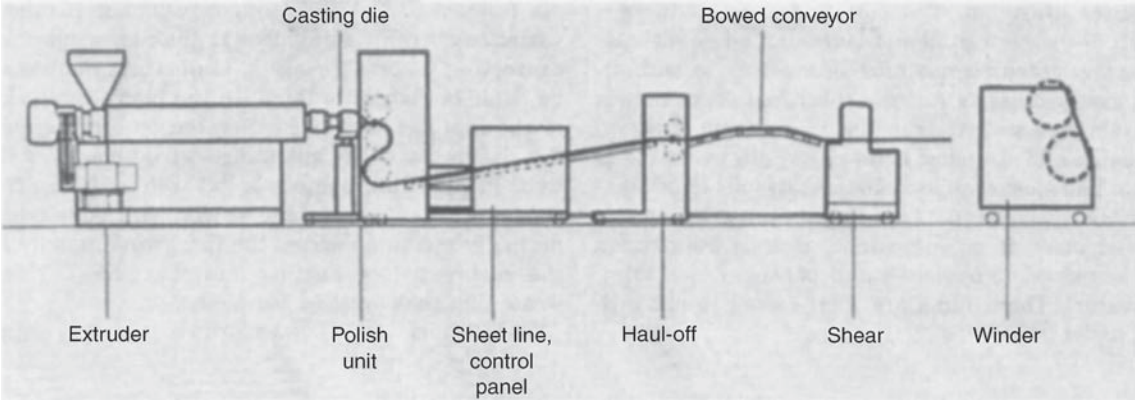

Figure 8. Sheet line.

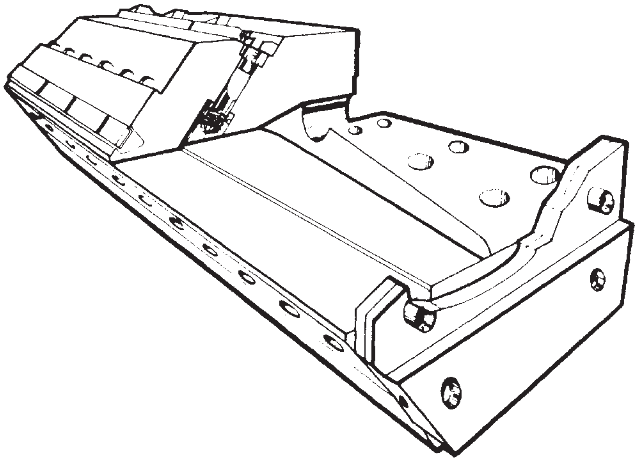

Figure 9. Cutaway of sheet die with restrictor.

along the mandrel and a slitting unit, the two webs are pulled through nip rolls. From the nip rolls the webs are wound on either dual-spindle turret-type or cantilevered winders. Large-diameter reels are required to handle foam sheet.

Sheet weight per inch (or centimeter) is governed by the amount of blowing agent incorporated in the mix. Sheet thickness is determined by adjustment of the die lips and the take-off speed of the nip rolls. Sheet orientation is controlled by a combination of die gap, blow-up ratio, and line speed.

Accurate metering equipment is needed for a good finished product. The blowing agent system calls for sophisticated controls to safely handle high-pressure gas products on the production line. The difficulties of operating a two-extruder system have been reduced through the use of microprocessors that automatically monitor and control a multitude of functions on the extrusion line.

EXTRUSION COATING

Michael G. Alsdorf
Extrusion Group, Egan Machinery

Updated by Staff

INTRODUCTION

Extrusion coating is a process in which an extruder forces melted thermoplastic through a horizontal slot die onto a moving web of material. The rate of application controls the thickness of the continuous film deposited on the paper, board, film, or foil. The melt stream, extruded in one or several layers, can be used as a coating or as an adhesive to sandwich two webs together.

Equipment for extrusion coating and laminating lines is normally associated with product groups, with some overlapping between groups. Substrates or web handling characteristics distinguish the difference among plastic films, paper, and paperboard combinations.

Three types of lines for extrusion coating and laminating are thin-film or low tension applications at operating web tension levels of 8–80 lbf (35.6–356 N), paper and its combinations in the middle range of 20–200 lbf (89–887 N), and high tension for paperboard applications at 150–1500 lbf (667–6672 N).

In extrusion laminating, a film of molten polymer is deposited between two moving webs in a nip created by a rubber pressure roll and a chrome-plated steel chill roll. In this continuous operation, rolls of material are unwound, new rolls are automatically spliced on the fly, and the surface of the substrate is prepared by chemical priming or other surface treatment to make it receptive to the extrusion coating and to help develop adhesion between the two materials (see Figure 1).

Pressure and temperature on the web and extrudate combine to produce adhesion. The substrate normally provides the mechanical strength to the resultant structure, and the polymer provides a gas, moisture, or grease barrier.

As materials, especially for food packaging, become more complex with ever-increasing performance standards, coating lines become more complicated. The requirements for new extrusion coating lines are high productivity, extreme flexibility, and labor-saving computerized and robotized equipment. Modern extrusion coating lines must be able to process the speciality resins that offer greater adhesion, allowing line speeds to be increased. The most common coating resins used is low-density polyethylene, but extends to ethylene–vinyl acetate, ethylene–acrylic acid, polypropylene, high-density polyethylene, and ionomers (1).

APPLICATIONS

Products from extrusion coating/laminating lines have six main market classifications: liquid packaging, flexible

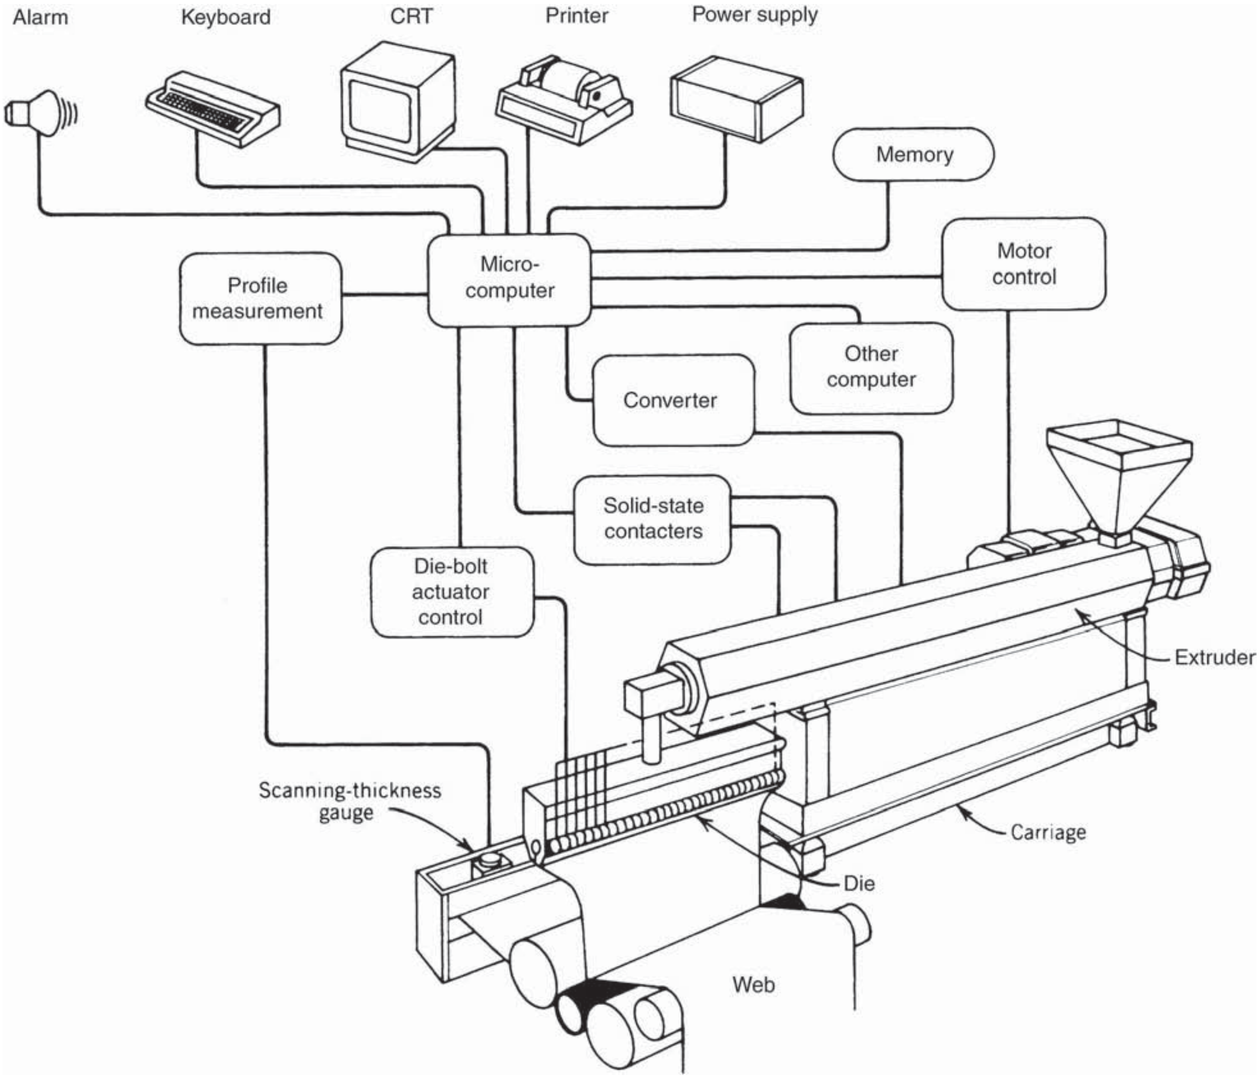

Figure 1. Simple extrusion-coating line.

packaging, board packaging, industrial wraps, industrial products, and sacks.

Liquid Packaging

Liquid packaging utilizes a single web-coated lightweight board, or a combination of board, plastic, and aluminum foil, for semirigid containers for milk, juices, water, oils, processed foods, sauces, cheese products, and aseptic packaging of liquids. The polyethylene-coated milk carton was largely responsible for the emergence of the extrusion coating industry in the 1960s, and as more commercial uses were found for polyethylene-coated materials, the industry grew rapidly (see Polyethylene; Cartons, gabletop).

In the 1980s, aseptic packaging made strong inroads in replacing traditional metal and glass containers (see Aseptic packaging). The sterile flexible “paper bottle,” which extends the shelf life of dairy products for months without refrigeration, is a major alternative form of packaging (2) (see Shelf life). It is also used to package fruit juices.

Although aseptic packaging systems differ, most of them use paperboard–foil–plastic composite material that is formed to shape, sterilized, and filled with a sterile liquid or semiliquid product under the sterile conditions. Customized extrusion-coating lines, complete with in-line laminating stations, are used to produce an almost unlimited variety of shapes, sizes, and printing options for aseptic and other packaging materials.

Flexible Packaging

The flexible packaging classification covers the combination of plain, printed, or metallized films, papers, polymers, and foil, used for protection, unitizing, dispensing, or holding of commodities. These include medicine and pharmaceutical supplies, foods, chemicals, hardware,

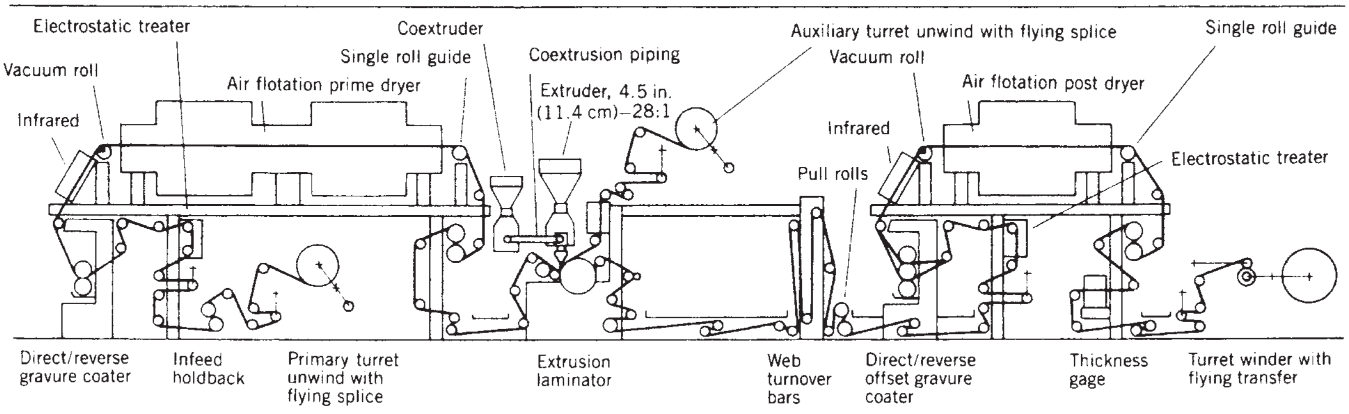

Figure 2. High-speed extrusion-coating line used to produce flexible packaging-type materials.

liquids, notions, sterile products, and meats. Flexible packages also include wrappers for fast food, the bag for “bag-in-box” containers, and the multilaminated web for Glaminate tube packaging (3) (see Bag-in-box, dry; Bag-in-box, liquid; Tubes, collapsible; Multilayer flexible packaging).

Flexible packaging lines are processing progressively thinner substrates of polyester, oriented polypropylene, and metalized materials (see Film, polyester; Film, oriented polypropylene; Metallizing). The light-gauge preprinted substrates used for snack foods require minimum tension to ensure that preprinted webs are not distorted. Machines to create these new structures are becoming increasingly complex. Thinner coating layers are more difficult to extrude on the coating machine, and often the coating head itself must be engineered to handle a variety of coating materials (see Figure 2).

Flotation drying, using air on both sides to float the web, is widely used in flexible package manufacturing because it handles light films well. Improved drying efficiency compared with roll-support dryers allows higher line speeds.

Board Packaging

In board packaging, heavyweight boards are coated, laminated, and then formed into boxes (folding cartons) for packaging detergents, tobacco, liquor, frozen foods, and bakery products (see Cartons, folding). Microwaveable and radiant oven trays (4) and ice cream cartons are also in this category. The plastic-coated containers protect against grease, moisture, and gas. Release characteristics can also be provided.

Industrial Wraps

Industrial wraps cover the range of heavy or reinforced papers, films, or boards used for products in which the extrusion-coated material may be added to other media used for products such as composite cans, drum liners, soap wrappers, and sheet overwraps for a variety of baled materials (see Cans, composite). The coated product is not necessarily used as a unit container, but as a wrapper or part of a protective structure.

Industrial Products

The industrial products classification takes in extrusion-coated or laminated material serving various industry requirements. Products include photographic-base papers, substitutes for bitumen coatings, base papers for silicone coatings, insulation backing, automative carpet coating, and metallized film balloons. Also in this category are functional laminates like credit cards and printed circuit boards, decorative laminates such as wallpaper, and disposables like tablecloths and various hospital and surgical supplies. As with industrial wraps, these products may or may not be associated with packaging.

Sacks

Sacks cover materials for multiwall paper bags and plastic-coated raffia. Intermediate tension lines produce coated scrim that is woven from tapes of oriented polyethylene or polypropylene. These materials are used for heavy-duty sacks and tarpaulins; and they have applications in building, recreational, and agricultural areas (see Bags, paper; Bags, heavy-duty plastic).

A miscellaneous classification would include coated foam used in the fast-food industry.

MACHINERY

Obviously, no single coating line can produce all the foregoing products. Today, various types of machinery are manufactured to produce coated and laminated products using substrates ranging from 0.4-mil (10-µm) film to 246 lb/3000 ft^2 (400 g/m^2) board, with coating weights 4.3–49 lb/3000 ft^2 (7–80 g/m^2), at widths 76.2–787 mil (300–3100 µm), and at speeds 1.1–33 ft/s (0.33–10 m/s).

The most important consideration in web processing or web handling equipment is the determination of the practical range for the system—the maximum and minimum unwind and winder roll diameters, maximum and minimum web-tension forces, splicing speeds, core diameters, and other process needs.

The unwind basically takes material in roll form and processes it continuously over a series of idler or driven rolls with a suitable amount of tension in order to minimize wrinkling yet not produce deformation. A dancer or transducer roll can be used for tension control; DC regenerative drives and electric or pneumatic brakes are used where applicable. Similar considerations apply to the infeed holdback when levels of tension required differ from those of the in-line operations. These sections tend to isolate tension transients from the unwinding roll.

Electrostatic treatment and flame treatment are available for enhancing surface tension or wettability conditions of the inert substrates prior to applying aqueous solutions (1). The direct/reverse gravure coater can be used for either priming, coating, or printing. Chemical priming is used mostly in flexible-packaging lines to promote adhesion between the extrudate and substrates such as cellophane, polyester, ionomer, nylon, or polyolefin films (see Film articles). Infrared preheating and vacuum rolls provide the means to dry the PVDC-coated web and effect proper web handling.

Air-flotation, driven-roll, idler-roll, or drum-support dryers are selected depending on the strength, support, or tension required for the substrates. Recirculation of heated air in the dryers is a common energy conservation practice in all these dryers. The single-roll web guide at the dryer exit and chill or pull rolls are needed for special web processing requirements.

The extrusion laminator along with the extruder-and-die system is the heart of the process. The backup chill roll, rubber roll, and large-diameter chill roll form a three-roll system. Two-roll laminators can be used for heavy substrates or paper-board applications. As the moving web enters the nip section, it is coated, laminated, or both. Ozone in close proximity to the entering web is used for oxidation of the molten polymer for improved adhesion in high bond level applications. Most of the heat is removed from the coating or laminate by the chrome-plated chill rolls. Chill rolls normally are steel and are constructed with a double-shell arrangement and spirally baffled. Outer shells of aluminum have been used for high coating weights. High-velocity chilled water is circulated to maintain a temperature rise between inlet and outlet of 2–4°F (1–2°C).

The coated or laminated structure is normally edge-trimmed at the laminator by razor, score, or shear cutting. Trim removal systems are installed just after the laminator. Slitting can also be done just prior to winding at a turret or single-drum winder.

Auxiliary unwinds can be located on, near, or over the extrusion laminator to provide a secondary substrate for laminating at the nip where the extrudate acts as an adhesive. These unwinds can consist of single-position or turret assemblies with flying splices for aluminum foil, oriented polypropylene or polyester film, paper, or paperboard substrates.

Web turnover systems, pull rolls, coaters, infrared heating, dryers, and web processing steps after the extrusion laminator are designed according to product needs. Thickness measuring devices include infrared and scanning of clear webs.

There are two basic winding techniques. The turret winder or center wind system is used for most flexible packaging materials. Tension is controlled by a dancer or transducer roll. The same design criteria for unwinds also applies to winders. The type of web, operating speed, tension range, and roll buildup must be properly controlled to wind up a satisfactory roll. Paper and paperboard products can be wound by surface methods on a single-drum winder.

All-plastic constructions require more advanced web controls. Many converters utilizing traditional wood cellulose substrates are specifying that their new coating lines must be able to handle all-plastic films. Wider tension ranges and air flotation dryers are two principal requirements of these convertible systems.

Other features being incorporated into various lines include DC-regenerative unwinds and infeed holdback drives for prices and low-level tension, direct/reverse gravure coaters for aqueous PVDC coating, infrared preheating, and vacuum rolls for web controls.

In the production of photographic-base papers, exacting specifications and special criteria for pigmented polymers are needed to produce coated materials that constantly provide high-quality photographs. The concept of tandem operations or coating two sides of a substrate in one pass can be applied to many flexible-packaging lines that produce combinations of paper, extrusion lamination to aluminum foil, and extrusion coating a polymer for heat sealing. Higher-operating line tensions can be used in producing structures with paper for granulated or powdered mixes and freezer-wrap or sugar-pouch materials. Polyethylene is not the only resin used for lamination or coating. Polypropylene, ionomer, nylon, ethylene–acrylic acid (EAA), ethylene–methacrylic acid (EMA), and ethylene–vinyl acetate (EVA) can also be part of a converter's inventory of resins.

Single-unit pilot coating lines feature an entire coating system preassembled and prewired at the factory and mounted on a structural steel base. These lines can be completely enclosed and have applications for the development of products such as the retort pouch, aseptic packaging, vacuum packaging, and other extended shelf-life products used to replace conventional glass and metal-can packages; they can also be used in the development of many types of medical-grade extrusion coatings (3).

Stainless steel is used when extreme cleanliness is required. The "cleanroom" machines are designed so that any metallic particles generated by machine friction are either contained or swept away by laminar air flow. Stainless steel is also used when lines are frequently washed with solvents that could remove conventional paint.

A typical pilot coating line consists of an unwind, coating heat, air-flotation dryer, dryer exit tension control, cooling station, extrusion coater, and rewinder, all aligned on a one-piece steel frame. Pilot coating lines are designed to handle narrow web widths and can be built so that components are cantilevered instead of being supported by traditional side-frames. The spindles, idler rolls, force transducers, and air-flotation bars are all mounted on a vertical backplate.

Extrusion-coating lines are experiencing increased automation. Raw material and roll stock can now be selected from a controlled inventory, delivered to the line, and handled through robotics (see Robots). The entire operation can be monitored and controlled by computer (see Instrumentation/controls).

Drives are under computer process control, and there have been advances in digital drives and in energy-efficient AC inverters. While a number of different drive systems have been installed and operated, the multimotor DC system is predominantly used for extrusion coating equipment. These drives can consist of as many as 10 motors in one line with a single control to bring the web up to operating speed. The tandem follower is another drive or computer feature whereby the extruder will increase or decrease in rate with line speed in order to maintain a fixed coating weight as the line speed is changed.

F

FILLING MACHINERY, BY COUNT

Accurate measuring is imperative in packaging to avoid costly overage and shortages that are now prohibited by law. As a basis for measurement, most packaging lines use either the weight of the package (see Checkweighing) or the number of pieces in the package. This article pertains to methods used to produce packaging that contain a specified number of pieces. Modern automatic counting systems are based on concepts that evolved in ancient times. They all are encompassed three basic functions that are as follows: parts representation, parts detection, and product handling.

PARTS REPRESENTATION

Counting is used to determine the amount of a specified batch and the method used to achieve this begins by selecting a basic system of representation. Systems of representation are used in all forms of counting. Units can be represented by fingers and toes, knots in a rope, or as in the packaging industry, they can be pulses of electrical current generated from specially designed detection units. Over the years, humans have engineered quick and accurate ways of counting, but no method is as accurate as a single-file count of an individual unit of product.

PARTS DETECTION

The next step in counting is detecting the unit of product to be counted. A person detects the product either by sight or by touch. Machines are designed to operate on the same principles and use either optical systems (sight) or nonoptical systems (touch).

Optical Systems. An optical system operates much like a human eye. A photosensitive receiving device is established, and the unit of product to be counted is passed within detection distance of it. There are many models of optical systems used in packaging, but most are based on either a simple digital photocell system or an intricate electronic analog detection unit.

In the photocell system, the breaking of a light beam fed to the photocell receiver indicates that a unit of product has passed through the detection zone. The break is then recorded as the counting of one unit of product. This method of detection is perfect for most product applications that meet specifications for light-blocking systems, but it is limited by the fact that the light source fed to the receiver must be completely blocked out before detection is recognized. This method is not efficient with transparent, overlapping, or bicircular objects (such as clear plastic), two pieces of material riding on top of each other, or objects with holes, which may trigger the photocell more than once.

Another approach to optical detection is the analog photo-optic system. This system is fast, flexible, and accurate, because certain parameters must be established and met before detection is recorded. The Photo Optic Shadow Detector (Sigma Systems, Inc.), for example, detects the dimensions of a specified shadow made by the unit of product when fed through the detection zone. Each shadow of a detected unit must meet certain parameters before being recorded. The parameters can be entered into the computer portion of the counting system to compensate for objects such as flat washers and O rings, which would trigger a photocell system twice, or clear plastic, which would not block out a light source but would cast a shadow that could be detected.

Nonoptical Systems. The nonoptical methods of parts detection are similar to human touch. The touch methods generally involve escapement devices, electrical contact, or magnetic-field contact. The escapement device is usually fully mechanical and is similar to an analog machine. Each unit of product must be of a specific shape and size. The product is fed into a receiving device that fits those exact parameters and then is discharged and recorded as a specific unit of product. This process is equivalent to placing dominoes in a box made just for dominoes. If only ten dominoes fit, then the unit of product would be recorded as ten units. This system is accurate, but it offers little flexibility. It commonly is used for high-speed counting of uniform products such as pills and tablets.

Another nonoptical method is the electrical-contact method, in which an electrical switch is triggered each time a part comes in contact with the switch. The part is then recorded as one unit of product. The response time and the ability of the product to actuate the mechanical switch-triggering device greatly affects the accuracy and flexibility of this type of system. The *magnetic system* is another touch-system method. Each unit of product to be counted must come in contact with or disturb the magnetic flow being transmitted from a magnetic source. As each unit of product is fed through the magnetic field, it is recorded as a counted unit.

Coupled with the detection system is a process known as *discrimination* (e.g., a farmer counting cows knows how to exclude sheep). This process has hampered the automated counting system greatly, because once this vital function leaves the dependability of the human senses, accuracy often suffers. Only two of the detection systems mentioned earlier can discriminate and are as follows: the photo-optic-analog system and the escapement-device system. In both, certain parameters must be met before a unit of product is recorded; the other systems record any item that is detected. Engineers have been working for years to improve the efficiency of the detection system to ensure an accurate count.

PRODUCT HANDLING

In almost every counting system, the process of getting the product to the detection zone and then moving it away from the zone must be achieved, whether the detection zone goes to the product or the product comes to the zone. This system of product movement is known as product handling. The product is usually brought to the detection zone, and in packaging, all of the methods bring the product to the zone in single file. There are various ways to do this. One is vibratory feeding, which is designed to vibrate a track or bowl filled with product, which in turn causes the product to vibrate along a designated path or ramp. The tracks or ramps narrow as the product nears the detection zone in order to create a single file. These feeding systems are the most flexible, because most objects lend themselves to vibration.

Another method is the *belt* or *V-belt system*. The product is placed in a master container and discharged onto a belt system. The width of the belt track is narrowed to allow only one part to pass at a time to achieve single-file feeding. Product handling plays an important role in the counting process, because even the most refined counting system will be inaccurate if the product is not presented to the detection zone in a manner acceptable to the detection device.

Many approaches to product feeding exist, but most counting systems allow free entry and exit of product through the detection zone. In packaging, however, it is sometimes necessary to retain all or part of the amount counted for a specific function. The retention is known as accumulation or partial accumulation. The accumulation functions usually are determined or predetermined by a manual function, in which an accumulation parameter, i.e., the amount of product desired, is assigned to the counting unit. The counting unit usually must meet the assigned parameters before permitting the accumulation functions to discharge the retained product. This function is essential when a manufacturer wants to place a predetermined amount of product into a specific-size container, e.g., accumulating 20 tablets, then discharging them into a package or bottle. It also plays an important role in the packaging process, because most packaging machines are intermittently cycled by the signal received from the counting system when the accumulation function discharges product. Most containers are aligned under the accumulation chute to receive the allotted amount of product.

As electronic technology advances, the ability to count and discriminate parts will improve. However, the attainable operating speeds will depend on the speed with which the unit of product can be fed into the detection mechanism and the speed of the product-handling system. The performance of any counting system must be objectively evaluated on its ability to count accurately and its adaptation to the intended use.

"Filling Machinery, by Count," in David Madison, ed., *The Wiley Encyclopedia of Packaging Technology*, 1st ed., by Sigma Systems, Inc., pp. 294–295.

FILLING MACHINERY, LIQUID, CARBONATED

The method for filling carbonated liquids (primarily beer and soft drinks) differs from other filling techniques (see Filling machinery, still liquid), because it is accomplished under pressure and uses the container as part of the control of net contents. Carbonated beverages, which tend to foam, require filling techniques that ensure the retention of the required carbonation levels in different sizes of cans and bottles. It is imperative that the carbonated liquid be processed in a way that prevents excess foaming, which would result in uncontrolled filling levels as well as impaired closing of the vessel.

The filling machine (filler) consists of a rotating bowl with a valve and CO_2 pressurization control, filling valves that attach to the perimeter of the bowl, a tabletop that contains the controlling technique for feeding in and taking away the container, a closing section that applies either a bottle closure or a can end, and a drive system that keeps all components in proper synchronization with each other.

The bowl must control the pressure on the liquid within it, yet be at a pressure lower than that of the system that feeds it. With this system, a continuous supply of product is assured with the least amount of turbulence. The level within the bowl is maintained by a simple float valve or similar device.

The filling valves embody the applied technology involved in filling carbonated products. Almost all of the machinery manufacturers of note employ the same principles with some variation in the mechanical interpretation of the concepts. To understand the valve's function, it is necessary to follow it through the various filling stages described in the following paragraphs.

The vessel is presented to the filling valve to ensure complete intimacy between both surfaces. This process is controlled by a pneumatic pressure system that holds the vessel firmly against the valve, yet tenderly enough to avoid crushing the thin metal cans or light plastic bottles.

The container rotates with the filler valve, and a mechanical trip actuates the valve to permit CO_2 from the upper part of the bowl (above the liquid level) to pressurize the container. The pressure in the container is now equal to or somewhat lower than the pressure in the bowl.

The valve is then actuated into the next stage, which permits the product to flow into the prepressurized container gravimetrically. During the filling phase (as fluid enters the vessel), it is essential that the CO_2 in the container be displaced. This displacement is accomplished through a vent tube, which is normally in the center of the valve and protruding downward into the vessel. As the product fills the vessel, it ultimately rises to seal off the vent tube or ball check. This stops the filling process because pressures in the bowl above and in the container below have reached an equilibrium.

Although the container is still in an intimate seal with the valve, another external latch actuates an internal chamber in the valve, which closes the connection to the bowl (both the liquid portion and the CO_2 charge above it) and simultaneously vents the container to atmosphere.

This step maintains control of the product in the container during the depressurizing step and assures that the product will be virtually foam-free when the container is removed from contact with the valve.

The tabletop, which employs an exit star wheel (not generally used on can fillers), sweeps away the lowered package from the rotating bowl and transfers it into the closing section at tabletop height. If the container is a can, then it is closed in the closing machine by an "end," which is rolled and seamed in place (see Can seamers) integrally with the can body with forces great enough to withstand high internal pressures. Bottles can be closed with a pryoff or twistoff crown; a rolled-on aluminum closure, which is threaded in place using the threaded portion of the bottle as a mandrel, or a prefabricated threaded closure applied by standard technique (see Capping machinery; Closures).

Carbon dioxide dissolves more readily in cold water than in hot water; thus, to keep foaming at a minimum and filling speeds at a maximum, it has been common to run beer and soft drinks as close to 32°F (0°C) as is practicable. To save the energy consumed by refrigeration, fillers have been introduced that operate at ambient temperatures. Controlling the CO_2 in the carbonating and filling stages means these operations must be accomplished at above-normal pressures, which complicates the internal parts of the filling valve and reduces rates of speed. The production rates of modern fillers have increased to approximately 2000 12-oz (355-mL) cpm and reportedly 1500 16-oz (473-mL) glass bpm. These increased rates of output are made possible by the use of programmable computers and new advanced instrumentation. Precise fill heights in the containers are controlled by the length of a vent tube in a bottle filler and ball check technique in a can filler. However, because of minor variations in the dimensions of glass and plastic bottles, more variability exists in volumetric content than in the exact volumetric measurement technique sometimes employed in "still" liquid filling.

FILLING MACHINERY, LIQUID, STILL

F. B. Fairbanks
Horix Manufacturing Company,
Pittsburgh, Pennsylvania

This article deals with the filling of noncarbonated liquids intended for packaging and distribution into rigid and semirigid preformed containers, such as glass bottles, sanitary cans, plastic bottles, and preformed paper cartons. Form/fill/seal packaging is not discussed (see the Form/fill/seal, horizontal; Form/fill/seal, vertical; Thermform/fill/seal articles), and the information relates only indirectly to such applications as the filling of paper cups in vending machines.

Table 1. Methods of Container Filling

Type of Container	Filling Method

	Overflow

Liquid-filling machines are classified here in terms of two fundamental characteristics: filling principle employed (see Table 1) and container-positioning method used (see Table 2). Except for a few specific restrictions (discussed below), the two characteristics are independent, but certain combinations are not commercially available. Packagers can select from a wide range of fillers, however. Among the members of the U.S. Packaging Machinery Manufacturers Institute (PMMI) alone, 61 companies offer liquid fillers (1), and this figure does not include machines made in other countries.

METHODS OF FILLING

In Table 1, the methods of fill are divided into two primary categories: the *sealed-container system*, in which the filling device seals positively against the container; and the *unsealed-container system*, in which the container is left open to the atmosphere during the fill process.

Sealed Container Filling System. In sealed-container filling, there are seven distinctly identifiable types of fillers. All sealed-container fillers fill to a controlled level in the container.

Table 2. Container Positioning Methods and Configurations

Positioning Method	Configuration
Manual	
Automatic, in-line	Single or dual lane
Automatic, rotary	Single or dual lane

Balanced-Pressure Fillers. The first three of the seven mentioned above are balanced-pressure fillers, in which product flows through a valve into the container from a tank of liquid located above the container, and air from the container is vented back to the headspace in the tank through the same valve. The typical embodiment of such a filling system, *gravity filling*—one of the simplest and most reliable—is illustrated in Figure 1. As the filling takes place through the sleeve-type valve illustrated, liquid flows from the tank through the liquid port into the container, and air within the container flows up the vent tube to the top of the tank. The container fills product to an exact level determined by the position of the vent port relative to the bottle. Any liquid in the vent from a previous filling cycle is returned to the product in the tank by the air flowing up the vent tube. If necessary, air or vacuum may be used to clean the vent before the start of fill.

A modification of pure gravity filling is the *gravity–vacuum filler*. In such a system, a low vacuum is maintained in the headspace in a sealed tank. When the container is brought into sealing contact with the filling valve and the valve is opened, the pressure of air in the container helps force any product in the vent back into the tank, accelerating the start of the filling process. The use of gravity–vacuum fillers also prevents the loss of product that would occur if a chipped or slightly broken container were filled. This savings is of particular advantage when filling more expensive products.

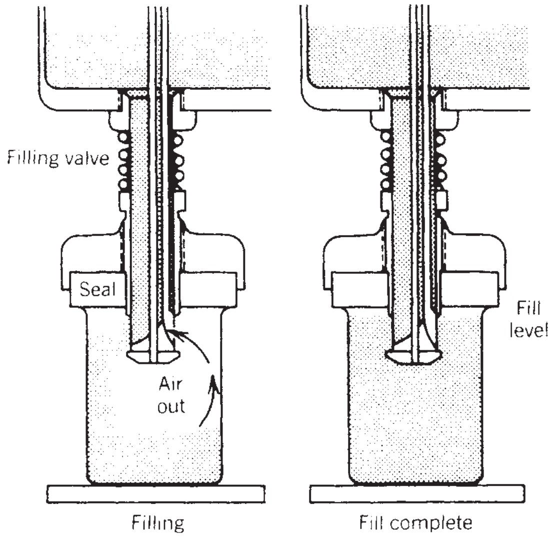

Figure 1. Pure gravity filling. (Courtesy of Horix.)

To fill thin-walled plastic containers, such as 1-gal (3.8-L) milk bottles, a pulsating vacuum in the tank is sometimes used to cause the container walls to flex in and out, assisting the foam in moving up the vents. The pulsations must be timed so that a container is not flexed inward at the position at which it is ready to break away from the filling valve, because this could cause underfill.

Thousands of different styles of filling nozzles, which use single ports, multiple ports, screens, sliding tubes, or check valves, are offered by various manufacturers. All these styles are designed to achieve the maximum production rate with the fewest number of filling valves and provide greater accuracy of fill. The selection of nozzle type is probably best left to the judgment of the machinery manufacturer, on the basis of experience and product testing.

Counterpressure fillers for carbonated beverages are discussed elsewhere (see the Filling machinery, carbonated liquid article).

Unbalanced-Pressure Fillers. Unbalanced-pressure fillers use a difference in pressure between that on the liquid to be filled and on the vent that permits air in the container to escape during the filling process. The usual combinations are listed in Table 1. The use of unequal pressure permits higher rates of product flow than possible with the balanced-pressure fillers. Unequal pressure is particularly advantageous when filling containers with small openings, viscous products, or large containers. Unbalanced-pressure filling has the disadvantage of requiring an overflow-collection/product-recirculation system, in contrast to the relative simplicity of balanced-pressure fillers. Higher liquid-flow rates do not necessarily result in faster filling because the additional foam generated by rapid entry of product into the container must be drawn off through the overflow system to obtain accurate filling-level control.

A schematic diagram of a typical *vacuum filler* is shown in Figure 2. The supply tank may be located either above or below the container to be filled. After the filling valve seals against the container and the valve opens, the vacuum on the vent draws the liquid into the container up to the filling level. Usually, a substantial quantity of

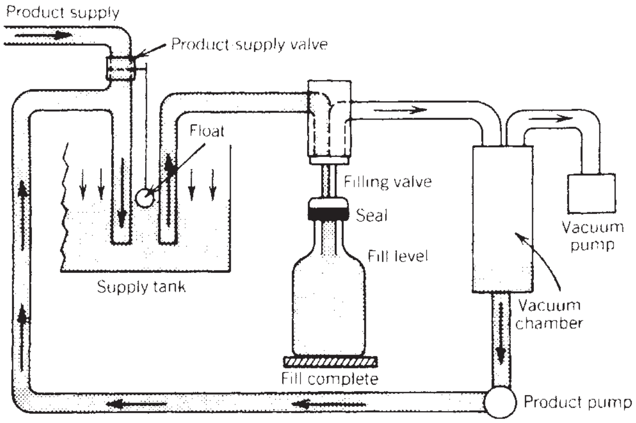

Figure 2. Pure vacuum filling. (Courtesy of PMMI.)

liquid is drawn into the vent, which leads to an overflow tank. Product is recovered in the overflow tank and then recycled.

The *prevacuumizing filler* is a special form of vacuum filling. On such a filler, a vacuum is first drawn in the container, evacuating the air. The valve then permits liquid to enter the container. Because such a system is complex and expensive, it is normally used only when liquid is being added to solids already in the container. Certain solids, such as peach halves, trap air. Such air entrapment may be eliminated by use of a prevacuumizing filler.

In an unbalanced-pressure *gravity filler*, the product-supply tank and the overflow tanks are open to the atmosphere, but the product tank is located above the container and the overflow tank is located below the container, permitting the differential pressure achieved by the difference in elevation to cause product flow. Such a filler is necessarily rather restricted in its ability to adapt to varying products and containers because the pressure difference is established solely by the product-tank and overflow-tank locations. Fillers of this type are not common.

A *pressure filler* is similar to a vacuum filler except that pressure is applied to the product. This may be achieved either by pressurizing the headspace over a tank or by direct pumping of the product to the filling valve. In the most common form of pressure filling, the product is pressurized, and the overflow tank is open to the atmosphere. Such a system allows unbalanced fill without vacuum. This is desirable when vacuum cannot be drawn on the product.

For example, drawing a high vacuum on alcoholic beverages can reduce the alcoholic content of the beverage. Applying a vacuum to a hot product, such as juice at 200°F (93°C) causes the liquid to flash. If desired, both the product and the vent can be maintained above atmospheric pressure, but with a higher pressure on the product. Such a filler is often used for filling lightly carbonated products, such as certain wines, using the pressure to retain the low carbonation in the product.

Unsealed Container Filling Systems.

Level-Sensing Fillers. Level-sensing fillers fill containers to a controlled level without sealing the container, as shown in Figure 3. Such a filling technique eliminates product recirculation and allows filling to a level in plastic containers that would bulge out or flex inward if pressure or vacuum were applied to the sealed container. A level-sensing filler uses some type of sensing means, typically a flow of ultra-low-pressure air. The rising liquid level in the container blocks air-flow, triggering a control system that shuts off product flow to the container. Such control mechanisms, which are required at each filling nozzle, are expensive, but high rates of fill may be achieved because there is no product overflow and no foam to be removed. Electronic sensing is also available.

Piston Volumetric Fillers. Currently, unsealed-container fillers are the most common, and volumetric filling is a frequently used method. In view of this popularity, many different kinds of volumetric fillers are available. For volumetric filling, piston fillers are most widely used. Table 1 indicates four subclasses of piston fillers, depending on the orientation of the pistons, specifically vertical or horizontal, and inlet arrangement.

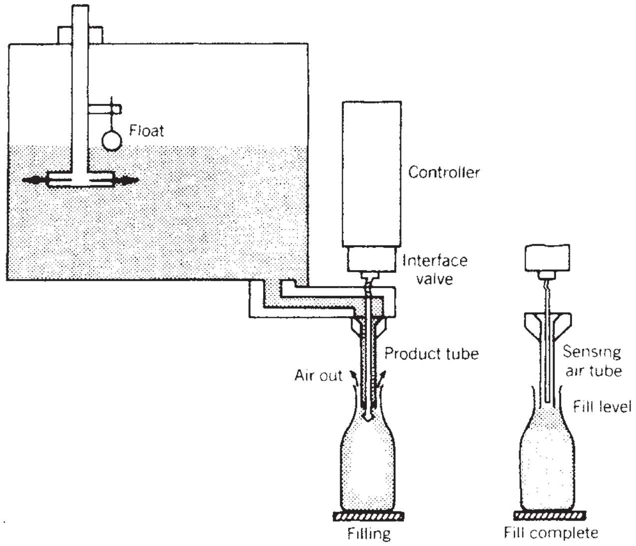

Figure 3. Level-sensing filling. (Courtesy of PMMI.)

1. *Cylinder Vertical, Closed Ends*. One station of a typical vertical-cylinder rotary filling machine is illustrated in Figure 4. The valve(s) controlling the product flow between the supply tank, measuring chamber, and dispensing nozzle may have either a rotary or a reciprocating motion. The rotary style, which is more common, is illustrated. The product is drawn into the cylinder from the liquid-supply tank when the piston moves upward. The valve then rotates to permit the premeasured volume in the cylindrical chamber to flow into the container. Usually, either a direct mechanical drive from a cam track or an air cylinder is used to stroke the piston. If an air cylinder is used to drive the piston, controls are usually such that the piston does not cycle if a container is not in place. This eliminates moving the liquid back and forth between the measuring chamber and the supply tank, a situation that is usually undesirable and may cause product breakdown with foods such as mayonnaise. It is not easy to uncouple a mechanically driven piston.
2. *Cylinder Vertical, Open-End Inlet*. In an alternative design, product enters vertical volume chambers through cylinders open at their upper ends, with a cam drive located below. A nonrotating plate with an orifice allows product to enter the open-ended cylinders at the appropriate position during the rotation of the filler bowl. Such a configuration is mechanically complex and generally considered difficult to clean. Fillers of this type have the advantage, however, of being able to handle products containing sizable solids in suspension.

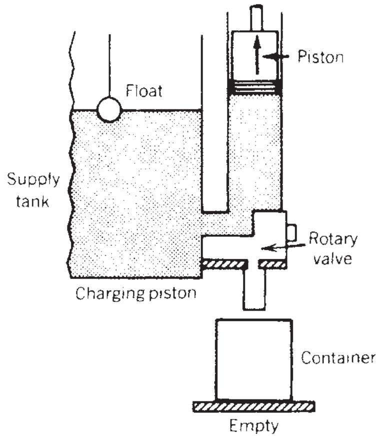

Figure 4. Piston volumetric filling. (Courtesy of PMMI.)

3. *Cylinder Horizontal*. Measuring cylinders may be mounted horizontally. Usually single-ended, they are similar to vertical cylinders in operating principle. They are frequently found on in-line, large-volume fillers to avoid excessive height for such machines. A volume cylinder may also be double ended, with inlets and outlets at both ends. Product under pressure flows into one end, which causes a floating piston to move and expel the liquid in the opposite end of the cylinder into the container. In some fillers, the double-acting cylinder may be used for a single fill, and the first half of the fill comes from one end. The flow pattern is then reversed to discharge product from the other end of the cylinder for the second half of the fill while the first end is being filled for the next cycle.

Rolling-Diaphragm Volumetric Fillers. The volumetric fillers described above normally have some type of a seal, such as V or O rings, between the pistons and cylinder walls. An alternative method for measuring volume is to use a rolling diaphragm; a typical arrangement can be observed in Figure 5. The diaphragm provides an absolute seal and also eliminates the friction contact of a seal with a cylinder wall. Such sliding causes abrasion and particle generation, which is seldom important, but minimizing particulate generation is important in the packaging of intravenous solutions and injectable drugs. Rolling-diaphragm volumetric fillers often employ flexible diaphragms or pinch valves to control product flow to and from the measuring chambers.

Displacement-Ram Volumetric Fillers. Another method for dispensing a specific volume of liquid is to use a displacement ram. The ram enters one end of a cylinder through a seal of some type, but the displacement ram does not touch the inside of the cylinder wall. An external air cylinder drives the ram, which displaces a controlled volume from the cylinder into the container. Such fillers are easy to clean.

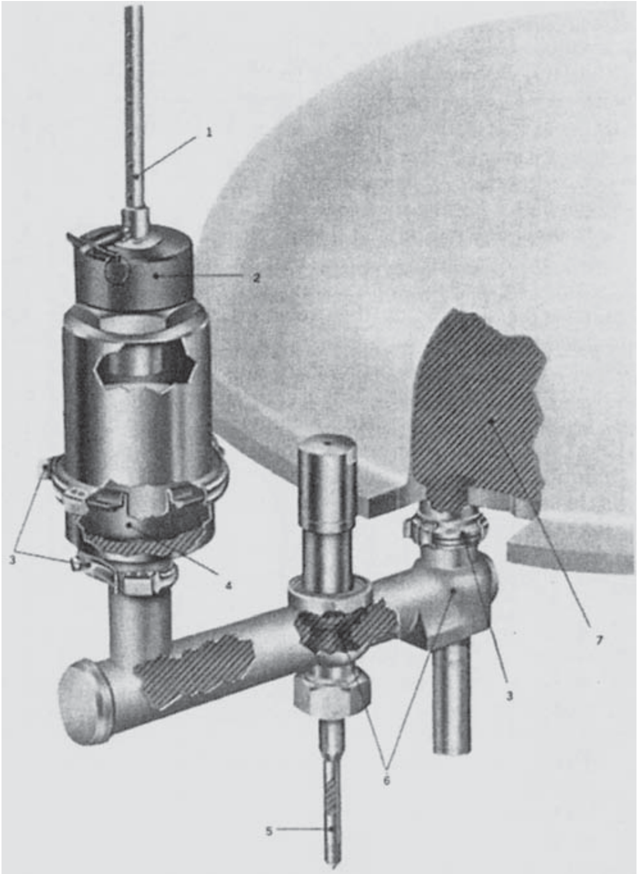

Figure 5. Rolling-diaphragm volumetric filling: (1) volume adjustment rod; (2) precision volume adjustment; (3) quick-disconnect design; (4) volume-chamber diaphragm; (5) product tube; (6) valve seats; (7) product supply manifold. (Courtesy of Horix.)

Volume-Cup Fillers. Cup-type volumetric fillers operate by first transferring the product from an open tank into measuring cups of precise volume. Depending on the design, each cup may be filled to a level matching that of the tank, or the cup may fill to overflow and then rise above the level of liquid in the tank. Each valve then opens at the bottom, permitting liquid to flow from the cup into a container. Although such fillers are appropriate only for low-viscosity liquids that do not cling to the sidewalls of the cups, for suitable applications the volume-measuring method is accurate, inexpensive, and reliable. Various volume-adjustment systems are provided. These fillers are usually rotary and are often designed to be easily changed, by means of a change of filling valves, to gravity or gravity–vacuum filling.

Turbine-Meter Volumetric Fillers. The amount of liquid dispensed from a nozzle can be measured by placing a turbine flowmeter in the line ahead of the nozzle. Such meters, which include an electronic counting and control system to start and stop flow, are accurate but expensive and are generally used only for filling large containers, i.e., ≥ 5 gal (≥ 19 L).

Positive-Displacement Volumetric Fillers. Viscous liquids may be moved directly from a supply system through a positive-displacement pump into a container. Volumetric measurement is achieved by accurately controlling the number of revolutions made by the pump. An auger may be used as the pump mechanism.

Peristaltic-Pump Volumetric. Peristaltic pumps are often used to fill sterile liquids, as they are easy to clean and have no sliding parts that might contaminate the product being filled.

Weight Fillers. On *gross-weight fillers*, each fill station is fitted with a weighing device, typically a beam scale, which acts to shut off product flow when a predetermined weight has been reached. Each scale is set for the maximum weight of container and contents. Adjustment for other containers and content weight may be made by adding special weights to each filling platform.

By using a load cell as the weighing device, the weight is electronically measured continuously, and liquid flow is stopped at a predetermined weight. With microprocessor controls, the change from one weight to another is simple. *Net-weight fillers* employ more advanced load-cell weighing devices. The tare weight of each container is measured, and then product fill proceeds until the proper net weight is in the container. Net weight filling is the most accurate method for filling free-flowing products. Such fillers are readily available with simple, easily cleanable, nonsliding contact valves. They are usually relatively expensive, as each filling station requires a load cell and its associated electronic interface. But, such costs are often justified by the reduction of product overfill possible with the increased accuracy.

Time-Fill Fillers. Time-fill filling consists of delivering liquid under pressure to an orifice that is open for a controlled length of time. Such a filler may be either of the controlled-pressure-head type or the constant-volume-flow type. On multistation *controlled-pressure-head* fillers, which are most frequently in-line, all orifices are opened for approximately the same length of time. Minor adjustments may be made at each station to compensate for individual orifice characteristics. Until recently, such time-fill fillers depended for their accuracy on maintaining a precise pressure head on the liquid at the orifice. This was achieved with pressurizing tanks or a liquid level established by flowing the product over a dam. Small pressure fluctuations are now acceptable, because a microprocessor controls the time each orifice is open, on the basis of measured pressure variations. Such fillers are designed for easy cleaning and changeover from one product to another. To date, such fillers have not generally been used for high-speed production runs. They are probably best suited to filling pint (473 mL) or smaller containers with free-flowing liquids.

The *constant-volume-flow* type of time filler is almost always adapted to a rotary filler. In a typical embodiment (see Figure 6), product is delivered continuously to the filler at a constant flow rate, using constant-displacement pumps or their equivalent. The amount of product entering each container is proportional to the length of time a nozzle is under the liquid ports. The time is determined by the rotational speed of the filler. Constant-volume-flow time fillers are relatively simple and inexpensive. They are capable of reasonable accuracy, particularly with products of medium to high viscosity. Leakage between plates is hard to control with low-viscosity liquids. The product flow must be simultaneously altered any time the filler is stopped or started. It is difficult to do this and maintain consistent filling accuracy. Because a no-container/no-fill mechanism is rarely provided, any missing containers cause product overflow, which must be collected and either returned for reuse or discarded.

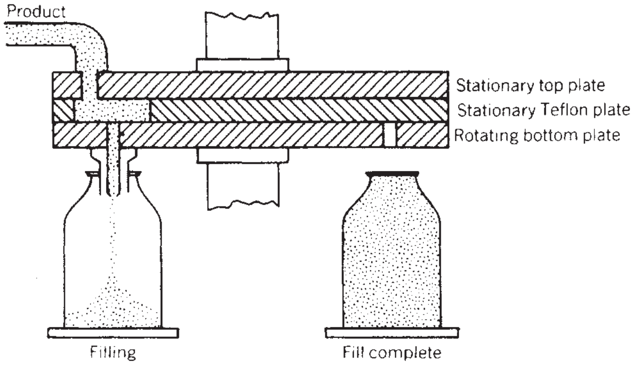

Figure 6. Constant-volume-flow time filling. (Courtesy of PMMI.)

Overflow Fillers. Some products can be filled by filling open containers, usually sanitary cans or widemouth glass bottles, to overflow. The liquid may flow from a pipe or over a barrier. In more advanced overflow fillers, the liquid flow into open containers is directed by moving funnels synchronized with the movement of containers. The headspace in the container, which is typically small, may be established in various ways. When brine is added to pickles, for example, the headspace is usually created by displacement pads that enter the container and establish the desired headspace. If solids are present, then the headspace pads also ensure that the solids are properly down into the container. Another method of establishing headspace is to tilt the containers slightly, permitting liquid to pour out. With some overflow fillers, an upwardly directed curtain of air prevents the overflowing liquid from contacting the outside of the containers. With careful adjustment of liquid flow rate and container speeds, the amount of fluid that is overflowed and recirculated may be limited to a very small proportion. Tilted-container overflow fillers are relatively fast and inexpensive. They are frequently used for filling juice in cans, but they normally cannot be used to fill narrow-neck containers.

CONTAINER POSITIONING

Filling machines may be characterized by the way they deliver containers to the liquid-dispensing mechanisms and remove them after filling (see Table 2).

Manually Loaded Fillers. The oldest and simplest method of container delivery and removal is by manual means. Filling occurs after one or more containers are in place. The containers may be raised to the filling valves or the valves lowered to the containers, or no relative motion may be required. Because of the amount of labor involved, manual filling is usually limited to small production runs.

In-Line Fillers. The simplest automatic fillers are single-lane in-line machines. In a typical machine of this type, containers, standing on a conveyor, are delivered to the filler. One or more containers back up behind a stop or gate. The barrier then opens, and a controlled number of containers move under the filling heads, where they are positioned by another barrier of some type. Conveyor motion is usually intermittent, with the conveyor stopped during the fill cycle to prevent tipping the containers. After the filling is completed, the positioning barrier opens, and the filled containers leave while unfilled packages enter.

The size and shape of a container are factors that determine how many containers may be filled simultaneously on an in-line intermittent-motion filler. Increasing the number of filling stations increases the total output of the machine, but this approach runs into space limitations and at a certain point, an additional valve is not cost-effective. Sixteen stations seem to be the maximum commercially feasible number of valves. If the containers are not straight sided, then there usually is difficulty in backing up any significant number behind a positioning stop; even with straight-sided containers, the process is limited by container dimensional tolerances. The size of the containers determines the position of the last container in a row relative to the first container. If the lead container is not properly positioned under a nozzle, then the accumulation of container dimensional tolerances may cause the trailing container not to be positioned under a nozzle.

An in-line filler may be used for in-case filling. A multiple array of filling valves is used to fill all the containers in a case at the same time. As with individual containers, two or three cases may be backed up for simultaneous filling. Such filling is possible only if the cases have reasonably consistent dimensional control.

A variation of in-line intermittent-motion filling is occasionally used to raise the containers relative to the filling nozzles. This is done (e.g., in filling mayonnaise or peanut butter) to change the position of the container relative to the nozzle during fill. On such a filler, the containers are moved by means of a pusher mechanism from the infeed conveyor onto a platform under the filling heads, and the platform is then raised. After the containers have been filled and the platform lowered, successive unfilled containers may be used to push the filled packages onto a discharge conveyor running behind and parallel to the infeed conveyor, or individual mechanisms may move the containers between the infeed and discharge conveyors. Some manufacturers offer a rising-platform device with a straight-through conveyor arrangement.

Dual-lane straight-line fillers permit more efficient utilization of filling stations. Containers move on two parallel conveyors. The filling nozzles, in a row, fill in one lane while container movement occurs in the other lane. The use of dual-lane fillers is generally considered only if the limit of the number of valves in a single lane has been reached. They are typically used for small containers because fill time is short relative to the time required for container movement.

Valve use is the percentage ratio of actual filling time, i.e., the time the valve is fully open, to the total cycle time for that valve from the beginning of filling one container to the start of filling the next container. Valve use is low on in-line fillers, i.e., 25% to 50% of cycle time, dependent on conveyor speed, container diameter, and actual unit-filling time required for the fill.

Rotary Fillers. The most common system for filling containers are moderate to high speeds is rotary filling. Containers arrive continuously on a conveyor and are spaced by some means into a rotating infeed star that delivers them, properly separated, to filling stations on the main rotary assembly. The timing mechanism normally employed to take containers coming at random to the filler is a feed screw; for large containers and low-speed operation, timing fingers, escapement wheels, or like devices may be used. The discharge from the main rotary is usually by means of a second star wheel with the same diameter as the first. However, if the liquid level is high in the container, either a large-diameter star or a tangential conveyor should be used to prevent spill.

On rotary fillers, valve utilization is almost independent of container size but is a function of filler diameter. For example, a 22-in. (56-cm)-pitch-diameter gravity filler for 32-oz (946-mL) containers has a valve utilization of 49%, whereas a similar gravity filler having the valves on a 60-in. (152-cm) pitch diameter has a valve use of 73%. The time that the valve is closed is necessary for the transfer of containers into and out of the rotary section and for the relative movement between container and filling valve needed to open and close the valve.

The concept of dual-lane rotary fillers, involving two lanes (inner and outer) on the main rotary, was proposed and patented many years ago. Except, perhaps, for large-diameter carbonated-beverage fillers, the system is not practical. Two infeed stars and two discharge stars (or a tangential system) would be needed, and such an arrangement greatly reduces valve use. The fact that valve spacing is limited in the inner row is a disadvantage as well, unless unequal production speeds are desired. In one configuration study, the valve use on an 80-valve, dual-lane, 60-in. (152-cm)-outer-lane-pitch-diameter machine is only 66%, compared with the normal 85% use of a 48-valve, 60-in. (152-cm)-pitch-diameter filler. Adding 67% in number of valves adds only 29% to the production capability.

Continuous-motion in-line fillers use a timing screw to position the containers under multiple filling heads, which move in synchronization with the containers.

Multihead in-line weight fillers may have a conveyor system that separates and stops a group of containers. Weighing platforms then lift the containers above the conveyor for the filling cycle. Alternatively, they may use a lateral transfer device to place the containers on the scale platforms.

Relative Motion. The relative motion between the container and the liquid-dispensing device can significantly affect filler performance. The various relative motions possible are none, raise container, lower valve, and raise container and lower valve.

In sealed-container filling (see Table 1), relative motion between the container and the valve is required to bring the valve into contact with the container. With manual container placement, the container can be raised against the valve, or the valve(s) can be lowered to one or more containers on platforms.

The valve use of rotary sealed-container fillers can be increased by lowering the valve (see Figure 7). With a descending valve, the valve can begin to enter the container at position 1, and it must be clear of the container at position 1′. If the container is to be raised up to the valve, the rise may not begin until position 2 because space must be allowed for the container platform to clear the infeed star. Likewise, the container platform must be in the full-down position by position 2′. As an example, with 40 valves on a 60-in. (152-mm) pitch diameter, arc 1–1′ is 327, whereas arc 2–2′ is 306. This 6% difference may be advantageous, but movement of each valve imposes other difficulties on filler design, often including the need for a flexible liquid connection to each valve. Such flexible connections often make cleaning more difficult. The combination of raising the container and lowering the filling valve is very rarely used, as it requires mechanisms for moving both elements, with all the disadvantages of each system.

In-line, sealed-container fillers are rather slow and not common, except for filling containers in a case. Most of those available operate by lowering the valves to the container, which permits the containers to remain on the conveyor. As with sealed-container fillers, level-sensing fillers require relative motion between the filling valves and the container. Rotary level-sensing fillers typically raise the container; in-line fillers bring the nozzle down to the package.

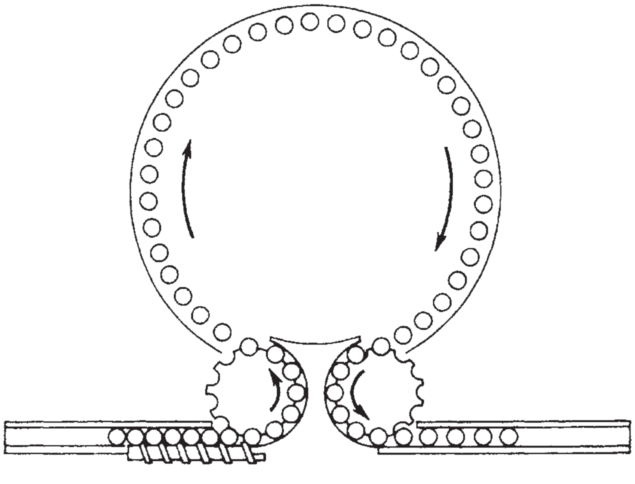

Figure 7. Rotary-filler arrangement.

Volumetric, weight, and time-fill fillers do not require relative motion between the dispensing nozzle and the package. Thus, for simplicity and economy, most of these fillers operate with the nozzle located above the container opening. However, two principal exceptions are as follows:

1. In filling containers with relatively small openings, such as long-neck plastic bottles, greatly increased rates of flow are possible if the product flow emerges from the side of the tube and is directed against the container wall (see Figure 1). Filling straight down into that style of container from above may cause air entrapment with consequent possible splashout or overflow at the end of the filling cycle. The lost time, if any, required to raise the container or lower the filling valve may be more than offset by the faster flow rates possible.
2. Viscous products such as mayonnaise and peanut butter are best filled volumetrically using a flow tube open at the bottom. To prevent air entrapment, the flow tube is maintained at a position very close to the rising surface of the liquid by lowering the container during the filling cycle.

CONSIDERATIONS IN DESIGN AND SELECTION OF FILLERS

Many factors must be considered in selecting filling machinery. These include such obvious factors as operating and maintenance costs, efficiency, reliability, size, speed, and materials of construction. Several considerations, discussed below, are specific to liquid-filling machinery and important to the satisfactory operation and use of such equipment.

Accuracy. The accuracy of fill is important for two reasons: (a) it is necessary to comply with state or other regulations as to labeled content [the regulatory agencies generally refer to the filling tolerances recommended in the *National Bureau of Standards Handbook 44* (2)] and (b) in addition to meeting legal requirements, however, packagers of most products desire to keep overfill to a minimum, thus minimizing product giveaway. Even with relatively inexpensive products, the amount given away with inaccurate overfilling on high-speed production lines can usually justify the higher cost of purchasing more accurate fillers.

Changeover and Cleaning. As a part of operating costs, the time and labor required for cleaning and preparing the filler for daily operation, changeover from one product to another or one container to another, and cleanup at the end of each day's production should be carefully evaluated. User needs may range from fillers that operate 24 h per day with no need for product or container-size change, to fillers for 30-min production runs, after which the filler must be completely sterilized and adjusted for a different container size. Comments are made above concerning the influence of filling techniques. The manufacturer's descriptions of container-positioning methods contain comments on cleanability, container-size flexibility, and ease of adjustment. Specific aspects of each filler design must be carefully considered in choosing the proper liquid filler for a particular application.

No-Container/No-Fill System. In general, it is desirable to have a filler equipped with some type of no-container/no-fill system. In most sealed-container fillers, the filling-valve mechanism is designed to automatically provide a no-container/no-fill system in conjunction with the action of the container and the filling valve coming together. Likewise, with most of the unsealed-container filling techniques, a relatively simple container-detection device can be used to prevent product flow if no container is present. The constant-volume time filler does not permit start or stop of product flow, but means such as drains in the container platform to catch the product flow may be provided. Alternatively, particularly on in-line fillers, a control system may be provided to ensure that a full row of containers is present.

Drive Location. The location of the main drive for the filler should be considered in filler selection. Usually, the main motor drive, or, alternatively, a lineshaft synchronization system, is located near floor level. Thus, the heavy drive components are conveniently supported and reasonably accessible for routine maintenance. Because the splash of corrosive products may significantly harm drive components even if they are protected against splash, some filler manufacturers locate the main drive above the product. This may not be desirable for filling food or drug products because of the potential for product contamination from drive lubricants.

Equipment Standards. Various industry-consensus standards are applicable in the United States:

ANSI B155.1-1994	*Safety Requirements for the Construction, Care, and Use of Packaging and Packaging-related Converting Machinery*, American National Standards Institute
3-A Sanitary Standard 17-06	*3-A Sanitary Standards for Fillers and Sealers of Single Service Containers for Milk and Fluid Mild Products*, International Association of Milk, Food, and Environmental Sanitarians; U.S. Public Health Service; The Dairy Industry Committee

The first standard is general but applicable to fillers. The 3-A Standard is specifically for milk fillers.

The packaging of certain products is regulated by government agencies. The packaging of fluid-milk products in the United States is usually regulated by local (i.e., county or state) authorities. They normally adopt the 3-A Standards without modification, but a few jurisdictions impose their own requirements, usually stricter. If fresh milk is packaged in flexible plastic containers, then the container is usually the legally specified measuring device. In such cases, volumetric tolerances normally follow the recommendation of the National Bureau of Standards (2).

The packaging of liquids in meat and poultry establishments subject to inspection by the United States Department of Agriculture (USDA) Food Safety and Inspection Service is governed by guidelines issued by the department (3, 4). Equipment for packaging food and drug products is regulated in the United States by the Food and Drug Administration (FDA) (CFR Title 21, Chapter I), and the packaging of distilled spirits by the Bureau of Alcohol, Tobacco, and Firearms (BATF).

FILM, CERAMIC COATED

Noe Obinata
Toppan Printing Company

For food packaging, gas/moisture barrier property is one of the key elements to provide longer shelf life of products. Aluminum foils, aluminum-metalized films, PVDC-coated films, or coextruded EVOH films have played major roles in barrier packaging. However, there are increasing demands for more sophisticated packaging, such as transparency, metal detector capability, microwaveability, retortability, and environmental friendliness as well as barrier properties. Ceramic-coated films are capable of meeting the demands and have become more and more popular recently.

Ceramic-coated films are AlO*x*- or SiO*x*-coated films of excellent barrier properties, having the potentially of reaching almost the same levels of O_2 and H_2O barrier

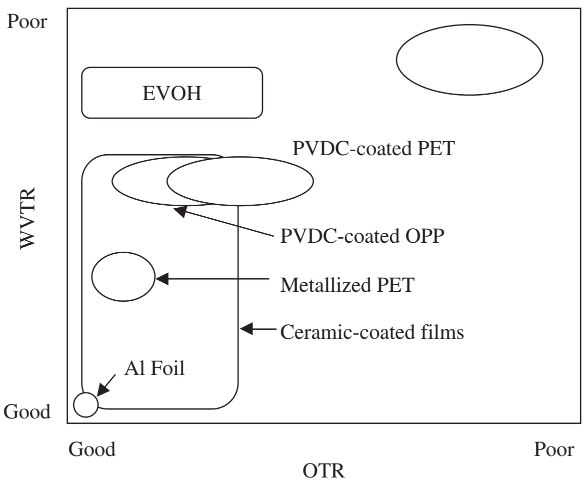

Figure 1. Oxygen and water vapor barrier map of typical barrier films (1).

as aluminum foil (Figure 1). Besides barrier properties, transparency is another important aspect of these films. Although the SiO_x layer is somewhat yellowish, both the AlO_x and SiO_x layers are clear, providing the marketing advantage of allowing the consumer to see the product inside the package and the quality control advantage of more reliable visual inspection. These films also have the advantages of metal detector capability and microwaveability. Unlike aluminum foil or metalized films, these metal-free films allow metal detectors to work properly and do not cause arcing in the microwave oven. Recent improvement also imparts these films with the exciting advantage of being retortable, with the durability to withstand the severe temperature and pressure conditions in the retorting process. In the past, only metal cans, glass containers, and aluminum–plastic pouches were retortable. Replacing the heavier and more bulky metal cans and glass containers with packages made of ceramic-coated films can result in significant cost/energy savings in transportation and waste reduction. A comparison of ceramic-coated films and other barrier films is shown in Table 1.

A physical vapor deposition process is typically used to form ceramic coatings. Figure 2 is an example of an AlO_x coating process. Aluminum is evaporated from a crucible tank by electron beam heating and then reacts with oxygen to form a thin layer of AlO_x onto a substrate. The process is done under high vacuum conditions to achieve efficient evaporation and deposition of the material.

Table 1. Comparison Between Ceramic-coated and the Other Barrier Films, where ○, △, and × are Excellent, Moderate, and Poor, Respectively

Films	Moisture Barrier	Oxygen Barrier	Transparency	Use of Metal Detector	Use of Microwave Oven	Retort Treatment
Ceramic-coated	○	○	○	○	○	○
Aluminum foil	○	○	×	×	×	○
Aluminum-metalized	○	○	×	×	×	○
EVOH	×	○	○	○	○	△
PVDC-coated	△	△	○	○	○	○

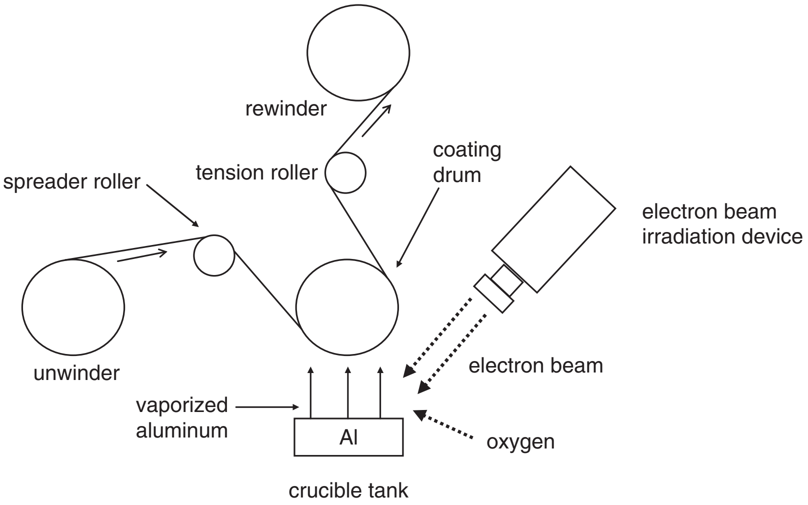

Figure 2. An example of an AlO_x coating process.

Table 2. Barrier Properties of GL/GX Films[a] (2)

Film	O_2 TR[b] (cm^3/m^2/day/MPa)	WVTR (g/m^2/day)
GX	2.0	0.05
GL-AE	5.0	0.6

[a] Films are laminated with LLDPE (60 μm).

[b] O_2 TR measured at 30°C and 70%RH, WVTR measured at 40°C and 90%RH.

Since its commercial introduction in 1989, the Toppan's GL films (ceramic-coated films with SiO_x or AlO_x coating) have been a family of leading transparent barrier films for food packaging applications. Later in 2002, the Toppan's GX films were introduced to provide higher gas barrier (Table 2). The collection of the GL and GX films now provides (a) the gas/moisture/aroma barrier, (b) transparency, (c) printability, (d) capability of microwave ovens and metal detectors, (e) retortability, and (f) environmental friendliness suitable for a wide range of food packaging applications. The GL/GX films have been used for more than 200 food and pharmaceutical products (Figure 3).

Driven by the demand for high-barrier transparent films, ceramic films have become increasingly accepted by packaging suppliers. Some major suppliers and their products are listed in Table 3. Most of the products are available in the United States and Europe. The Mitsubishi's Techbarrier® uses PVA as a base film for high oxygen barrier, but extra care must be taken against moisture absorption under humid conditions. The Toyobo's Ecosyar® uses the two-component process of AlO_x and SiO_x simultaneous coating. According to the supplier's catalogue, the two-component process could provide both advantages of AlO_x and SiO_x, meaning that high density and good barrier are from AlO_x while flexibility and high impact strength are from SiO_x.

Usage of ceramic-coated films has steadily increased in recent years. Their versatile characteristics meet changing demands of food packaging, such as higher barrier, visibility inside the package, and retortability. In particular, retort applications will support expansion of using ceramic-coated films as consumption of retort-pouched food has increased on a world basis. The major market for ceramic-coated films is in food packaging applications; however, a recent trend suggests that the applications of these films for pharmaceutical and electronic products could rise in the next future, although more improvement of the films may need to be made.

FILM, EDIBLE

John M. Krochta
Food Science and Technology,
UC Davis, University of
California, Davis, Davis,
California

DEFINITION AND FUNCTIONS

Edible films are stand-alone structures that have appearance and protective functions similar to synthetic polymer films. However, they are comprised of edible proteins, polysaccharides, lipids and/or resins, and other components that render them edible. Thus, they can be consumed with a packaged product, resulting in less packaging that requires disposal. Also, since edible films are made from renewable resources, they contribute to package sustainability.

Edible films by convention have thicknesses $\leq 10\,\text{mil}$ ($\leq 254\,\mu\text{m}$), above which they would be considered sheets. They can be used as food wraps, and some can be formed as food casings or can be heat-sealed into pouches for food products. Edible films can also be formed as coatings directly on the surfaces of food and pharmaceutical products, thus becoming a part of the product.

Present uses of edible films include collagen casings on sausages to inhibit moisture loss and oxygen transport and provide structural integrity; hydroxypropylmethyl cellulose (HPMC) pouches for premeasured food and beverage ingredients; gelatin capsules for pharmaceuticals to improve product appearance, structural integrity, ingestibility and stability; and dissolvable breath strips made from a number of different edible materials. Present uses of edible films as coatings include shellac and wax coatings on fruits and vegetables to prevent moisture loss and improve appearance; methyl cellulose (MC) and HPMC coatings on fried foods to reduce fat update; shellac, wax, and zein coatings on confections and drug tablets to provide moisture resistance and improve appearance; and MC and HPMC coatings on drug tablets to improve product stability appearance and ingestibility.

Edible films and coatings are generally seen as having considerable potential for applications far beyond present uses for improving product quality and safety. In addition to controlling moisture, oxygen, aroma, and/or oil transport and protecting products from mechanical forces, edible films and coatings can act as carriers for edible antioxidants, antimicrobials, and other additives. Furthermore, edible films can be positioned within food products as separation layers to reduce migration of moisture, lipids, and solutes from one food component to another.

In some instances, edible films and coatings have potential for reducing use of synthetic packaging films. However, they are not intended to eliminate the need for nonedible protective packaging. Rather, they are intended to work with conventional packaging to improve product quality and shelf life. To the degree that an edible-film wrap, casing, pouch, capsule, or coating functions to protect the product from the environment, the amount and complexity of nonedible protective packaging can be reduced, leading to source reduction and improved recyclability. For example, an edible pouch for premeasured dry milk powders used in bakeries may only need a recyclable paperboard box as a secondary package. Or, an edible oxyen-barrier coating on roasted peanuts could eliminate the requirment for an oxygen-barrier layer in a flexible pouch, resulting in a single-layer moisture-barrier package that is more easily recycled. In addition, after packaging is opened, an edible coating can continue to protect the product.

The objective of this article is to review the materials, manufacture, properties, applications, and trends of edible films. The area of microencapsulation of food and drug ingredients is not covered.

FILM COMPOSITION

Components of edible films must meet the same rigorous standards applied to all food ingredients. Materials used in formation of edible fims must be generally recognized as safe (GRAS) for intended use or sanctioned by the *U.S. FDA Code of Federal Regulations* or the *U.S. Pharmacopoeia/National Formulary* (or equivalent). It is also necessary that all edible film components be included on the product label, to provide information critical to consumers with allergies or intolerances to particular food components.

Film Formers

Film-forming materials available for edible films fall generally into the categories of polysaccharides, proteins, lipids, and resins derived from plants and animals. Protein film formers include collagen, gelatin, casein, whey protein, corn zein, wheat gluten, and soy protein (1–4). Polysaccharide film-forming materials include cellulose derivatives, starch and starch derivatives, carrageenan, alginate, pectinate, and chitosan (5, 6). Layering and blending of proteins and polysaccharides show potential for optimizing film properties (7–9). Films can also be produced from purees of foods such as fruits and vegetables, which contain combinations of ingredients (10). The polar hydrogen-bonding character of polysaccharides and proteins produces films that have (a) high moisture permeability, (b) low oxygen and lipid permeabilities at lower relative humidities, and (c) compromised barrier and mechanical properties at higher relative humidities. Edible lipids and resins include carnauba wax, candelilla wax, beeswax, triglycerides (e.g., milkfat fractions), acetylated monoglycerides, fatty acids, fatty alcohols, sucrose fatty-acid esters and shellac (11–15). Lipid and resin materials are not polymers and, therefore, do not generally form coherent stand-alone films. However, they can provide gloss and/or moisture-barrier coatings on food or drug surfaces, or they can constitute the moisture-barrier component of a composite film. Composite films can consist of either (a) a lipid layer supported by a polysaccharide or protein layer or (b) lipid material dispersed in a polysaccharide or protein matrix (16, 17).

Materials used for edible films also have potential for replacing synthetic polymers in some nonedible applications, including replacing synthetic polymer coatings on paper or on other synthetic plastics (18, 19). Besides being derived from renewable resources, they are biodegradable; and when used as coatings for paper or plastic, they have potential for being more easily separated to make the paper or plastic more easily recyclable.

Plasticizers

Like synthetic polymer films, edible films often require incorporation of low-molecular-weight plasticizers to improve film flexibility and durability. Plasticizers generally interrupt polymer chain-to-chain interactions and lower the glass-transition temperature (T_g), resulting in greater flexibility but also, unfortunately, increased film permeability. Plasticizing materials acceptable for edible films include sucrose, glycerol, sorbitol, propylene glycol, polyethylene glycol, fatty acids, and monoglycerides. Depending on the composition, size, and shape of plasticizer selected for a certain polysaccharide or protein film-former, the effect on barrier properties relative to the improvement of mechanical properties can be minimized (20, 21). Water is also a plasticizer for polysaccharide and protein edible films. Thus, film moisture content as affected by content of other plasticizers and the surrounding relative humidity can have a dramatic effect on edible-film properties.

Other Additives

Edible films can be considered active packaging, because their edibility provides a function beyond passive barrier. Edible films show promise for being additionally active through incorporation of antioxidants (22), antimicrobials (23–27), nutrients, nutraceuticals, flavors and colors to enhance food safety, nutrition, and quality (28–30). For some food-coating applications, addition of surfactant to a film formulation may be necessary to ensure good surface wetting, spreading, and adhesion (31).

FILM MANUFACTURE

Methods for forming films include a wet (solvent) casting method and a dry (extrusion) method (32). Besides solvent casting, lipid films and coatings can also be formed from a melt.

Solvent Casting

This approach to forming edible films from aqueous, aqueous–ethanol, or ethanol solutions or dispersions is similar to production of certain synthetic films (e.g., polyvinyl chloride) by solvent casting. The solution or dispersion is spread on a smooth surface. After the solvent evaporates, a film can be stripped from the surface. With the exception of collagen, corn zein, and wheat gluten, most of the polysaccharide and protein film-forming materials are soluble in water. This can be an advantage in terms of film manufacture and use, but makes films whose properties are especially vulnerable to moisture. Corn zein and wheat gluten films must be formed from aqueous–ethanol solution or from an aqueous dispersion, but provide a somewhat improved moisture barrier compared to other protein-based films formed from aqueous solution. Wax films, layers, or coatings can be formed from ethanol solution. Edible-film production that requires ethanol necessitates appropriate safety measures and solvent recovery for commercialization. Water-insoluble whey protein films result from heat-treated aqueous whey protein solutions due to denaturation and subsequent intermolecular crosslinking of individual whey protein molecules (33).

Edible films from methyl cellulose (MC) and hydroxypropylmethyl cellulose (HPMC) are manufactured commercially by solvent casting on a continuous belt, with subsequent drying, removal, and winding of the resulting film. Such films can be formed into edible, water-soluble pouches for food ingredients. Gelatin capsules cast from aqueous solution find broad use in the pharmaceutical industry. Hard capsule halves are formed on steel pins by dipping into gelatin solution, followed by drying and removal from the pins (34). After a drug is filled into a hard capsule half, two interlocking halves are joined to form the full capsule. Soft capsules containing a drug or vitamin are formed from two previously formed sheets of plasticized gelatin by injection of the drug at the moment when the two sheets are brought together between the rotating halves of roller dies (35).

Polysaccharide–lipid bilayer films with excellent moisture-barrier properties have been produced from aqueous–ethanol solutions of cellulose derivatives with lipids (36, 37). As the solvent evaporates, phase separation results in bilayer formation. Lipid layers or coatings can be formed directly from ethanol solution or aqueous emulsion. Stable emulsions of lipids in proteins or polysaccharides produce well-dispersed composite films with improved moisture barrier compared to protein or polysaccharide films alone, but inferior moisture barrier compared to bilayer films. Research efforts continue to develop composite edible films with good moisture-barrier properties (17, 18).

Extrusion

Water-insoluble, edible collagen film sausage casings and meat wraps are made by regenerating collagen that is extracted from animal hides. Collagen casings and wraps are produced by extruding a viscous, aqueous suspension of purified acidified collagen into a neutralizing coagulation bath, followed by washing, plasticizing, and drying (38). Some polysaccharides and proteins display thermoplastic behavior, and this property is being explored for edible-film production by thermoplastic extrusion (39). Successful, efficient production of edible films using conventional extrusion equipment would improve commercialization opportunities.

Molten Casting

Lipid films, layers, and coatings can be produced by cooling of a melt to produce a solid structure. Challenges include the high temperatures required for some melts, film thickness control, adhesion, and brittleness of some materials. Forming a lipid layer from a melt on a precast polysaccharide or protein film is an alternative approach for manufacturing an edible composite film with good moisture-barrier properties.

FOOD AND DRUG COATING

Formation of edible films as coatings on foods and drugs generally consists of solvent casting directly on the food or drug surface. Application of film-forming solution, suspension, or emulsion can be by dipping, spraying, dripping, or enrobing.

Fruits and Vegetables

Edible coatings on whole and minimally processed fruits and vegetables generally serve to reduce moisture loss, improve appearance, and, in some cases, control oxygen and carbon dioxide exchange and/or carry an antimicrobial (40–42). Materials commonly used include beeswax, carnauba wax, candelilla wax, shellac, and mineral oil. These materials cannot form stand-alone films, but form continuous coatings on the fruit or vegetable surface. Film coatings based on polymeric materials such as cellulose derivatives, chitosan, and proteins have been developed to reduce oxygen and carbon dioxide exchange for respiration and ripening-rate reduction. Coating solution or emulsion is most typically sprayed or dripped onto the fruit or vegetable and/or onto a bed of brushes rotating either below or above the produce, followed by drying. Thorough distribution of the coating over the entire fruit or vegetable is dependent on a clean, dry produce surface and suitable surface tension and viscosity of the coating formulation.

Confections, Nuts, and Drug Tablets

Edible coatings on confections, nuts, and tablets serve to resist moisture change, reduce oxygen uptake, improve structural integrity, and make the product more palatable by adding gloss and/or flavor or, in the case of drugs, by masking flavor and improving ingestibility (43, 44). Materials commonly used include shellac, corn zein, cellulose derivatives, waxes, and acetylated monoglycerides. The most common method of coating involves controlled spraying (or ladeling) and drying of coating formulations on the product surface in a rotating, horizontal drum-like chamber called a “pan.” Formation of a uniform coating depends on good product coverage, thorough product tumbling action to help distribute the coating formulation, and rapid drying to allow gradual buildup of the coating. Coatings can also be formed on product surfaces in a fluidized-bed system. Coating formulations are sprayed into a fluidized-bed of the product, where tumbling action spreads the coating formulation and the fluidizing air dries the coating. This method is commonly used in the pharmaceutical industry, but has potential for use in coating foods such as nuts that have consistent size and shape (45). Successful pan-coating and fluidized-bed-coating depend on suitable coating-formulation surface tension and viscosity.

Other Foods

Many other foods have been considered for coating to improve quality and safety. Coatings have been developed for meat, poultry, and seafood to prevent moisture loss and oxidation and to improve color, flavor, and microbial stability (43, 46, 47). Such coatings can be applied by dipping, spraying, foaming or brushing. Coatings and batter-and-breading ingredients have been studied and commercialized for reducing fat uptake in fried foods (48, 49). Application is normally by dipping, brushing, spraying or enrobing. Requirements of edible films and coatings are especially stringent for military and outer-space food applications (50). Edible coatings have also been developed for use in low-energy osmotic dehydration of foods, to reduce solute uptake without slowing water removal (51).

FILM PHYSICAL PROPERTIES

Standard methods for testing packaging materials are used to detemine properties of edible films. Depending on which food or drug application is considered, different barrier, mechanical, surface, and optical properties are of most interest. Tables 1–3 compare the permeability and mechanical properties of edible films made from representative materials presently used or proposed for use. It is essential to understand that plasticizer content and test conditions (temperature and relative humidity) have important effects on film properties. Increasing relative humidity increases the moisture content of polysaccharide- and protein-based films, resulting in increased permeability and decreased strength. Thus, comparison of edible-film properties must be approached with caution.

Because of their polar hydrophilic nature, polysaccharides and proteins form films that are poor moisture barriers compared to the low-density polyethylene (LDPE) packaging film commonly used to protect foods and drugs from moisture (Table 1). However, when polysaccharides or proteins are combined with edible waxes or fatty acids in composite films where the polysaccharide or protein provides film structural integrity, films with moderate-to-good moisture-barrier properties result. HPMC- and MC-based composite films have been developed which are bilayer in nature, with resulting excellent moisture barrier properties. This occurs because the water-vapor permeabilities of waxes and fatty acids rival that of LDPE. In the case of wax coatings on fruit and vegetable surfaces, it is not necessary to use the film-forming and lipid-supporting nature of an edible polymer.

The polar nature of polysaccharides and proteins results in films that are good oxygen barriers at low-to-intermediate relative humidity (rh) (Table 2). Polysaccharide and protein films are better oxygen barriers at 50% rh than is LDPE film, which is a poor oxygen barrier. Protein edible films appear to be better oxygen barriers than polysaccharide, resin, or lipid films, with permeabilities approaching that of the excellent oxygen barrier provided by ethylene–vinyl alcohol copolymer (EVOH) at low-to-intermediate rh (see Ethylene–vinyl alcohol copolymer). In addition, the molecular composition and literature data

Table 1. Water-Vapor Permeabilities of Selected Edible Films Compared to Low-Density Polyethylene Film

Film	Test Conditions[a]	Permeability [(g · mm)/(m^2 · day · kPa)]	Reference

for polysaccharide and protein edible films suggest that they are good lipid and aroma barriers.

Edible films appear to have tensile strength (TS) and elongation (E) values roughly between those of LDPE and polystyrene (Table 3). Plasticizer level has a dramatic effect on properties, with tensile strength decreasing and elongation increasing with increased plasticizer content. Edible film toughness values (approximately TS × E) are far below that of LDPE film commonly used to make bags and pouches. However, they are sufficient to allow many applications. Small pouches are being produced successfully from HPMC for food ingredients, and casings and

wraps are being produced from collagen. Other edible film materials are also being explored for these uses. Edible films formed as coatings on food or drug products do not require the mechanical properties of stand alone films used as wraps, pouches, or casings.

MATERIAL AND APPLICATION TRENDS

Much research in recent years has been devoted to quantification of the barrier and mechanical properties of edible films produced from both old and new materials. Although most effort has been devoted to moisture and oxygen permeabilities and tensile properties, increased attention has been given to aroma-barrier (71), surface (72), optical (72, 73), and sensory (74) properties and consumer attitudes (75). Availability of such data should lead to more rational selection of edible-film and coating systems for food and drug design. Besides the various waxes, acetylated monoglycerides, shellac, zein, collagen, gelatin, MC, and HPMC in current use in food and drug products, wheat gluten, soy protein, casein, whey protein, triglycerides, fatty acids, alginate, carrageenan, aloe vera, and chitosan are among materials that have received increased attention as potentially useful materials in edible films. New coating materials being developed include water-based proteins and polysaccharides to replace ethanol-based shellac and corn zein in some applications (76). Of particular interest have been multicomponent film-forming formulations that combine the advantages of the individual components. For example, multicomponent composites have potential for combining the film-forming and oxygen-barrier properties of a polysaccharide or protein with the moisture-barrier properties of a lipid.

Considerable research is also being devoted to improving the efficiencies of forming edible films as coatings on foods and to quantification of the effects of coatings on food moisture gain or loss, food oxidation, fruit and vegetable respiration, and product gloss. Advantages can be derived from ability to extrude edible films as an alternative to solvent casting for some applications. In addition to the current uses mentioned earlier, edible film coatings have been studied or proposed for applications ranging from (a) prevention of moisture loss, browning, and microbial growth with fresh-cut fruits and vegetables to (b) prevention of moisture migration and oxidation in frozen foods.

Interest in increased food quality and shelf life has resulted in research on incorporation of antioxidants in edible films to complement their oxygen-barrier properties. Increased concern with food safety has resulted in research on the ability of edible films to provide antimicrobial compounds to the surfaces of foods. Incorporation of antimicrobials in edible films and coatings prevents their rapid diffusion into the food interior, maintaining a minimum inhibitory concentration at the food surface for longer periods of time. Table 4 shows representative antimicrobial-incorporated edible films that have shown ability to inhibit bacterial growth.

CONCLUSIONS

Edible films comprised of proteins, polysaccharides, lipids, and/or resins and other edible components have much potential for complementing conventional packaging for improvement of food and drug quality and safety. Utilization of an edible film, formed into a pouch or formed as a coating, can reduce the amount and improve the recyclability of the conventional packaging. Investigation of new materials, development of new film-forming and coating methods, and determination of film and coating properties have increased the possibilities for commercial applications. Addition of antioxidants and antimicrobials to edible films and coatings can enhance their protective function. Interest in increased food quality and safety and decreased and more sustainable packaging, along with improved edible-film properties and economics, will result in increased use of edible films in the future.

FILM, FLEXIBLE PVC

Anil G. Doshi
Bordon, Inc., Resinite Division,
North Andover, Massachusetts

Flexible poly(vinyl chloride) (PVC) film is well established as a versatile, cost-effective packaging material. The ability of PVC to accept and respond to a range of additives makes it a unique and popular packaging material. A variety of production processes are used to manufacture PVC film for a variety of applications. Film can be produced by blown or cast extrusion, calendaring, or solution casting in thicknesses ranging from 0.0004 in. to >0.004 in. It can be produced as a highly flexible, permeable stretch film or an oriented shrink film.

PVC resins, the principal component of PVC films, are made by polymerizing vinyl chloride monomer using suspension, emulsion, or bulk polymerization. PVC resin is a free-flowing white powder. Of the approximately 11 billion pounds of PVC resin produced in the United States in 1994, about half a billion pounds went into packaging applications (1). Flexible PVC packaging film applications are estimated to have consumed about 200×10^6 lb of PVC resin.

COMPOSITION

The ingredients used in manufacturing of flexible PVC films depend on the intended applications. The selection of the proper additive type and level are key parameters that influence the characteristics of the PVC packaging film. Food packaging, the single largest application for flexible PVC films, requires the use of ingredients sanctioned by the Food & Drug Administration (FDA). Non-food-packaging applications offer a broader range of additive selection.

RESIN

Suspension polymerized PVC resin, having a K value of about 66–68, is typically used to produce flexible PVC packaging films. The resin is usually classified as film-grade, indicating good absorptivity, a very low level of gels and contamination, and very good heat stability.

PLASTICIZER

Plasticizers are the major additives, and their prime purpose is to impart flexibility (2). Essentially, all PVC packaging films contain one or more plasticizers. Food-packaging applications require the use of only FDA-sanctioned plasticizer. Because of the balance of plasticizing efficiency, cost, and availability, adipate plasticizers are most commonly used. For non-food-packaging applications, the plasticizer choice is vast, but the majority that are used are nontoxic and often FDA-sanctioned. Phthalate and adipate esters are dominant in such applications. Most flexible PVC film formulations also use an oil epoxide, typically epoxidized soybean oil. This additive, frequently called a *secondary plasticizer*, imparts flexibility as well as considerable heat stability during processing.

HEAT STABILIZERS

The main function of a heat stabilizer is to prevent discoloration during processing (3). Heat-stabilizer selection for flexible PVC film is a complex matter, dictated by the application, manufacturing process and interaction with other additives. For food-contact applications, stearates of calcium, magnesium, and zinc are most often used. They are relatively inefficient and are often boosted by oil epoxies and phosphites. For nonfood applications, organometallic salts of barium and zinc are popular and offer excellent heat stability.

LUBRICANTS

Lubricants are added to PVC compounds to facilitate processing and control processing rate (4). The effectiveness of lubricants depends on their marginal or complete insolubility in PVC compounds. External lubricants reduce sticking of the melt to hot-metal surfaces; montan ester waxes, paraffins, and low-molecular-weight polyethylenes are commonly used. Internal lubricants affect the frictional properties of the resin particle surface during processing and thus control the fusion rate of the resin. Fatty acids, esters, and metallic soaps are frequently used.

OTHER COMPONENTS

Most other components of a flexible PVC film are added to impart a specific physical property. Esters of multifunctional alcohols, with the proper hydrophobic–hydrophilic balance, are added at low levels to impart antifog and antistatic properties. Inorganic additives such as clay or talc, as well as organic additives such as amides, can be added for slip and antiblock properties. Pigments may be added for tinting and coloring.

METHODS OF MANUFACTURE

Essentially all flexible PVC packaging films are produced from externally plasticized resin containing other additives; this is extruded through a film-forming die. Two; basic methods are used: blown-film extrusion and slot-die-cast extrusion. The blown film process dominates PVC packaging film production.

PVC resin is blended with selected additives using a high-intensity mixer. Mixing time varies with the actual formulation used as well as the equipment. Mixing is complete when the compound (blend of resin and additives) is once again dry and free-flowing and the additives are completely dispersed. The compound is typically heated, through shear energy, to 230–260°F and then discharged to a ribbon blender to be further mixed and cooled to the desired temperature. This compound is often referred to as *dry blend*.

Dry blend may be pelletized for later use or fed directly to a blown-film extruder. Equipment needs to be expressly designed for the heat-sensitive PVC compound, requiring streamlined flow with no "dead spots." The film is wound using surface or center winders and sold in roll form, in a variety of widths. Flexible PVC film can also be preferentially or biaxially oriented to provide shrink characteristics. This is usually accomplished by using a two-roll orienting unit or bubble inflation under controlled temperatures and strain rates. Tentering equipment can also be used, usually with slot-die-cast extrusion equipment.

MARKETS

Food Packaging

Most flexible PVC film is used for packaging food products, particularly fresh red meat. Properly formulated flexible PVC stretch films features high oxygen permeability, toughness, resilience, and clarity, making it ideal for in-store wrapping of fresh meat. Packaging of fresh fruits and vegetables in flexible PVC film is primarily performed in-store. Films are formulated for high gas transmission rates and provide excellent shelf life to the respiring produce, including sensitive mushrooms.

Packaging of chilled, tray-packed poultry parts is often done with flexible PVC film. The toughness and resilience of PVC film, plus its good heat sealability in a wet environment, make it a material of choice in this centralized packaging application.

The ability to be readily printed with solvent- and water-based inks, without the need for any special surface treatment, have figured prominently in both meat and poultry packaging, for brand identification and merchandising. A recent development has been the imprinting of a safe handling label, mandated by USDA, on the film itself. This ensures 100% compliance at the store level on all packages of raw meat.

Institutional packaging is the second-largest food-wrap application for flexible PVC film. These films, in a thickness range of 0.4–0.6 mil (10–15 μm), are wound on rolls and placed in dispenser boxes with a cutter blade. They are used in institutional kitchens, cafeterias, restaurants, and caterers to overwrap food trays, salads, glassware, and utensils. The films feature excellent cling, clarity, stretch, and dispensability.

Properly formulated flexible PVC films are also used for frozen-food storage, as well as in boxed beef operations and in-store bakeries and delicatessens.

Table 1. Typical Properties of 1-mil (25.4 μm) Flexible PVC Film

Property	ASTM Test Method	Flexible PVC Meat Package Stretch Film	Flexible PVC Dispenser Film	Flexible PVC Shrink Bundle Film
Specific gravity	D1505	1.23	1.27	1.3

[a] MD, machine direction.

[b] TD, transverse direction.

[c] NA, not available.

Nonfood Packaging

Oriented PVC films are widely used to overwrap boxed goods such as games and toys. One of the newer applications for oriented, flexible PVC is in the bundling of multiple aseptic packs. Ranging in thickness from 0.6 to 1.2 mils (15 to 30 μm), such films provide high shrink at low temperatures, resulting in a firm unitized pack, without any distortions, offering merchandising appeal. Heavy-gauge flexible PVC, 2–6 mils (51–152 μm), has been used as a component of windowed cards for many years. Toughness, formability, good dielectric sealability, and merchandisability are properties that lend themselves to the packaging of hardware, flashlights, and automobile parts.

Table 1 lists typical physical properties of the main types of flexible PVC packaging films.

FILM, FLUOROPOLYMER

A. B. Robertson
Allied Fibers and Plastics
Updated by Staff

INTRODUCTION

Fluoropolymers are a family of materials that have a general paraffinic structure with some or all of the hydrogen atoms replaced by fluorine. All members of the fluoropolymer family are available in film form, but only Aclar film is used extensively in specialty packaging applications. Honeywell is a supplier of Aclar film. Some of its useful properties are extremely low transmission of moisture vapor and relatively low transmission of other gases, inertness to most chemicals, outstanding resistance to forces that cause weathering (UV radiation and ozone), transparency, and useful mechanical properties from cryogenic temperatures to temperatures as high as 300°F (150°C). The initial interest in Aclar film was for packaging military hardware, but its water-vapor-transmission properties led to interest by pharmaceutical companies for packaging moisture sensitive products (see Pharmaceutical Packaging). Available in several grades, Aclar is more expensive than most thermoplastic films.

COMPOSITION AND EXTRUSION

Aclar is a trade name (Honeywell) for film made from Aclon, a modified PCTFE (polychlorotrifluoroethylene) fluoropolymer that contains greater than 95 wt% chlorotrifluoroethylene (1). It is converted to film by melt extrusion (see Extrusion). It is a difficult thermoplastic to extrude because it has a very high melt viscosity and a low, critical, shear rate for melt fracture. The commercially available films have different machine-direction and cross-direction properties because some orientation is induced during fabrication. Aclar 22 films have good tear strength and can be used unsupported as well as in thermoformable laminates (see Laminating; Thermoforming). Aclar 33, made from a different copolymer, offers superior dimensional stability and resistance to chemicals and water vapor transmission.

FABRICATION

Aclar film can be heat-sealed (see Sealing, Heat), laminated, printed, thermoformed, metallized (see Metallizing), and sterilized (see Healthcare Packaging). The unsupported and laminated varieties can be handled and processed on most common converting and packaging machines. Unsupported and laminated films can be heat-sealed by machines that employ constant heat, thermal impulse, radiofrequency, or ultrasonic energy. In some cases, special precautions must be observed.

Most Aclar film for packaging is converted to some type of laminate. It can be laminated to paper, polyethylene (low and medium density), and to preprimed PVC, aluminum foil, polyester, nylon 6, and cellophane. A typical extrusion lamination (see Extrusion Coating; Multilayer Flexible Packaging) uses molten LDPE as an adhesive between the fluoropolymer film and one of the substrates listed above. An MDPE tie layer produces a laminate with better properties at elevated temperatures. Laminates can also be produced by adhesive lamination. In that case the Aclar film should be preprimed. Preprimed film can be bonded to polymeric substrates with two-component urethane adhesives. The adhesive system is applied in water or organic solvent, and the liquid is evaporated in an oven. Because of its low surface energy, Aclar film does not have acceptable bond strength to most substrates unless the film is corona-treated (see Surface Modification) to increase its surface energy. With corona treatment, the film can be laminated to aluminum and steel foils by using an epoxy-polyamide curing adhesive.

All grades and gauges can be thermoformed. Typical thermoforming temperatures are 350–400°F (175–205°C). It is done close to, but not above, the melting point of the film. One of the important uses of Aclar film is the use of thermoformed laminated Aclar 22A/PVC in blister packs for ethical drugs. Heavier gauges (5–10 mil or 127–254 μm) of unsupported Aclar film can be thermoformed using ceramic or quartz heating units. Thermoformed film and laminates should be quick-quenched to maintain low crystallinity and prevent brittleness.

Table 1. Approximate Comparative Transmission Rates

[b] Dry gas at room temperature.

Most applications require transparency, but Aclar film can be metallized with aluminum. Corona-treated film can be printed with polyamide-based inks (see Inks). Best results are obtained if the film is corona-treated in-line prior to printing.

PROPERTIES

Aclar film can be sterilized with steam and with ethylene oxide (ETO) systems. Radiation sterilization of Aclar film in the cobalt-60 dosage range of $2.5\text{–}5 \times 10^6$ rad ($2.5\text{–}5 \times 10^4$ Gy) have been tested. Tests at 1×10^6 rad (1×10^4 Gy) (2) indicate that little or no property loss occurs at that dosage (see Radiation, Effects of). Aclar films have outstanding barrier properties to water vapor and to other gases (see Barrier Polymers). Properties at a wide variety of temperatures can be determined by a method that is described in Ref. (3). Table 1 compares transmission rates of Aclar films with a number of other films.

Aclar film is inert to acids, bases, strong oxidizing agents, and most organic chemicals. It exhibits excellent dimensional stability in inorganics, including water, salt solutions, strong acids, and bases. Some polar organics, especially hot polar solvents, diffuse into Aclar film and act as a plasticizer. These solvents cause it to become more flexible and sometimes hazy. There are no known solvents that dissolve the film at temperatures up to 250° (120°C). Mechanical properties are usually not an important factor in packaging applications because the important mechanical properties are those of the laminates. Aclar films are not particularly strong or tough, but they have outstanding abrasion resistance, important in clean-room packaging of military hardware.

APPLICATIONS

Aclar film is used in military, pharmaceutical, electrical/electronic, and aircraft/aerospace component applications. It serves as a key component of a transparent laminated barrier construction that meets the requirements of the MIL-F-22191, Type I specification (see Military Packaging). This laminate is used for packaging moisture-sensitive military hardware. Aclar also passes the liquid oxygen (LOx) compatibility impact test under NASA specification MSFC-106A. It is used for packaging components designed for service in liquid oxygen and other oxidizers used in spacecraft applications. Gas sampling bags made of Aclar are used on the Space Station (4).

The major commercial applications are in packaging moisture-sensitive drugs. Aclar Flex 380 exhibits 10 times the barrier protection of other films. It can reduce medical errors and streamline operations by streamlining quality control, product inspection, labeling, and product identification (1). Laminates are used for rigid and semirigid blister packs, lidding, unit-dose packages, and aseptic peel-packs. They are also used in medical applications—for example, as an overwrap for plastic containers for biomedical specimens and/or pathology specimens. This application requires a film that is sterilizable by heat and ETO and that does not absorb or denature biological fluids. Aclar film laminates are used in oxygen-rich environments for packaging items in liquid nitrogen (4).

SAFETY CONSIDERATIONS

Aclar film is inert and nontoxic and safe to handle at ordinary temperatures. It is thermally stable for up to one hour at temperatures as high as 446°F (230°C). It can be processed for a few seconds at temperatures as high as 554°F (290°C), provided that the machine is ventilated with an exhaust fan. Vacuum forming is typically done at 374°F (190°C) with exhaust-fan ventilation. If Aclar film is continuously processed at temperatures above 446°F (230°C), the processing machinery should be equipped with ventilating equipment or the work should be performed in an exhaust hood. The film should not be disposed of by burning. Exposed to flame, it degrades to fluorochlorocarbon gases, some of which are toxic. In the presence of oxygen and olefins or polyolefins, it may form HF and/or HCl when exposed to flame. These acids are toxic if inhaled and are corrosive to metals (5).

FILM, HIGH-DENSITY POLYETHYLENE

R. H. Nurse
J. S. Siebenaller
American Hoechst Corporation
Updated by Staff

INTRODUCTION

High-density polyethylene, (HDPE) film has been used for a variety of specialty applications since the mid-1950s, but it was not until the 1970s that significant growth began. Today polyethylene is the third largest resin commodity after poly(vinyl chloride) and polypropylene (1). Plants using Ziegler and chromium catalysts to make film reported production of 450 thousand tons/year. Japan and Asia use twice as much film as the United States and Western Europe (1). Much of this film is used for grocery sacks and merchandise bags and a few other nonpackaging applications. HDPE film is also used for a variety of packaging uses that require the unique property profile that HDPE films provide.

In packaging applications, HDPE films compete with LDPE and LDPE/LLDPE blends, cast PP (see also Film, Non-oriented Polypropylene), and oriented PP (see Film, Oriented Polypropylene). These polyolefin films have many properties in common, but with some significant differences in degree. Typical HDPE film properties are shown in Table 1.

HDPE, by virtue of its higher density, exhibits higher tensile strength, lower WVTR, and greater stiffness than LDPE or LLDPE/LDPE blends. PP films can offer higher tensile strength because of a higher degree of crystallinity and the ability to be biaxially oriented. PP films also have excellent optical properties due to fine crystal structure and biaxial orientation behavior. LDPE and LLDPE/LDPE blends exhibit good clarity due to their lower degree of crystallinity. HDPE is the most opaque of the three polyolefin types. This is an advantage if opacity is desired, because a relatively low amount of pigment is required to achieve that opacity (see Colorants). LLDPE and LLDPE/LDPE blends exhibit higher tendency to elongation under load because of their lower crystallinity and, hence, lower tensile modulus. This property is useful in stretch-wrap applications (see Films, Stretch), but it is a disadvantage if low elongation is required (as in handled grocery sacks). It is important to recognize, however, that the properties of all polyolefin films can be tailored during polymerization or through the use of blends or coextrusions.

PACKAGING APPLICATIONS

Two of the most important applications for HDPE film are retail grocery sacks and merchandise bags. HDPE films have replaced large quantities of glassine for packaging cereals, crackers, and snack foods. In these applications, clarity is not desirable, and the translucency or opacity of HDPE films is an advantage. They are used in conjunction with bag-in-box vertical form/fill/seal equipment (see Bag-in-Box, Dry Product; Form/Fill/Seal, Vertical). Rubber-modified HDPE film is used for medical overwraps. HDPE films are also used to produce shipping sacks. Heavy-gauge coextrusions of HDPE with low-density polyethylene are used for all-plastic shipping sacks (see Bags, Heavy-Duty Plastic), and thin-gauge HDPE films are used as moisture-barrier plies in multiwall bags (see Bags, Multiwall). Very thin embossed HDPE film is also used as a replacement for tissue paper; and without embossing, it is used as an inner wrap for delicatessen products. HDPE film is also used for foods that are heated in the package (boil-in-bag items) (2).

FILM POLYMERS

Three principal polymer properties can be adjusted to tailor the performance of HDPE films (see Polyethylene, High-Density). Density plays the most significant role as a measure of the degree of polymer crystallinity. Crystallinity has a direct influence on tensile strength, WVTR, hardness, opacity, and coefficient of friction. HDPE film resins are 0.941–0.965 g/cm^3, depending on comonomer type and

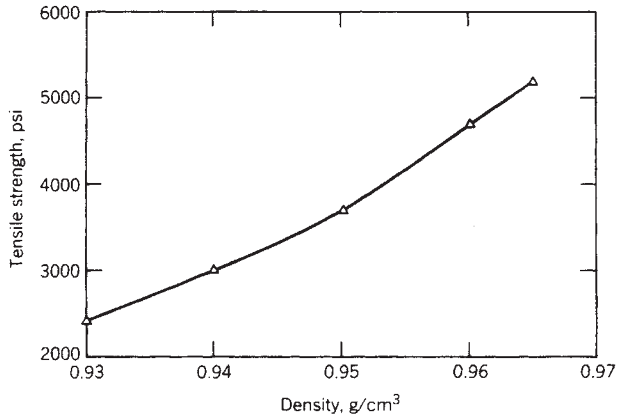

Figure 1. Influence of density on tensile strength. To convert psi to MPa, divide by 145.

concentration. The most common comonomers are butene and hexene. As density increases, tensile modulus and tensile strength increase as well (see Figure 1). The same is true for film hardness and, to some extent, for water-vapor transmission rate (see Figure 2).

The molecular weight (MW) of the polymer has a significant influence on toughness and impact strength. For many years, HDPE films were made from medium-molecular-weight (MMW) or low-molecular-weight (LMW) polymers, for applications that required only medium-to-low toughness. The development of high-molecular-weight (HMW) polymers changed the range of applications available to HDPE films (3). The influence of MW on film impact strength is significant (impact resistance increases with molecular weight), but the processing of the resin is critical as well (4).

Molecular-weight distribution (MWD) is the third parameter influencing resin design, because it influences processing. Broad-MWD resins are easier to process than narrow-MWD resins. The ability to process HDPE at economic speeds and at controlled melt temperatures requires careful resin design. High-flow LMW film resins can be narrow or medium in MWD and still be extruded at high output rates without excessive shear that would degrade the polymer. MMW resins require some careful control for high-speed extrusion (5). The use of HMW-HDPE film resins requires extreme MWD control to ensure both acceptable output rates and control of melt temperatures. Thermal degradation must be avoided to maintain the long molecular chains necessary to impart high impact strengths. This MWD has been achieved in some cases by bimodal polymerization technology. The polymer chemist has certain secondary design criteria available to fine-tune the HDPE film polymers. These include special process stabilizers, high-heat stabilizers, antistatic agents (see Additives, Plastics), different comonomer types, and the physical form in which the resins are supplied (i.e., pellets or coarse powders).

FILM MANUFACTURING

Chromium-based catalysts can be used quite widely for production of HDPE grades, but some of the best films, in terms of mechanical properties and extrusion rates, are bimodal resins made from Ziegler catalysts passing through two or more reaction zones. Most recently, metallocene resins have been used to produce extremely high clarity resins, despite the high density (6).

HDPE films are produced using two principal extrusion techniques: blown and cast (see Extrusion). The most common is blown-film extrusion, in which $1\frac{1}{2}$ – to 6-in. (3.8 – to 15.2-cm) extruders extrude the resin in tubular form. The tube is cooled, collapsed to a flat film, and either wound in tubular form or slit and folded. The properties of blown HDPE film are highly dependent on the type of resins used and the design of the extrusion equipment employed (6). MMW-HDPE films, monolayer or coextruded, are generally made with extruders in the $2\frac{1}{2}$ – to 6-in. (6.4– to 15.2-cm) diameter range operating at relatively low screw speeds yet achieving high output at moderate melt temperatures. The screw *L:D* ratio is normally 25–30 and the barrel design is normally smooth. These conventional extruders do not allow full

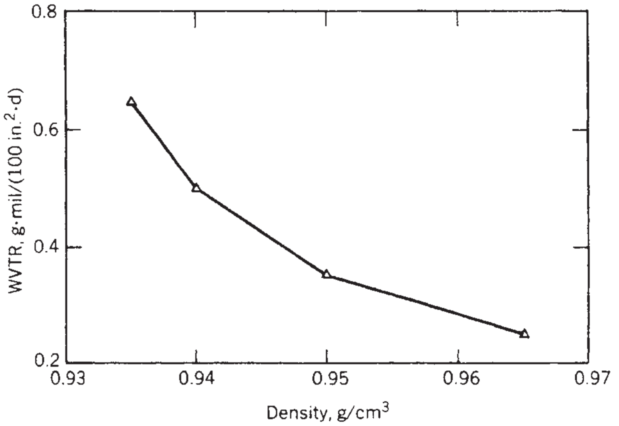

Figure 2. Influence of density on WVTR. To convert g · mil/(100 in.^{2} · d) to g · mm/(m^2 · d), multiply by 0.3937.

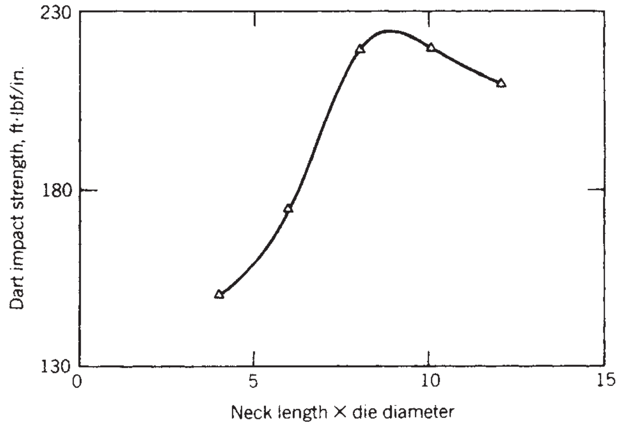

Figure 3. Effect of neck length on film toughness. To convert ft · lbf/in. to J/m, multiply by 53.38 (see ASTM D256).

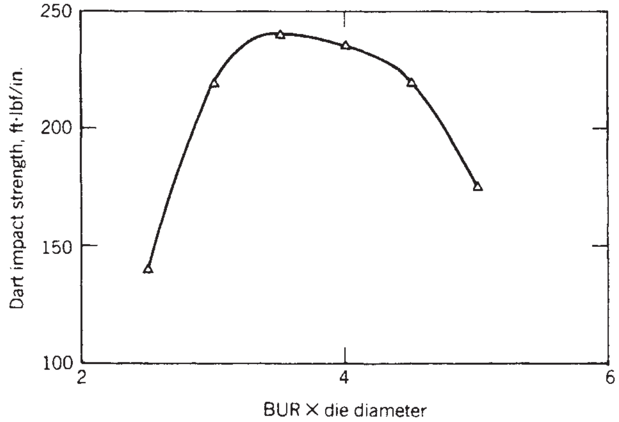

Figure 4. Effect of blowup ratio (BUR) on film toughness. To convert ft · lbf/in. to J/M, multiply by 53.38.

development of the resin capability in terms of optimum toughness, but they serve a useful role in providing high outputs at economic rates for applications which do not require the full–strength potential of HDPE.

In contrast, other designs for HMW–HDPE film extrusion are based on forced-feed grooved sections. They operate at high screw speed, using relatively short (18–21) *L:D* ratios. These extruders achieve high output with the minimum residence time required to produce a homogeneous melt for the subsequent blowing and orientation processes necessary to develop the optimum toughness and tensile strength. For HMW film it is imperative to use a relatively long neck length (frost height) (6–10 × die diameter) and high blowup ratio (3–5 × die diameter) to achieve balanced properties. The influence of these processing parameters on the optimum toughness of the film is illustrated in Figures 3 and 4.

LMW-HDPE films are generally made with cast-film technology, in which free-flowing polymer melts are extruded from flat dies on to substrates or chill rolls. These polymers do not have the melt strength necessary for the blown film process and their applications are limited.

FILM, ORIENTED POLYESTER

John Newton
ICI, Delaware

Updated by Staff

INTRODUCTION

Biaxially oriented polyester film is considered a high-performance film. It is used in numerous applications, including graphic arts, information storage and display, labels, solar control, membrane touch switches, pressure-sensitive tapes, hot-stamping foils, photoresists, fiberglass-reinforced panels, postlamination, ID and smart cards, and, last but not least, packaging.

World supply of PET film continues to expand. The domestic manufacturers of PET film for the merchant market are DuPont Films (Mylar, Melinex), Mitsubishi (Hostaphan), Toray Lumirror), Terphane (Terphane), and 3 M (Scotchpar).

FILM MANUFACTURING PROCESS

Polyester is produced by combining ethylene glycol and either terephthalic acid or dimethyl terephthalate in a condensation reaction. PET film can be either cast or oriented. The oriented variety can be either blown or tentered (stentered). Tenter-oriented PET film is the most versatile because the process imparts an improved combination of physical properties.

In the cast-tentered process, the molten resin is extruded onto a cooled casting drum (see Figure 1). The film is oriented in the machine direction by heating, then stretching the film to three to four times its original length. The film is then heated again in a tenter (a large oven consisting of several heating zones) and drawn three to four times in the transverse direction (see Figure 2). The film proceeds to the hottest zone of the oven, where the now biaxially oriented film is heat-set, or annealed. This prevents the film from shrinking back to its original unstretched shape.

Film processing conditions affect shrinkage, gloss, tensile strength, elongation, and other characteristics. The film can be treated or coated, within the manufacturing process or afterward, to change or enhance its properties.

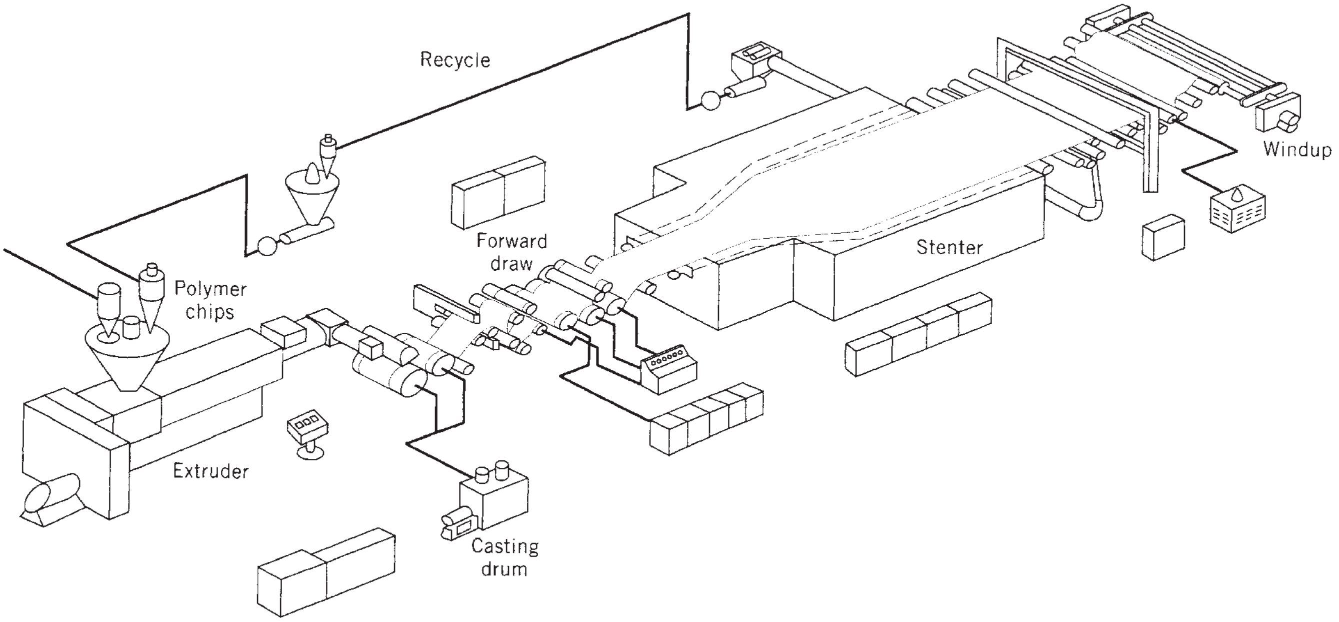

Figure 1. Film processing.

FILM PROPERTIES

PET has an outstanding combination of properties that make it valuable to the converting and packaging industries. Base PET film offers mechanical strength, dimensional stability, moisture resistance, chemical resistance, clarity, stiffness, and barrier properties. It handles well and can be printed or laminated (see Table 1). In response to customer needs, polyester film manufacturers have developed many technologies that change film properties to achieve useful effects (see Table 2).

Thermal

Polyester film gains excellent thermal properties through the heat-set process, allowing it to be processed and used in a wide range of temperatures. It tolerates temperatures ranging from −70°C to 150°C for several hours or more, and can withstand even higher temperatures for shorter time periods, making it suitable for extended drying ovens, hot stamping, and packaging processes that form, fill, and seal.

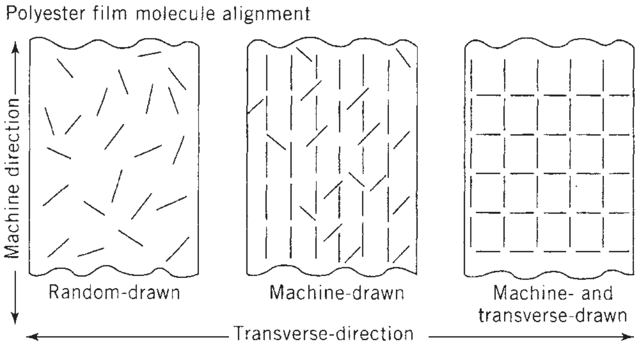

Figure 2. Polyester orientation.

Barrier

Flavor preservation is a major concern in the packaging industry. Barrier-type films constitute 50% of current U.S. PET film consumption. Polyester film has demonstrated an excellent ability to retain flavor and exclude odor from outside the packaging (see Figures 3 and 4). Metallizing or coating with PVC can provide greatly increased barrier properties.

Metallizing. Metallized films provide value to food packagers concerned with package integrity and shelf life. Metallized materials are decorative and also enhance properties such as moisture, light and gas barrier, flavor protection, protection against static electricity, and excellent machineability. Films other than polyester are now being metallized and used in packaging. However, polyester is still chosen when superior thermal stability and moisture and oxygen barrier are desired. Increasing the metal thickness further improves these barriers (see also Metallizing, vacuum).

PVC. PET can be coated offline (after the manufacturing process) with poly(vinylidene chloride). PVDC-coated PET is used in transparent packages to provide good barrier properties without metallizing. Typical coating thickness is 0.0001 in. (approximately 2 lb per ream). A major application for PVC-coated PET is in packaging processed meats such as hot dogs and luncheon meats.

Flavor Scalping

PET film is an excellent flavor and odor barrier for packaging products that contain strong flavors, smells, and migratory agents. The sealant that is used in a package is important if flavor scalping (the loss of flavor from a product to the laminate or environment) is an

Table 1. Typical Properties of Polyester Films

			Typical			
	Property		Gauge	Values	Units	Test Methods
Physical	Nominal yield		48	42,200	in.^{2}/lb

issue. A coextruded, heat-sealable PET used as the sealant layer scalps significantly less flavor from products than does a PE sealant or an ionomeric (surlyn) sealant layer (see Figure 5).

The sealant (in conjunction with the laminate chosen) can either adsorb the flavor or allow permeation through the sealant and perhaps the laminate. PET film as a barrier web and coextruded, heat-sealable PET as a sealant layer each provide superior flavor barriers in comparison with other packaging films and sealants.

SURFACE MODIFICATIONS OF PET FILMS

Corona Treating

Corona treatments use an electrical charge to raise the surface tension of film and enhance its wet-out properties. Corona treatment more closely matches the energy of the coating surface to the energy of the substrate surface. This promotes the polyester film's adhesion to various materials used in different phases of conversion. Corona treating has been an accepted method for over 30 years. Its use is limited, however, because the treatment level dissipates with time.

Pretreatments

Polyester can be pretreated in-line for a variety of surface properties, making the coating an integral part of the film. With pretreatment, the coating is so thin that it is virtually invisible. The specific coating to be used depends on customer needs and processes, including the inks or solvents to be used, the processing equipment, and the demand of the end use. Pretreatments can improve handling by affecting slip characteristics on one or both sides. Some pretreats create a film surface that is receptive to a broad range of coatings and inks. Antistat pretreatments reduce static, which can cause handling problems and compromise worker safety during processing. Other pretreats produce superior metal adhesion for certain end-use applications.

Coextrusion

Coextrusion is another method for changing film properties. This process involves casting together two or more

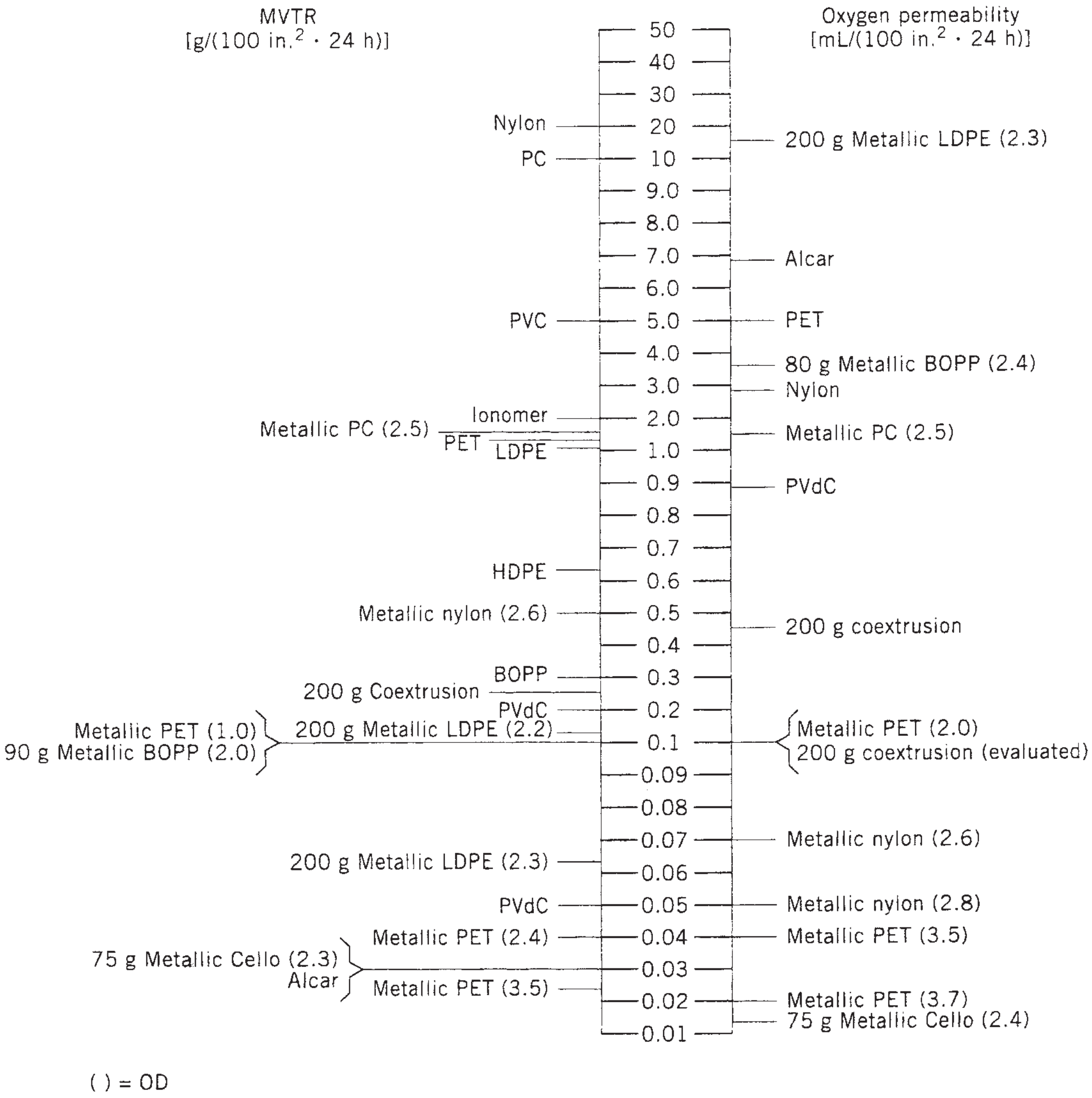

Figure 3. Barrier comparison. (Base substrates are 1 mil/metallic substrates 48 g unless noted otherwise.)

layers of polyester film to produce desired surface properties (see Figure 6). For instance, one layer of clear film can be coextruded with a layer of matte film, or a film that handles well can be coextruded with a layer of heat-sealing polyester, or resins of different colors can be coextruded. The first commercially available coextruded PET film imparted gloss and resisted glass fiber bloom when used as a construction material for pool enclosures and glazing. Today, one of the major applications for coextruded PET is metallized snack-food laminations, where it provides an absence of microcracking, a broad seal range, temperature resistance, excellent barrier properties, and improved handling.

Other Surface Modifications

Techniques for producing high-barrier transparent coatings have been available for many years. However, they were not economically viable. Sputtering techniques using indium tin oxide and aluminum oxide have produced films with oxygen transmission rates equal to those of metallizing. More recently, plasma treatments using silicon oxide products have also yielded barrier properties equal to metallized polyester (see Figures 3 and 4).

TYPES AND APPLICATIONS

Flexible packaging is a large and ever-changing source of demand for oriented PET film. Applications continue to grow as manufacturers change processes and properties to meet customer needs. In the past, polyester was considered the premier packaging material because of its unique characteristics. However, many companies continued to look for more economical ways of packaging. In many cases, they were able to maintain product integrity while using a less expensive package.

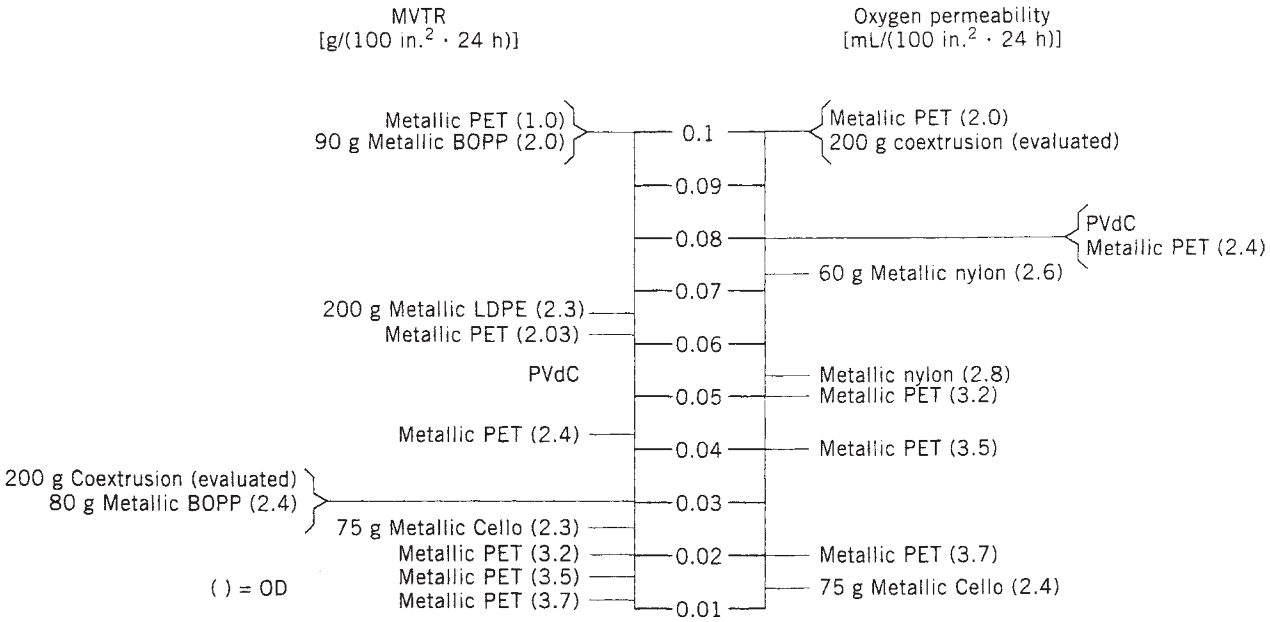

Figure 4. Barrier comparison. (All substrates are 48 g unless noted otherwise.)

In this day of downsizing and consolidation, however, companies are investing in equipment that allows them to run faster and use fewer people, and polyester is regaining its cost-competitiveness. To run equipment at full potential, polyester is preferred by converters because of its excellent ability to maintain registration (temperature stability) and because of its outstanding uniformity across the web and from point to point. The companies that use these converted products are also looking to reduce their costs by running faster. At one time, candy bars were wrapped at a rate of 100 per minute; today they exceed 400 per minute. Companies using polyester for packaging can obtain these higher speeds without distortion.

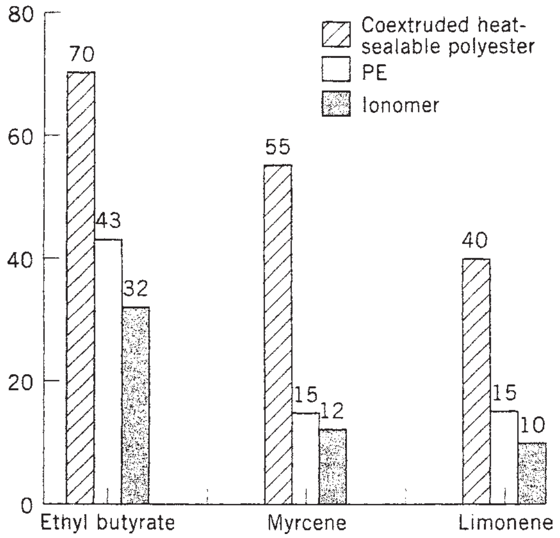

Figure 5. Percent of flavor compound retained. This graph indicates the percentage of flavor compound retained in orange-flavored Kool-Aid powder. Ethyl butyrate, myrcene, and limonene are the three key flavor components in the orange-flavored powder drink mix. The laminate structures were paper/poly/foil/PE, paper/poly/foil/ionomer (surlyn), and paper/poly/metallized heat-sealable PET.

Coffee

Coffee has long been packaged in metallized polyester structures for the fractional pack market. Typically, it has been used for restaurants and offices. PET in conjunction with aluminum foil and metallizing has taken a substantial portion of the coffee-packaging market previously held by metal cans. The brick-pack concept offers better economics and reduced shelf space.

Boil-in-Bag

Boil-in-bag applications typically use a 0.5-mil PET film with 2-mil medium-density PE adhesive lamination. A two-part adhesive system is used. The PET film is necessary for good dimensional stability in fabricating and sealing the pouch. It also provides heat-dimensional stability during the boiling operation (1).

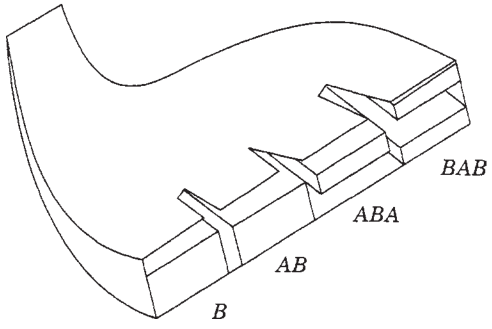

Figure 6. Coextrusion.

Bag-in-Box

Typical structures are polyethylene/metallized PET/polyethylene. Metallized PET is used because of good oxygen- and moisture-barrier properties and resistance to flavor scalping. Wine was the first application for this type of structure. Today it is also used for bulk packaging of condiments such as ketchup and mustard, as well as for foods such as tomato sauce (see Bag-in-box-liquid product).

Retort

The term *retort* refers to the process of sterilizing (cooking) a product after it is already packaged. A typical structure contains PET/aluminum foil/high-temperature adhesive/cast polypropylene (as a sealant layer) or PET-aluminum foil/HDPE (2). This type of packaged provides flavor that is closer to fresh vegetables in comparison with canned vegetables.

Dual Ovenable Lidding

PET is typically used as a lid to cover frozen single-serve dinners packaged in CPET trays. PET film can withstand the temperature differential of the freezer-to-oven transition, for both convection and microwave ovens. This market has a unique requirement: The film must seal to the tray, but must be peelable after heating.

Standup Pouches

The conversion from rigid containers to standup pouches in the United States has begun. Although the new packaging is touted for source reduction, the conversion will be driven by economics. The cost of producing, transporting, and storing unfilled flat pouches is less than that of rigid containers. Also, the pouches easily accept high-end graphics to create bolder, brighter packages on the shelf. These structures are typically thicker laminates (5–7 mil) to provide the stiffness necessary to stand on the shelf. PET, when reverse-printed on the outside of these packages, provides the thermal stability necessary to heat-seal through the thickness of the laminates (see Standup pouches).

Medical Applications

Oriented polyester film is ideal for packaging of medical and surgical devices because of its clarity (visibility) and temperature stability during sterilization. Untreated polyester has no migratory products. The PET film is combined with special paper and spun-bonded polyolefin, which allow gases to permeate both ways and restrict unwanted bacteria. Ethylene oxide is the preferred sterilization method today. Other techniques include steam and gamma radiation. The properties of polyester film are not affected at the highest levels of γ radiation. Sheets are also used to make X-ray film and test strips (3).

Shrinkable PET

Historically, both tamper-evident sleeves and labels have been made of vinyl. Over the last few years, Europe has begun to insist on products other than vinyl because of environmental concerns. Now being offered in Europe is a polyester that provides 50% shrink in the transverse direction and 5% in the machine direction.

Hot-Stamping Foils

The preferred substrate for hot-stamping foil has, for many years, been polyester film. The typical thickness is 48 gauge. Most of the film used is heat-stabilized to allow for better quality in processing and reproduction. In the normal hot-stamping process, heat and pressure are applied to produce a decorative image. Metallic hot-stamping foils are used to decorate boxes and bottles for the cosmetics and personal-care industries. A pigmented stamping foil is used to code or date products.

Holograms

In the past, holograms were used primarily as security devices on credit cards. Polyester was initially chosen as a substrate for use in this application because of its high-temperature stability and dimensional stability, along with its ability to be produced in thin gauges (48 gauge). The ability to use continuous processes with wider film widths has led packagers to begin incorporating holograms into packaging. New polyester films are being developed that allow holograms to be produced at faster speeds without coating (see also Holography).

Labels

The label industry uses many substrates, including paper, PVC, styrene, polypropylene, and polyester. Polyester plays many roles in this industry. It is sometimes used as a base stock that receives printing or bar codes. It can also be used as a protective cover lay or as a release liner. It is available either in transparent or white. The ease with which polyester can be metallized makes it suitable for high-quality decorative applications such as personal-care products, cosmetics, and pharmaceuticals.

ENVIRONMENTAL CONCERNS

PET film has a number of opportunities to stand out against other flexible-packaging films as more and more environmental pressure is placed on the packaging industry. Polyester is a good environmental choice because it is inherently more recyclable than other plastics and because of its capacity for including recycled content.

The biggest impact on the environment comes from reducing the amount of overall material used in packaging. Source reduction is driven by economic forces as well. Rigid containers (glass, metal cans, rigid plastics, etc.) are being converted to flexible standup pouches where possible. Flexible standup pouches can reduce the amount of packaging material by 70–80% when compared to a rigid container. Empty pouches occupy 70–90% less landfill volume. Rigid containers (plastic, cardboard, etc.) are also being source-reduced to the minimum technical requirements for their particular product.

PET film can also accommodate postconsumer recycled (PCR) feedstock within its manufacturing process. The

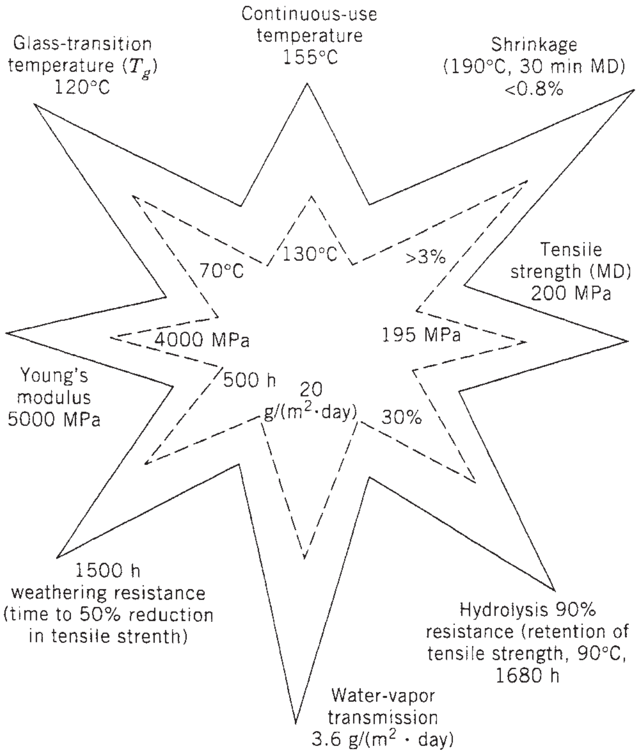

Figure 7. PEN films.

feedstock can be mechanically recycled, which requires a relatively pure PET feedstock. Mechanically recycled PET soda bottles can create a feedstock pure enough for FDA compliance. The feedstock can also be chemically recycled by either methanolysis or glycolysis process and can remain in FDA compliance. PCR feedstock is more expensive than virgin PET resin because of the additional processing involved (see also Recycling).

PEN FILMS

Opportunities in the packaging market were created by the introduction of PEN film and resin for bottles. PEN [poly (ethylene naphthalate)] is a member of the polyester family with a higher glass-transition temperature that delivers improved performance characteristics. The most important is its barrier properties. Teonex is the world's first PEN film developed by Teijin DuPont films. Compared to PET, PEN provides approximately five times the barrier for carbon dioxide, oxygen, or water-vapor transmission (see Figure 7). PEN also provides superior performance at higher temperatures when compared to PET. When used as a resin for rigid-container packaging, PEN allows them to be hot-fillable and both returnable and rewashable. As a film, PEN provides 25% greater stiffness, allowing thinner designs and greater barriers simultaneously (4).

FILM, ORIENTED POLYPROPYLENE

Eldridge Mount
EMMOUNT Technologies,
Fairport, New York

Oriented polypropylene film was made commercially for the first time by Montecatini of Italy in the late 1950s. Shortly after Imperial Chemical Industries (ICI) of the United Kingdom entered into OPP film production, Kordite (the predecessor of ExxonMobil's Commercial Films Division), Hercules, Olin, and DuPont started production in the early 1960s. Through the mid-1980s, OPP manufacturing equipment was engineered using in house expertise at the first 10–20 OPP manufacturers, but today orientation equipment suppliers supply the engineering expertise supplying turnkey lines around the world as the demand for OPP films continues to grow. Orienting lines are typically 6–8 M in width with 4–10 M lines in operation. Line speeds range from a low of 200 M/min (for older machines), to 500 M/min (for a modern orienter).

In 2000, world demand stood at about 2,801,000 tonnes and was in balance with annual capacity followed by a 5-year period of excess capacity which is just now coming back into balance with capacity at a world-wide demand of approximately 5,000,000 tonnes (1, 2). Market growth of approximately 5–6% is expected for the next 10 years with world–wide capacity growing to approximately 9,000,000 tonnes by the year 2015. This assumes the continued shutdown of older slower and narrower lines which are rapidly becoming obsolete based upon their economics as well as aspects of their machine design. Growth of OPP markets is driven by technological product innovations, geographic expansion, and population growth as the per capita consumption of OPP increases with economic development. In the last 10 years, capacity growth has been primarily in the Far Eastern markets (China and India) as well as in Latin America and Central and Eastern Europe. Production capacity has been decreasing in North America, Japan, and, to a small extent, Western Europe. Also, a great deal of consolidation has been taking place in the market, with several manufacturers being absorbed by other companies.

As of 2007, there were reported to be 195 producers and 516 orienting machines (2).

Treofan is a large multinational OPP manufacturer with offices in the United States, England, and Europe; manufacturing operations are located in Mexico, Germany, Belgium, Italy, and South Africa.

The three largest producers in North America are:

- ExxonMobil, with plants in the United States, Canada, Belgium, Netherlands, and Italy
- A. E. T. (Applied Extrusion Technologies, Inc.), with three North American plants
- Amtopp

Other North American manufacturers include: Vifan, Toray America, 3 M, BIAX Int. (Canada), B.C.F. (Bemis-Curwood Films), Intertape Polymer, General Electric, and Steiner Films.

The two largest manufacturers in South and Central America are VITOPEL (Votorantin) in Brazil and Biofilm in Colombia and Mexico, with more than 10 other producers (Treofan, Sigdopack, Polo Films, OppFilm, Bopp Ecuador, Teleplastic, Agusa, Altopro, and Masterpack).

In Europe, ExxonMobil Plastics Ltd. and Innovia Films Ltd. are the largest producers, and consolidation of many of the original manufacturing companies continues in Europe. Other producers are: Dor Films, Treofan, Vifan, BOLLORÉ, Manuli, Polinas, Bimo, Radici, Derprosa, and about 12 other, smaller producers spread from Finland to the old Eastern Block countries to Greece to Spain.

In the Far East there has been a large growth of OPP capacity over the last 10 years, with large increases in capacity in China and India. Japanese capacity has decreased as older capacity is shut down and replaced with imported materials. A number of other producers are located in Taiwan, South Korea, Indonesia, Malaysia, Turkey, Egypt, India, and Israel.

RAW MATERIALS

The four resin categories used for OPP films are: homopolymer, copolymer, terpolymer, and modified resins (see Polypropylene). Homopolymer resins are made by polymerizing propylene monomer with a variety of catalyst. Copolymers incorporate 0.1–15% ethylene as a comonomer with propylene. The amount of comonomer used depends on the film's end use. Terpolymer production uses butene along with the ethylene and propylene feeds. Polypropylene homopolymer resins are also modified with terpenes to give them certain heat sealing properties (see Sealing, Heat) and to improve moisture barrier and film production. The homopolymer PP, is typically isotactic PP, and advances in molecular architecture control has permitted improvements in film properties and productivity. Due to advanced catalyst technology, syndiotactic PP, is now available and has been used in OPP shrink film production (3) but has not resulted in any broad change in OPP film.

MANUFACTURING PROCESS

When a film is biaxially oriented, it is mechanically stretched in the solid state (at a temperature below its melting point), in perpendicular directions. This aligns the film's molecules in the transverse machine direction (TD) and in the machine direction (MD). Once biaxial orientation has taken place, the film exhibits a marked improvement in optical properties: mechanical strength, moisture barrier, and low temperature durability over cast polypropylene film (see Film, Non-oriented Polypropylene). The increase in strength allows OPP film to be made as thin as 0.45 mils (11 μm) and still function as a laminating substrate for packaging applications (see Laminating; Multi-layer Flexible Packaging). Films as thin as 0.25 mils (6 μm) are routinely used for capacitors and under special conditions films as thin as 0.04 mil (1 μm) can be made. Balanced orientation is obtained when the degree of orientation, as expressed by the film's tensile strength, is approximately equal in each principal orientation direction. There are two different methods of orienting OPP film. They are called the "double bubble tubular" and "tenter frame". While both processes were in completion in the early stages of OPP technology, today the Tenter frame process dominates world-wide production of OPP films.

Double Bubble Tubular Process

In this process, molten polypropylene resin is extruded through a circular die (see Extrusion) and is water-quenched to control the polymer morphology of the tube and the tube is collapsed by a pair of nip rolls. At this point, the quenched tube is relatively thick (e.g., 1000 μm for a 25-μm finished film) and capacity of the bubble line is generally controlled by quenching rate of the tube. Next the tube is transported to the reheating section, where it is reheated by circular radiant heaters to it orientation temperature which is above the polymer's T_g (see Polymer Properties) and below the melting temperature. Air is injected into the tube after the first nip and held captive by a second nip, and the increased air pressure forms an expanded bubble between the nips (see Figure 1). At the same time the bubble is expanded, the bubble is pulled by the second nip at a speed faster than it is fed by the first nip. The size of the bubble's circumference controls the amount of transverse (TD) orientation and the speed differential between the first and second nips controls the degree of machine direction (MD) orientation.

After orientation, the film bubble is collapsed at the second nip and is either wound up as a heat shrinkable film or is reinflated and annealed for use as a stabilized, heat-set packaging film (4). Heat stabilization in the double bubble process is accomplished by one of several methods. In the "third bubble" approach (5), the oriented bubble is reinflated while the film's temperature is elevated to a point chosen for the required level of stability, but below the orientation temperature, and then is cooled. Alternatively, the collapsed bubble is passed over a series of heated rollers (6), raising the film's temperature as outlined above, and then quenched on cold rolls. In other cases the film has been held by clips and reheated in a tenter oven with parallel chains as described below (7).

In all heat stabilization methods, the film is mechanically restrained from shrinking back in the machine

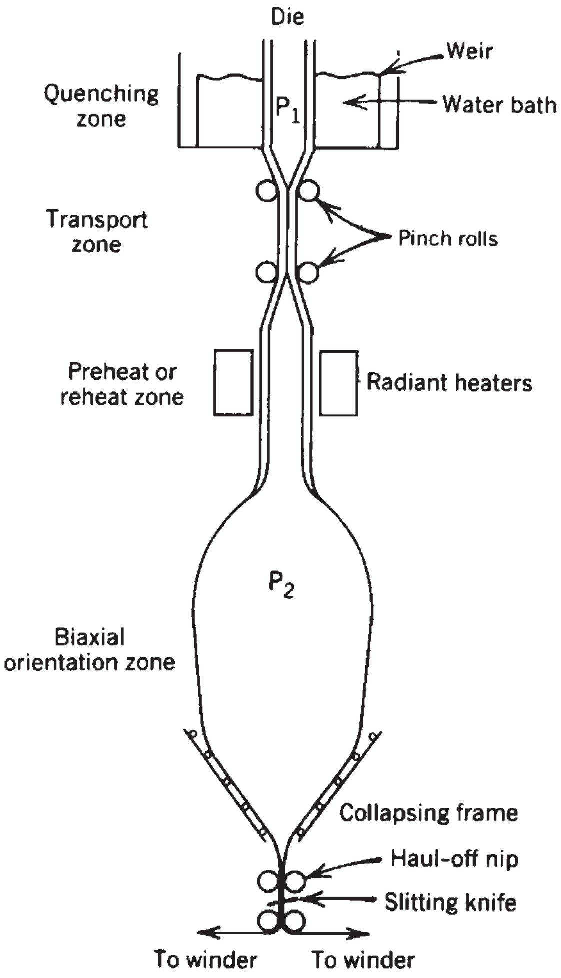

Figure 1. Schematic diagram of double bubble process.

direction (MD). The amount of restraint in the transverse direction (TD) varies from no restraint or 1–3% percent width relaxation, down to essentially no restraint. This heat treatment relaxes most of the high internal stresses and tensions built up in the film during orientation and provide a functionally stabilized product. However, most double bubble films will be less dimensionally stable than a film produced on a tenter frame, and in some instances (e.g., tobacco over wrapping films) this can be an advantage.

In the bubble-orientation process, after heat stabilization the sides of the collapsed bubble are slit and the film is wound simultaneously into two mill rolls. During this winding operation the film is frequently corona treated (see Surface Modification). This surface treatment consists of a controlled electron and ion bombardment. The film is slightly oxidized (3–8% oxygen incorporation), thereby increasing its surface free energy, which produces a multitude of sites that are chemically attracted to the polymers used in off-line coatings, printing inks, and laminating bonding-agents such as adhesives and polyolefin extrudate.

Tenter Frame Process

In this process, polypropylene resin is extruded out of a horizontal flat die, sometimes called a slot die. The extrudate is quickly cooled by a chilled roll, and a chilled roll is immersed in a water bath or in a cold water bath.

Today the majority of lines use a chilled roll immersed in a water bath. The quenching produces a sheet of controlled morphology approximately 1000 μm thick (for a 25-μm film). This heavy sheet is then reheated in contact with heated rollers to its orientation temperature (above the polymer's T_g but below its melting point). After reheating, it is first oriented in the MD. The first mechanical stretching is accomplished by drawing the sheet between a set of two, closely spaced, rollers, with one roller rotating faster (e.g., the fast roll) than the preceding roller (the slow roll) (Figure 2). On some lines a number of faster and slower roll sets are used, stretching and thinning the sheet in two or more sequential steps.

The next step is TD orientation, which is done in a "tenter frame." The tenter frame has two closely spaced endless chains with film holding clips which diverge apart to give a wider spacing at the end of the tenter (see Figure 3). The MD-stretched film enters the smaller open end and is gripped securely by its sides with spring-loaded mechanical clips (Figure 4). The clips are mounted on moving chains that run along lubricated tracks on each side of the frames. As the chains move forward and outward along these tracks, the film is stretched in the TD. Evolutions in clip design have greatly improved the manufacturing capabilities of orienting equipment and the subsequent increases in film speeds.

To achieve good heat stabilization, the film, still securely held by the clips, moves on into a heat-setting (annealing) oven section. In this section, the clip/chain systems at each side of the film have passed out of the diverging TD stretching section into a section of the tenter in which the chains run parallel to each other. Here the film is subjected to elevated temperatures for a few seconds while it is completely restrained in both directions. In some instances the TD stability can be improved by decreasing the width of the film, by bringing the chains

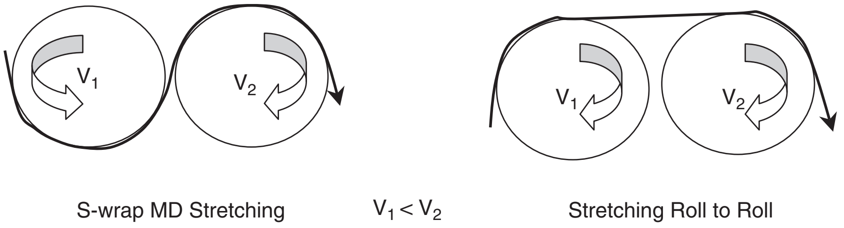

Figure 2. Schematic diagram of the machine direction orientation.

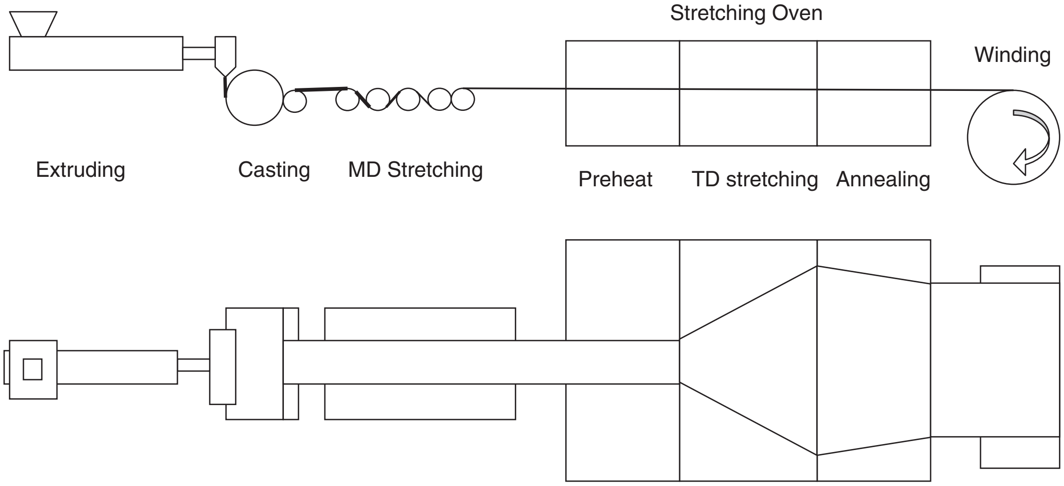

Figure 3. Schematic diagram of sequential biaxial film orienter.

1–4% closer together during the annealing process. The film is then cooled, released from the clips, has the thicker, unstretched portion under the clips removed, is generally corona- or flame-treated, and finally is wound up into mill rolls. Most modern OPP Tenter lines wind a roll the full width of the orienter, but some tenter frame users split the full width film into two roughly equal-sized mill rolls by slitting in-line (see Slitting and Rewinding) for subsequent use in film coating or metallization equipment.

Following orientation and stabilization, regardless of the process used, the freshly produced rolls are usually stored on racks for several days. During this time, remaining internal tensions are relaxed and a higher degree of crystallinity develops from secondary crystallization in the film. Additives included in the resin, such as those needed for slip, are also given time to bloom to the surface (see Additives, Plastics). After the proper time interval, the OPP film is ready for further processing in an off line coating and/or a finished slitting operation.

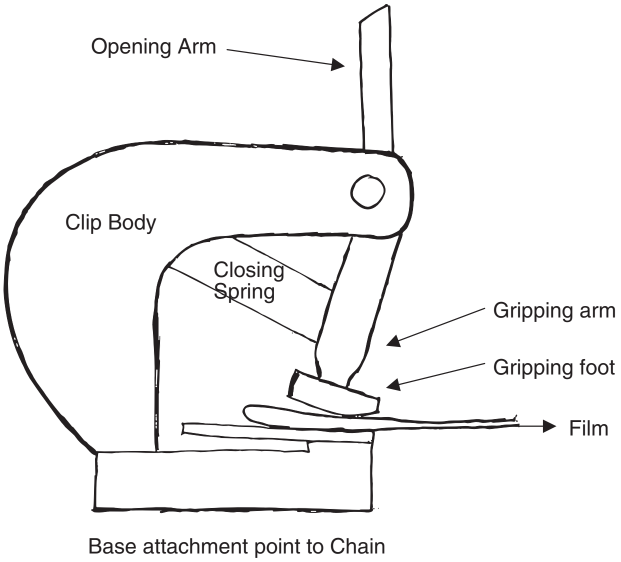

Figure 4. Side view of early style film stretching clip.

In some instances an additional MD stretching unit has been added after the TD oven to induce an additional MD stretch to the biaxially oriented film. This is done to increase the MD shrinkage of the film to make it suitable for heat-shrinkable labels and may be done inline on the film orienting equipment (8) or out of line during slitting (9).

In the early days of OPP film production when outputs were relatively low, double bubble lines were 120 in. (3.05-m) in circumference and tenter frames were 120 in. (3.05-m) wide. Over the years, larger lines have been engineered for both processes. At one time, 240-in. (6.1-m) circumference double bubble lines were in operation in Europe, but due to their low speeds and outputs, the majority of production capacity installed since the mid-1980s has been high-speed 6.1-m-to 10.0-m-wide tenter frame lines. Today the “standard” tenter line is 8.2 m and produces film at greater than 500 m/min. This movement to a much wider (and faster) line has greatly increased the OPP film producers’ productivity and has also significantly reduced the generation of narrow side rolls in slitting operations as film converting (e.g., coating, metallizing, printing, and laminating) equipment, has also increased in width. Both factors have contributed to OPP film’s reputation of being the most economical of all highly engineered, high-performance flexible packaging materials.

OPP FILM PROPERTIES

The very low density of polypropylene (0.905 g/cm^3) allows OPP film to have the greatest area-coverage yield per unit of weight of any commercially significant thermoplastic or cellulose-based sheet. Only cavitated opaque films can have a lower density (e.g., 0.6 g/cm^3) than clear OPP. This high area yield and ability to be made into very thin films are important contributions to its overall favorable economics, because the film is sold by the kilogram but used by the square meter, which give it the lowest cost/coverage area of comparable thickness films.

Thermal Properties

OPP films are intermediate in their temperature resistance as compared to other polymer films. With a melting point of 165°C, polypropylene films are more temperature-resistant than polyethylene films but less resistant than polyester films.

Normally, a heat-set OPP film can withstand brief contact (0.5 to 1 s) with sealing mechanisms that are 149°C (300°F), or slightly above that, without significant distortion in the seal areas (10). Sealing mechanisms above this temperature are possible with reduced residence time (<0.5 s) but do create progressively greater distortion potential until at about 154°C (typical orientation temperature) the film attempts to return to its unoriented dimensions, leaving the heated portions of the seal severely distorted. Because of this thermal shrinkage at higher temperatures, OPP film's sealing range has an upper limit of 149–152°C (300–305°F).

When subjected to elevated air temperatures for several minutes, heat-set OPP film will display a range of dimensional changes, depending on the temperature to which they are exposed. Below 75°C, OPP film shows very little or no shrinkage at extended heating times, and a package wrapped in this material maintains its dimensional integrity at normal packaging and distribution temperature histories. At a temperature of approximately 105°C the film will show 1–2% MD shrinkage and perhaps a TD width change of 0.5% shrinkage to 0.5% growth within 7 min. However, at 135°C and 7 min, the film will shrink approximately 3–5% in the MD and 2–3% in the TD. The actual dimensional change values and shrinkage versus. temperature profile will depend upon the manufacturing methods used to produce the film. Consequently, heat-set OPP films will show some shrinkage if they are exposed to very hot environments such as is found in retort packaging (250°F (121°C) at 15 psi 103 kPa)), and care should be exercised when choosing OPP for high-temperature applications.

In some cases OPP films are made purposely unstable so that they may be used for heat shrink films. These are used in two principal markets today, namely, shrink overwrap films and roll-on shrink on bottle labels. For shrink overwrap, at 135°C the film may shrink 35–50% in both the MD and TD directions while for shrink labels the films are designed to shrink uniaxially from 8–25% in the MD with 0% TD shrinkage.

Physical Properties

There are relatively few physical property differences between films made by the two processes (see Table 1). Both films possess excellent moisture-barrier properties but poor oxygen and aroma barriers. Moisture barrier increases and decreases proportionately with the thickness of the film under consideration. Tensile strength and elongation of blown films tends to be about the same in both directions (balanced). TD strength is higher than MD strength in tenter-frame films, and MD elongation is higher than TD elongation (unbalanced). Tenter-frame film has generally superior heat stability over blown film because of more severe annealing conditions that can be practiced in the tenter-frame operation. Double bubble OPP films have somewhat better impact strength. However, only in the most demanding and arduous packaging applications would these relatively small differences become significant.

Optical Properties

Standard OPP films are naturally high-clarity and high-gloss films offering excellent printing graphics product visual identification. However, many OPP suppliers also offer clear films with a low-gloss, matte surface, to aid in product graphic appeal and differentiation. Opaque, white films with 20–30% light transmission are also widely available as are metallized films with 1% or less light transmission and high reflectivity for light-sensitive products.

PRODUCT DEVELOPMENTS AND COEXTRUSION TO SEVEN LAYERS

The first two OPP films produced were single-layer homopolymer shrink film and heat-stabilized film that could not be heat-sealed. The former had limited application because of its need for hot-wire sealing and tremendous shrink energy, which originally precluded it from wrapping high profile products. The development of copolymers allowed the widespread development of propylene shrink films which today have replaced much of the original PVC shrink films and compete strongly with crosslinked polyethylene shrink films. Additionally, the development of special polymeric coatings and polypropylene copolymers and terpolymers during the 1960s, 1970s and 1980s respectively, has alleviated the lack of sealability problem in many applications.

The original heat-set OPP film gained wide acceptance as a laminating substrate when combined with heat-sealing polymer-coated cellophanes (see Cellophane) and glassine papers (see Glassine). The OPP film contributed strength, moisture barrier, and high surface gloss to the lamination. However, before acceptance was forthcoming from the marketplace, OPP film producers had to improve the film's slip characteristics over the relatively high coefficient of friction (COF) that is natural to the film and improve the low surface wetability. The addition of internal surface-blooming slip agents reduces the film-to-film COF to 0.2–0.4. This COF provides excellent machineability on automatic bag-forming machinery used in the snack food and candy industries, while surface oxidation improved wettability. Converters developed the hot-melt adhesive-based, heat-sealing thermal stripe that allowed the production of lap back seals on vertical form/fill/seal machines (see Form/Fill/Seal, Vertical). This technology widened the use of OPP film laminations for snack foods, candy, and pasta products. Today the use of three-layer coextruded films permits the direct formation of lap seals without the need for thermal strip technology. Another

application for this non-heat-sealing film is the inner liner of paper bags for products such as cookies and pet foods.

Since this early beginning, the history of OPP product development of has been the creation of improved barrier technologies and the development of surfaces with special attributes to permit the use of the base sheets barrier properties in packaging and industrial applications. The primary protection that OPP inherently supplies is that of a moisture barrier. Additional barriers have been added during the development of new products such as oxygen, barriers, aroma (chemical) barriers, and light barriers. However, it is the moisture barrier property, combined with the unusually low polymer density, which results in the maximum possible product coverage with one of the lowest moisture permeabilities for clear films. When these two features are combined with special surface attributes such as sealability, printability, laminatability, coatability, metallizability, and machineability, a high-quality, low-cost packaging film emerged which replaced almost all of the cellophane then in use in snack food packaging. In addition to cellophane replacement, OPP has made further inroads into glassine paper and some foil markets as well. Today this combination of properties still drives the expansion of OPP films into new packaging applications and developing markets.

In order to reach this point, several weaknesses of OPP film relative to packaging in general and cellophane in particular had to be addressed. The inherent limitations to homopolymer OPP film are: no sealability, high COF surfaces, low surface wettability, static generation, and a lower use temperature range than cellophane.

In order to overcome these weaknesses in the product, both film and packaging machine changes were required. The temperature limitations were overcome by improvements in packaging machine design and temperature control of sealing jaws as well as the use of special acrylic and PVDC polymer coatings and the use of low-melting copolymers and terpolymers as film sealing surfaces. Today the machine evolution is complete and packaging machines are designed with OPP film as a primary wrap. Static generation occurs at all surfaces and, due to the high dielectric strength of OPP, must be eliminated at each point where static interferes with packaging machine performance. Product formulation approaches have been hampered due to a lack of Food and Drug Administration FDA-approved additives and the relatively high additive levels that would be required. Surface wettability is overcome by coating with acrylic polymers; for uncoated films, it is overcome by the surface oxidation of the film with corona, flame, or atmospheric plasma treatment on the film orienter and perhaps at subsequent converting steps. The development of multilayer coextrusion systems has also permitted the incorporation of non-propylene skins to be used, such as EVOH and nylon, which has further broadened to the range of product developments. The development of low COF surface modifications has relied almost exclusively on film formulation developments and has seen many developments over the years. The original surface modification for COF was a formulated acrylic coating that combined excellent printability, low COF, and broad sealability. The second development was the use of fatty acid amides that when added to the polypropylene, would diffuse to the film surface (called slip bloom) with time and heat treatment after film orientation. While this lowered film COF, it is difficult to control and the additive often interferes with printing ink adhesion, metallization, and lamination bonds. Today this slip blooming technology has been replaced by the use of mineral and polymeric particles that are dispersed in the film surface layers as well as the use of silicone oils for higher temperature applications. This gives a film COF's of 0.25–0.5. While these COF values appear high by the original standards, the films all exhibit a low but uniform force to transport the film over the forming collar and through packaging machines. It is this low film transport force which is the critical property for proper machineability and not the film-to-film COF.

Today, OPP film has found wide acceptance and continues to grow as new markets are developed making use of its special product characteristics. Many of the technologies developed to permit the use of OPP have gone through several developmental generations as new resin and additive technologies were invented to overcome the limitations of the first generation film modifications. Today, developments in polymer metallocene catalysis continues, thereby generating new propylene resins such as high-crystallinity polypropylene and syndiotactic polypropylene. How these new development and resins will impact future growth in OPP packaging and new film modification technologies is currently unclear.

SEALABILITY

The quest for functionality through heat-sealing on conventional sealing mechanisms used on most packaging machines let OPP film producers down four avenues of development. The first was the modified polymer route. This film uses a polypropylene that is modified with natural and synthetic terpene resins. The film is heat-sealable, although its sealing range is relatively narrow (25°F or ~14°C), and it does not have good hot-tack-seal strengths needed for form/fill/seal packaging. In overwrapping applications where the product to be packaged is contained in a carton or some other self-supporting structure, this OPP film has found good acceptance. Because this film is only partially heat-stabilized, it can be snugly tightened around the carton or bundle through the use of a heat tunnel. One version is used today as a cigarette-packaging material. However, this technology has largely been supplanted by surface sealability modifications.

The second method of imparting sealability to OPP film is by addition of an offline heat-sealable coating based on an acrylic polymer (see Acrylics). This coating adds flavor and aroma barrier, but no moisture or oxygen barrier properties to the OPP film. However, it does provide a relatively wide sealing range of 80°F or ~45°C and adds sparkle and good machine slip characteristics. It has a film-to-film COF of 0.2–0.3. It has high-volume use in horizontal form/fill/seal operations (see Form/Fill/Seal, Horizontal) for items such as baked foods (cookies in particular) and candy. As an overwrap film, it is used for pet foods and various tobacco products such as cigarettes, cigars, and pipe-tobacco cartons. Its hot-tack and seal-strength characteristics are such that it is used extensively for VFFS packaging of lightweight products, such as snack foods, but is not generally proposed for similar packaging of heavy products. These acrylic coatings are compatible with many inks (see Inks) and adhesives (see Adhesives) used by converters and are also heat-sealable with the PVDC coatings used on cellophane, glassine, and other OPP films (see Vinylidene Chloride Copolymers).

The third method to obtain heat sealability is to coat the OPP film offline with a PVDC coating, which also overcomes the gas-barrier deficiency. This is required because oriented polypropylene film in its uncoated form is not considered to be a gas-barrier film (see Table 1). Its oxygen permeability is relatively high at 73°F (23°C) using 1.00-mil (25.4-µm)- thick film (see Table 1). PVCD-coated films fall into four categories. The first is readily machineable on heat-sealing, automatic packaging equipment. The sealing range in this case is relatively wide (60–80°F or 33–45°C), and the oxygen-transmission rate is improved (see Table 1). These films are available with one or two sides coated. The former is a laminating substrate for use with other OPP films and cellulosic materials, to package snack foods and candies. The two-side-coated product is used in unsupported form for bags and carton overwraps. In all of these applications, an aroma barrier (which the PVdC supplies) is generally desired by the end-user.

The second category of PVDC-coated OPP film has a superior gas barrier and an oxygen-transmission rate of 8–12 $\text{cm}^2/(\text{m}^2 \cdot \text{d})$. However, because its sealing range is no more than 50°F (28°C), this film is not used for its heat sealability. Rather it is used as a laminating substrate with various other materials for the controlled atmosphere packaging of coffee, natural cheese, and processed meats (see Controlled Atmosphere Packaging).

The third category combines an acrylic coating on one side and a PVDC coating on the other side. The advantage cited for this film is that it provides a degree of gas and improved aroma barrier, is lap sealable, machines well, and costs somewhat less that two-sided, heat-sealable, PVDC-coated OPP films.

The fourth category of PVDC-coated films is the combination of the high-barrier PVDC coating with a broad-seal-range, coextruded sealant skin. This film is used as a laminating film with the high-barrier PVDC buried in the structure and makes use of the excellent seal properties of the coextruded skins (see below).

The fourth avenue of development of heat sealability of OPP films is through coextrusion. Although coextruded, multi-ply, heat-sealing OPP films have been available since 1955; this type of film came into large-volume usage during the late 1970s and early 1980s. This was in large part due to the development of ethylene propylene copolymers (EP copolymer) and later by ethylene, butylene propylene terpolymers (EBP terpolymer), resins, and advances in the technology of coextrusion die design. Coextrusions are made using several basic approaches. In one approach, two or more extruders feed their individual molten polymer streams to a single manifold extrusion die (see Coextrusion, Flat; Coextrusion, Tubular). In the upstream section of the die is a round or rectangular "feed block" mechanism that brings these polymer flows together into layers before passing them to the single cavity (manifold) where they are deformed into a single wide, thin rectangular sheet as it passes out of the die lips. Another method is termed "tandem" coextrusion. With this procedure the film's core material is extruded from its own extruder and die. This extrudate is then extrusion-coated (see Extrusion Coating) from one or more extruders and dies, or it is hot-nip laminated to other compatible, independently manufactured films. In recent years this "tandem" coextrusion has been largely replaced with multi-manifold coextrusion technology. In this OPP technology, generally three separate die manifolds are contained together in the same die body. As the polymer flows toward the die exit, the separate layers are combined together in layers and then exit the die lips together. This technology has permitted the combination of resins that cannot be coextruded by the feed block method or "tandem" methods describe above. More recent developments have combined the feed block with the multi-manifold dies to produce five and more layers in a single sheet. In all coextrusion cases the multilayered sheets are moved into the orientation units of the line. Coextrusions can be made by both the blown bubble and tenter frame processes.

Polypropylene does not anchor well to many other polymers. As a result, great care must be taken in the choice of materials used in OPP film coextrusions; otherwise inter-ply bonds may be broken during orientation or, later, by the stresses of package forming techniques and distribution. Other demands on outer ply materials include hot-slip characteristics that allow easy film movement over hot-packaging machine parts and surface-slip characteristics for good overall trouble-free automatic high-speed machining. The ply destined to be printed or laminated must also be corona- or flame-treated.

Today, most coextruded OPP films consist of two to five layers. The majority of the film's mass is in the core ply that is usually made with virgin homopolymer and some regrind. One or both sides of the core may be covered with a polypropylene-rich copolymer or terpolymer, an ionomer (see Ionomers), or a vinyl acetate-modified polyethylene layer. The choice of polymer depends on the purpose for which the finished film will be used. Polypropylene-rich copolymers of propylene and ethylene are used for their good hot-tack seal strengths and excellent finished seal strengths. Terpolymers of propylene, ethylene, and butene are used to improve the film's breadth of sealing range, and today's terpolymers have been developed to give excellent hot-tack strength as well. Vinyl acetate-modified polyethylene plies are used for their anchoring potential in offline coating, laminating, and metallizing operations (see Metallizing). Ionomer resin is used for its wide sealing range and ability to repel grease and oils. It is somewhat difficult to handle in the orientation process; but once oriented and heat stabilized, it provides lower level seal strengths of about 300 g/in. (116 N/m) which can be used advantageously in packages that demand an easy-open feature. Ionomer-skinned films are not generally made by

Table 2. Coextruded OPP Film Sealing Temperature Ranges

OPP Film	Sealing Temperature Range
Copolymer group A (0.5–e.0%)	30–50°F (16–28°C)
Ethylene copolymer group B (≥4% ethylene)	60–70°F (33–39°C)
Terpolymers (ethylene and butane)	85–95°F (47–53°C)
Ionomer	95–105°F (53–58°C)

the tenter process due to its aggressive adhesion to hot metal surfaces used in the process and are only produces on bubble equipment. These films are therefore at risk of disappearing as lower productivity bubble lines are shut down in favor of higher productivity tenters.

Coextrusion sealing temperature ranges very greatly, depending on the sealing ply materials. General categories are listed in Table 2.

Thin coextruded OPP films, 0.57–0.70 mil (14–18 μm) thick, are often laminated to other substrates such as polymer-coated cellophane, glassine, paper, and other OPP films for snack food, candy, processed cheese, and pasta-product packaging. In unsupported form they package lightweight products such as single-serving packages of crackers used in restaurants.

Medium-weight films, 0.800.90 mil (20–30 μm) thick, are used for carton and tray overwraps by the bakery and candy industries, as well as for form/fill/seal single wall pouches by pet food producers. A specially designed medium weight material is used as a cigarette package overwrap. Heavy, thick coextruded OPP films, over 1.00 mil (25.4 μm) thick, are normally used in unsupported form to package cookies, candies, snack foods in small bags, and other products that need the stiffness, strength, excellent moisture barrier, and rich feel offered by these films.

OPAQUE FILMS

White opaque film is one of the fastest growing OPP film developments in the United States and Western Europe. The most widely accepted film products of this type are made by the tenter-frame process. Homopolymer resin is evenly mixed with a small amount of foreign particulate matter. In one product, when the thick filled sheet is oriented, the polypropylene pulls away from each particle, creating an air-filled void (closed cell). After heat stabilization the OPP film is similar to a micropore foamed product. In the second product, the material is produced as a filled film without voids. The opacity is a direct result of the amount of particulate material included in the film.

In the film with air-filled voids, the imparted opacity and whiteness is created to a small degree by the encapsulated particulate matter. However, the primary opacification is brought about by light rays bouncing off the polypropylene cell walls and the air within each cell. The refractive index of the air is less than for polypropylene. This refraction difference results in TAPPI opacity of about 55%. The light diffusion gives the film the visual effect of pearlescence. Brightness values are calculated at 65–75% by the GE method. The actual gauges of this white opaque film are deceptively thick when their area yield per unit of weight is considered. A 1.5-mil (38-μm)-thick cavitated OPP film has an area yield of 30,000 in.^{2}/lb (427 cm^2/g), which is about the same yield provided by a 1.0-mil (25.4-μm)- thick transparent OPP film.

Coextrusion and out-of-line coating techniques have greatly expanded the market acceptability of white opaque OPP film. By using these approaches to film manufacture, the film can be made one- or two-side heat-sealable. These steps can also increase the film's moisture, oxygen, and aroma barrier. White opaque OPP films are finding growing volumes in snack-food packaging, candy-bar overwraps, beverage-bottle labels, soup wrappers, and other applications that traditionally have used specialty paper-based packaging materials. White opaque films are also finding new applications such as photographic paper and digital printing substrates.

METALLIZING

The use of OPP film as a metallizing substrate is another area of new market growth (see Metallizing). In this process, aluminum is vaporized onto one side of a film or paper in a high-vacuum environment. The speed of the substrate's passage over the vaporization pots controls the amount of metal deposited on the film. If the metallized surface is to be used primarily for decorative purposes, a relatively light coating of approximately $4\,\Omega^2$ (1.6 optical densities, OD) is applied. This gives OPP film, originally in transparent form, a light-transmission rate of about 5%. If the metal coating is used for significant improvement of the finished film's barrier properties, a heavier disposition of $2\,\Omega^2$ (2.2 OD) is employed. This level lowers light transmission to about 0.6%. Moisture and oxygen barrier are improved dramatically (see Table 1). In packaging, metallized OPP films are widely used in snack-food laminations and for confectionery wraps.

Today further product design advances have been made by coextruding non-polypropylene polymer surfaces, that, when metallized, lower the moisture barrier properties of the metallized film relative to metallized OPP and below that of metallized polyester (PET) films while approaching the oxygen barrier properties of metallized PET (11). Further developments have produced developmental samples of metallized OPP that have moisture and oxygen barriers significantly better than metallized PET and approaching the properties of foil. This is accomplished by the incorporation of non-polypropylene layers such as PETG (12), nylon (13), HDPE (14), and EVOH (15) for the metallized surface.

LABELS

This is a growth area for OPP films with cavitated and clear films gaining wide acceptance in many labeling applications. The broad label categories where OPP is making inroads are inmold labels, roll-fed labels, pressure-sensitive labels, roll-fed shrink labels, cut and stack for hot melt, and wet glue. The OPP film functions as a carrier for sophisticated coatings that give many of the surface properties needed for the label applications.

FILM, PERFORATED

Nazir Mir
Perftech, Inc., Oswego,
Illinois

INTRODUCTION

There is a growing interest to use flexible polymeric films with "improved" gas and water vapor transmission properties for horticultural packaging and other food and industrial applications. Fresh produce is still respiring, taking in oxygen and giving out carbon dioxide, and thus its packaging requires polymeric films with selective oxygen and carbon permeability matching the requirements of this respiring product. The word "improved" in the first sentence above means those films having suitable gas and water vapor transmission properties to match the requirements of the application. While high-barrier films (those with low transmission rates) are usually used to protect shelf-stable foods against oxygen and water vapor, those films are not suitable for packaging fresh produce. Films with improved gas and moisture transmission properties for fresh produce are generally achieved by one or a combination of the following: (a) selection of polymeric films, (b) addition of fillers during film extrusion, and (c) perforations.

Improved films are constantly being developed to satisfy the needs of the marketplace. Some of those films include high (6–18%) ethylene vinyl acetate content, low-density polyethylene (Elvax) films by DuPont, oriented polypropylene (OPP) laminates by BP Amoco, styrene butadiene block copolymer (K-Resin) films by Phillips Chemical, ultra-low-density ethylene octene copolymer (Attane series) films by Dow, and polyolefin plastomer octene copolymer (Affinity series) films by Dow (1).

Plastic films can also be incorporated with inert organic fillers such as $CaCO_3$ and SiO_2 or organic minerals such as zeolite. Such films may then be biaxially oriented to create small perforations generally in the range of 0.14–1.4 μm in diameter (2). The gas and vapor transmission properties of these films can be manipulated by adjusting the particle size of the filler and the degree of stretching.

Ethylene manipulation is extremely important for storability of some horticultural crops. Some additives such as zeolites may also confer ethylene adsorption properties to the film. Ethylene adsorption capacity by zeolite may be reduced markedly by the presence of water vapor. It has been shown that the ethylene adsorption capacity of a zeolite impregnated film was negligible at 100% RH compared to its maximum capacity at 0% RH (3). Because most horticultural packaging applications are at conditions near water vapor saturation, the use of such films has not yet had any major commercial success.

MANUFACTURING TECHNOLOGY OF PERFORATED FILMS

Perforated films are plastic films that have holes drilled through all the layers of the film. Depending on the size of perforation, the film may be called microperforated or macroperforated films. Microperforated films have perforations in the range of 5–300 μm in diameter, while macroperforated films have perforation exceeding 300 μm in diameter. Generally speaking, microperforated films are largely used to increase the gas properties of packages containing high-respiring produce such as broccoli, bananas, and leeks.

Currently, much marketing effort is focused on improving the presentation and utility of value-added fresh produce products. As a result, the produce industry is shifting more and more toward product offerings in trays as opposed to traditional breathable bags. The most commonly trays used are either polyester or polypropylene, both of which are quite impermeable to the gas exchange in the thicknesses used for these applications. Thus, to account for the respiratory requirement of the packaged product, the trays need to be lidded with a highly gas-permeable membrane. This can conveniently be achieved using microperforation technology while keeping the sealabilty, machineability, ink adhesion, and other properties unchanged during the process. Macroperforated films are largely used to increase the moisture properties of films for packing whole produce (such as tomato, pepper, banana) and cold and hot bakery products.

There are several postmanufacturing technologies available for perforating plastic films. These technologies include (a) mechanical puncturing by cold needle, and (b) plastic melting at directed spots by hot needles, flame, low-energy electrical discharge, and high-energy electrical discharge and lasers. The cold and hot needle technologies and the flame technology are commonly used for macroperforation, while the electrical discharge and lasers technologies are commonly used for microperforation.

The technologies for macroperforation have been available in the industry for a relatively long time. Electrical discharge systems for microperforation of plastic films is a mature technology. Although the perforations on plastic films can be achieved reliably with electrical discharge systems, most systems have certain film thickness limitations beyond which it is almost impossible to achieve perforation consistently.

Laser technologies for perforation of plastic films are relatively new. Practically speaking, laser systems contain three key elements: (1) a laser medium that generates the laser light, (2) a power supply that delivers energy to the laser medium in the form needed to excite it to emit laser light, and (3) an optical cavity that concentrates the light to stimulate the emission of laser radiation. Since the introduction of laser systems for perforation of plastic films to the marketplace, technological improvements in all these three components have improved dramatically. For instance, the systems have evolved from weak 20-W power sources to 2-kW power sources, from split beam technology to beam compression and recently to polygon mirror directing, which ensures that the beam strength stays constant throughout the laser exposure interval. This function has remarkably increased the speed and quality of the perforations on a number of plastic films. Figure 1 illustrates such a system.

Perforation of plastic films is commonly achieved by CO_2 laser systems. The laser energy generated through such a system is absorbed by a plastic film in directed spots. The film in those spots are heated, melted, and eventually evaporated, leaving perforations in the film. Although the principle of laser-drilled perforations is common in all plastic films, there is a strong interaction between the nature of the films and their laser absorption characteristics. Some films may need a very small dose of energy to melt, while for others it may be almost impossible to drill holes under commercial requirements.

TRENDS

A new trend in flexible film business is to offer materials as blends of two or three different polymers, in which each polymer performs a specific function such as improving strength, transparency, or gas transmission to meet specific product requirements. Laminated film structures are also becoming common for a number of value-added fresh produce applications. The structural complexity of these new films imposes a number of challenges and, at times, imposes restrictions on the successful application of lasers on the perforation quality and frequency of these films. The perforation quality is often measured by shape, size, and aspect ratio. Depending on the shape of perforations, the aspect ratio can be 1 or >1. The circular perforation has an aspect ratio of 1; and as the shape of the perforation deviates from the circularity, the aspect ratio begins to increase. The oblong perforation has an aspect ratio of 1.2 to 1.4. The aspect ratio is defined as the length of the perforation in machine direction divided by the length of the perforation in transverse direction. It is either circular or oblong.

The adhesives in laminated structures can also interfere with the laser energy absorption process and may dramatically reduce the speed of laser perforation process. In some instances, the adhesive may serve as a strong sink for the laser energy, thus making it impossible to drill a hole through all layers of the laminate. Thus, it is conceivable to think that the development of operating perforation procedures for films that vary in chemical

structure due to variations in polymer blending or adhesion of various layers in a laminate can often be extremely complex, time-consuming, or impractical for commercialization. The development of a successful perforation protocol for these films is usually driven by knowledge of the interaction of laser energy with film structural components, and then whether or not the perforated product can be marketed as a packaging solution at a cost that would suit the utilizing industry.

FILM, PLASTIC

Allen G. Kirk
E. I. Du Pont de Nemours, Inc.,
Wilmington, Delaware

Films are continuous membranes that can separate one area from another. These membranes can vary in thickness, ranging from less than that for rigid containers, to sheeting, to film, and even to thin coatings. Usually films are considered self-supporting and less than ~10 mils (250 μm) in thickness. No definition is given for a minimum thickness, which can vary depending on the material of construction of the film; however, thicknesses of <1 mil (25 μm) are common.

An important feature of most films discussed in this article is *heat sealability*, which refers to the thermoplastic property of the film, or coating on the film, which allows it to be fashioned into pouches, bags, and overwrapped packages by virtue of its ability to make a hermetic seal to itself. Heat sealing is accomplished by heating up the film areas then applying the hot areas to each other under pressure. Sometimes these operations occur simultaneously. During heat sealing, the polymer molecules become entangled; the better the intermingling, the stronger the seal. The time allowed for heat sealing in a typical high-speed food-packaging machine is less than 1 s, during which time heat-seal strengths of very high values can be achieved, i.e., several pounds per inch of seal width.

FILM USES

Because of their ability to keep two areas (or volumes) separated from each other, films have come to have a multitude of commercial uses over the years, particularly in the area of food packaging. Films do provide protection to the foodstuffs being displayed, and in doing so they can provide a multitude of other functional attributes. They can function as barriers for gases, vaporous flavor components, or moisture from escaping from the food, thus preserving its freshness. They can also protect the foodstuff from attack by undesirable outside agents such as air (oxygen), moisture, or sunlight, thus ensuring that the food does not become rancid or soggy. The film material can serve as a partial gas barrier, thus allowing some gases to escape but not others; the choice of packaging film to protect fresh vegetables and fruit can be very selective, especially if the vegetables and fruit are already cut or sliced for customer convenience. For fresh produce, the film must allow CO_2 to easily leave the package while allowing only low levels of air (oxygen) to enter the package for longer shelf life.

Films also provide a billboard for information about the contained product, directions on how to open the package, recommended dose levels, warnings about toxic contents, nutritional information, and universal product code (UPC) symbols for pricing and inventory control. This information can be displayed in a multicolor and aesthetically pleasing way on the packaging film so that it "sells" itself and acts as an impulse-buying aid. In addition, the transparency and high clarity of the film can provide a window in the package to allow the consumer to judge desirability of the product before buying or to judge remaining quantity in the package after purchase and as it sits in the consumer's home.

Film applications can be large, as in the case for some construction uses. Films or sheeting materials are used to wrap houses and buildings under construction, thus serving as moisture and wind barriers in the finished construction. Film products can be used in highway construction, as leakage barriers in municipal water reservoirs and as protective liners for municipal solid-waste landfill sites. Film applications can be small, such as the push-through blister pack for individually packaged medical pills. Packaging film uses can be categorized as follows.

Overwrap. This type of packaging usually involves unwinding a roll of flat film into the packaging machine, where it is folded around the object, the film sealed to itself, and the finished package removed by cutting the film. Typical products packaged by this method include small packs of snack crackers and cookies. The machine is commonly called a "horizontal make-and-fill machine." Products such a potato chips, corn chips, and bags of candy are packaged in vertical form/fill/seal machines in which a roll of flat film feeds into the machine over a forming collar where the film is formed into a tube. This tube is sealed along the back with a vertical heat seal, and then the bottom cross seal is made. The open-top tube is filled with the product and indexed down, and the top cross seal is made simultaneously as the bottom seal is formed for the next pouch to be filled and as the filled pouch is removed from the packaging machine. Coated cellophane, coated oriented polypropylene (OPP) film, and laminated films typically are used for this packaging application.

Skin Packaging. As the term implies, this type of packaging involves forming a skin of film over the object being packaged and sealing the skin film tightly to a heat-seal-coated display card. This is accomplished by placing the object to be packaged, usually a hardware item, onto the coated display card, then draping a hot sheet of film over the entire assembly, and applying vacuum to the backside of the permeable display card. The vacuum pulls the cooling hot film down over the object and applies pressure to assist in making the seal to the display card. Typically ionomer, low-density polyethylene (LDPE), or polyvinyl chloride (PVC) resin films are used for this packaging applications, and the board coating is LDPE or ethylene-vinyl acetate (EVA) (See the Skin packaging article).

Blister Packaging. Preformed blisters are filled with the object, the coated paperboard is placed over the filled blister, and the assembly is heat sealed. Small hardware items and small notions are commonly packaged in this manner.

Shrink Packaging. This type of packaging refers to the use of a film manufactured in such a way that when it is heated it will contract in both directions, reducing its surface area. When this type of film is wrapped around an object and sealed around its edges, then sent through a shrink tunnel where large volumes of heated air wash over it, the film will react to the heat and contract down to the object, thus making an attractive skin-tight package. A vent hole must be cut into the film to allow the trapped air to escape from the package as is undergoes film shrinkage in the hot-air tunnel. Shrink-film resins are polyethylenes, polypropylenes, PVC, polyesters, and some coextruded structures. Articles packaged in this manner are numerous and can include frozen poultry, pizzas, stationery, toys, cassettes, and compact disks.

Stretch Packaging. This packaging technique is useful for bundling objects together for convenience in shipping or handling. Resins used in this application include linear LDPE (LLDPE), LDPE, EVA, PVC, and some copolymers of polypropylene. Typically, when stretch wrap is used for pallet bundling, the tacky film is wound around the pallet many times to ensure tightness, the film cut, and the film end stuck down on the wrapped pallet. There is no need to heat seal or use mechanical fasteners with this packaging technique.

PLASTIC-FILM RESINS

It would not be possible to cover all resins that have been fabricated into film in this article. What are presented here are typical resins used over the years as packaging films.

Food packaging has successfully employed films for many years, starting in the 1920s in the United States with the introduction of cellophane film, which was used initially to package loaves of bread that had been previously overwrapped in paper. Because it was transparent, cellophane allowed the bread to be viewed by the customer before purchase. Uncoated cellophane is composed of regenerated cellulose, a softening agent, and water as a plasticizer. Although it is not moistureproof, it is impermeable to gases when the film is kept dry. Additional slip, antistatic, and antifog properties can be provided by special formulations applied as coatings to the base sheet. Cellophane is not a thermoplastic and does not have a melting point, heat sealability is possible only by applying a heat-seal coating such as nitrocellusose (NC) or polyvinylidene chloride (PVDC) to the base sheet.

By the early 1950s, LDPE resin was developed and began serving as the first major human-made (synthetic) thermoplastic packaging resin. Because this resin has a melting point and is thermoplastic, the packaging industry developed thermal extrusion equipment to extrude thin films of this new resin for packaging. Polypropylene (PP), which is another popular packaging resin, was first produced during the 1950s. However, it did not develop commercially until the 1970s, when new high-efficiency catalysts were discovered for its production. PP competed effectively for many of the cellophane packaging applications. Although cellophane had attractive properties of clarity, stiffness, gas barrier, and heat resistance, it also had disadvantages of limited shelf life because of the loss of volatile plasticizer. This loss of plasticizer caused the cellophane to embrittle to the point where the packaged product was no longer protected. PP has the inherent attributes of clarity, toughness, thermoplasticity, and heat sealability after being coated by PVDC. PP also has the advantage of having a density lower than that of cellophane; thus, more square inches of packaging film are possible from a pound of PP than from a pound of cellophane film—a definite economic advantage. As PP is a thermoplastic resin, it did not have the thermal resistance to provide fail-safe high-temperature sealing protection against substrate burn through on the packaging machine. Additionally, the lower modulus PP could not be fed easily through the push-feed packaging equipment developed years earlier for the stiffer cellophane. Feeding problems for PP were exacerbated by its greater tendency to generate and hold static charge, which caused clinging and feeding jams in the packaging machine. These serious packaging problems were eventually eliminated by machinery redesign and by improvements in PP base-sheet and coating technology. Plastic-film resins can be categorized by the chemical process used to form the molecules in the polymer resin backbone.

Addition Polymerization (Homopolymers). Polymers in this category include LDPE, HDPE, PP, polybutylene (PB), and polystyrene. During the polymerization or building of the polymer molecules, the individual monomer units (ethylene, propylene, and butylene, respectively) are chemically connected together in the pressure reactor in the presence of high temperature and an appropriate catalyst. By control of the residence time in the reactor, the number of these monomer connections can be varied. Long reactor time, longer polymer chain length, and higher molecular weight result. By controlling molecular weight, the manufacturer can control polymer resin properties such as viscosity, which, in turn, can control final film properties such as toughness. These resins, called *aliphatic resins*, are prepared from monomers that consist of only carbon and hydrogen atoms. The characteristic chemical structure in the polymer backbone is a carbon-to-carbon bond ($-CH_2-CH_2-$) that links the individual monomer units together. Aliphatic ethylene and propylene homopolymer resins are nonpolar, have good clarity, and have relatively low melting points that range from $\sim 105^\circ C$ for LDPE to $125^\circ C$ for high-density polyethylene (HDPE), and $165^\circ C$ for PP. Polystyrene does not have a melting point but does exhibit a Vicat softening point at $T \leq 106^\circ C$. Because their monomers are derived relatively easily from petroleum feedstocks and the corresponding resins are used in large-volume packaging applications, resin cost/pound is not high, particularly for LDPE, HDPE, and PP. LDPE resins can be found, for example, as premade flexible bags and pouches and other large-volume packaging applications. HDPE, which is stiffer and tougher, is used as grocery bags and multiwall bags and bag liners. PP, as described above, has replaced cellophane film in many food-packaging applications. Some of these applications include overwrap for cigarette packs, snack-food packs, and pouches and bags for potato and corn chips. PB has found some applications as a meat-packaging film and as an additive for hot-melt adhesives.

Addition Polymerization (Copolymers). Polymers prepared from combinations of two or more monomers can give rise to plastic resins with a wide range of properties not possible from homopolymers. Resins of ethylene/propylene (E/P), ethylene/butylene (E/B), ethylene/hexene (E/H), and ethylene/octene (E/O) are possible combinations. The last three mentioned resins are gaining popularity as new aliphatic polymers with a much broader range of thermal and mechanical properties than previously possible. These resins, which are designated metallocene polyethylenes (mPEs) are prepared using the relatively new constrained geometry catalysts that allow the tacticity and branching of the polymer molecule to be better controlled, which yields polymers with narrower molecular distributions and lower densities. mPE resins are aliphatic copolymers somewhat endowed with the properties of the higher polarity copolymers described below.

Addition copolymers can also be prepared with ethylene and a polar second monomer. These polar monomers can include acrylic acid (AA), methacrylic acid (MAA), ethyl acrylate (EA), and vinyl acetate (VA). Because these monomers contain oxygen atoms in addition to carbon and hydrogen and because oxygen is a heavier atom and rich in electrons, the polymerization of these polar monomers results in a copolymer resin with higher polarity than carbon- or hydrogen-containing aliphatic resins. Resins of E/AA, E/MAA, E/EA, and E/VA are characterized not by an unusual chemical linkage between the repeated monomer units but rather by the polar nature of the copolymer in the polymer chain with the ethylene monomer. The E/AA and E/MAA resins, which are also called *acid copolymer resins*, have good clarity, low haze, and lower melt and sealing temperatures, and they can adhere strongly to polar substrates such as paper, foil, and some highly polar film resins. Thus, they have found use more in specialty packaging applications and in association with multilayer structures for meat, cheese, snack foods, and medical items. E/VA resins typically contain between 5% and 40% VA comonomer, with VA contents above about 25% used largely in hot-melt adhesive applications. Packaging-film applications employ resins with lower VA contents ranging from 5% to about 18%. These compositions are not too sticky, and films of these compositions can be handled on typical packaging machines; however, often slip and antiblock additives must be incorporated into the resin to ensure the proper slip level. Because of the low crystallinity, toughness properties at low temperatures, and low melting points, E/VA resins are used as a poultry and meat wrap, bag-in-box for liquid packaging, stretch film, and as ice bags.

Because E/AA and E/MAA resins contain free-acid groups, they can be partially neutralized to form a class of resins called *ionomers*. The ionomers serve some of the same market applications and have excellent hot-tack sealability, the ability to seal through contamination, and grease/oil resistance. These polar copolymer resins find use in packaging meat, cheese, breakfast cereals, and many other wet and dry products. They also are used as skin-packaging films for hardware products.

Condensation Polymerization. Some chemically reactive polar monomers can react with each other or with a second monomer to form a polymer chain and a small volatile second molecule. Many times that second molecule is water; thus, water seems to "condense" from the reaction. Removal of this second molecule leaves the relatively clean polymer behind. Resins made by this condensation polymerization route include polyamides or nylon, and polyester. Nylon resins are made from diamines and dibasic acids and are characterized by the amide group ($-$CONH$-$) in the polymer backbone. Nylon resins are identified by the number of carbon atoms in the monomers. Thus, homopolymer nylon 6 can be prepared from a monomer with six carbons in a straight line with reactive end groups on each end. Also nylon 6/6, 6/10, and 6/12 can be prepared from two monomers with the differing number of carbon atoms. Polyamides are regarded as semicrystalline resins with high melting points (175–275°C). As packaging films, they offer toughness, chemical resistance, resistance to oils and greases, and moderate gas barrier. Food products packaged in polyamide films include meats and cheeses.

Polyesters similarly are formed by reaction between an aromatic diacid such as terephthalic acid or the dimethyl ester of terephthalic acid and a polyalcohol such as ethylene glycol. These resins are characterized by the ester group ($-$CO$-$O$-$) linking the monomer units in the polymer backbone. Thus, these resins contain a stiff aromatic molecule within the polymer backbone as well as a flexible aliphatic portion. This stiff resin can be extruded into oriented high-tensile-strength film, metallized, and heat-seal coated to yield a packaging film in a thin gauge. In combination with other sealant coatings or laminations, polyester films are used as boil-in-bag pouches and for processed-meat packaging.

Chlorinated Vinyl Addition Polymerization. Polyvinyl chloride resin for film applications is prepared by suspension polymerization and employs the vinyl chloride ($CH_2{=}CHCl$) monomer. A homopolymer resin is polymerized from this monomer by a free-radical process. After purifying and removing excess water, this rigid resin must be blended with softeners or plasticizers to reduce its glass-transition temperature and render it a usable resin. For a more detailed discussion on how to modify melt temperature and glass-transition temperature in polymers, refer to Nielsen (1). Other additives such as lubricants and thermal stabilizers are blended into the resin as well. Packaging applications for PVC film include fresh meat, shrink film, and blister packs. For more details on how packaging film choices are made for different foodstuffs, refer to Jenkins (2).

MULTILAYER FILMS

Laminated film structures refer to multilayered structures composed of many monofilm layers. By effecting adhesion between the layers, more sophisticated film properties can be obtained in a single film. Heat-sealable films can provide the outside layers and can cover interior layers of nonthermoplastic materials such as foil, metallized film, or paper. Previously made films that contain light-blocking levels of TiO_2 can be printed before being laminated with a clear glossy, heat-sealable film, thus yielding an attractive multilayered film that can be heat sealed, providing protection of the product from ultraviolet (UV) degradation, and exhibiting striking printed panels. Because each monofilm of the laminate must have been previously prepared individually as a self-supporting film, the final multilayered laminates can end up thick and costly.

Coating of monofilms also provides a higher level of property sophistication to monofilms. Frequently, solvent coatings are applied to films to provide heat sealability or an enhanced gas and moisture barrier to the film. Vacuum metallization can be considered a form of coating. This technique enhances light opacity and gas- and moisture-barrier properties of the film. Individual coating thicknesses are usually less than 1 mil (25 μm); thus, coating a monofilm does not substantially add to its thickness.

Coextrusion describes a process in which a multilayered film is prepared by adhering several individual film layers within the body of the extrusion die. This process can prepare as many as nine separate layers of film within the same final film. Each resin may have its own extruder feeding a melt stream into the complex feed block attached to the die. Sometimes, one extruder will feed melt into two or more separate flow streams by the use of a stream divider within the feed block. This practice is fairly common for the extruder supplying the tie layer resin, which is the resin used to adhere two dissimilar resin types in the final multilayered film. Many factors must be considered when choosing the tie layer resin for a coextruded structure (3). Obviously, the initial cost for coextrusion equipment is high. However, this technique is popular and can provide outstanding film property combinations at a reasonable cost.

BASIC FILM–FORMING PROCESSES

Thermoplastic resins such as ethylene and propylene homopolymers and copolymers, and the condensation polymers described above, by definition have a melting temperature above which they are not rigid solids but rather viscoelastic materials. As such, they are soft plastic melts that can be formed into shapes convenient for packaging and other commercial uses. Several typical thermal processes are available for effecting this conversion from the small pellet supplied in the resin bag, box, hopper truck, or hopper railroad car to the final film structure. The following descriptions describe the preparation of monofilms; however, keep in mind that the coextrusion process is also possible for all these extrusion processes. Refer to Figure 4, which relates typical EVA resin melt flow requirements to film manufacturing process type.

Extrusion-Cast Film. In this process, the plastic resin pellets are introduced into the feed hopper of the extruder, where they are funneled down into the extruder barrel and onto the rotating screw (see Figure 1). As the screw rotates, it drives the pellets deeper along the hot barrel, compressing and heating them and applying force or shear so that the air spaces between the pellets are driven out and the pellets are heated to the melt temperature or softening temperature of the resin. The screw, which is driven by a powerful electric motor, is typically composed of three separate regions: (a) the *compression zone*, which is closest to the feed hopper; (b) the *transition zone*; and (c) the last region, which is called the *metering* or *blending zone*. Each zone occupies about one third of the screw length. The compression zone heats up the pellets driving out the air, the transition zone describes the length of the screw where the transformation from solid pellet to melted resin takes place, and the metering zone allows the melt pool to become homogenized so that a uniformly mixed melt stream is presented to the heated die. The die serves the purpose of fixing the dimensions of the final shape of the polymer. Thus, most dies have a circular cross section to the melt inlet, which then gradually transforms to the thin and wide cross section of the film. As the flat, thin sheet of polymer melt exits the die, it is quenched to a lower temperature below its melting point, thus solidifying it into the final and desired shape. Often the quenching is accomplished with water-cooled metal drums or rolls with a high-gloss chrome-plated and smooth finish so that the quenched surface on the film is flat and blemish-free. By controlling the takeoff speed of the quench roll at a faster rate than what the melt exits the die, the film thickness can be reduced and controlled. This differential in speed also impacts some final film properties, such as toughness, stiffness, and film clarity or haze. Basically, this stretching of the film melt as it is cooling causes the polymer molecules to become better aligned or oriented in the long direction of the film machine direction (MD). This molecular alignment is responsible for enhance stiffness and toughness properties. The film is then accumulated as rollstock on the windup turret of the cast-film line. Film widths of ≤ in 120 in. are possible by this process. The length of the film is defined by how much is wound on the roll, and usually as one film roll is being completed, the windup turret can be indexed around so that a new roll can be started without interrupting the continuous resin flow through the extruder and die. The rolls are then removed from the windup turret and slit to the width desired by the customer. Property-enhancing lubricants, stabilizers, or colorant additives can be added to the resins pellets at the feed hopper. They will become mixed with the melt stream by the extruder screw. These additives can be added as powders to the feed hopper or more likely will be added as a preblended concentrate in pellet form.

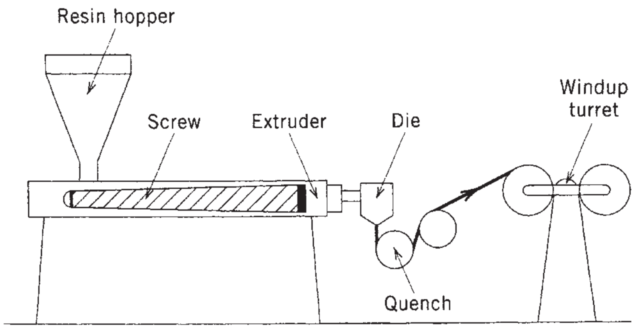

Figure 1. Cast-film line.

Extrusion-Blown Film. The blown-film process (Figure 2) is somewhat similar to the cast-film process in that a plasticating screw extruder is employed to convert the solid resin pellets into a uniform plastic melt. The blown-film process employs a circular or annular die to form the film, which is then stretched over and around a captured bubble of air. The film is usually air quenched, collapsed as a flat tube, and wound up on the windup stand. Sometimes, the bubble is slit in the vicinity of the nip rolls so that two sheets of film may be fed down to the windup stand. This bubble process can be oriented so that the film extrudes upward, downward, or in the horizontal direction. The bubble may be long but typically is 20–30 ft long. Bubble diameters may be 6 ft or more. The resin used in a blown film process must have a high melt strength to sustain the relatively high hoop stress and MD tension. This process requires that the melt emerge from the die then quickly flare out or inflate around the captured air

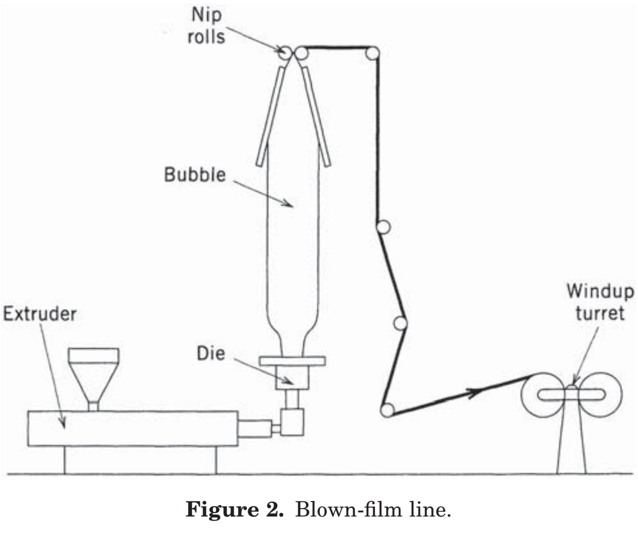

Figure 2. Blown-film line.

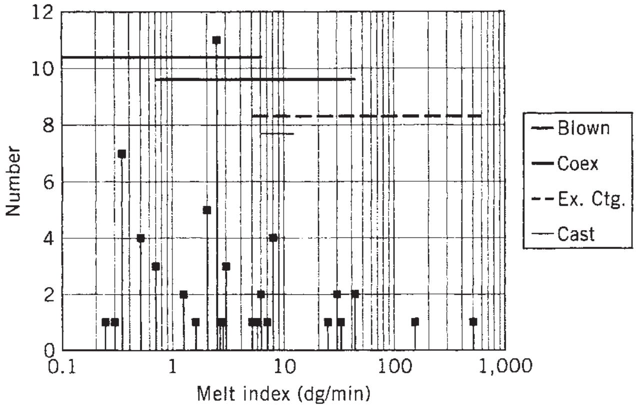

Figure 3. Resin meet flow vs. extrusion process.

bubble while it is being cooled. Thus, the polymer melt is being cooled and biaxially oriented at the same time. The ratio between the annular die diameter and the final bubble diameter defines the "blowup ratio" (BUR) for the film from this process. The die gap opening and BUR define the final film thickness. Because the blown film process requires such high polymer melt strengths, higher molecular-weight polymers must be used and are reflected in the typical melt index values of <1–5 dg/min for polyolefin resins (see Figure 3). Coextrusion-blown-film processes are useful for preparing multilayer films. Care must be taken to ensure that the tacky heat-seal layer ends up as the outside of the bubble and not the bubble inside, where it might stick to itself as the warm bubble is collapsed at the nip. One advantage of the blown-film process is that it yields a film tube and not a flat film with thick edge beads. Thus blown-film products can be more efficiently used because the thicker edge beads are not present and do not need to be removed or recycled.

Extrusion Coating. As this name implies, the extrusion coating process is employed to apply a thin layer of polymer film onto an existing film structure (see Figure 4). Thus, it is not usually used to make structural monoextruded or coextruded films. It is often used to apply a thin sealant layer to paper, foil, or plastic film. As Figure 4 shows, this process resembles a cast-film process. Extrusion coating requires that the exiting melt curtain quickly contact and adhere to the substrate film. Thus, the proper compatibility and adhesion between the substrate and the extruded resin is important as is the need for the resin to have a relatively high melt flow value (see Figure 3). Typical extrusion coating resin melt flow values can range from about 8 dg/min up to values of several hundred decigrams per minute. The adhesion between the melt curtain and the substrate is aided by the pressure on the nip roll. Because the high-melt-flow polymer is hot and quickly contacts both to the coated stock and the quench roll, the quench-roll surface is usually machined or treated to reduce adhesion. Chill-roll release additives can also be incorporated into the resin to prevent sticking (see the Extrusion coating article).

America, Inc., Gordonsville,
Virginia

Poly(vinyl chloride) (PVC) is extraordinarily adaptable to custom compounding for desired performance. This diversity of physical properties at relatively low cost has been the driving force behind its popularity in the packaging industry.

HOMOPOLYMER PVC RESIN

Commercial PVC resin is a dry free-flowing powder produced by the polymerization of vinyl chloride monomer [see Poly(vinyl chloride].

Molecular Weight and Viscosity

The fundamental property of PVC is its molecular weight: a measure of its means polymer chain length and a parameter proportional to the resin's viscosity. In general, higher-molecular-weight (higher-viscosity) resins require higher processing temperatures and yield film or sheet with higher heat-distortion temperatures, impact resistance, and stiffness than do resins of lower average molecular weight. The processing equipment for generating film and sheet for the packaging industry demands low- to medium-viscosity PVC resins with relative viscosities of 1.75–2.10, in contrast to extrusion pipe and construction markets that typically use medium- to high-molecular-weight resins.

Heat Stability

All PVC resins are subject to thermal degradation during processing and must be compounded with appropriate heat stabilizers to minimize discoloration. These stabilizers serve to scavenge free radicals that perpetuate degradation, as well as hydrogen chloride, the principal degradation product. The highly complex thermal degradation mechanism proceeds by an "unzippering" process whereby liable allylic chlorides act as reaction sites for the liberation of hydrogen chloride and the formation of conjugate-bonding systems. When the conjugation exceeds six bonds in length, color development begins and, if unchecked by ample and appropriate use of heat stabilizers, will progress from a very subtle yellow tint to amber and, finally, to black. Commerical processing methods occasionally generate "burned" material that has reached these initial stages of degradation. It is important to recognize that such thermal degradation is both time- and temperature-dependent and that although stabilizers retard the rate of degradation during processing, they do not prevent it. The stabilizers also help protect the film or sheet during subsequent processing (e.g., thermoforming) and during the lifetime of the package itself.

COMPOUNDING FOR PROPERTIES

Among all polymers used in the packaging industry, PVC is widely regarded as the most versatile and suitable for custom compounding to deliver special properties (see Additives, plastics). It may be compounded for high clarity and sparkle or for maximum opacity and it accepts a full range of custom colorants (see Colorants). Properly compounded, PVC film and sheet are approved for food and drug contact and are available with residual vinyl chloride monomer (VCM) levels below 10 ppb. Examples of what custom compounding can produce are shown in Table 1.

Table 1. Examples of Custom Compounding

Higher heat-distortion temperatures for hot-fill packaging
Ethylene oxide (ETO) sterilizable film without water-blush for medical devices
Improved low-temperature impact resistance for drop tests of shipping cartons
Improved UV resistance
Improved outdoor weatherability
Improved sealability (impulse heat, RF, ultrasound)
Denesting formulations for machine-fed blisters
Static-resistant formulations
Optimum performance in laminating to other materials (PVDC, PE, etc.)
Formulations for vacuum metalizing
Improved printability
Absence of "white break" or crease whitening

After identification of such desired properties for the specific packaging application, the compounder selects a suitable resin viscosity. If the film is to be approved for food or drug contact, the resin's VCM level must be low enough before processing to ensure that the resulting film will meet all customer requirements on residual VCM. A heat stabilizer must then be selected. Tin mercaptides are frequently chosen because of their high efficiency, excellent early color, good light stability, and excellent crystal clarity in the product (1). Some of these stabilizers (octyl tins) are cleared for food and drug contact. Uncleared options include lead stabilizers, which are limited to opaque systems, and combinations of barium, cadmium, and zinc. Although there are a few calcium/zinc systems in limited use in food packaging, the tin stabilizers dominate the packaging field. Octyl tins are the principal systems used in food and pharmaceutical packaging (2). Stabilizers are also available that impart improved UV resistance. All of the stabilizers mentioned above are used in rigid PVC at only very small loadings.

In contrast, impact modifiers may constitute up to 15% of the product's weight. As a result, the proper selection and loading of impact modifier is an important compounding decision. Clear packaging films typically contain MBS impact modifiers because of their superior clarity, heat stability, and room-temperature efficiency. ABS modifiers are good for opaque products, and chlorinated polyethylene (CPE) and acrylics (see Acrylics) are often selected for outdoor applications and/or low-temperature environments in opaque systems. Pigments may then be added to provide custom color, and titanium dioxide is generally used at levels as high as 15% to provide the desired level of opacity. Fillers may be used for cost reduction in opaque systems and, in many cases, to improve such physical properties as impact strength, stiffness, and heat-distortion temperature. Present in very low levels are a variety of proprietary lubricants and processing aids that are necessary to facilitate processing and to provide desirable properties such as slip, denesting, and improved thermoformability for the film processor/packager. Flame retardants, antioxidants, coupling agents, antistatic agents, phosphite stabilizers, and a host of additional additives may be included if necessary. Because of this tremendous facility for custom compounding, and the variety of products that result from it, Table 2 must be considered only as a general guide to typical rigid PVC properties.

FILM AND SHEET PRODUCTION METHODS

Extrusion (see Extrusion) and calendering are the principal methods of producing rigid PVC for the packaging industry. Extrusion is used to produce very thin blown films (see Film, flexible PVC) as well as heavy-gauge sheeting nearly 1 in. (2.54 cm) thick produced by sheet-die methods. Calendering requires a much greater capital investment, but it offers much greater production rates, superior gauge control (cross direction and machine direction) (±5%), superior cosmetic quality including clarity, and much wider versatility in accommodating gauge and

Table 2. Typical Physical Properties of Rigid PVC (Clear)

Property	Test Method[a]	Units	Values
Specific gravity[b]	D1505		1.30–1.36

[c] 20 mil (508 μm) unmodified.

width changes. Calendered film and sheet generally have better dimensional stability, which provides thermoforming consistency throughout a given lot. Rigid calendered PVC is available in thickness of 2–45 mil (51–1143 μm) with gloss, matte, or embossed surfaces, either in rolls or in sheets up to about 60 in. (1.5 m) wide. Calendering is the principal means of processing rigid PVC film for packaging.

Calendering

In a modern rigid PVC calendering operation, compounding is done by computer-controlled electronic scales that supply precise amounts of each ingredient to a high-intensity mixer designed to incorporate all liquids into the resin particles and to secure uniform distribution of all powdered ingredients. Blending is generally done for a specific time period and to a specific temperature. The still-dry, free-flowing blend is then charged to a feed hopper where it is screw-fed into a continuous mixer such as an extruder or kneader. Under the action of this mixer's reciprocating screw in the confined volume of the mixing chamber, the blend begins to flux or masticate into the plastic state. It is then forced out of the barrel of the mixing chamber. The continuous strand may be chopped into small fist-sized buns of hot material or simply exit as a continuous rope. This material may then be directly conveyed to the calender, or it may first pass through a two-roll mill. The calender is a large unit, typically consisting of four or five heated rolls designed to process masticated PVC buns into a continuous web of designated width and thickness (see Figure 1).

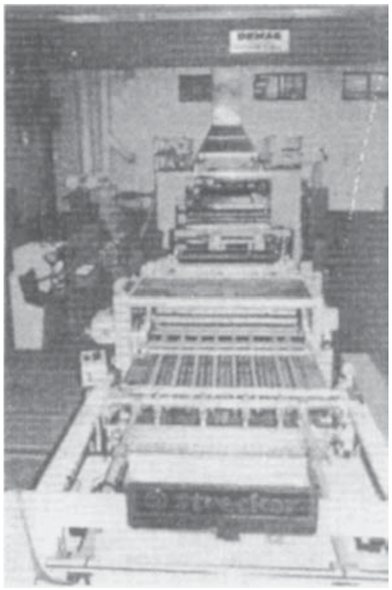

Figure 1. PVC calender.

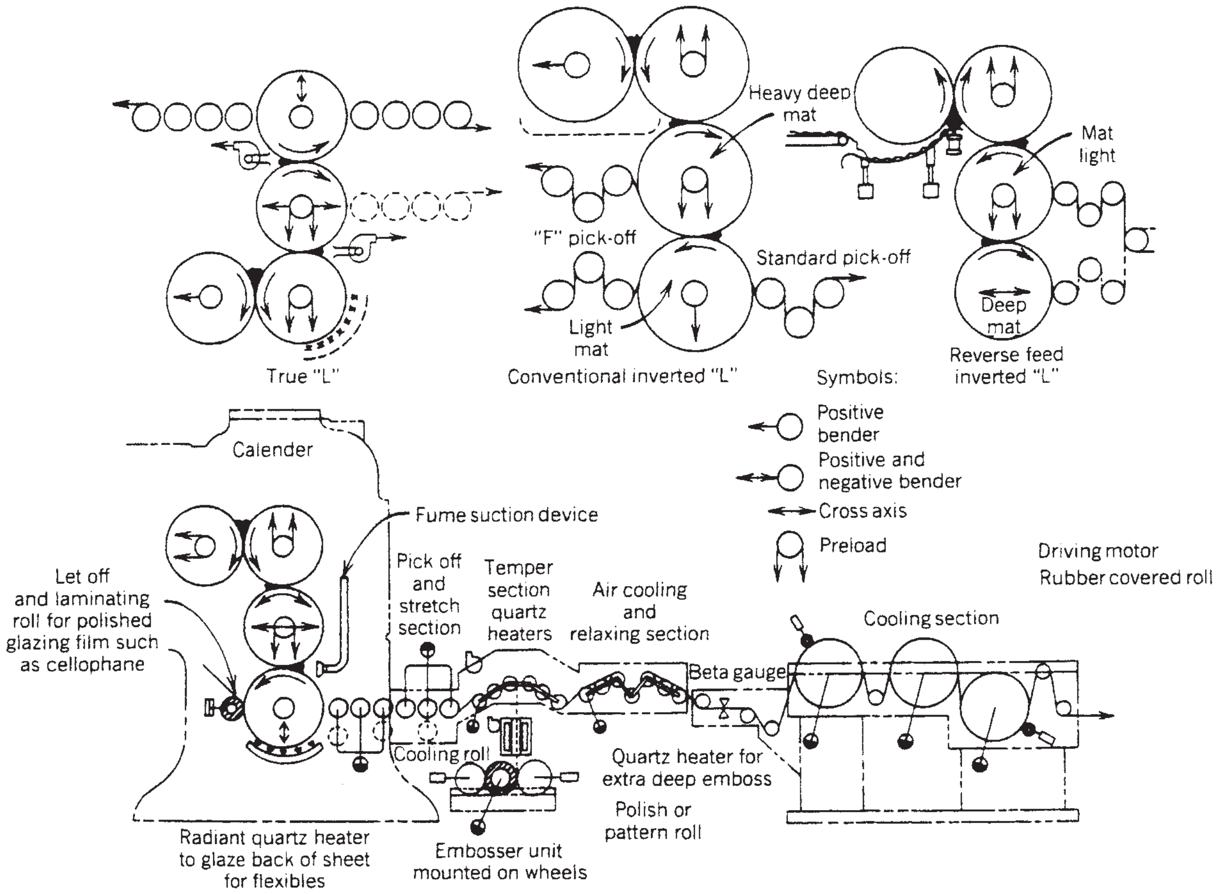

Figure 2. PVC calender operation.

Figure 2 illustrates the typical "L" and "inverted L" configurations generally used for rigid and flexible production, respectively (3). The calender rolls have separate temperature and speed controls as well as roll bending and crossing capabilities to control profile across the web. Proper use of these controls, along with speed and stretch in the takeoff train, allows the production of an extremely flat sheet with a profile tolerance of less than ±5% across and down the web. Such control is maintained by continuous beta scanning equipment that traverses the web constantly and calls for adjustments in nip openings, skew, and/or roll bending. Such constant inprocess monitoring and continuous profile adjustments is a significant advantage of calendering over other processing methods. By using special grit-blasting techniques, the third and fourth calender rolls may be custom-surfaced to generate a uniform two-sided matte product. Alternatively, one or more downstream embossing stations may be utilized to produce a custom surface on one or both sides of the film. Antistatic and or de-nesting slip agents may be applied to the surface(s) of the web after separating from the last calender roll. Finally, after the cooling section, the web is cut in-line into finished sheets or wound about a core into a master roll for subsequent custom slitting. Typical slit widths are made to the nearest 1/32 in. (0.8 mm) on 3- or 6-in. (7.6- or 15.2-cm) cores with roll diameters of 14–40 in. (36–102 cm).

PACKAGE PRODUCTION BY THERMOFORMING

Most commercial PVC packages are the result of thermoforming rollstock into custom blisters. In those cases where further enhancement of PVC's own oxygen and/or moisture barrier properties are required, barrier materials (see Barrier polymers) such as PE, PVDC, or fluoropolymer film (see Film, fluoropolymer) may first be laminated to the PVC web prior to thermoforming. Thermoforming processing conditions are generally dictated by the PVC material itself regardless of lamination. Since PVC is an amorphous material (see Polymer properties), it softens over a large temperature range and has no sharp melting point. There are two temperatures ranges in which rigid PVC can most readily be formed (see Figure 3). It must be emphasized that these temperatures are actual film temperatures that must be measured with thermocouples located directly on the surface of the film (heating-element temperatures are very much hotter).

The first plateau at 221–275°F (105–135°C) is the elastic area best for most high-speed form/fill/seal pressure-forming machines (see Thermoform/fill/seal). In this area, the film has sufficient hot strength to elongate or stretch to the conformation of the mold. Between 275°F and 338°F (135°C and 170°C) is a region of inadequate elongation for proper forming; and attempts to process in this area may result in blowing holes, tearoffs, and poor

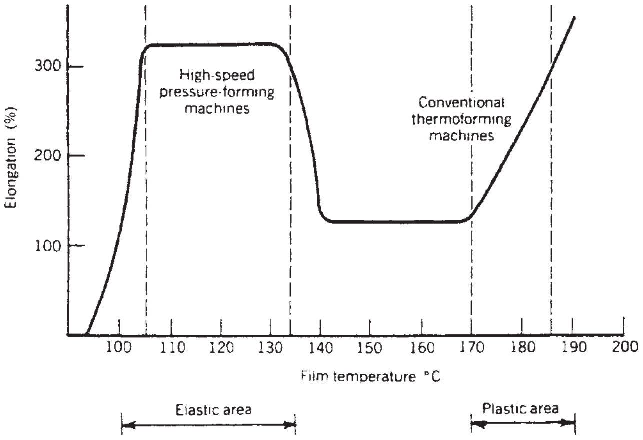

Figure 3. Temperature ranges for PVC thermoforming.

definition. Failure to respect this "no man's land" is among the most common reasons for thermoforming problems seen in the field by PVC technical service representatives. The elongation quickly increases in the film at 338°F (170°C), and excellent forming is possible up to about 365°F (185°C). This is the range for optimum performance for conventional commercial thermoforming machines (see Thermoforming). Beyond 365°F (185°C), the material will sag excessively, resulting in webs, wrinkles, holes, or thin areas. In general, rigid PVC film thermoforms best when the film temperature is slightly above 338°F (170°C), with relatively cool molds (as low as 50–60°F or 10–16°C), and when plug assist temperatures are about 194°C (90°C). Mold design should avoid exceeding a 1:1 draw ratio, and a few extra degrees of draft and extra radius on corners will help avoid problems.

Film Shrinkage for Optimum Forming

Since distinct types of equipment are used in each of the two forming regions, it is particularly important that the PVC-film supplier have a thorough understanding of the appropriate shrinkages to be put into the feedstock for each type of machine. PVC destined for pressure-forming over the lower temperature region should have its shrinkage controlled by the producer at 284°F (140°C), a temperature that will release all plastic memory relevant to the processing range of 221–275°F (105–135°C). Typically, best results are achieved with PVC film having 284°F (140°C) shrinkages of 2–5% in the machine direction and 0–1% in the transverse direction. Such very slight growth in the transverse direction is desirable to compensate for the repeating necking-in that may otherwise occur across each line of blisters such as those used for press-through packaging of ethical drugs.

In the higher temperature range for conventional thermoforming, film shrinkages should be controlled by the film supplier at 350°F (177°C), a temperature that will release all plastic memory relevant to this higher processing range. Best results are typically achieved with PVC film having 350°F (177°C) shrinkages of 4–8% in the machine direction and −1 to +1% in the transverse direction. Excessive shrinkages may cause the film to pull out of the chains, clips, or frame. Insuffcient machine direction shrinkage and/or excessive transverse growth may led to webbing. Thermoforming machine operators often respond to such webbing problems by reducing operating temperatures to prevent excessive sag, but this step can result in blowing holes and poor wall distribution because it takes the film out of the optimum thermoforming temperature range and elongation falls off rapidly. Careful shrinkage control is critical to successful thermoforming of rigid PVC film with all types of forming equipment. Proprietary process controls are available in modern PVC calendering technology to custom produce film with the proper shrinkages for optimum thermoformability within each temperature region and on each design of forming equipment.

PACKAGING MARKET

U.S. consumption of calendered rigid PVC film and sheet in 1994 is estimated at 523×10^6 lb (237,000 tons), not including an additional 30% for extruded sheet. About 63% of this calendered production was used in packaging (see Table 3). Total 1994 consumption of calendered rigid PVC film and sheet for packaging was 330×10^6 lb (150,000 tons).

Table 3. U.S. Markets for Calendered Rigid PVC Film and Sheet

FILM, SHRINK

George D. Wofford
Cryovac Division, W. R. Grace &
Co.-Conn., Duncan, South
Carolina

Shrink film is a name given to a unique family of films that are distinguishable by their attributes, production processes, and end uses. They are composed of two basic categories: poly(vinyl chlorides) (PVCs) and polyolefins. Although most plastics exhibit some amount of free shrink and shrink force at elevated temperatures, true shrink films (sometimes known as *heat-shrinkable films*) provide a high degree of free shrink with a controlled level of shrink force over a broad temperature range.

Shrink force must be controlled to prevent crushing or deforming the product being packaged. Providing the proper level is important to the marketing of toys; games; cards, calendars, and other paper products; hardware; food; and a variety of merchandise where a tight, glossy package appearance is essential.

Shrink films are produced by uniaxially or biaxially orienting a sheet or tube of film by imposing a draw force at a temperature where the film is softened but kept below its melting point, then quickly cooled to retain the physical properties generated during orientation. It is important to note that the orientation temperature occurs between the vicat softening point (ASTM D1525) and the melting point, but is not directly related to the glass-transition temperature (T_g) as some literature would indicate. This can be seen in Table 1, which compares glass-transition temperatures to vicat softening points for several polymers.

Table 1. Glass-Transition Temperatures and Vicat Softening Points of Common Polymers

Polymer	T_g (°F)	Vicat (°F)
Polystyrene	181–201	208
LLDPE	−188 to −5	177–220
Polypropylene	7–41	307
PVC	158–176	183

Prior to orientation, the molecules of the film are randomly intertwined, exhibiting no particular alignment. However, when a draw force is imposed, the amorphous regions are straightened and oriented to the direction of force. By applying proper cooling, the molecules will be frozen in this state until sufficient heat energy is applied to allow the chains to shrink back. One can visualize this phenomenon by stretching a rubber band and dipping it into liquid nitrogen. It will remain stretched as long as it is kept at sufficiently cold temperatures. However, when enough heat energy is applied, the rubber band will shrink back to its original relaxed state.

Orientation on a commercial scale can be achieved using either of two methods: a tenter-frame or a bubble process. Tenter-frame technology produces a variety of "heat-set" products, of which biaxially oriented polypropylene (BOPP) is the most common. Heat setting is a process whereby a film is reheated in a constrained state such that the shrink properties are destroyed. Other important characteristics derived from orientation (optics, tensile strength, and modulus) remain intact, however. Current tenter-frame technology does not allow the production of materials with a high degree of free shrink and shrink force due to the mechanics and thermodynamics of the process.

In the tenter-frame process, a flat sheet is produced and cooled on a chill roll, which is usually immersed in a waterbath. The sheet then proceeds through a machine-direction orientation (MDO) unit, where it is heated and stretched to the desired ratio. On exiting the MDO unit, the sheet enters the transverse-direction orientation (TDO) unit, where it is reheated and stretched. BOPP is commonly stretched 700–800% in both the machine and transverse directions. After exiting the TDO, the material is wound into large mill rolls for aging (aging allows secondary polymer crystallization, ensuring film flatness and roll uniformity) and converting. Some tenter-frame systems have additional downstream equipment for retensilization and further heat setting or annealing. The primary suppliers of tenter-frame systems are Brückner (Germany), Mitsubishi (Japan), and Marshall & Williams (United States).

The second commercial method is the bubble process, sometimes referred to as a *tubular process*. A primary tube is produced by blowing the film onto an external mandrel or casting it onto an internal mandrel. Water is used to help cool the tube at this point.

After it has been cooled, the tube is reheated and air is used to inflate it into a bubble. On inflation, it is oriented

Moisture barrier	Cryovac BDF1000
Moisture, gas, and aroma barrier	Cryovac BDF3000

in both directions simultaneously, typically 700–800% for BOPP. Other films are oriented 200–1000% in either direction. After orientation, the bubble is cooled using an air ring. The tube is slit and separated, and then each half is wound onto mill rolls for aging and converting. Additional in-line processing, such as corona treatment for materials that will be printed at a later time, is often used with this technology. Commercial tubular orientation equipment suppliers include Prandi (Italy) and Gloenco (England). ICI, the developer of much of the early technology, exited this market in the mid-1980s.

Shrink films were limited to monolayer constructions until recently. Technological advances over the past decade have led to the development of multilayer coextrusions. These process improvements have enabled films to be designed with greater control over desired characteristics to meet a much broader range of packaging requirements. Table 2 lists the major shrink films offered in the U.S. market.

The key attributes that are important to shrink films include shrink, sealability, optics, toughness, and slip. Each of these attributes is composed of several facets. For shrink properties, they are onset temperature, free shrink, shrink force, shrink temperature range, memory, and overall package appearance. For sealing properties, one must also consider ease of trim sealing, trim seal strength, trim seal appearance, static lap sealability, and thermal lap sealability. For optics, it is important to consider clarity, gloss, and haze.

There are three aspects to toughness: impact strength, slow puncture resistance, and tear resistance. Impact strength measures how well a material resists a sudden force, such as when a box is dropped from a certain height. Slow puncture resistance measures how well a material resists a gradual increase in tension, such as when someone tries to poke a finger through a piece of film. Tear resistance is the measure of how well a film resists tearing once it has been nicked or abraded.

Finally, for slip, it is important to consider both hot slip (such as a warm package being placed in a carton during packoff) and cold slip (important in removing a package from a carton). Many other attributes must be considered for any given application, depending on the nature of the product being packaged. Film properties along with potential advantages and disadvantages are shown in Tables 3, 4.

Packaging equipment for shrink films are available in a variety of models and price ranges, depending on the features desired (see Wrapping machinery, shrink film). An important attribute for equipment is the sealing method. Until recently, most sealing systems for typical shrink-film applications used a hot wire in order to seal and cut the film at the same time. More recently, hot-knife systems have gained popularity on many models because of their increased durability.

The wire or knife seals the film against a pad that is covered with Teflon tape. Impulse seals are also employed for a number of applications. Time, temperature, and pressure are the three variables that must be balanced to optimize seal quality. If the time that the sealing head is held on the film is not long enough, the temperature is too low, or the pressure is insufficient or uneven, the seal quality will be poor. Conversely, if the sealing temperature or the pressure is too high, the result may be a weak spot just behind the seal area, causing failure during distribution.

To prevent seal failure problems, there must be an appropriate amount of time for cooling of the seal prior to any force being applied to the film. This cooling time

Table 3. Typical Shrink-Film Properties

Film Type	Unrestrained Shrink (% at 260 °F)	Clarity (%)	Ball Burst (cm/kg)	Coefficient of Friction
Polyethylene monolayer	70–80	40–65	16–24	0.11–0.14
Polyethylene multilayer	70–80	80–90	21–28	0.22–0.32
Polypropylene or EPC monolayer	25–45	75–82	4–10	0.26–0.38
PP/EPC multilayer	50–60	75–85	10–20	0.30
PVC, biaxial	30–55	75–80	6–10	0.20—blocked

Table 4. Advantages and Disadvantages of Various Film Types

Film Type	Advantages	Disadvantages
Polyethylene monolayer	Low cost High slip Strong trim seals More dimensionally stable than PVC Printable	Low modulus Narrow shrink temperature range
Polyethylene multilayer	Excellent optics Low cost Strong trim seals Broad shrink temperature range High abuse resistance Printable	Low modulus
PP or EPC monolayer	High modulus High gloss Low cost High shrink force	Low abuse resistance Easy tear High shrink temperature required Low seal strength
PP/EPC multilayer	High gloss Low cost Strong trim seals Broad shrink temperature range High abuse resistance High modulus Printable	Low abuse resistance Easy tear High shrink temperature required Low seal strength
PVC, biaxial	Low shrink temperature High modulus Low shrink force	Weak seals Noxious fumes created during sealing Corrosion problems Poor machinability Poor slip

allows the molten seal to solidify and prevents it from wrinkling or bunching. PVC shrink films can exhibit another sealing problem. They form a carbon buildup on the seal head, which must be cleaned regularly; otherwise, this will create a charred seal on the package. Some of the more common equipment manufacturers include Doboy, Great Lakes, Hanagata, Ilapack, Omori, Shanklin, and Weldotron (see also Sealing, heat).

One other piece of equipment needed to provide a sharp, tightly finished package is a shrink tunnel. In order for adequate shrinkage to occur, the package must be exposed to the correct temperature and airflow for the proper amount of time. The ultimate goal is to have a package that is tightly shrunk with no excess material or "ears" on the corners of the finished package. PVC films do not require the same level of temperature control as do polyolefin films, since they shrink more easily when exposed to heat. Shrink tunnels are generally purchased in conjunction with packaging equipment to ensure correct sizing for speed and product application.

FILM, STRETCH

Thomas B. Brighton
Tenneco Packaging, Deerfield,
Illinois

Unitization with elastic plastic films (stretch film) is a U.S. innovation that began in the early 1970s and has spread throughout the world to become the most widespread means of containing unit loads. This article focuses on the selection, use, and properties available for stretch packaging unit loads and individual products. Little reference is made to mechanical equipment systems available to accomplish stretch-film unitization.

SAVING WITH STRETCH FILM

Stretch film is a product that thousands of companies throughout the United States and abroad used every day in tremendous quantities. And, although acceptance and audience of stretch film continue to grow, the majority of stretch-film users know little of its true potential or how it has developed over the years.

INTRODUCTION

Stretch film is such an effective product that it is often easy to take all that it does for granted. This section is intended to serve as a "reminder" of (a) the benefits of unitizing and (b) the additional benefits that you reap by unitizing with stretch film. As part of the discussion on the benefits of stretch film, the testing of packages and unit loads are addressed. Finally, in order to give you background knowledge on stretch film, this section also reviews the development and refinement of stretch film over the years. All these issues are covered under the following sections:

- Why Unitize?
- Why Unitize with Stretch Film?
- Testing Packages and Unit Loads
- The Evolution of Stretch Film

Why Unitize?

Unitization is defined as a process in which smaller individual items are gathered and made into larger unit loads.

The benefits of unitizing products are many. Although unitization can be achieved with other packaging materials, none does it as effectively and cost-efficiently as stretch film. But before discussing the merits of stretch film, it is important to first understand why its necessary to unitize. Here are the reasons.

Lower Handling Costs. In general, whenever a load of packaged products increases in quantity, size, and weight, the cost per unit handled becomes lower. Unitizing products, therefore, significantly reduces handling costs.

Labor Savings. Without exception, the handling of loose boxes is more time-intensive than handling a unitized load. Thus, another benefit of unitization is the amount of labor hours saved in the movement and shipment of packaged goods. The end result is a quicker flow of goods throughout factories, warehouses, and cross-dock operations while utilizing fewer hands.

Transportation Savings. Since unitizing accelerates the speed at which goods are moved, carrier vehicles spend less time at unloading/loading docks. This reduction in unloading/loading time provides valuable cost savings to the company that unitizes and the customers receiving its prodcuts.

Protection. The protection that unit loads afford an operator are threefold:

1. Unit loads reduce incidents of pilferage and theft because packages from an enclosed load are difficult to remove. Moreover, unit loads are much easier to track than individually packaged products, making the "disappearance" of goods more detectable.
2. Unit loads, which are placed on pallets and moved by lift truck, are less likely to suffer damage in transit than lose boxes carried by hand, because lift trucks keep pallets closer to the ground. For instance, whereas small boxes (≤ 20 lb) may often receive impacts from 30 in. or higher when accidentally dropped, a unit load on a pallet will seldom receive 12 in. in drop.
3. It is less likely in LTL (lift-truck load) shipments that dense, heavy items will be parked on top of palletized unit loads. Hence, your goods stand a greater chance of not being damaged. This benefit, however, does not hold true for cartons shipped individually.

Inventory Control. Unitizing products facilitates improvements in control of inventory since large unitized loads (as opposed to parcels of smaller ones) can be identified, counted, and managed more easily.

Customer Service. Customers appreciate the effects of unitizing because it allows them to unload their trailers and move goods through their warehousing systems more efficiently.

Why Unitize with Stretch Film?

From the advantages listed, the importance of unitizing is clearly evident. What is equally important to realize is that stretch film accomplishes each of these unitizing functions better than any other packaging material. Also, stretch film performs additional functions that other unitizing materials simply cannot:

- *Low Supply Cost*. Compared to other packaging and bundling materials, stretch film is the lowest in cost to use because it offers the most yield for the dollar.
- *Protection from Moisture, Dirt, and Abrasion*. Stretch film protects against these elements, safeguarding the goods it wraps.
- *Reliable Performance*. With stretch film, you can quickly see the holding performance and protection it offers. The holding power, however, of other packaging materials such as adhesives is not always immediately noticeable since they can unravel, loosen, or come undone without being noticeable a few minutes or hours after observation. Stretch film, manufactured by a company committed to quality, will produce consistent results every time it is used.
- *Automation*. Stretch-film machines are either partially or fully automated, which improves the productivity of the packaging process, reduces labor, and alleviates back-breaking and time-consuming work.
- *Scan-through Optics*. The clarity of the stretch film enables UPC codes to be quickly read and scanned while protecting labels and lot codes printed underneath the film.
- *Ease of Removal*. Stretch film only clings to itself and not surfaces, making its removal fast, clean, and easy.
- *Elimination or Reduction of Other Packaging Materials*. The superior load-holding capability of stretch film either eliminates the need for or helps scale down the bulk of other packaging materials (e.g., in some cases, stretch film may enable thinner cardboard cartons to used for packaging goods).

- *Recycling.* Stretch film is recyclable. In fact, several stretch-film manufacturers will pick up and recycle your stretch film if you qualify for their recycling programs.

Testing Packages and Unit Loads

Stretch film saves you money. By offering superior unitizing and protective capabilities, it drastically reduces product damage, which contributes to your bottom line. But you do not have to take anyone's word for it. There are two in-plant tests you can perform to get an initial feel for the durability of the unit loads you wrap in stretch film before sending them off to your customers.

The first preshipment test is "test course handling." In this test a lift truck equipped with forks or slip sheet attachment approaches the unitized load, picks it up, accelerates, corners, decelerates, and sets the load down. The lift truck then repeats this same test once again, except this time moves in reverse. A typical test sequence includes two to seven repetitions, with an average of four repetitions for the assurance required by most users.

The second preshipment test is the "free-fall drop." This test does exactly what its name implies. In this test, one end of a unit load is raised to a specified height of 3–12 in. and released to fall flat on the floor. The drop is then repeated on the opposite end of the unit load. Drop height will depend on the weight of the unit load and the assurance level that is desired.

Further shake-table or vibration-table test procedures will provide you with stretch-film load–force data for your products. It is recommended that you work closely with your local stretch-film packaging sales professional when packaging new products or considering stretch-film changes.

The Evolution of Stretch Film

Although many people enjoy the benefits of stretch film today, stretch film was not developed overnight. The creation and development of stretch film has been a gradual process, one that continues to undergo refinements to this day. For a better idea of where stretch film has been and where it's headed, let's take a look at this timeline:

NEW PACKAGING SOLUTIONS

When you mention stretch film, most people conjure up the image of a load of boxes or goods wrapped on a pallet. For good reason. This application is the most popular one for stretch film. But an "on pallet" application is just one of hundreds that stretch film is capable of performing. All it takes is a little imagination and ingenuity to customize stretch film for your own uses. An increasing number of companies are looking to stretch film to bundle and package goods once wrapped in other materials such as tape, twine, strapping, and corrugated boxes. In this section, some of these innovative applications and the benefits derived from them are shared with you under the following headings:

- Stretch-film advantages
  - Versatility
  - Protection
  - Productivity
- Cost benefits

Year	Machine Evolution	Film Development	Volume and Cost per Average Unit Load Wrapped
Early 1960s		Shrink-wrap use begins to grow in Europe	
1965		Shrink wrap adopted in United States	30 oz/$1.50–2.00
1973	Lantech develops first U.S. stretch-film wrapping equipment	Mobil develops the first stretch film	
		Introduction of Mobilrap "C" (LDPE) 30–50% stretch	18 oz/$1.10
1974		PVC stretch films introduced	
1976		EVA stretch films introduced	
1978		First LLPDE film introduced with much higher stretch levels	10–12 oz/50–80¢
1980	Prestretch introduced	Hand-wrap market begins to grow	
	Powered prestretch equipment introduced 150–250%	Stretch film cling at high stretch a challenge	
1981		Convenience hand wraps introduced	8 oz/50¢
	Machinery and film advances allow prestretch up to 300%	Cling consistency improves with better control by film manufacturing	
1983		Nonmigratory cling introduced	
		Higher-load–force cast films introduced	4–6 oz/25–40¢
1987			
		Thinner gauge (50, 60) become available	
	Bi-stretch (trademark) introduced	Mobile introduces stretch-film recycling program	4 oz/25¢
1991			
		Postconsumer recycled content (PCM) hand wrap introduced	
1992			

Stretch-Film Advantages

Think about all the areas in your operation where you currently use tape, twine, strapping, and so on, and chances are that stretch film can do a better job. Stretch film surpasses other bundling materials for the following reasons:

VERSATILITY

Stretch film is able to fit the contours of any product. Door and window manufacturers have switched over in increasing numbers to stretch film. Stretch film, because of its stretchability, has largely replaced the custom-size boxes that were once needed to package the different-size doors and windows being produced.

Stretch-film clarity makes products easier to identify. Labels and lot and UPC codes can be read as well as scanned because of the transparency of stretch film. Food wholesalers and distributors have taken advantage of this feature in implementing and expediting their cross-docking practices.

PROTECTION

Stretch film provides better holding force than do other bundling and packaging materials. Because stretch film spreads across the entire surface area of a load, its holding force is dispersed, not concentrated at only a few points like strapping. This attribute enables stretch film to maintain exceptional load integrity. The furniture industry has come to recognize the ability of stretch film to hold even the most unstable of loads together, which is why an increasing number of component manufacturers have turned to stretch film to bundle loose furniture parts, such as table and chair legs and stair banisters.

Because stretch film clings only to itself, it does not leave any sticky or messy residue on product surfaces. This feature has made stretch film a favorite of the furniture industry. With stretch film, there are no glues or adhesives that can damage fragile finished wood. As a result, furniture manufacturers use stretch film for a wide variety of tasks, some of which are to keep furniture drawers shut so that they do not open in transit, attaching accessories to furniture pieces and to wrapping-desk and table tops.

Unlike other bundling and packaging materials, stretch film protects the products it wraps from dirt, moisture, and abrasion. Carpet and textile manufacturers depend on the protective attributes of stretch film to safeguard their rolls of carpet and fabric.

PRODUCTIVITY

Stretch film increases productivity. Thanks to automated stretch-film machines, newspaper companies have been able to bind stacks of newspapers together more time-efficiently and cost-effectively by reducing much of the manual handling involved.

Cost Benefits

Stretch film costs less than most conventional bundling and packaging materials. But the savings you earn with stretch film goes way beyond just a lower unit cost. Stretch film also saves you money in the following ways.

Stretch film offers more yield than do other bundling materials. Because stretch film has the ability to stretch, you get more product per square inch than with any other bundling material.

Stretch film can eliminate or reduce the need for secondary packaging materials. One example of a stretch packaging cost savings is that of a national T-shirt manufacturer who used to package its T-shirts for shipment in expensive corrugated boxes. However, once it was seen that stretch film could do the same job at a fraction of the cost, the company switched to stretch film. Today, the company is saving $5000 a day in packaging and shipping costs.

Stretch film eliminates or reduces the need for tertiary packaging. Because of superior load-holding force of stretch film, money once spent on tertiary materials such as strapping, twine, and kraft paper can now be saved and better spent.

Stretch film saves on shipping costs. Since products bundled in stretch film are usually more compact—this reduction in size is achieved by eliminating the need for extrabulky packaging materials like boxes—they take up less space in freight trucks. More space in the back of a truck means additional space for more of your products—and that saves you money!

SELECTING THE RIGHT FILM FOR THE RIGHT JOB

There is a wide array of stretch films available on the market, each designed to meet different needs. Choosing the right stretch film(s) for your operation can be a bit confusing. In this section, the variables to choosing the proper stretch film for your particular needs are explained. Finally, this section discusses the characteristics of the different types of stretch film and explain how they are made. All these issues are covered under the following headings:

- Proper film selection
- How stretch film is made
  - Extrusion
  - Coextrusion
  - Cast fabrication process
  - Blown fabrication process
- Process influence on stretch-film properties
- Opaque and color tint films

Proper Film Selection

Whenever selecting film, the following variables should be taken into account.

Type of Product. Stretch-film type is dependent on what you are wrapping. Lighter, more fragile goods require a lower-gauge film to avoid being crushed whereas heavier, more solid goods can withstand the pressure of higher gauges.

Type of Load. There are two factors that determine load type: weight of the load and uniformity of its outside surface. In stretch film, load types are distinguished by the first three letters of the alphabet. A loads have no irregularities, B loads have protrusions of ≤3 in., and C loads have protrusions of >3 in.

Type of Equipment. Machine stretch levels will help determine what type of film is necessary to wrap a load. Whereas higher gauges were once required for machines with high prestretch levels, Mobil is now manufacturing thinner, tougher films that are able to endure greater levels of stretch while maintaining their strength.

Film Thickness. Commonly available gauges for stretch film range from 0.5 to 3.0 mil. Load type, weight, and height are important determinants in selecting film thickness. As prestretch increases, it is extremely important that the stretch film not lose its strength.

Light gauges are excellent dust covers for already secure and strapped loads. Heavy gauges or new-technology metallocene-based films are excellent for loads that require a high degree of containment.

Film Width. Most stretch films range from 2 to 70 in., but can be made up to 100 in. by request. Rotary spiral equipment usually uses 20-in.-width film, but can also use 25- and 30-in. film. Full-web equipment uses a wide variety of widths depending on load height.

To determine which film widths are best for your individual applications, contact a packaging sales professional for assistance.

How Stretch Film Is Made

Understanding how stretch film is made, and the resulting properties that each type of film possesses, can help you when it comes time to purchase the proper film for your operation. The following industry terms, accompanied by diagrams, describe the various manufacturing processes of stretch film and the types of film that are produced as a result:

Extrusion. This is the first step in the production of stretch film in which plastic (polyethylene) resin pellets are converted into melted plastic. For this melting to occur, the resin pellets are loaded into the hopper funnel of the extruder and dropped by gravity into the barrel where the mixture is heated to its melting point. This liquefied plastic is then pushed forward by a continuously turning screw. In the final phase of extrusion, the molten material (or extrudate) is pushed through an opening called a *die*, which shapes the plastic for film formation. (See Figure 1.)

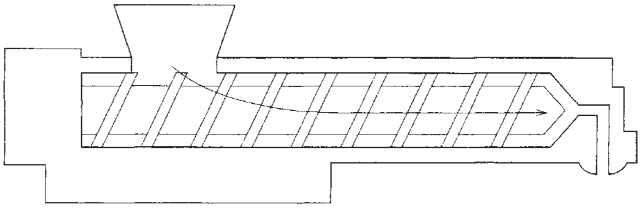

Figure 1. Extruder.

Coextrusion. Coextrusion is a form of extrusion using multiple extrudates and dies to create stretch film with multiple layers. Coextrusion involves the simultaneous extrusion of two or more layers of plastic that are brought together while still melted and then cooled to form a multilayer film. The layers of this film may or may not be different materials and may or may not exhibit different properties. (See Figure 2.)

Cast-Film Fabrication. After the extrusion process melts the plastic, this plastic is pushed through a slit-shaped die. The plastic is then formed into a sheet as it falls into a roller and is pulled vertically downward, orienting the polymer in that direction. This sheet is cooled by passing it through chill rolls, which are kept cool by circulating water inside them. Finally, the sheet is cut into the proper combination of widths and wound into finished stretch film rolls. (See Figure 3.)

Blown Fabrication Process. In the blown fabrication process, the extrudate is pushed through a round-shaped die. This action forms a continuous hollow tube from the extrudate, which is blown vertically upward. During this phase, the film is pulled or oriented in both the pulling (machine) and sideways (transverse) direction. High above the die, the tube is cooled and squeezed shut by a collapsing framework and a set of nip rolls. The flattened tube is then slit and wound into rolls. (See Figure 4.)

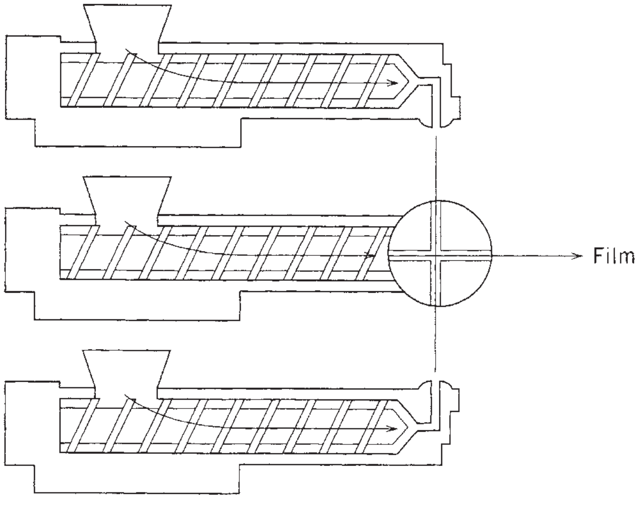

Figure 2. Coextrusion.

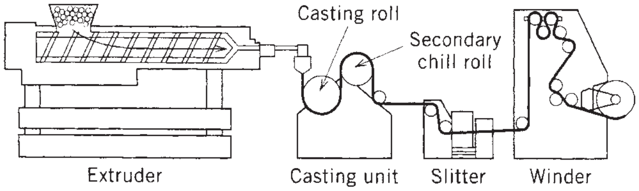

Figure 3. Cast-film fabrication.

Process Influence on Stretch-Film Properties

Cast films are typically different from blown film because of the difference in the way the plastic is oriented and cooled.

In the cast process, film is cooled more rapidly than in the blown process. This faster cooling, which is induced by the chill rollers, causes single-direction orientation in the film. In other words, the polyethylene molecules are cooled so quickly that the molecular structure is formed longitudinally in long, bidirectional branches.

By contrast, blown film is cooled slowly by air while the tube of plastic is drawn upward. This slower cooling allows for the polyethylene molecules to become oriented in all directions, producing a film with tougher puncture resistance.

The differences in these two manufacturing processes produce the following differences in cast and blown stretch films:

Cast Film	Blown Film
Clear	Hazy
High gloss	Dull
Lower modulus—stretches easily	Tough
Quiet unwind	Noisy unwind
	Stiffer film—high load containment
Tear resistance (cross direction)	
Extensibility	
Nonmigratory cling	Migratory cling
Good-to-excellent gauge control	Poorer gauge control
Good puncture resistance	Excellent puncture resistance
Gauge band potential	Gauge spread across roll (rotating die)

Although these are textbook examples of the differences between cast and blown films, it is important to note that through use of various polymers, additives, or process alterations, these differences can be reduced and even reversed. This ability to manipulate the manufacturing process has enabled the stretch-film manufacturer to produce films that combine the best properties of blown and cast films into one film.

Opaque and Color-Tint Films

Opaque and color-tint films are available from film suppliers as special production runs. Because these requests are customized, opaque, and color-tint films have longer lead times and higher costs than do standard stretch films and must meet sizable minimum-order requirements (see Colorants).

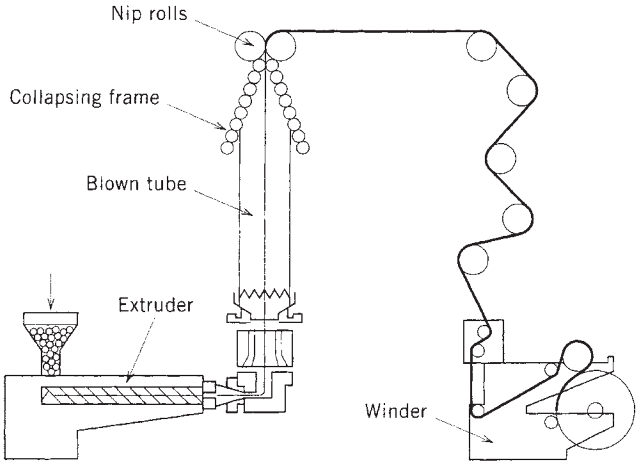

Figure 4. Film-blowing equipment.

MEASURING STRETCH-FILM PERFORMANCE

To most people, if a unitized load maintains its integrity as it moves from point A to point B, it has performed well. However, numerous tests can be completed to thoroughly analyze and measure film performance. Many of these tests can be conducted and evaluated only in a laboratory, but there are a few that any operator can complete with some very simple tools.

This section answers the following stretch-film performance questions:

- What properties are important?
- How can the properties be measured?
  - In the factory or warehouse
  - In the laboratory
- What effect does my machine have on film performance?

What Properties Are Important?

Because there are hundreds of different stretch films now available, knowing how to evaluate film is an important key to success. Equally important is how to use this information to determine load-wrapping cost.

The following is a list of the top six attributes most commonly evaluated:

1. *Tensile Property*. How much even force can be used before the film breaks?
2. *Puncturing*. How much pointed force can the film take before puncturing?
3. *Tearing*. How much force, after a cut has been made, can the film take before tearing?
4. *Optical Scanning*. How much can be seen and read through the film?
5. *Cling on Slip*. How much does the film stick to itself or other surfaces?

6. *Load Force*. How much actual force does the film place on the load?

It is important to note that all of these film attributes are related. Depending on the specific film application, the importance of each attribute will vary. Also, be aware that each film has a balance of attributes and that producing a film that meets maximum performance levels with each attribute would yield an overall weaker film because you cannot affect just one attribute without affecting all of them.

HOW CAN THE PROPERTIES BE MEASURED?

In the Factory or Warehouse

A knowledgeable stretch-film sales professional will employ effective methods to measure film performance on-site. One such method tests the actual stretch level of film after being placed around a load. Using a stretch wheel and a tape measure, the percentage of stretch your machine delivers is calculated in order to ensure that you are not overstretching or underutilizing your stretch film.

Force-to-load is another test that should be performed. The point of this exercise is to measure the pressure the stretch film places against a load. By applying a force-to-load gauge to the stretch film, the apparatus reveals whether the film is administering the appropriate amount of force to contain a load of goods. Snapback is yet another demonstration test used to measure film performance. In the snapback test, you ascertain film recovery; that is, how much has the stretch film returned to its original shape after its been stretched? Film with poor recovery has been stretched beyond its limits and will cause the load to lose integrity over time.

Finally, the “cut and weigh” is a test used to demonstrate the actual cost savings of a particular film in comparison to other brands. In the cut and weigh, a load wrapped in stretch film is cut, removed entirely from the load, and measured on a scale. The same load is then wrapped in another manufacturer’s brand of stretch film and is also cut, removed, and weighed. The two weights are then compared.

To see these film performance measurements done firsthand, contact your local packaging sales professional.

In The Laboratory

The following properties are routinely tested in the lab:

- *Tensile properties* are determined by measuring film performance as it is elongated at a constant rate. By measuring the force required to elongate the film, the following properties can be determined: *yield strength*—the point where a film permanently deforms as a result of force applied during elongation; *ultimate tensile strength*—the maximum force a film can withstand in a tension test measured in psi (pounds per square inch); and *elongation*—the percent increase in film length at its break point.

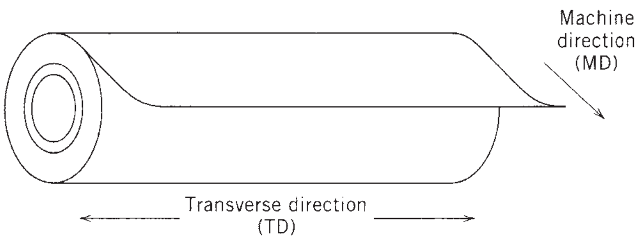

Figure 5. Full-dimensional orientation.

- *Puncture and tear properties* are easy to visually identify while the film is stretched around a pallet load. A film that has poor tear and puncture characteristics will usually fail, forcing an operator to compensate by increasing the number of pallet wraps or loosen the tension. This is an expensive way to compensate for having the wrong film or a film with poor quality. In the lab, puncture resistance is measured by the force needed to puncture the film. This is accomplished by pushing a pear-shaped probe through a tightly secured piece of film. It is measured in inch-pounds or in pounds per mil if film-gauge correction is required. Tear tests or an “Elmendorf test” is simply the force required to propagate a precut slit in a film sample. Another common name for film tearing is “zippering.” The Elmendorf test is measured in grams or grams per mil if gauge correction is required. Tears can occur in both vertical (machine) and horizontal (transverse) directions. (See Figure 5 for clarification.)
- *Optical properties* describe the film’s ability to transmit light (haze) or reflect light (gloss). Both of these properties are significant in determining film clarity.
- *Haze* is a quantitative measure of film transparency, which is very important for scanning labels and identifying pallet-load contents.
- *Gloss* is a measure of surface finish and the films ability to reflect light shine. The higher the percent gloss, the better the shine. Cast-manufactured films tend to exhibit better clarity than do blown films and have higher gloss.
- *Load-force properties* describe the amount of force a film can provide after it is stretched wrapped to a pallet of goods. As mentioned earlier, this test is done in the field as well as in the lab. The load-force property is very important because it is a key to keeping pallets loads tightly unitized. The best way to measure load force is to use a force-to-load gauge. This gauge will show the actual force (pressure) being placed on the load by the film.
- *Cling and slip properties* are measured with an Instron apparatus. Both cling and slip is measured in grams. Cling is simply the ability of a film to stick to itself or another smooth surface. Cling is affected by the amount of tackifier additives, such as polyisobutylene (PIB) in blown films, which are added or by the smooth outer surface of cast films. To

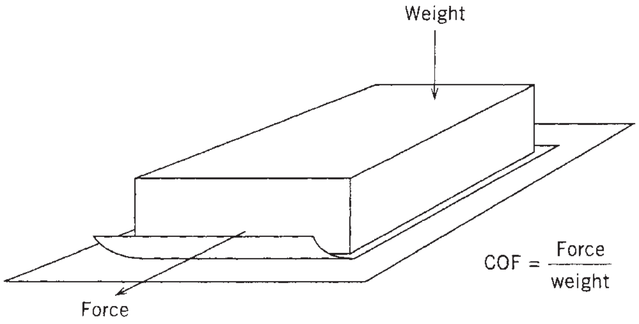

Figure 6. Measurement of coefficient of motion.

determine slip, a film is measured for its *coefficient of friction* (COF), which is a measure of the amount of force required to move a film sample with no cling out from underneath a standard unit of weight. (See Figure 6.)

What Effect Does My Machine Have on Film Performance?

Film performance is critical when determining which film can offer the best load protection at the lowest cost. Often, the equipment used to apply film has a dramatic impact on the film. A film that performs well on one machine may not offer the same results on another system; for instance, stretch levels may differ by machine. Even equipment operators can affect film performance by mishandling the product, not keeping equipment clean and running efficiently, or not stretching the film to its maximum potential.

The challenge is to look beyond a "no complaints" or "it's not broken, don't fix it' mentality to evaluate true film perfomance. In other words, how can a user methodically evaluate film performance levels to discover the best film for the operation under consideration? By employing the film performance measurements outlined in this section, you can make sure that your stretch film is performing up to its full potential.

INSPECTING AND HANDLING STRETCH FILM

Because stretch film exhibits toughness when wrapped, most people would think that stretch film rolls are not fragile. But they are. Caution must be exercised when handling stretch-film rolls and loading them onto the wrapping machine to avoid edge damage, which will cause tearing during prestretch. This section will teach you proper roll-handling techniques and enable you to spot roll defects by covering the following topics:

- Stretch film handling and storage
- Manufacturing defects

Stretch-Film Handling and Storage

Stretch-film rolls, especially their edges, are sensitive to damage. Bumps, nicks, and cuts on the outer edges will easily render the roll unusable. As a result, the rolls must be handled with care. The following are some recommended tips on handling stretch film rolls:

- *Step 1—Minimize Roll Handling.* The packaging that holds a stretch film pallet together has been designed to be opened as close as possible to the wrapping machine. For exactly that reason, it is recommended that pallets of stretch film be stored as close as possible to the wrapping machine to minimize roll handling and prevent damage that could be caused by dropping the rolls.
- *Step 2—Inspect Rolls.* After opening your pallet of stretch film, the rolls should be inspected for shipping damage that can occur if they have shifted in transit. This damage can take the form of dents, product rubs, and gouges, nicks, and tears. Should these exist, try to remove them by unraveling the first few layers of the roll before loading it onto the machine.
- *Step 3—Keep Film Away from Surfaces.* Stretch-film rolls are designed with a 1/4-in core protrusion on each end. When either placing stretch film on the floor for storage purposes or on a machine roll carriage, always make sure that the core, and not the film, is touching the ground or machine surface. The less the film comes in direct contact with any surface, the less likely that your roll edges will become damaged.
- *Step 4—Keep Film Away from Excessive Heat.* To prevent film damage, keep rolls away from heating vents or machines that give off an inordinate amount of heat.

Manufacturing Defects

Several defects can occur in the manufacture of stretch film. Users of stretch film should be aware of these defects (highlighted in italics in legends to Figures 7–13) which may adversely affect film performance.

The best way to avoid manufacturer defects is to pick a manufacturer who places extremely high emphasis on quality, consistency, and performance.

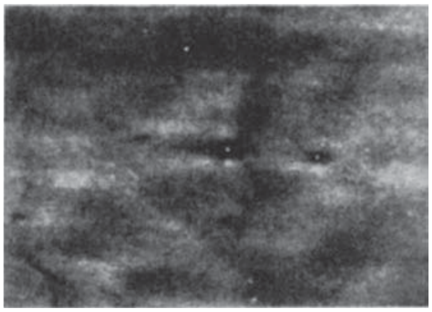

Figure 7. *Gels*—round, hard, clear spots that are high molecular weight or unmelted polymer. Caused by abnormalities in resin or poor mixing. Large gels can cause holes to occur during the wrapping process, which may result in film breaks.

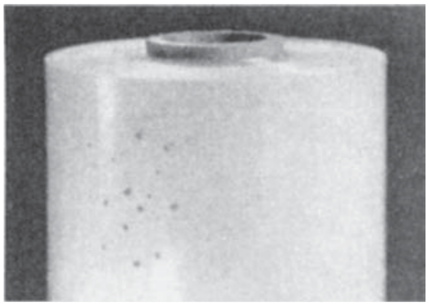

Figure 8. *Black specks*—degraded polymer or other film imperfections caused by a foreign material. Not a common problem. Gives appearance of poor film quality.

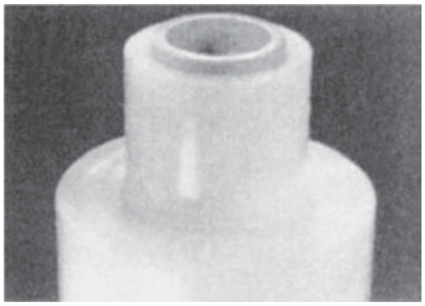

Figure 9. *Roll telescoping*—the sliding of inner layers of the film in a roll or the core out of a roll, increasing roll width and making the roll unusable. This is typically caused by tackifier levels and winding conditions.

Maintaining Consistent Stretch Levels

To measure the degree of stretch your film achieves, you need only three tools: a stretch wheel, a tape measure, and knowledge of a simple mathematical formula.

A stretch wheel is 10 in. in circumference, rotates on an axis, and is held in place by a handle. Jutting out from this wheel is an ink mark that makes a black mark every 10 in. on a roll of unstretched stretch film when the wheel is allowed to rotate freely against the film.

To measure exactly how much a sheet of film has stretched, roll your wheel horizontally against the outer layer of film while it is on the spindle of the machine. Make sure that at least four black marks have been made. Initiate the wrap cycle so that the film is stretched. Measure the distance between the marks. (*Note:* Make sure that you measure the marks that do not cross corners, but are on the flat side of the pallet.)

Now, using your mathematical formula, subtract 10 in. from your measured distance and multiply that difference

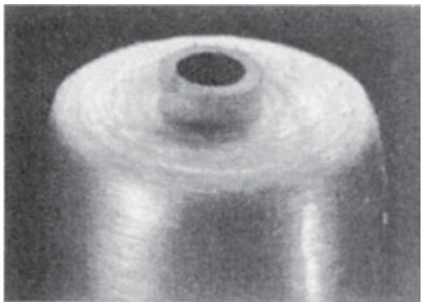

Figure 10. *Feathered edges*—extension of a layer or layers of film past the end of a film roll. Caused if the film wanders back and forth during winding. If these loose edges fold over, they may cause spiral tears during film unwinding.

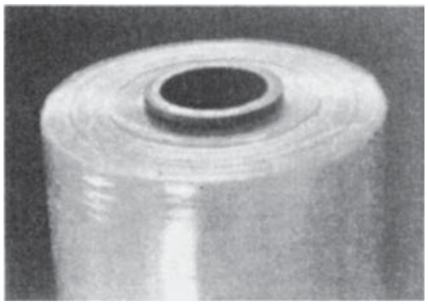

Figure 11. *Scalloped edges*—sawtooth-appearing film edges caused by poor slitting. Can cause web failure from edges.

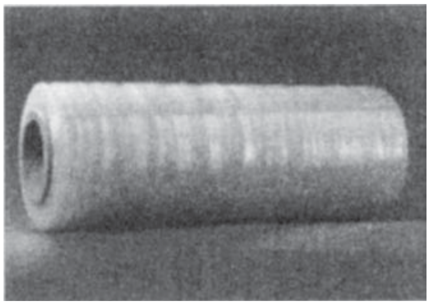

Figure 12. *Gauge bands*—hard or soft rings on a roll of film, caused by gauge (thickness) variations in the film. Normally, gauge bands do not result in any wrapper failure. If a failure does occur, it will come from a wrinkle in the band area. It will appear as a slit starting between the prestretch rolls.

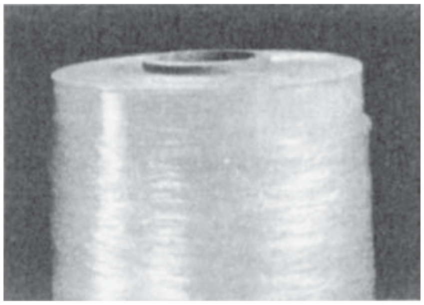

Figure 13. *Tails–overwind*—material that is disrupted by the automatic index or transfer of the winder. During the transfer from a full roll to any empty core, the web tends to draw in and wrinkle. This allows additional air to be trapped and results in a disrupted film appearance.

by 10. The answer is the percentage of stretch that film has endured.

Example: After a sheet of film has been stretched, the distance between the two black wheel marks reads 27 in. Subtract 10 from this number (27−10 = 17), and then multiply 17 by 10 (17 × 10 = 170). (*Answer:* The film was stretched 170%.)

FILM PROBLEMS

There are some problems that can occur when using stretch film. As seen in the preceding section ("Inspecting and Handling Stretch Film"), some of these problems are manufacturer-related and some are shipping related. Stretch-film problems can also stem from equipment conditions, wrapping speeds, and operator ignorance. However, as long as you know how to identify these problems, most have correctives.

This section focuses on how to spot common stretch-film problems and what you can do to rectify them when they arise. Stretch film failures and solutions will be covered under

- Film breaks
- Film "tails"
- Tackifier buildup

Film Breaks

There are three common film breaks that can be identified by the way the stretch film tears. These breaks and the solutions required to repair them are described in the following list.

Edge. An edge tear starts at the top or bottom of a roll and tears in a diagonal direction. It is usually caused by a nick in the film edge. To fix the problem, simply unwind the film until the imperfection is gone. (See Figure 14.)

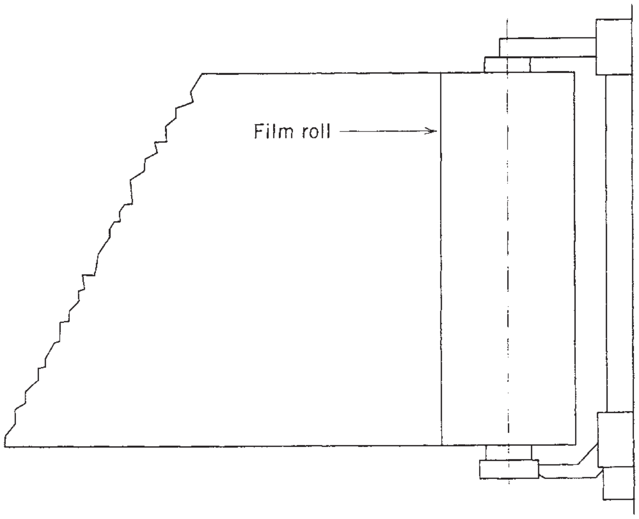

Figure 14. Film break at edge.

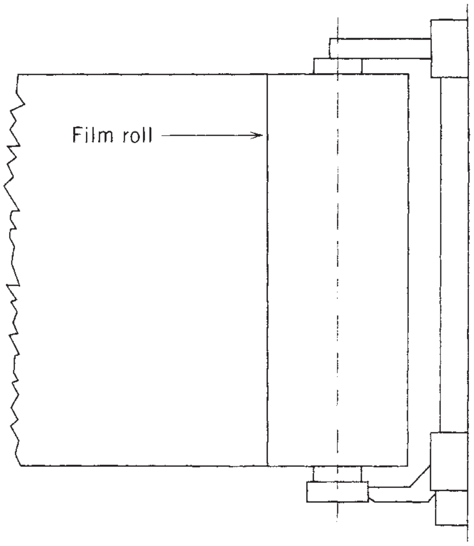

Figure 15. Ultimate break.

Ultimate Break. An ultimate break is a straight-line break with pointed edges. The break occurs when the film has been prestretched beyond its limits. To avoid this type of break, reduce the percentage of prestretch on your machine. (See Figure 15.)

Gel. A gel is a V-shaped break in the film caused by resin imperfection or some other manufacturing problem. Before replacing this roll of film, first try to correct the problem by lowering the F2 and/or prestretch percentage on your machine. (See Figure 16.)

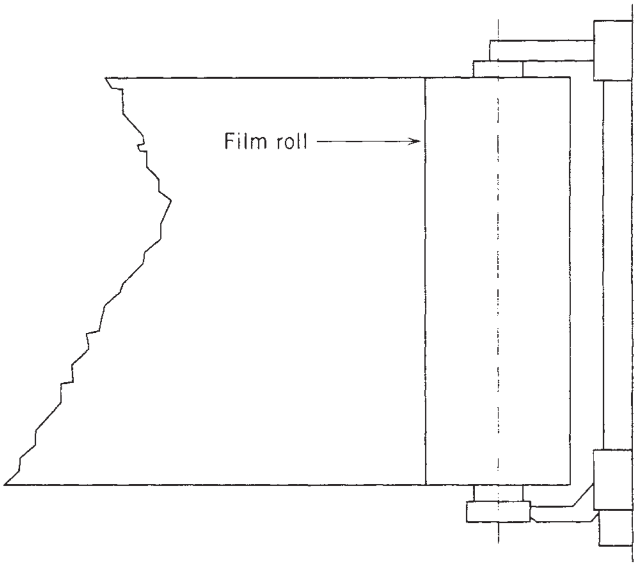

Figure 16. Gel or V-shaped break.

Film "Tails"

A stretch-film "tail" is a loose end piece of stretch film that hangs off a wrapped pallet.

Tails loosen or fall down on wrapped pallets if cling is too low or there is too much dust on the film. But tails occur primarily because film is cut off under tension. To avoid creating tails, the final wrap should be made with a reduced stretch percentage and lowered F2 so that the film elasticity does not pull the tail free of the load.

Tackifier Buildup

Tackifier, the most common of which is PIB, is an additive responsible for giving blown stretch film its cling. Over time, tackifying agents will build up on machine rollers. If allowed to accumulate, tackifier residue can cause stretch film to stick to the rollers and to itself.

To avoid this scenario, machine rollers should be cleaned on a regular basis. It is advised that a mild detergent (isopropyl alcohol makes a good cleaner), warm water, and a nonabrasive cloth be used for this purpose because of the sensitivity of the machine rollers.

ENVIRONMENTAL EFFECTS ON FILM

The strength and protection stretch film affords the packages it wraps has made it the unitizing material of choice among thousands of businesses worldwide. But this is not to say that stretch film is without its limitations. There are certain environmental and physical conditions that can impair regular stretch film's performance. This section reveals what these conditions are so that you can avoid them and get the most out of your stretch film. The topics discussed are

- Outside storage
- Static discharge
- The effect of temperature on film
- The effect of dust and grit on film
- Stacking pallets

Outside Storage

Regular stretch film is not designed for prolonged outside storage. Stretch film is subject to photodegradation from the ultraviolet rays in normal sunlight, which substantially weakens the film.

If wrapped pallets are to be stored outside for more than several weeks, they should be covered. Otherwise, for prolonged outdoor applications, specially formulated ultraviolet-irradiation (UVI)-stabilized films should be used. With UVI film, UV protection is optimized when used in conjunction with opaque tinting.

Static Discharge

Stretch films will support a static discharge and, therefore, should not be used in explosion-prone environments. Since stretch film can induce a static charge, electronic devices packaged in stretch film run the risk of suffering damage. Static buildup, however, can be dissipated through use of Christmas garland or static eliminators.

Effect of Temperature on Film

Generally, higher temperatures make film softer and easier to deform. Lower temperatures make film stiffer and harder to stretch and deform. At higher temperatures, where film is softer, machine-direction tensile strength, tensile yield, puncture force, and transverse-direction tear resistance all decrease. Machine-direction ultimate elongation increases.

At lower temperatures, the opposite is true. Machine-direction tensile strength, tensile yield, puncture force, and transverse direction tear all increase. Machine-direction elongation decreases. If temperature plays a role in your stretch-film requirements, contact your packaging sales professional, who can recommend films that are best suited for your particular needs.

Effect of Dust and Grit on Film

Dust has an adverse effect on film, causing it to lose its cling. In high-dust and high-grit environments, debris can build up on the prestretch and metal rollers and cause failures in film performance. As mentioned earlier in this section, the debris that collects on the rollers is often the result of a buildup of tackifying agents. PIB, the most common cling additive, can accumulate over time, causing the film to wrap and/or sharp objects to be embedded in the rubber rollers. Therefore, it is of utmost importance to keep the rollers clean and free of buildup.

Stacking Pallets

Too much pressure may be placed on pallets by stacking them too high. Two is the recommended limit.

GLOSSARY OF TERMS

Antiblock. Substances added into plastic materials that retard or prevent film layers from sticking together.

Blowup ratio. The ratio of "bubble" or "tube" diameter to extrusion die diameter. A primary consideration in determination of transverse-directional (TD) shrinkage and a partial determinant of machine-directional (MD) shrinkage.

Blown film. Film that is fabricated by continuously pumping the polymer through a circular orifice (die). Once through the die, this polymer is then drawn upward and filled with air, creating a tube. The volume of air contained within the tube stretches the tube out to the desired width and, in conjunction with rate at which it is being pulled away from the die, the desired thickness is created.

Caliper. The thickness of a film or bag, normally expressed in mils or as "gauge" (0.9 mil = 90 gauge = 0.0009 in.).

Cast film. Film that is fabricated by continuously pumping the polymer through a straight slot orifice (die), then chilling this hot sheet of plastic immediately afterward by contact with a colled roll. Film width is determined by the length of the slot. Thickness is determined by how fast the casting roll pulls the plastic away from the slot (or die).

Cling. The characteristic of stretch film that makes it stick to itself or other clean objects.

Coefficient of friction. A dimensionless numerical representation of the ease with which two objects or surfaces will slide against each other. Low numbers slide easily. Total range due to the test definition is 0–1.

Coextrusion. Fabrication of a multilayer film by pumping the various materials through separate extruders and then merging the extrudates into a common die assembly. These die assemblies are constructed to maintain distinct material layers with fusion occurring at the boundaries, due to the pressures and temperature of the extrudates.

Copolymer. A plastic or polymeric whose chemical composition consists of more than one basic hydrocarbon type. The materials are chemically bonded and remain in combination, thus influencing the performance by their own distinct characteristics.

Crosslinked PE. A polyethylene that has been specifically treated by chemical or physical means to cause intrachain bonding.

Crystallization. The formation of distinct, ordered, and repeated molecular groups. Polyethylene forms varying amounts of crystalline structure depending on process conditions and original molecular makeup. The remaining portion is amorphous (which is the antonym of crystalline). Ice is crystalline; water is amorphous.

Dart drop. A method of measuring a film?s impact strength or dynamic toughness. A hemispherical shaped, weighted “dart” is dropped onto a film sample. The weight at which 50% of the samples are punctured is considered the WF_{50} reading.

Die. A device used in extrusion processes to shape the extrudate. Circular dies are used for blown products, and slot dies are used for cast products.

Drawdown ratio. Commonly expressed as the ratio of the width of the extrusion die orifice to the thickness of a particular film. Frequently, however, and more correctly, it is a ratio involving die orifice, blowup ratio, and final film thickness as follows: die gap/(film gauge × blowup ratio).

Eldastic recovery. The ability of a material to return to its original shape or size after having been deformed or subjected to strain.

Elmendorf tear. A testing method used to quantify a material?s resistance to tearing forces. Generally, a sample is slit (initiated tear), then the force required to tear apart the sample is measured and given as the tear value.

Elongation at break. The strain or deformation required to break a sample. Generally expressed as a percentage by dividing the strain (distance) at which a sample breaks by the original sample length.

EVA. Abbreviation (acronym) for the copolymer ethylene vinyl acetate. Small percentages (1–18%) of vinyl acetate monomers are frequently polymerized with ethylene to provide greater extensibility or greater low-temperature strength or to improve sealability.

Extrudate. Molten polymer.

Extrusion. The process of feeding, melting, and pumping a material such that a desired shape or configuration can be created. It is a continuous process and utilizes a device similar to a meat grinder.

Film yield. Generally expressed as the square inches of a film (area) that weighs one pound if the film is 1 mil (0.001 in.) thick. Coverage is on a per pound (lb^{-1}) basis. This should not be confused with yield point, yield strength, or tensile yield, which are strength measurements. Polyethylene yields 30,000 $in.^2$/lb at 1 mil.

Gauge. Used as a synonym for film thickness or film caliper. Sometimes expressed as 80- or 100-gauge, which equates to 0.8 or 1 mil, respectively, or 0.008 or 0.001 in., respectively.

Gauge band. A conformation irregularity found in rolls of material. A thick area in a film will produce a raised or elevated ring in a finished roll of product. Conversely, a thin area will result in a soft ring in a finished roll.

Gloss. The shine or sparkle of a surface. In LDPE film, gloss is described as the amount of light reflected from the surface. Standard technique places a light source and a receiver at 45° angles from the surface. The number value produced is roughly the percentage of light reflected from the source into the receiver.

Haze. The lack of film transparency. It can be induced by process considerations, inherently due to molecular configurations or created by pigmentation. It is measured by determination of the percentages of light not transmitted through a film sample.

Homopolymer. a plastic resin or polymer whose entire chemical molecular structure is of a single hydrocarbon group. It is made by feeding a single monomer to the reactor.

Impact strength. The ability of an object or material to resist rapidly applied destructive forces. Refer to “Dart drop.”

LDPE. Low-density polyethylene—any polyethylene homopolymer whose density is between 0.913 and 0.925 g/cm^3 (g/mL).

Modulus. Short for modulus of elasticity, which is a numerical value reflecting a material’s resistance to deformation. A film with a high modulus is hard to stretch or elongate.

Monomer. The incremental or elemental chemical elements before polymerization. Ethylene is a monomer.

Neckdown. The “narrowing” tendency of a film when it is being stretched or pulled. Occurs when film is stretched in the machine direction, resulting in decreased transverse direction width.

Opaque. Film that is impervious to light: 100% haze level.

Polyisobutylene (PIB). Tackifier additive in blown film that gives it cling.

psi. Abbreviation for pounds per square inch ($lb/in.^2$). A unifying statistical measurement by which various thickness of material can be tested, equated, and compared without regard to actual specimen thickness.

Puncture performance. The relative comparison of a material’s resistance to failures caused by penetration—for example, how easily your finger pokes through a film sample.

PVC. Abbreviation for poly(vinyl chloride). In film form, it is used as a meat or produce wrap, as stretch film, and as a high-clarity shrink wrap for consumer or retail packaging.

Polymer. Means "many members." A structure generated by the repetitious joining of many of the same elementary units. Natural polymers are cotton, wood, or protein. Synthetic polymers are polyethylene, polystyrene, nylon, and so on.

Polyolefin. Polymers of basic unsaturated hydrocarbon chains containing at least one double bond (e.g., polyethylene, polypropylene, and polybutene). Not PVC or PVA.

Reactor. The equipment used to transform ethylene gas to polyethylene.

Stress relaxation. Primarily it is the phenomenon of force decay as a function of time. It means that the "rubber band" tying a stretch load together exerts less force as time passes. This rate of decrease varies greatly with different polymers. PVC has an early decay that is much greater and more rapid than that of LDPE.

Stretchability. A combination of factors related to the ability of a material to be stretched or elongated—for example, how easily and to what extent a film stretches and whether it will return to its original length.

Tack. An adjective used to describe a film's resistance to slide against itself or another surface, or its resistance to separation from itself. Similar terms are *surface adhesion* or *cohesion, surface seal, wetting of film layers, blocking*, or *cling*.

Tackifiers. Chemical substances added to increase the tack of the parent or base material.

Tear resistance. The resistance of a film to be torn. This is quantified by Elmendorf tear testing, and is measured as the force required to propagate an initated tear in the MD or TD direction.

Tensile ultimate. This is a stress level, measured in psi, beyond which the specimen will break. It is the laboratory-measured, maximum stress (applied force) that the material will withstand. Tensile indicates that test is conducted with a pulling or tensioning type of loading.

Tensile yield. This is a stress level, measured in psi, beyond which permanent deformation occurs. "Tensile" indicates that the specimen is pulled or "tensioned" rather than compressed. Up to this stres or applied force level, a release of the force will result in the specimen returning to its original size. Pulling with a higher force will result in an elongated sample, even after the force is removed.

Tint. A slight coloring that allows light transmission and relatively good clarity.

Toughness. An overall strength measurement that takes into account both the amount of pull and the amount of elongation a sample can withstand. A tough material will resist breakage by both resisting force and by elongating. A brittle material (e.g., glass) will resist force, but will break instead of deforming; hence it has low toughness. LDPE, which is plastic or tough, both resists and elongates—hence is tougher than glass. The rate of force application has significant effects on toughness, so comparisons must include testing data.

Ultimate Strength. Same as "Tensile ultimate."

Wide web. Wrapping with a roll of film approximately the size of the load.

Wrap. One revolution of a machine turntable.

Yield stretch. Same as "Tensile yield."

Zippering. Lack of resistance to tear propagation of an initiated TD cut or tear. Once the film has been torn or cut, the resulting slit rapidly opens and completes a full-web break.

FILM, TRANSPARENT GLASS ON PLASTIC FOOD-PACKAGING MATERIALS

RUSSELL J. HILL
BOC Coating Technology,
Concord, California

INTRODUCTION

Commonly used polymeric packaging materials, such as polyethylene terephthalate (PET), oriented polypropylene (OPP), and biaxially oriented nylon (BON), do not have sufficient oxygen or water-vapor barrier properties for many packaging applications. To resolve this issue, multilayer material structures that incorporate aluminum foil and polymeric films, aluminum metallized films, PVDC-coated films, or coextruded EVOH films routinely are applied. However, environmental considerations and the push toward source reduction have created a market need for a thin-film transparent oxygen or water-vapor barrier coating that is friendly to the environment and convertible into usable packaging materials and at the same time capable of meeting the cost requirements of the food-packaging industry. The coating should also use a low-temperature process to coat heat-sensitive polymeric films such as OPP and BON.

The goal of the scaleup process for the QLF transparent barrier coating was to design and manufacture equipment to provide SiO_x-coated material that is environmentally friendly, recyclable, microwavable, crystal-clear in transparency, excellent in adhesion to the substrate, and able to allow metal detection. In addition, the coating must withstand mechanical stress and the high temperatures generated during extrusion lamination and heat seal. It should be printable, able to run at a high speed on standard converting equipment, and be cost-competitive compared with existing barrier materials. For commercial success, the coating process must be capable of producing high throughputs to meet the low coating cost demands of the packaging industry.

WHY PLASMA-ENHANCED CHEMICAL VAPOR DEPOSITION (PECVD)?

Coatings of SiO_x can be produced by several methods that include sputtering, evaporation, and PECVD.

Table 1. Comparison of Glass-Coating Technologies

Feature	Sputtering	Evaporation	PECVD
Vacuum (torr)	10^{-3} (proc.) 10^{-6} (base)	10^{-6} 10^{-6}	10^{-2} 10^{-2}
Power (kw)	Thousands	Hundreds	Tens
Process temperature	High	High	Low
Source	$Si + O_2$	SiO/SiO_2	Monomer
Source cost	High	High/medium	Low
Source utilization	Roughly 40%	Roughly 25%	>50%
Coating thickness	400–500 Å	1500–3000 Å	150–300 Å
Film color	Yellow	Yellow	Clear
Coating bond	Mechanical	Mechanical	Chemical
Barrier (unlaminated)	Medium	Medium	High

Extensive R&D programs have been completed to investigate each technology to determine the most effective method for creating a SiO_x coating to meet scaleup process goals. At the same time, a prototype machine was built capable of coating rolls 660 mm wide to prove the production and economic viability of whichever process was chosen. This system had the capability to use all three technologies. Table 1 shows the results of the study that led to the focus on the PECVD process. Sputtering was disqualified early, because of large power requirements and low deposition rate. The process was not economical for food packaging.

In contrast, the main advantage of evaporation was the *potential* to run at very high line speeds, comparable with those speeds used in vacuum metallizing of aluminum. This potential has not been realized. SiO cannot be evaporated at as high a rate as aluminum. If it is evaporated at a power level to give the same rate as aluminum, then molten SiO is spattered onto the film, which causes holes in the film. Also, the thickness of the coating needed to gain a suitable barrier is much greater than that for aluminum metallizing (1500–3000 Å vs. 200 Å).

On the basis of the coating work carried out, the PECVD process showed much more promise than evaporation in terms of economics and coating performance. The economics for the PECVD process are better than those for evaporation, because the vacuum requirements are less stringent, which means that the time to change rolls should be less; the power requirement per unit area is less; cooling requirements are less; raw material is inexpensive and available; source usage is higher, mainly because of patented equipment design; and coating thickness is less.

SCALEUP OF MANUFACTURING SYSTEMS

The SiOx deposition process described is a low-pressure, low-frequency, and low-temperature PECVD process that uses a mixture of helium, oxygen, and the organosilicon compound hexamethyldisiloxane (HMDSO), as shown in Figure 1. The plasma source uses a multipole magnetic field to confine the plasma to obtain enhanced deposition rates at low pressures. The resulting silicon oxide is the QLF barrier coating.

The three coaters used in the course of the maufacturing scaleup effort are shown schematically in Figure 2. The QLF coating was initially developed in a small research roll coater. Because of technical risks and the capital cost required to build a 1.5- or 2-m-wide vacuum roll coater, the strategy involved incremental steps in scaling up the coating process from a web width and speed of 0.3 m wide at 0.3 m/min, to 0.66 m wide at 100 m/min, then 1.5 m at >100 m/min and finally to 2 m at >100 m/min. The challenge to incrementally increase the web width and speed was recognized because of the need to develop hardware capable of running under the process conditions required to achieve the target barrier performances and line speeds. BOC coating technology (BOCCT) has systematically scaled up the process using statistically designed experiments that optimized the parameters through different treatment conditions as well as the use

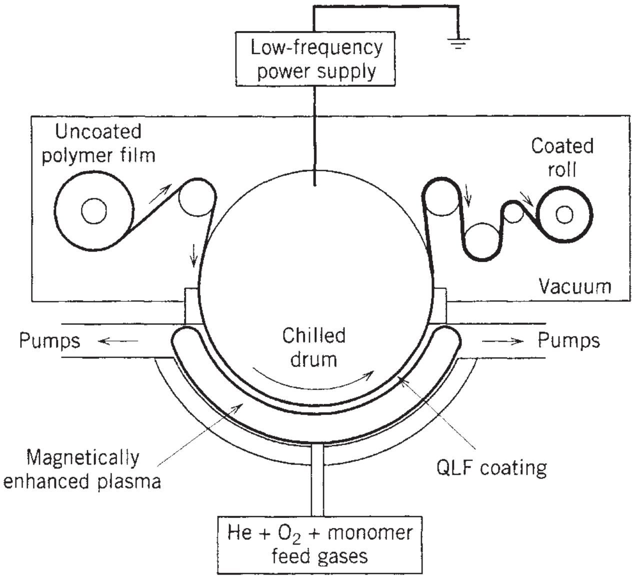

Figure 1. Proprietary plasma-enhanced chemical vapor deposition.

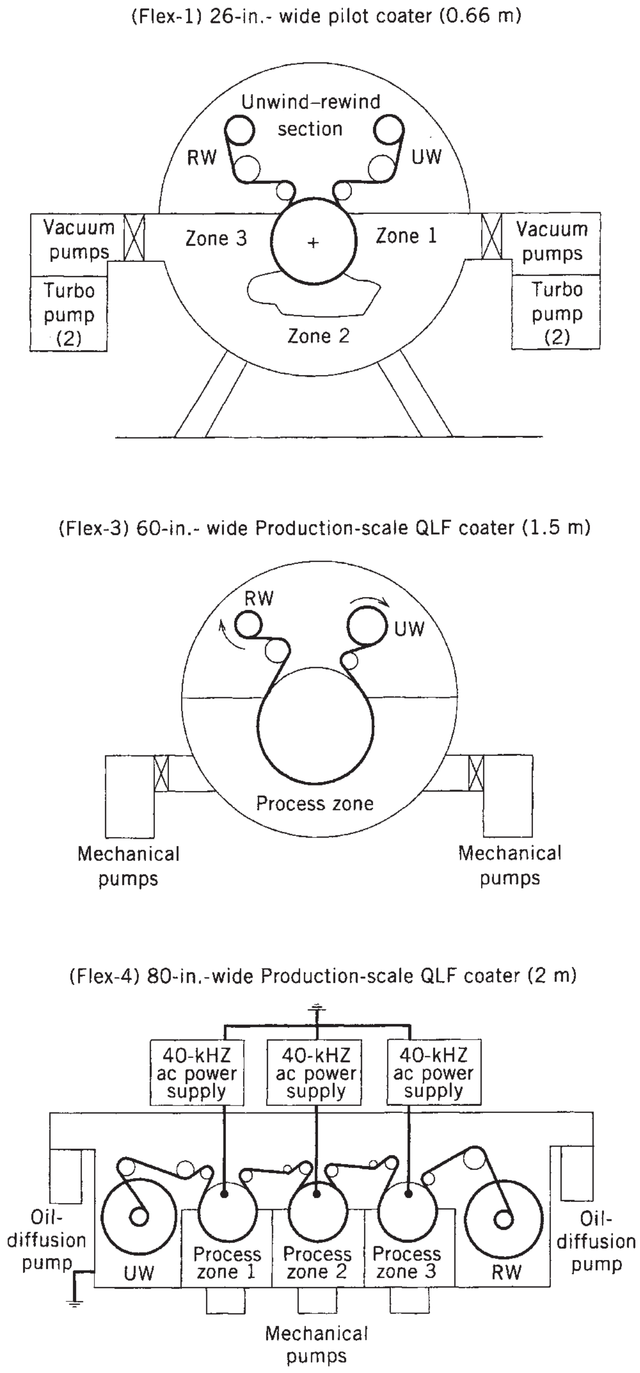

(Flex-1) 26-in.- wide pilot coater (0.66 m)

of previous experience from other vacuum coating machines.

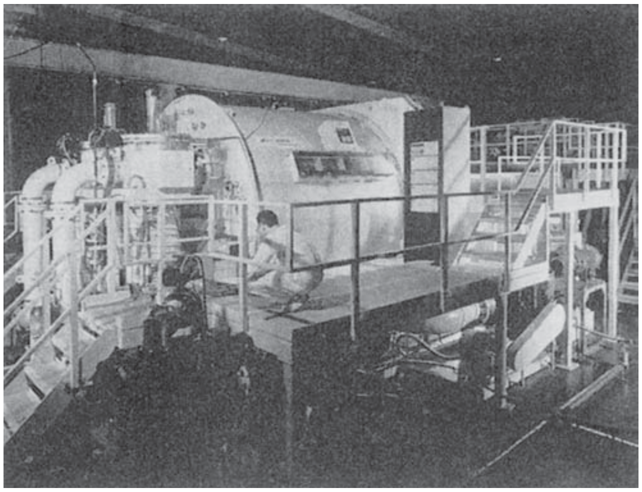

Figure 3. Flex-3: production-scale QLF roll coater.

The first scaleup phase was completed in a development coater that can mechanically handle 0.66-m-wide webs at speeds from 0.1 to 150 m/min. The second scaleup phase was conducted in a production-scale coater that can handle 1.5-m-wide webs at speeds from 10 to 300 m/min (Figure 3). The process scaleup in this coater was completed using HMDSO as the monomer. The third scaleup phase is a production coater that can handle 2-m-wide webs at speeds from 30 to 300 m/min (Figure 4). This is a modular design production coater with three isolated process zones that provide flexibility for pretreatment and/or posttreatment or for deposition with different chemistries.

BARRIER PERFORMANCE

The *unlaminated* oxygen transmission properties achieved to date for PET and OPA are listed in Figure 5 and 6. A typical oxygen transmission rate (OTR) for uncoated PET is 115 cm^3/(m$^2 \cdot$ 24 h). With QLF coating applied at a speed of 100 m/min, the OTR is reduced to 1.1 cm^3/(m$^2 \cdot$ 24 h). Increasing the line speeds to 200 m/min will result in an OTR reading of 2 cm^3/(m$^2 \cdot$ 24 h). The opportunity for high barrier performance on other substrates is also possible. Production rolls of OPA with QLF coating run at line speeds of 300 m/min demonstrate an OTR of 7 cm^3/(m$^2 \cdot$ 24 h). These results represent the flexibility a roll coater can offer. *Whether a customer is targeting a high or medium*

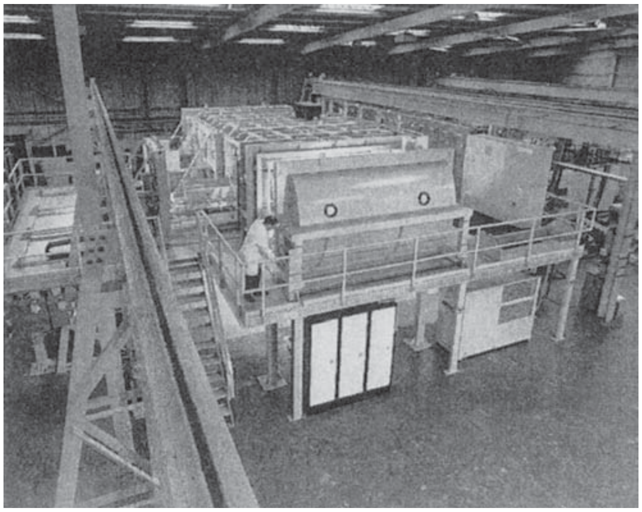

Figure 4. Flex-4: production-scale QLF roll coater.

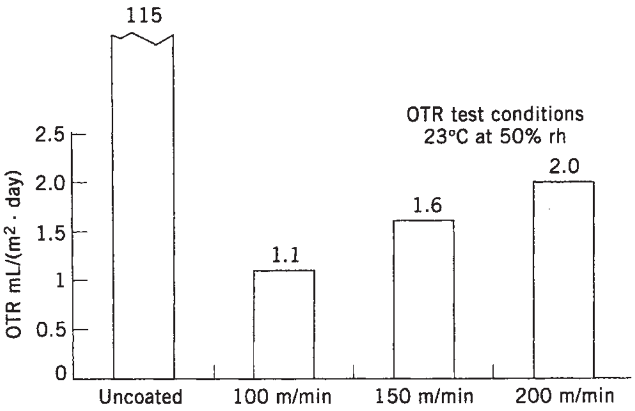

Figure 5. OTR of 12-μm PET with QLF coating.

barrier application, a roll coater can satisfy their requirements.

Initially, the technology was focused on an effort to optimize the oxygen barrier primarily for liquid packaging. Continued development was targeted toward upgrading and optimizing the process for water vapor (WVTR) as well. As indicated in Figure 7, the WVTR for PET with QLF coating has been reduced from a level of 5.6 g/(m^2 · 24 h) in August 1995 to 1.4 g/(m^2 · 24 h) in December 1995. Development efforts are now focused on increasing line speeds and on introducing a range of different substrates to the PECVD process. (See also Barrier Polymers.)

CONVERTING

Successful large-scale acceptability of QLF-coated materials is dependent on the ease of convertibility as well as on their cost and barrier properties. Extensive research has been dedicated to determining how "robust" QLF coatings are in varying converting processes. Because of the strong chemical bond that exists between QLF coatings and PET, converting results have been encouraging. Several packaging converters have successfully adhesive- and extrusion-laminated QLF-coated PET, which maintain barrier properties and achieve excellent bond-strength results. Good ink adhesion also was achieved directly on the QLF-coating surface. BOCCT can supply a recommended list of inks and adhesives on request.

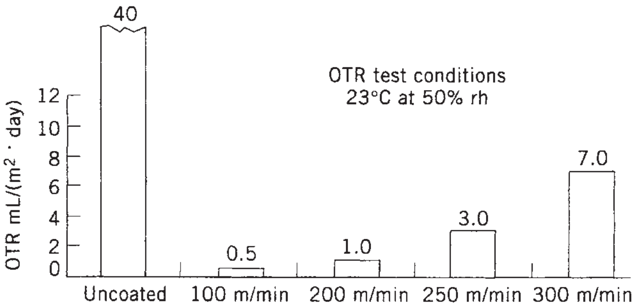

Figure 6. OTR of 15-μm OPA with QLF coating.

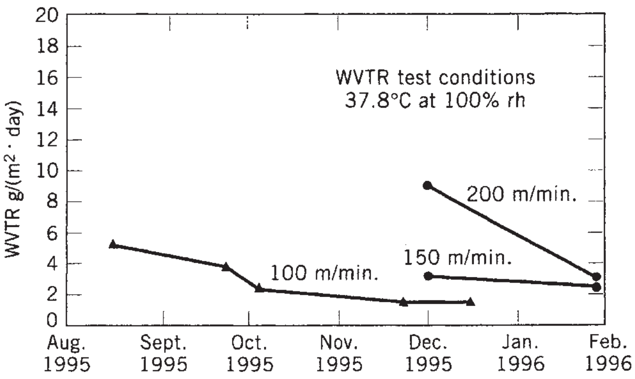

Figure 7. WVTR of 12-μm PET with QLF coating.

Gelbo flexing, which is a test commonly used to simulate stresses encountered in finished-packaged shelf life in the marketplace, is also being investigated. Earlier papers (1,2) already have reported that the finished-packaging structures with the QLF coating survived the tests when properly laminated.

COMMERCIALIZATION OF QLF BARRIER COATING

The transparent oxide barrier market has been plagued by high cost and/or difficulties in converting or printing on the barrier coating surface without losing the barrier properties. One of the most crucial success factors in the transparent high-barrier market is the ability to provide a better, or comparable, material at a lower cost. QLF coatings are not only the most "robust" transparent oxide coatings available in the marketplace—they also provide the most competitive economics.

Today, BOCCT roll coaters are built to offer the converter or film manufacturer the flexibility to target both the medium-barrier and the high-barrier markets. Depending on the barrier level one is looking to achieve, QLF coating costs can range from < \$0.03 to < \$0.045/m^2. These costs will continue to lower as more advances in line speeds and barriers are achieved.

The use of commercial size coaters to improve the QLF coating performance is continuing. QLF coatings are FDA approved, provide a better barrier than polyvinylidene chloride (PVDC) coatings, and are insensitive to humidity changes as opposed to ethylene vinyl alcohol (EVOH). Replacement of these coatings on substrates such as PET and BON are the initial targets for large-scale commercialization of QLF coatings.

CONCLUSION

QLF barrier coatings have been scaled up from a 0.3-m-wide web laboratory coater at a line speed of 0.3 m/min to a 2-m-wide web production coater capable of 300 m/min. BOCCT is committed to continued improvements in both line speeds and barrier performance. Currently, technology-driven converters and film manufacturers are forming partnerships with BOCCT to make QLF coatings a commercial reality.

QLF coatings applied to PET substrates can now perform with barriers and line speeds that exceed even the most demanding expectations of the packaging industry. Meeting the demand in the packaging industry for an environmentally friendly, transparent barrier coating is the goal of BOCCT.

FLEXIBLE INTERMEDIATE BULK CONTAINERS

Bruce Cuthbertson
Flexible Intermediate Bulk
Container Association
Updated by Staff

INTRODUCTION

Flexible intermediate bulk containers are defined as an intermediate bulk container, having a body made of flexible fabric, which (1) cannot be handled manually when filled, (2) is intended for the shipment of solid material in powder, flake, or granular form, (3) does not require further packaging, and (4) is designed to be lifted from the top by means of integral, permanently attached devices (lift loops or straps) (1).

Flexible intermediate bulk containers (FIBCs), also known as "big bags," "bulk bags," and "bulk sacks," were first manufactured in the late 1950s or early 1960s. There is some controversy as to where the first FIBCs were made; however, it is known that FIBCs were made in the United States, Europe, and Japan during the time period mentioned above. The first FIBCs were constructed with heavy-duty PVC-coated nylon or polyester where the cut sheets are welded together to form the FIBC. These FIBCs were made with integrated lift slings around the container, or were attached to a specially made pallet, or were manufactured a metal lifting device that the container sat on. These handling devices allowed the container to be filled from the top and discharged from the bottom.

The initial cost of these heavy-duty containers is high; therefore, they are designed to be reused many times in a closed-circuit system, where problems of control logistics, prevention of contamination, cleaning, and liability for loss or damage can be agreed on by the shipper and receiver of the product.

Flexible intermediate bulk containers manufactured with polyolefin fabrics were experimented with in England, Japan, Canada, and the United States all at about the same time in the late 1960s to the early 1970s. It was the development of these high-strength light-weight fabrics (i.e., polypropylene) that spurned the growth of the flexible bulk bags that is universally used today.

The rapid growth in Europe in the manufacture of FIBCs occurred in the mid-1970s during the oil crisis. The oil-producing countries building program required large quantities of cement. The demand for cement was shipped in FIBCs at the rate of 30,000–50,000 metric tons per week from Northern Europe, Spain, and Italy to the Middle East.

The demand for bulk bags in the United States grew slower than in Europe until 1984, when the U.S. Department of Transportation (DOT) agreed to grant exemptions for the shipment of hazardous products in FIBCs. Performance standards for FIBCs were established and issued by the Chemical Packaging Committee of the Packaging Institute, USA under T-4102-85. These standards were used to obtain exemptions until DOT included flexible containers with the other types of IBCs in the regulation HM181-E for hazardous products.

DESIGN

The flexible bulk container offers many features that are unique to this package. It can be folded flat and baled for shipment to the user. The weight of a bulk bag to ship one metric ton of product weighs 8–10 lb, offering a low package:product weight ratio. The cost of FIBCs is competitive with other forms of packaging because it is usually utilized without pallets. They are easy to store and handle in warehouses with standard equipment. When shipping by boat, the FIBCs are gang-loaded with up to 14 bulk bags on a spreader bar, and they are shipped as break bulk.

The standard diameter of FIBCs is 45–48 in., designed to fit two across in a truck or a shipping container. Special configured containers are made to meet specific requirements of the container user.

FIBCs generally are manufactured to meet specific requirements of the container users. The height of the container, the diameter and length of the spouts, coated or uncoated fabric, and whether a polyethylene liner is necessary will be specified according to the type of product that will be shipped.

USES

Modern FIBICs transport over 0.25×10^9 t of goods per year. They are used to store and move a variety of products such as cereals, powdered chemicals, flour, and animal feeds. With a capacity of of up to $3\,m^3$ and load capability of 0.5–2 t, FIBCs are highly cost effective, easily recyclable, and ideal for free-flowing granules, powders, pellets, and flakes (2).

When hazardous products are shipped in FBCs, the UN mark for the product must be printed on the container body. In the United States the manufacturer of the container is self-certifying and marks the container according to the regulations HM 181E. All other countries require the container manufacturer to submit containers to third-party testing for certification.

FIBCs containing nonhazardous or nonregulated product when shipped export from the United States must have performance testing certification if destined for a country that require performance standards for bulk bags.

The following regulation numbers apply for performance standards for containers with regulated products: United States, HM 181E; United Nations, Chapter 16; England, B.S. 6939; Canada, CGSB 43.146.

FOAM, EXTRUDED POLYSTYRENE

Phillip A. Wagner
The Dow Chemical Company,
Midland, Michigan
Updated by Staff

INTRODUCTION

Polystyrene foam sheet is a reduced-density sheet made from polystyrene by the extrusion process. Produced in many forms, it is most easily classified by its density and thickness. This article deals with a sheet that has densities of 3–12 lb/ft^3 (0.05–0.19 g/cm^3) and thickness 0.012–0.250 in. (0.3–6.35 mm). Foamed thermoplastics provide excellent insulating properties because of their low thermal conductivity, good shape retention, and good resistance to moisture pickup (1).

The first extruded foam sheet was produced in 1958 by extruding expandable polystyrene beads. In the early 1960s, the direct-gas-injection extrusion technology was developed and is by far the most widely used system today. In the late 1980s and early 1990s, there was a decrease in the volumes of foam produced due to the environmental issues related to the blowing agents being used and disposal of the foam. The use of new and more ecologically acceptable blowing agents and increased recycling of the products has reduced these concerns. Most of the foam is used for disposable packaging such as meat and produce trays, egg cartons, containers and trays for carryout meals, and disposable dinnerware. It is also used for drink cups, bottle labels, miscellaneous cushion packaging, and applications where it is laminated to paper or films. A large percentage of all foam sheet produced is thermoformed to manufacture the finished product. When it is laminated with paper, it is usually fabricated by die cutting and scoring to produce folding containers.

PRODUCTION

There are four direct gas injection processes to produce polystyrene foam sheet. All four have the same objectives: to melt the polymer, uniformly mix in the blowing agent and nucleator, cool the melt, and allow the mix to expand into a biaxially oriented sheet. The four processes employ large-diameter or long L/D extruders, twin screw extruders, the Winstead system using a single screw extruder and its cooling system, and the two single-screw extruder tandem system. Of these processes, the tandem system is most successful and widely used (see Figure 1).

The tandem extruder system utilizes two single-screw extruders: a primary extruder for melting, mixing, and feeding the extrudate to a secondary extruder for cooling and additional mixing of the extrudate prior to exiting an annular die. Most tandem systems use 4.5-in. (11.4-cm) primary extruders and 6-in. (15.2-cm) secondary extruders with output rates of 500–1200 lb/h (227–544 kg/h). As producers strived for higher output rates, 6-in. (15.2-cm) primary and 8-in. (20.3-cm) secondary extruders with output rates of 900–2000 lb/h (408–909 kg/h) have become more popular. Tandem foam lines are supplied by several extruder manufacturers (see also Extrusion).

In addition to the rather unique extrusion system, the die–mandrel–takeoff system must be carefully designed. As mentioned above, an annular die is generally used because of the three-dimensional expansion of the foam. The foam is drawn over a cooling sizing mandrel to cool the foam and provide the desired sheet width. Blowup ratios and the die diameter:mandrel diameter ratio must be calculated according to the density and desired orientation of the foam to be produced. Ratios of 3:1 to 4.5:1 are common. This tubular sheet is slit into the required widths as it is drawn off the mandrel and is then wound into rolls.

RAW MATERIALS

The ingredients required to produce foam sheet are resin, nucleator, and blowing agent. The resin is normally a high-heat general-purpose polystyrene such as Dow Styron 685D. Nucleators, such as talc or a citric acid–sodium bicarbonate mixture, are added to provide foaming sites to obtain the desired cell size and uniformity. The chlorinated fluorocarbons formerly used as blowing agents have been replaced with more environmentally friendly substitutes, such as HCFCs (HFC-152a) or low-molecular-weight hydrocarbons such as butane or isopentane, carbon dioxide, and blends of these blowing agents (1). The blowing agent is dissolved and held in solution by the pressure in the extruder (2). The blowing agent is injected into the primary extruder approximately two-thirds of the way up the barrel. This is accomplished by the use of a positive-displacement volumetric pump. The amount and

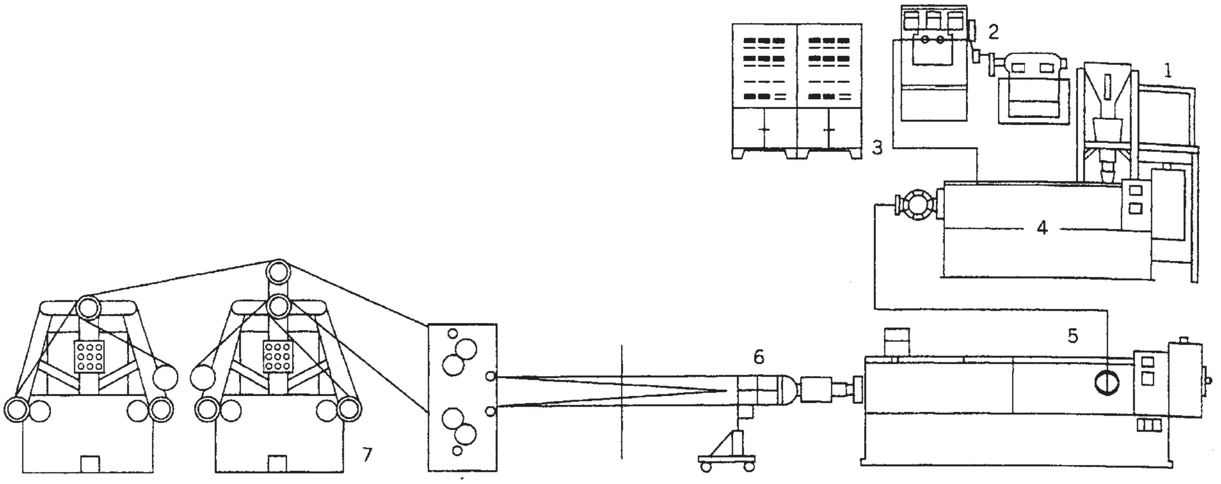

Figure 1. A two-extruder tandem system for the production of foamed sheet: (**1**) continuous feeding and blending system; (**2**) volumetric pump system; (**3**) process control; (**4**) primary extruder; (**5**) secondary extruder; (**6**) annular die and cooling mandrel; (**7**) draw rolls and winders.

type of blowing agent control the density of the foam produced. Figure 2 shows the relationships for three of today's most commonly used blowing agents. The foam can also be colored for aesthetics by the addition of color concentrates (see also Colorants).

A large percentage of all foam sheet is thermoformed to produce the final product. To achieve good postexpansion of the sheet, the sheet should be allowed to age for 3–5 days. This aging allows cell gas pressure to reach equilibrium. Matched metal molds are normally used in the thermoforming process. Oven temperature control is critical for consistent thermoforming. Scrap produced from the extrusion and thermoforming process can be reprocessed by grinding the scrap and densifying it in an extruder.

ENVIRONMENTAL CONCERNS

Ecologically, polystyrene foam is very easily recycled, and significant quantities are presently being reused. It also conforms favorably to current forms of disposal, such as landfill and incineration. In landfill, foam remains inert, but it packs and crushes easily and there is no pollution of underground water streams by decaying material. In incineration the chief products of combustion are water, carbon dioxide, and carbon monoxide, which are typical of organic materials, and the Btu (British thermal unit) value is high. If burned without enough oxygen, polycyclic aromatic compounds, carbon mooxide, and carbon black are produced. Use of polystyrene for food packaging has been banned in some U.S. cities (San Francisco and Oakland are the latest to pass bans). Recycled polystyrene can be used for park benches, flower pots, and toys.

FOAM PLASTICS

K. W. Suh
M. H. Tusim
The Dow Chemical Company,
Midland, Michigan

Foamed plastics, which are also known as *cellular plastics* or *plastic foams*, have been important since primitive humans began to use wood, a cellular form of the polymer cellulose. Cellulose is the most abundant of all naturally occurring organic compounds, which represents approximately one third of all vegetable matter in the world. The high strength:weight ratio of wood, the good insulating properties of cork and balsa, and the cushioning properties of cork and straw have contributed to the development of the board range of cellular synthetic polymers in use today.Cellular polymers have been commercially accepted for a wide variety of applications since the 1940s. The total usage of foamed plastics in the United States rose from about 2.1×10^6 tons in 1993. It is expected to rise to about 2.9×10^6 metric tons in 1998 (1).

NOMENCLATURE

A *cellular plastic* is defined as a plastic whose apparent density is decreased substantially by the presence of numerous cells disposed throughout its mass (2). In this article, the terms *cellular polymer, foamed plastic, expanded plastic*, and *plastic foam* are used interchangeably to denote all two-phase gas–solid systems in which the solid is continuous and composed of a synthetic polymer or rubber.

THEORY OF THE EXPANSION PROCESS

Foamed plastics can be prepared by various methods. The most widely used, which is called the *dispersion process*, involves dispersion of a gaseous phase throughout a fluid polymer phase and the preservation of the resultant state. Other methods of producing cellular plastics include sintering dispersed small particles and dispersing small cellular particles in the plastic. The latter processes are relatively straightforward techniques of lesser commercial importance.

The expansion process has been the subject of extensive investigation because it is the foundation of foamed plastics (3–6). In general, the expansion process consists of three steps: creation of small discontinuities or cells in a fluid or plastic phase, growth of these cells to a desired volume, and stabilization of the resultant cellular structure by physical or chemical means.

Bubble Initiation. The development of bubbles within a liquid or polymer solution is generally called *nucleation*, although the term actually refers only to those bubbles that separate from the supersaturated liquid or polymer solution in the presence of an initiating site such as a surface irregularity. This process has several sources: (a) dissolved gases that are normally present in the liquid or polymer solution and forced into supersaturation by increased temperature; (b) low-boiling liquids that are incorporated into the system as blowing agents and forced into the gas phase by increased temperature and decreased pressure; (c) gases produced as blowing agents, eg, by the water—isocyanate reaction used for CO_2 production in polyurethane foams; and (d) chemical blowing agents that decompose thermally to form a gas.

Bubble nucleation is affected by many conditions. Physically, the effects of temperature, pressure, and in some cases humidity are fairly obvious. Other important parameters are surface smoothness of the substrate, surface characteristics of filler particles, presence and concentration of certain surfactants or nucleators, size and amount of second-phase liquid bubbles, and the rate of gas generation.

In many cases, bubbles of gas and other contaminants are already present in the liquid or polymer solution, and these serve as sites into which the gas may diffuse. The number and size of these gas bubbles may be another important factor in bubble development.

Bubble Growth. The initial bubble is ideally a sphere that grows as a result of the interaction of the differential pressure (ΔP) between the inside and outside of the cell and the interfacial surface tension (γ). The radius (r) of the bubble at equilibrium is related to these factors as shown in equation (1):

$$\Delta P = \frac{2\gamma}{r} \tag{1}$$

The differential pressure is larger for a small bubble at a fixed surface tension. Accordingly, smaller bubbles tend to equalize these pressures by growing faster, breaking the wall separating the cells, or by diffusion of the blowing agent from the small to the large cells as indicated by equation (2):

$$\Delta P_{1.2} = 2\gamma\left(\frac{1}{r_1} - \frac{1}{r_2}\right) \tag{2}$$

where $\Delta P_{1.2}$ is the difference in pressure between cells of radius r_1 and r_2. Therefore, the rate of growth of the cell depends on the viscoelastic nature of the polymer phase, the blowing-agent pressure, the external pressure on the foam, the cell size, and the permeation rate of blowing agent through the polymer phase.

Bubble Stabilization. Bubble stability during growth is a function of the type and concentration of surfactant, rate of bubble growth, viscosity of the fluid medium, differential pressure variations, and presence of cell-disrupting agents such as solid particles, liquids, or gases. As the cell walls are squeezed into polyhedra, a wall-thinning effect takes place, and liquid is drained from cell-wall faces into the lines of cell intersections to form ribs or struts, which are typically triangular in cross section. This cell-wall membrane thinning can continue to the point where the cell walls collapse and the cells open. This becomes an important characteristic of most plastic foams and affects properties such as thermal conductivity, moisture absorption, breathability, and load bearing.

Ultimate stabilization occurs as a result of either chemical reaction continuing to the point of complete gelation or the physical effect of cooling below the second-order transition point to prevent polymer flow. As the final solidification is approached, the previously formed bubbles may be distorted by the system flow or gravity, which thereby produce anisotropy in the cellular structure. This effect must be considered when evaluating the physical properties of plastic foams by obtaining samples oriented in specific directions to the process flow.

PROPERTIES

The data in Table 1 show the broad ranges of properties of rigid foamed plastics (7); the manufacturer should be consulted for the properties of a particular product. The properties of some commercial flexible foamed plastics are given in Table 2 (7). These values depend on several structural variables and should be used only as general guidelines (see also the Polymer properties article).

The properties of a foamed plastic depend on composition and geometry, which are often referred to as *structural variables*. Furthermore, they are influenced by the foam structure and the properties of the parent polymer. The polymer phase description must include the additives present.

Cells. A complete knowledge of the cell structure of a particular polymer would require the size, shape, and location of each cell. Because this is impractical, approximations are employed. Cell size has been characterized by measurements of the cell diameter and as a measurement of average cell volume. Mechanical, optical, and thermal foam properties depend on cell size.

Geometry. Cell shape is governed predominantly by final foam density and the external forces exerted on the cellular structure before its stabilization in the expanded state. In the presence of external forces, the cells may be elongated or flattened. Cell orientation can influence many properties.

Fraction open cells. An important characteristic of the cell structure is the extent of communication with other cells. This is expressed as *fraction open cells*.

Gas composition. In closed-celled foams, the gas phase in the cells can contain blowing agent (so-called captive blowing agent), air, or other gases generated during foaming. Thermal and electrical conductivity can be profoundly influenced by the cell-gas composition.

Mechanical Properties. In mechanical properties, rigid foams differ from flexible foams. The tests used to characterize them are therefore different, as are their application properties. In the last two decades, a separate class of high-density, rigid cellular polymers called *structural foams* (density $>0.3\,\mathrm{g/cm^3}$) have become commercially significant.

Structural variables that affect the compressive strength and modulus of a rigid plastic foam are, in order of decreasing importance, plastic-phase composition, density, cell structure, and plastic state. The effect of gas composition is minor with a slight effect of gas pressure in some cases.

Structural foams or foams with integral skins are usually produced as fabricated articles in injection-molding or extrusion processes. They have relatively high densities, and cell structures are composed primarily of holes in contrast to a pentagonal dodecahedron structure in low-density plastic foams. Because structural foams are generally not uniform in cell structure, they exhibit considerable variation in properties with article geometry.

In flexible foams, which are used in comfort cushioning, packaging, and wearing apparel, different mechanical properties are emphasized than for rigid foams. The compressive nature of flexible foams, both static and dynamic, is their most significant mechanical property. Other important properties are tensile strength and elongation, tear strength, and compression set.

Thermal Properties. The thermal conductivity of cellular polymers has been thoroughly studied in heterogeneous materials and plastic foams (8). Heat transfer can be separated into its component parts as follows:

$$k = k_s + k_g + k_r + k_c \tag{3}$$

where k = total thermal conductivity and k_s, k_g, k_r, and k_c represent solid conduction, gases conduction, radiation, and convection, respectively.

As a first approximation, the heat conduction of low-density foams through the solid and gas phases can be expressed as the product of the thermal conductivity of each phase and its volume fraction. In most cellular polymers, the conduction through the solid phase is determined primarily by the density and the polymer-phase composition. Although conductivity through gases is much lower than through solids, the amount of heat transferred through the gas phase in a foam is usually the largest component of a total heat transfer because of the large gas-phase volume. Ordinarily, convection cannot be measured in cells of diameter less than $\sim 4\,\mathrm{mm}$ (8). Because most cellular polymers have cell diameters of $<4\,\mathrm{mm}$, convection can be ignored. Radiant heat transfer through cellular polymers has also been studied (8). The increase in k at low densities is caused by increased radiant heat transfer; at high densities, by an increasing contribution of k_s.

The thermal conductivity of most materials decreases with temperature. When the foam structure and gas composition are not influenced by temperature, the k of the cellular material falls with decreasing temperature. The thermal conductivity of a cellular polymer can change on aging under ambient conditions if the gas composition is influenced by aging. This is the case when oxygen or nitrogen diffuses into cellular foams that initially have an insulating fluorocarbon blowing agent in the cells (8). The thermal conductivity of foamed plastics varies with thickness (9). This has been attributed to the boundary effects of the radiant contribution to heat transfer.

The specific heat of a cellular polymer is the sum of the specific heats of each of its components. The contribution of the gas is small and can often be neglected.

The coefficients of linear thermal expansion of polymers are higher than those of most rigid materials at ambient temperatures because of the supercooled liquid nature of the polymeric state. This large coefficient is carried over directly to the cellular state. A variation of this property with density and temperature has been reported for foams in general (10).

Moisture Resistance. Plastic foams perform better than other thermal insulation materials when exposed to moisture, particularly when subjected to a combination of thermal and moisture gradients.

Moisture absorption and freeze–thaw resistance of various insulations and the effect of moisture on thermal performance show that in protected-membrane roofing applications, the order of resisting moisture pickup is extruded polystyrene γ polyurethane $>$ molded polystyrene (11). Water absorption values for insulation in use for 5 years were 0.2 vol% for extruded polystyrene, 5 vol% for polyurethane without skins, and 8–30 vol% for molded polystyrene. These values correspond to increases in k of 5–265%. For below-grade applications, extruded polystyrene was better than molded polystyrene or polyurethane without skins in terms of moisture and thermal resistance.

Electrical Properties. Electrical insulation takes advantage of the toughness and moisture resistance of polymers along with the decreased dielectric constant and dissipation factor of the foams. In addition, because of the low dissipation factor and rigidity, plastic foams are used in the construction of radar domes.

Environmental Aging. The response of cellular materials to light and oxygen is governed almost entirely by the composition and state of the polymer phase. Expansion into the cellular state increases the surface area; reactions of the foam with vapors and liquids are correspondingly faster than those of solid polymer. All cellular polymers deteriorate under the combined effect of light or heat and oxygen; this may be alleviated by additives.

Other Properties. Cellular polymers by themselves are poor materials for reducing sound transmission. They are, however, effective in absorbing sound waves of certain frequencies. Materials with open cells on the surface are particularly effective in this respect. The presence of open cells in a foam allow gases and vapors to permeate the cell structure by diffusion and convection, thus yielding high permeation rates. In closed-cell foams, the permeation of gases or vapors is governed by the composition of the polymer phase, gas composition, density, and cellular structure. The penetration of visible light through foamed polystyrene has been shown to follow approximately the Beer–Lambert law of light absorption (10).

The resistance to rot, mildew, and fungus is related to moisture absorption. Therefore, open-cell foams support such growth better than do closed-cell foams.

MANUFACTURING PROCESSES

Cellular plastics and polymers have been prepared by processes that involve many methods of cell initiation, growth, and stabilization. The most convenient method of classifying these methods seems to be based on cell growth and stabilization. According to equation (1), the growth of the cell depends on the pressure difference between the inside of the cell and the surrounding medium. Such pressure differences may be generated by lowering the external pressure, i.e., decompression; or by increasing the internal pressure in the cells, i.e., pressure generation. Other methods of generating the cellular structure are by dispersing gas or solid in the fluid state and stabilizing this cellular state, or by sintering polymer particles in a structure that contains a gas phase (see Table 3).

Foamable compositions in which the pressure within the cells is increased relative to that of the surroundings are called *expandable formulations*. Both chemical and physical processes are used to stabilize plastic foams for expandable formulations. There is no single name for the group of cellular plastics produced by the decompression processes. The operations used are extrusion, injection

molding, and compression molding. Physical or chemical methods may be used to stabilize the products.

EXPANDABLE FORMULATIONS

Physical Stabilization. Cellular polystyrene, poly(vinyl chloride) (PVC), polyethylene, and copolymers of styrene and acrylonitrile can be manufactured by this process.

Chemical Stabilization. This method has been used successfully for more materials than the physical stabilization process. It is generally more suitable for condensation polymers than the vinyl polymers because of the fast yet controllable curing reactions. Chemical stabilization can be used for foam formation from polyurethane, polyisocyanurate, phenolic, epoxy, and silicone resins.

DECOMPRESSION EXPANSION PROCESSES

Physical Stabilization. Cellular polystyrene, cellulose acetate, polyolefins, and poly(vinyl chloride) can be manufactured by this process.

Chemical Stabilization. Cellular rubber and ebonite are produced by chemical stabilization processes.

Dispersion. In several techniques for producing cellular polymers, the gas cells are produced by the dispersion of a gas or solid in the polymer phase followed, when necessary, by stabilization and treatment of the dispersion. In frothing, a quantity of gas is mechanically dispersed in the fluid polymer phase and stabilized. Latex foam rubber was the first cellular polymer produced by frothing. In another method, solid particles are dispersed in a fluid polymer phase, the dispersion stabilized, and the solid phase dissolved or leached, thus leaving the cellular polymer. Cellular polymers called *syntactic foams* are made by dispersing an already cellular solid phase in a fluid polymer and stabilizing the dispersion.

USES

Concern over energy conservation and safety has stimulated growth in applications for insulation and cushioning in transport. A healthy economy is also expected to increase the demand for cushioning in furniture, bedding, and flooring as well as for packaging. Structural foams are widely used as substitutes for wood, metal, or unfoamed plastics. Table 4 shows the demand for plastic foams in the United States.

Cushioning. The properties of significance in the cushioning applications of cellular polymers are compression–deflection behavior, resilience, compression set, tensile strength and elongation, and mechanical and environmental aging. The broad range of compressive behavior of flexible foam is one of the advantages of cellular polymers because the needs of almost any cushioning application can be met by changing either the chemical nature or the physical structure of the foam. Flexible urethanes, vinyls, latex foam rubber, and olefins are used to make foamed plastic cushioning for automobile padding, seats, furniture, flooring, mattresses, and pillows.

Thermal Insulation. Thermal insulation is the largest application for the rigid materials because of their thermal conductivity, ease of application, cost, moisture absorption, and transmission permeance. Plastic foams that contain a captive blowing agent have much lower thermal conductivities than do other insulating materials. The low-thermal-conductivity polyurethane foams are used in refrigerators and freezers. Polystyrene foam is popular where cost and moisture resistance are important, and polyurethane foams are used in spray applications.

Extruded polystyrene foam is found in residential construction as sheathing, perimeter, and foundation insulation. Both polystyrene and polyurethane foams are highly desirable roof insulators.

Packaging. The entire range of cellular polymers from rigid to flexible is used for packaging because of their low cost, ease of application or fabrication, moisture susceptibility, thermal conductivity, consumer appeal, and mechanical properties, especially compressive properties.

Extruded Polystyrene Foam Sheet. A polystyrene foam sheet is made from a combination of polystyrene resin, blowing agents, nucleating agents, and pigments in an extrusion process (12, 13). A polystyrene foam sheet is used in many shapes and can usually be characterized by its stiffness and low density, generally 2–12 lb/ft^3 (32–190 kg/m^3). Sheet products are typically 0.015–0.150 in. thick.

The major uses for foam sheets are for disposable applications such as carryout cups and clam shells, plates, bowls, egg cartons, and meat and poultry trays. New market growth has come in the applications of a polystyrene foam sheet for use in art boards, insulated boxes, and bottle wraps. For applications that require extra stiffness or modulus, films or paper may be laminated to the foam. The foam sheet can be fabricated by die cutting and scoring, in addition to thermoforming to shape and bend the foam.

Typically, the foam-sheet process uses an annular die in the production of thin sheets. Single-screw, twin-screw, long-barrel single-screw, and tandem-extruder systems can be used with the latter being most common.

Expanded Polystyrene Beadboard. Expanded polystyrene (EPS) beadboard is produced with expandable polystyrene beads. These beads are impregnated with 5–8% pentane and sometimes with flame retardants during suspension polymerization. The beads are preexpanded by fabricators with steam or vacuum and aged. Then they are fed to steam-heated block molds where expansion and fusion of beads continue. The molded blocks are sliced after curing. Block densities range from 13 to 48 kg/m^3, with 24 kg/m^3 the most common for cushion packaging and 16 kg/m^3 for insulation.

Expandable polystyrene bead-molding products account for the main portion of the drink-cup market and are used in packaging materials, insulation board, and ice chests.

Extruded Polystyrene Loose-Fill Packaging. Loose-fill packaging particles are used in void-filling packaging applications. The foamed particles provide cushioning for lightweight, often fragile products. The foamed particles are usually resilient and are low in density [bulk density properties under <0.30 lb/ft^3 (4.8 kg/m^3)] and can be reused many times. Polystyrene loose-fill particles can be recycled. The growth of this market has been affected by the development of starch-based extrusion products.

Expandable polystyrene beads for loose-fill packaging are produced by the extrusion process. Virgin and recycled polystyrene with nucleating agents and additives are fed into the extruder, and blowing agents are usually fed downstream into the extrusion process. The blowing agents used have progressed from chlorofluorocarbons (CFCs) to hydrochlorofluorocarbons (HCFCs) to hydrocarbons or blends of hydrocarbons with carbon dioxide. Some extrusion processes can use expandable beads (pentane/isopentane blowing agent) for feedstock.

Loose-fill particles are produced by a foam-at-the-die process, or by an expandable-bead process. In the foam-at-the-die process, the molten gel is allowed to foam to a density of approximately 1–2 lb/ft^3. The foam is then cut at the die face or downstream after some cooling has occurred. The subsequent density reduction is accomplished by steam treatment, followed by air aging. The foam may be steamed and aged 2–3 times to decrease the density to below 0.25 lb/ft.^{3}

The expandable-bead process produces an unfoamed particle that has the blowing agent incorporated into the bead. The expandable beads are produced at a central extrusion location and then shipped to local expanders. Local expansion facilities are needed because of the lightweight nature of the final product. The expandable beads are exposed to steam as done with the foam-at-the-die process but will require an extra expansion step.

Polyolefin Foam Sheet and Plank. Polyolefin foams are closed-cell foams that are tough, flexible, and resilient and are used in applications such as cushioning, flotation, furniture overwrap, water sports, surface protection, and many other uses. The energy-absorbing characteristics of polyolefin foams make them excellent foams for use in cushioning applications. Polyethylene and polypropylene foams are low-density products, generally less than 10 lb/ft^3 (160 kg/m^3), which are made by the extrusion process. These foams are made in many forms—plank, sheet, rounds, and multiple strands—and can be made with crosslinked or non–crosslinked formulation.

Polyethylene and polypropylene foams are usually produced from a combination of virgin and recycled resins, blowing agents, nucleating agents, and other additives such as colorants, antistatic additives, and flame retardants. Both polyethylene and polypropylene can be made into sheet-type products, typically 0.06–0.625 in. thick (2–15 mm) by up to 72 in. (1800 mm) wide. Because of the low melt strengths typical of polypropylene, only polyethylene is used in the manufacture of large cross sections of foam of 2–4-in. (50–100-mm) thickness and 24–48-in. (600–1200-mm) width. Planks of foam are often fabricated into specific shapes to meet the packaging requirements of electronic components such as computers and their monitors, the handling requirements for water sports uses such as boogie boards, or the part separation requirements of multiple-use industrial applications.

Noncrosslinked polyolefin sheet foams can be made on single-, dual-, and twin-screw extrusion lines that are designed to mix in large quantities of blowing agents and then extruding the supersaturated gel through an annular die at the proper temperature, usually very near the crystalline melting point. Figure 1 shows the theoretical relationship between the blowing-agent content and the expected foam density. To produce a foam with a density of ~ 2 lb/ft^3 (32 kg/m^3), the extrusion system must be able to mix in 6–16 lb of blowing agent per 100 lb of resin, depending on the blowing agent selected. The gel pressure at the die is also very important. If the

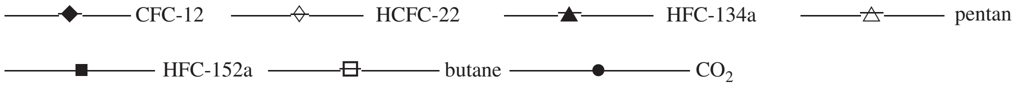

Figure 1. Effect of blowing-agent concentration of theoretical foam density.

pressure is too low, then the blowing agent will begin to come out of solution and will allow the molten gel to begin foaming prior to exiting the die lips. If this occurs, then severe disruption of the skin surface will occur and a poor-quality foam will result. Blowing agents are injected into the molten resin gel downstream from the hopper. The exact location will depend on the type of equipment being used. To extrude sheet products that are very wide and very thin, an annular die and forming mandrel is used. The proper-size forming mandrel allows the extruded tube to be stretched both radially and downstream at the same time, and the mandrel provides a means to cool the inner surface of the foam tube. The cooled tube is then slit at one or two locations and subsequently wound into rolls. Plank extrusion is usually through a more rectangular-shaped die onto a conveyor belt or some other means to move the foam away from the die. Plank extrusion is usually through a more rectangle-shaped die onto a conveyor belt or some other means to move the foam away from the die. Plank extrusion usually requires higher rates than sheet because of the larger die opening and the need for maintaining sufficient pressure to prevent prefoaming.

Polyolefin foam manufacture generally uses physical agents, which are materials that are a gas at the foaming temperature (usually at the resin melting point). Chemical blowing agents are rarely used in noncrosslinked applications. Blowing agents for polyolefin foam extrusion are now typically hydrocarbons (14) or a blend of hydrocarbon and carbon dioxide. Prior to the Montreal Protocol agreements, CFC-114 was the main foaming agent used in polyolefin foams. CFC-114 was an excellent foaming agent because of its solubility and permeability characteristics. Another strong attribute was its nonflammable characteristic. With the Montreal Agreement, use of CFCs was prohibited after 1991 in noninsulating applications. The CFC-114 replacement list for foaming agents was not long. Hydrocarbons (propane, butane, and isobutane), HCFCs (22,142b), HFCs (152a, 134a), and carbon dioxide were considered. Most of the replacement options included an increase in flammability and an increase in cost to the manufacturing operations. The use of carbon dioxide is attractive in terms of cost, flammability, and environmental safety, but the processing aspect makes total substitution difficult. Because of the high vapor pressure of this physical gas, maintaining the proper resin-blowing-agent solution characteristics at the die is very difficult. The Clean Air Act of 1990 (CAA) has since further reduced the blowing-agent alternatives. The CAA has prohibited the use of HCFCs, leaving only hydrocarbon and their blends, HFCs (15), and carbon dioxide, or blends thereof.

Crosslinked foams offer higher temperature stability, more flexibility, finer cell size, and better thermoforming properties than do noncrosslinked foams. Crosslinking of the olefin resin is accomplished by chemical crosslinking (such as dicumyl peroxide or silanes) or radiation crosslinking via X-ray or electron-beam exposure (7). Typically, the polyethylene resin, additives, crosslinking agents, and chemical blowing agents (such as azodicarbonamide) are mixed together at temperatures below the activation temperature of the blowing agents, and then extruded into a flat sheet that can be rolled up, or into some other profile, prior to expansion into a foam product.

Crosslinking occurs before the foam-expansion step. Expansion is done by exposure of the crosslinked sheet to hot (~200°C) air. Generally, chemical crosslinking is used in the production of thick products, whereas radiation crosslinking is used for thinner foams.

HEALTH AND SAFETY FACTORS

Flammability. Plastic foams are organic and therefore combustible. All plastic foams should be handled, transported, and used according to manufacturers' recommendations and local and national regulations.

Virtually all plastic foams are blown with inert gases, chemical blowing agents that release inert gases, hydrocarbons containing three to five carbon atoms, chlorinated hydrocarbons, and hydrochlorofluorocarbons such as HCFC-22, HCFC-141b, and HCFC-142b.

Atmospheric emissions. Certain organic compounds generate smog photochemically. Interaction with the total environment must be considered in developing environmentally acceptable blowing agents. The products of combustion of plastic foams are usually carbon monoxide and carbon dioxide with smaller amounts of many other substances.

The presence of additives or unreacted monomer in certain plastic foams can limit their use where food or human contact is anticipated. The manufacturers' recommendations and existing regulations should be followed.

FOIL, ALUMINUM

Foil Division, Aluminum Association

Updated by Staff

INTRODUCTION

Aluminum foil is a thin-rolled sheet of pure or alloyed aluminum, varying in thickness from about 0.00017 (4.3 μm) in. to a maximum of 0.0059 (150 μ) in. (1). By industry definition, rolled aluminum becomes foil when it reaches a thickness less than 0.006 in. (152.4 μm) (see Table 1). Aluminum foil is widely sold in the consumer market in rolls of 50 cm in width and in varying lengths.

Aluminum, from which the foil is made, is a bluish silver-white trivalent metallic element that is very malleable and ductile. Noted for its light weight, good electrical and thermal conductivity, high reflectivity, and resistance to oxidation, aluminum is the third most abundant element in the earth's crust (1).

Aluminum always occurs in combination with other elements in mineral forms such as bauxite, cryolite, corundum, alunite, diaspore, turquoise, spinel, kaolin, feldspar, and mica. Of these, bauxite is the most economical mineral for production of aluminum. It can contain up to 60% alumina, which is hydrated aluminum oxide. It takes about 4 kg of bauxite to produce 1 kg of aluminum (2).

Alumina is converted into aluminum at a reduction plant or smelter. In the Hall–Héroult process, the alumina is dissolved in a molten salt called *cryolite*. The action takes place in steel boxes lined with carbon called *pots*. A carbon electrode or anode is lowered into the solution, and electric current of 50,000–150,000 A flows from the anode through the mixture to the carbon-cathode lining of the steel pot. The electric current reduces, or separates, the alumina molecules into aluminum and oxygen. The oxygen combines with the anode's carbon to form carbon dioxide. The aluminum, heavier than cryolite, settles to the bottom of the pot from which it is siphoned into crucibles. The molten aluminum is eventually processed into products.

FOIL MANUFACTURE

One of aluminum's most common uses is as foil. Aluminum foil is generally produced by passing heated aluminum-sheet ingot between rolls in a mill under pressure. Ingot is flattened to reroll sheet gauges on sheet and plate mills and finally to foil gauges in specialized foil-rolling mills.

Table 1. Physical Properties of Aluminum Foil

Property	Value
Density	$0.0976\,\text{lb/in.}^3$ ($2.70\,\text{g/cm}^3$)
Specific gravity	2.7 (approx.)
Melting range	1190–1215°F (643–657°C)
Electrical conductivity	59° IACS. vol., 200% IACS (approx.), weight
Thermal conductivity	53 W/(m · K) at 25°C
Thermal coefficient of linear expansion	13.1×10^{-6} per °F, 68–212°F (23.6×10^{-6} per °C, 29–100°C)
Reflectivity for white light, tungsten filament lamp	85–88%
Reflectivity for radiant heat, from source at 100°F (37.8°C)	95% (approx.)
Emissivity, at 100°F (37.8°C)	5% (approx.)
Atomic number	13
Atomic weight	26.98
Valence	4
Specific heat at 20°C	0.21–0.23
Boiling point	3200°F (1760°C)
Temperature coefficient of resistance (representative values per °C) at 20°C	0.0040–0.0036
at 100°C	0.0031–0.0028
Low-temperature properties—aluminum increases in strength and ductility as temperature is lowered, even down to −320°F (−195.6°C)	

A second method for producing aluminum foil, rapidly gaining popularity, involves continuous casting and cold rolling. This method can eliminate the conventional energy-intensive and costly steps of casting ingot, cooling, transporting to rolling plants, and then reheating and hot rolling to various gauges. Some lubrication is needed during the rolling stages, otherwise the foil surface becomes marked in a herringbone pattern. These lubricants are sprayed on the foil before passing through the rolls. Only oils approved for food contact must be used for foil intended for food packaging (3).

First produced commercially in the United States in 1913, aluminum foil became a highly marketable commodity because of its protective qualities, economic production capability, and attractive appearance. The first aluminum foil laminated on paperboard for folding cartons was produced in 1921. Household foil was marketed in the late 1920s, and the first heat-sealable foil was developed in 1938.

World War II established aluminum as a major packaging material. During the war, aluminum foil was used to protect products against moisture, vermin, and heat damage. It was also used in electrical capacitors, for insulation, and as a radar shield.

After the war, large quantities of aluminum foil became available for commercial use. Its applications boomed with the postwar economy. The first formed or semirigid containers appeared on the market in 1948. Large-scale promotion and distribution of food service foil in 1949 quickly expanded the market. Aluminum foil's compatibility with foods and health products contributes greatly to its utility as a packaging material.

Standard aluminum foil alloying elements are silicon, iron, copper, manganese, magnesium, chromium, nickel, zinc, and titanium (see Table 2). These elements constitute only a small percent (in most cases, no more than 4%) of aluminum-foil alloy composition.

PROPERTIES

Chemical Resistance

Resistance of aluminum foil to chemical attack depends on the specific compound or agent. However, with most compounds, foil has excellent to good compatibility.

Aluminum has high resistance to most fats, petroleum greases, and organic solvents. Intermittent contact with water generally has no visible effect on aluminum otherwise exposed to clean air. Standing water in the presence of certain salts and caustics can be corrosive.

Aluminum resists mildly acidic products better than it does mildly alkaline compounds, such as soaps and detergents. Use with stronger concentrations of mineral acids is not recommended without proper protection because of possible severe corrosion. Weak organic acids, such as those found in foods, generally have little or no effect on aluminum. A clear vinyl coating, however, is recommended for use with tomato sauce and other acetic foods.

Temperature Resistance

Since aluminum foil is unaffected by heat and moisture, it is easily sterilizable and is actually sterile when heat-treated in production. Unlike many packaging materials, aluminum foil increases in strength and ductility at lower temperatures. Its opacity protects products that would otherwise deteriorate from exposure to light (see Table 3).

Table 2. Principal Aluminum-Foil Alloys

Alloy and Temper (Aluminum Association Number)	Aluminum, %	Principal Other Elements,[a] %
	Non-Heat-Treatable	
1100–H19	99.00	0.12 Cu
1145–H19	99.45	
1235–H19	99.35	
1350–H19	99.50	
3003–H19	97.00	0.12 Cu, 1.2 Mn
5052–H19	96.00	2.5 Mg, 0.25 CR

5056–H39		
	Heat-Treatable	
2024–T4	91.8	4.4 Cu, 0.6 Mn, 1.5 Mg

[a] Nominal compositions.

Mechanical Properties

The addition of certain alloying elements strengthens aluminum. The alloys produced from these compositions can be further strengthened by mechanical and thermal treatments of varying degree and combinations. For this reason, the mechanical properties of aluminum foil are significant to an understanding of its versatility.

The lowest, or basic, strength of aluminum and each of its alloys is determined when the metal is in the annealed, or soft, condition. Annealing consists of heating the metal and slowly cooling it for a predetermined period of time. Reroll-stock from which foil gauges are produced is annealed (a process of heating and cooling) prior to the foil-rolling operations to make it softer and less brittle.

All alloys are strain-hardened and strengthened when cold-worked, as in foil rolling. When the product is wanted in the soft condition, it is given a final anneal (1).

CONVERTING

Aluminum foil is converted into a multitude of shapes and products (see Table 4). Processes involved may include converting mill rolls of plain foil by rewinding into short rolls, cutting into sheets, forming, laminating, coloring, printing, coating, and the like (4) (see Slitting and rewinding; Laminating; Printing; Coating equipment).

Packaging products account for about 75% of the market for aluminum foil (5). Aluminum foil is also used in households and institutions as a protective wrap, as well as for decorative and construction purposes.

Among packaging end uses, aluminum foil is formed into semirigid containers produced from unlaminated metal for frozen and nonfrozen foods, as well as caps, cap liners, and closures for beverages, milk, and other liquid foods (see Closure liners; Closures). It is also formed into composite containers with films and plastics to package powdered drinks, citrus and other juices, and motor oil and other auto supplies (see Cans, composite).

Aluminum foil combined with other materials such as paper or plastic film can be used to package a host of basic nonfood products, including tobacco, soaps and detergents, photographic films, drugs, and cosmetics (6).

When water-vapor or gas-barrier qualities are critical to the success of a packaging material, aluminum foil is usually considered. Aluminum-foil containers are odorless, moisture-proof, and stable in hot and cold temperatures. They were originally developed to supply bakers with cost-cutting disposable pie plates and bake pans.

A major reason for the wide use of aluminum foil in packaging is its versatility. It is adaptable to practically all converting processes and can be used plain or in combination with other materials. Aluminum foil can be laminated to papers, paperboards, and plastic films. It can be cut by

Table 3. Functional Properties of Aluminum Foil

Form Thickness	Continuous rolls and sheets 0.00017–0.0059 in. (4.3–150 μm)	Hygienic	Sterile when heat-treated in production; smooth metallic surface sheds most contaminants and moisture of sterilization
Maximum width	68 in. (1.7 m) for pack-rolled lighter gauges; 72 in. (1.8 m) for gauges 0.001 in. (25.4 μm) and heavier, single-web rolled	Sterilizable	Metal unaffected by heat and moisture of sterilization (except for staining in some cases)
Impermeability	(WVTR)[a] 0.001 in. (25.4 μm) and thicker is impermeable; 0.00035 in. (8.9 μm) has a WVTR of ≤ 0.02 g/100 in.^{2} (0.065 m^2); 24 h at 100°F (37.8°C)/100th—WVTR drops to practically zero when 0.00035-in. (8.9-μm) foil is laminated to appropriate film	Nontoxic Tasteless, odorless	Inert to or forms no harmful compounds with most food, drug, cosmetic, chemical, or other industrial products Imparts no detectable taste or odor to products
Corrosion resistance	Aluminum's natural oxide shielding, which is maintained in the presence of air, renders it substantially corrosion resistant	Opacity permanence	Solid metal, transmits no light; highly corrosion-resistant in most environments
Compatibility with food, drugs, and cosmetics	Nontoxic; corrosion-resistant to many compounds in solution	Sealability	Excellent dead fold and adhesion to a wide variety of compounds
Formability	Dead fold	Insignificantly magnetic	Provides excellent electrical, nonmagnetic shielding
Nonabsorptivity	Proof against water and wide variety of liquids	Nonsparking	The leading metallic material for applications with volatile, flammable compounds
Greaseproof	Nonabsorbent		

[a] WVTR = water-vapor transmission rate.

any method and can be wrapped and die-formed into virtually any shape. Foil can be printed, embossed, etched, or anodized.

Foil Lamination

In many laminations, light-gauge foil is the primary barrier against water-vapor transfer. While creasing can create pinholes or breaks in this barrier, problems can be minimized by proper lamination (see Laminating machinery).

Laminations of foil and waxed paper have been popular as overwraps and liners for cereal packages for more than 40 years. Snack foods that once presented a problem because of their high oil content are now wrapped by specially formulated foil-paper and foil-film laminates.

Aluminum foil laminates have been designed to meet exacting requirements of drugs used in transdermal medication systems that deliver medication through the skin at a constant rate over a specific period of time.

Peelable foil-laminated pouches protect transdermal drugs. Space-shuttle astronauts wore a U.S.-quarter-sized transdermal patch behind the ear to help prevent motion sickness.

Printing

Either side of foil may be printed directly, or the foil may be laminated to a reverse-printed clear film to provide attractive designs with accents. Use of transparent inks through which the foil can be seen produces pleasing metallic colors with no loss in brightness or sparkle.

The same presses and the same types of processes used for printing paper and plastic films are used for printing on foil and foil-paper laminations. Processes include rotogravure, flexography, letterpress, lithography, and silk screen (1) (see Printing; Decorating). Inks for all of these processes are readily available in formulations expressly made for printing on aluminum (see Inks).

To provide anchorage for the inks, prime or wash coatings are nearly always used on foil to be printed. The coatings also provide a barrier that prevents offsetting of undesirable materials from the paper to the foil surface.

Embossing

In-line or out-of-line printing and embossing units allow designs of limitless combinations of color and form. Any embossing pattern in foil produces two basic visual effects, namely, three-dimensional patterns or illustrations and continual reflective contrasts.

Foil embossing often is performed in continuous roll form by passing the web or sheet through a roll stand equipped with one engraved steel roll and a soft matrix roll of paper. The pressure for embossing may be obtained by maintaining the paper roll with the axis in a fixed position and using only the weight of the steel roll to

Table 4. Classifications for Converted and Nonconverted Aluminum-Foil End Uses[a]

Packaging End Uses

Semirigid foil containers (including formed foil lids) produced from unlaminated metal for
  Bakery goods
    Frozen
    Nonfrozen
  Frozen foods, other than bakery
Caps, cap-liners, and packaging closures for
  Beverages and milk
  Foods
Composite cans and canisters (including labels and liners for composite cans) for powdered drinks; auto supplies; food snacks; citrus and other juices; refrigerated dough; other refrigerated and frozen products
Flexible-packaging end uses (including labels, cartons, overwraps, wrappers, capsules, bags, pouches, seal hoods and overlays for semirigid foil containers)
Food products
Dairy products—cheese, butter, milk, milk powder, ice cream, dried and dehydrated food products—fruit, vegetables, potato products, soup mixes, yeast
Baked goods—bread, cookies, crackers
Cereals and baking mixes—cereals, rice, cake mixes, frosting mixes, macaroni products
Powdered goods—coffee, tea, gelatins, dessert mixes, drink powders, cocoa, dry concentrates, sugar, salt
Meat, poultry, and seafoods (fresh, frozen, irradiated, dried, retorted)
Frozen prepared foods
Confections—candy, mints, chewing gum, chocolate bars (converted foil only)
Dry snack foods—potato chips, popcorn, including coated popcorn
Beverages—soft drinks, beer, distilled liquors, wines
Food products, NEC[b] (including pet foods)
Nonfood products
  Tobacco—cigars, cigarettes
  Soaps and detergents
  Photographic film and supplies
  Drugs, pharmaceuticals, cosmetics, toiletries, kindred products
  Nonfood products, NEC[b]
  Military specification packaging[c]

Selected Nonconverted Foil Products[d]

Packaging end uses (unmounted, unconverted foil stock sold to end-users for candy and gum wraps)

depress the negative pattern into the paper roll (see Figure 1).

FLEXIBLE FOIL PACKAGES

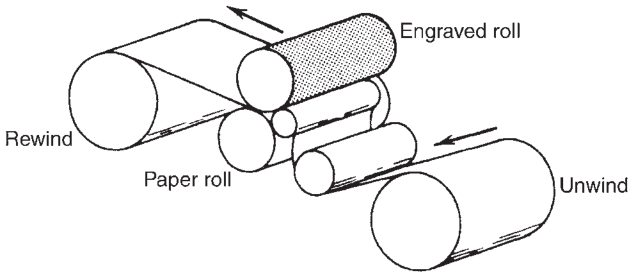

Figure 1. Foil embossing unit. An engraved steel roll, usually the top roll, carries the design, and a matching paper roll becomes the matrix. This matrix roll is constructed of layers of paper (wool-rag) rings compressed solidly into one continuous mass and mounted on an appropriate core.

Flexible foil-containing packages are extremely popular for food packaging because they provide superior flavor retention and longer shelf life than packages formed from other flexible materials. Flexible foil packaging is impervious to light, air, water, and most other gases and liquids. The packages protect contents from harmful oxygen, sunlight, and bacteria (see Figure 2) (see Multilayer flexible packaging).

One of the most important flexible-packaging applications of aluminum foil is the form/fill/seal pouch (1). Pouches are formed continously from roll-fed laminated material and are filled and sealed immediately as formed (see Form/fill/seal, horizontal; Form/fill/seal, vertical; Pouches). The pouch is one of the oldest automated-package forms. The retort pouch, developed in the early 1950s, represented a significant advance in food packaging. It is a flexible package made from a laminate of three materials: an outer layer of polyester for strength; a middle layer of aluminum foil as a moisture, light, and gas barrier; and an inner layer of polypropylene as the heat seal and food-contact material (7) (see Retortable flexible and semirigid packages).

The Q-Pouch is a new foil-lined paperboard pouch that can be turned into a drinking cup. A user of the package simply rips the top edge along perforations and squeezes the sides of the packet. Scored paperboard opens into a hexagon-shaped cup.

Aluminum foil is also used to some extent for bag-in-box liquid packaging (see Bag-in-box, liquid).

FOIL LIDDING

Another popular packaging application is the flexible closure or flexible lid. The flexible closure got its start with single-service dairy creamers, yogurt, and cheese dips. It is also widely used in the healthcare industry, especially in hospitals, where the trend is toward disposable packaging (see Healthcare packaging). Liquid medications are also packaged in single-dosage containers, which are convenient and provide easy evidence of tampering (8) (see Pharmaceutical packaging; Tamper-evident packaging).

Flexible lids were introduced in 1966 when a U.S. Health Service regulation required that the pouring lip of dairy containers be covered during shipment and storage. Besides covering the pouring lip of the container,

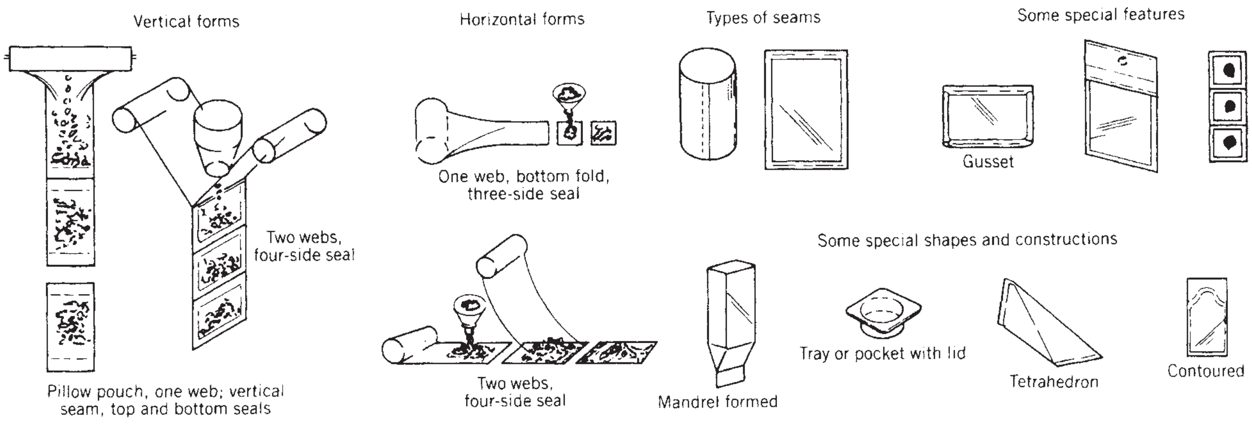

Figure 2. Features and constructions of pouches.

a heat-sealed foil lid offered a more reliable seal, longer shelf life, and greater protection than other lidding materials.

The use of inductive heat-sealing equipment instead of conductive heat sealing is broadening the applications for foil lidding. Inductive sealing does not heat the lid by direct contact. Heat is brought into the lidding stock by a magnetic field through which the container and lid pass. The magnetic field heats the foil in the lid, and an effective hermetic seal forms between the lid and the container. Flexible foil lidding can be used on glass, plastic, or composite cans. This key development enables the aluminum foil industry to provide tamper-evident packaging (see Tamper-evident packages).

REGULATED PACKAGES

Aluminum foil is an integral part of many tamper-evident packages. Although the term came into prominence only in the 1980s, this kind of packaging has been on the market before then. As now defined by the *Proprietary Association*, a tamper-evident package is “one which, if breached or missing, can reasonably be expected to provide visible evidence to consumers that the package has been tampered with or opened” (9).

Of 11 methods listed by the Proprietary Association that conformed to the regulation when it was first pronounced, six featured aluminum foil as part of the tamper-evident system.

For a system to be tamper-evident, its package cannot be removed and replaced without leaving evidence. It is extremely difficult to mend or repair a foil-membrane seal after it is broken or to return an aluminum rollon cap to its original state once it has been removed.

One of the first major laws that required protective packaging was the Poison Prevention Packaging Act of 1970, which essentially said that drugs and dangerous substances must be packed in child-resistant packages. This type of package includes blister packs of plastic–foil–paper combinations; tape seals of paper or foil which adhere to the cap or shoulder of a bottle; and pouches that can be tighly sealed.

ASEPTIC PACKAGING

Most aseptic packages are laminations of paperboard, plastic, and aluminum foil. In aseptic packaging, the product is sterilized with high heat and then cooled. The package is sterilized separately, and then the sterile product and packaging are combined in a sterile chamber (see Aseptic packaging).

Foil provides superior adhesion for the containers that, in the main, hold highly acidic products. In almost all methods of aseptic container manufacturing, aluminum foil is used as a barrier to light and oxygen.

ALUMINUM AND MICROWAVE OVENS

In 1984, Underwriters Laboratories undertook a study on the use of aluminum foil trays to reheat food in microwave ovens. Using various models of microwave ovens and standard types of aluminum trays containing frozen foods, the study concluded that (10):

> The power density of microwave radiation emissions did not exceed maximum allowable limits.
>
> There was no significant change in heat going into various liquids and frozen foods in aluminum containers as compared to other containers.
>
> The temperatures in the foods and liquids being tested were generally comparable in the various containers.
>
> The foil trays containing different amounts of water and empty trays produced no fire emissions of flaming or molten metal.
>
> The test trays used for heating frozen foods in accordance with specific instructions did not increase the risk of radiation, fire, or shock hazard.

Susceptors are a unique and successful innovation in food packaging for microwave heating of a variety of foods such as pizza and popcorn (11). They are microwave-absorbent materials used in the microwave oven to generate surface heating on the food to induce browning and crispness. A susceptor is typically constructed of a metallized PET film (about 12 mm thick) laminated to a thin paperboard. The paperboard provides dimensional stability, while the very thin metal layer discontinuous layer of aluminum (usually 30–60 Å) is responsible for generating localized resistance heating when exposed to microwaves.

SEMIRIGID PACKAGING

Other classifications of aluminum packaging include semirigid and rigid containers. Semirigid containers include those that are die-formed, folding cartons, and collapsible tubes. Die-formed containers are one-way disposable devices such as pie plates, loaf pans, and dinner trays. Folding cartons come in many sizes and shapes and hold such products as dry cereals, eggs, and milk or other liquids (see Cartons, folding; Cartons, gable top). Collapsible tubes were first made of lead and used by artists more than 100 years ago. In modern times, a proprietary aluminum foil/film version of the collapsible tube holds toothpaste and products of similar consistency, including hair coloring and depilatories (1) (see Tubes, collapsible).

Aluminum foil provides the barrier to permeation of the oils used in most products and compounds that go into the tubes.

Aluminum tubes have the advantage of providing light weight, high strength, flexibility, and good corrosion resistance. Aluminum tubes also have low permeability and offer quality appearance. Traditionally, aluminum collapsible tubes were impact-extruded, but a new process forms the laminated rollstock into continuous tubing by use of heat and pressure. The tubing is cut into individual sleeves and is automatically headed by injection molding.

As opposed to flexible containers that conform to the shape of the product, semirigid containers have a shape of their own. They can be deformed from their original shape either while they are emptied (as in the collapsible toothpaste tube), or before they are filled (as with the folding carton).

Die-formed aluminum containers are among the most versatile of all packages. They easily withstand all normal extremes of handling and temperature variation. A product in an aluminum container can be frozen, distributed, stocked, purchased, prepared, and served without soiling a single dish.

Bare foil is used for most formed aluminum-foil products, but protective coatings are used on the containers for some foods and other products. Although the frozen-food tray is the most common, the aluminum-formed container is available in scores of shapes and sizes from the half-ounce portion cup to full-size steam-table containers for institutional feeding. Closures for these containers vary from laminated hooding to the hermetically sealed closure according to the amount of protection needed for the product.

Folding cartons offer protective and display characteristics unique in packaging and have some of the advantages of both the flexible and the rigid container. Before use, when it is folded flat, the folding carton offers the storage economy of the flexible bag. When it is filled, it offers much of the protection of the setup box.

RIGID CONTAINERS

Composite cans and drums feature aluminum foil combined with fiber. They are widely used for refrigerated dough products, snack foods, pet foods, and powdered drink mixes.

In some processes, a composite can is made up of paper–polyethylene–aluminum foil–polyethylene laminated stock with a foil-membrane closure. Cans are produced from preprinted gravure rolls of bottom aluminum stock (see Cans, composite).

FOOD PACKAGE DEVELOPMENT

Kit L. Yam
Department of Food Science,
Rutgers University,
New Brunswick, New Jersey

The food packaging development process requires many considerations and activities. Below are some steps that may be used as a reference to develop a food package.

Step 1: Determine Product/Package Requirements. The first step usually involves optimizing the product formulation; determining the stability of the product particularly to light, O_2, and H_2O; evaluating the processing methods, existing equipment, plant capability; working with marketing to determine the desired shelf life, distribution chain, cost constraints, launch timing, product positioning, package size. During this step, the marketing group typically leads the discussion based upon consumer data, while the technical group provides input on feasibility.

Step 2: Select Package Materials and Equipment. This step usually involves working with suppliers of packaging materials and machinery to identify options; determining cost and availability; comparing stock versus custom package; working closely with product development to better understand ingredients and possible issues relating to packaging; complying with regulations. Since timing is critical to package design, it is important to identify potential issues that may delay the timeline.

Step 3: Evaluate Prototype Packages. This step usually involves conducting shelf-life testing to determine quality retention at ambient and elevated temperatures, conducting distribution testing to determine robustness and integrity of package, conducting product/package interaction testing; evaluating feasibility of scale-up at final production facility. Scale-up package at production facility is important prior to initial run to identify potential process issues.

Step 4: Test Packaging System in Market. This step usually involves producing final food packages; confirming that all major requirements are met; retrieving packages from market for evaluation and confirmation, monitoring consumer feedback during test market or national rollout; refining package/process design if necessary. Final package is tested as part of a concept fulfillment test to confirm consumer acceptance of product and package.

INTRODUCTION

The approach to National Aeronautics and Space Administration (NASA) food provisioning has changed over the last 45 years and will continue to change to accommodate the different mission profiles and vehicle designs. The goal of NASA's food scientists is to provide the crew with a safe, nutritious, and acceptable food system while efficiently balancing appropriate vehicle resources such as mass, volume, and crewtime. Because future NASA exploration missions will range in duration from 2 weeks to 6 months to an eventual 2.5-year mission to Mars, certain requirements for food packaging have been established. Similar to food industry needs, the packaging materials will need to act as a barrier that can interface with the crew/consumer, facilitate use of existing or new processing methods, prevent light transmission, and meet puncture requirements. However, unique to NASA is the requirement not to release toxins into the closed environment of the vehicle (off-gassing) and to insure seal strength to withstand changes in g-forces and atmospheric pressure. In particular, oxygen and water vapor transmission will need to be adequately prevented to maintain sensory and nutritional quality for the duration of the missions. These missions can be as long as 3 years. Mission specific proposed oxygen transmission and water vapor transmission values have been calculated using maximum allowable ingress or egress values for current products, various mission lengths, and the areas of two current pouch configurations.

This article will provide a historical and current perspective to NASA's packaged food system. In addition, as NASA returns to the moon and goes on to Mars, the food packaging requirements will change, and potential food packaging recommended attributes are provided.

HISTORY OF PACKAGING FOR NASA FOOD SYSTEMS

Mercury (1961–1963). Food packaging for space flight has been in use since Mercury 6 where John Glenn consumed 119.5 g of pureed applesauce from an aluminum tube. Mercury flights used collapsible aluminum tubes having Sunex 11-S lining that made use of a polystyrene extension tube called a "pontube" for consumption (Figure 1). As flights progressed, bite-size (ready-to-eat single serving shelf stable items) and up to four rehydratable foods made their way into the available menu

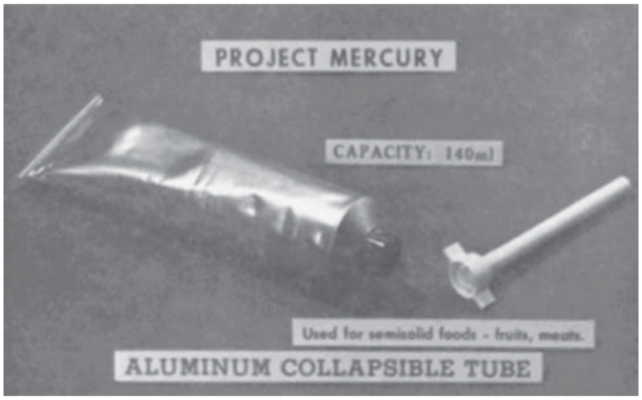

Figure 1. Aluminum collapsible tube with "pontube" used for project Mercury.

selection. Plexiglass dispensers were used for some bite-size items, whereas a three-ply laminate of clear plastic was used for other bite-size items and rehydratables (1). However, the progression to include more types of food items led to packaging related issues that resulted in decreased caloric intake. During Mercury 9, astronaut Cooper only consumed 696 kcal of the 2369 kcal available to him at launch because of problems with the food container and water dispenser during flight (2).

Gemini (1965–1966). The Gemini food was packed in a four-ply plastic laminate comprised of an inner and outer layer of polyethylene and fluorohalocarbon with polyester layers between. Overwrap material for these flights was a polyolefin-aluminum foil-polyester laminate (3).

For Apollo missions, the primary packaging material used for the rehydratable and bite-size foods was a four-ply laminate of polyethylene-Mylar (biaxially oriented polyethylene terephthalate) -Aclar® (polychlorotrifluoroethylene)-polyethylene. Rehydratable food packages used a one-way spring valve at one end for water insertion and a folded polyethylene tube for zero-g consumption at the other end. These rehydratable packages also contained a separate compartment for a germicidal tablet (1 gram of 8-hydroxyquinoline sulfate) for stabilization of uneaten food residue. Figure 2 shows two examples of rehydratable items used for Apollo missions.

Meal units, which were arranged by crewmember nutrient requirements, mission timelines, and spacecraft stowage-volume configurations, were overwrapped in a four-ply aluminum foil/plastic laminate and evacuated to a pressure of 29 inc. vacuum after a triple flush with nitrogen. Overwrapped meals were labeled by mission day, meal, crewman (by color-coded Velcro® patch), and serial number. Meals were attached to each other using a nylon lanyard to ensure ease of sequential retrieval in flight (4).

Apollo (1968–1972). The Apollo missions increased in duration resulting in a need to improve the food system. During the Apollo missions, several improvements to the food packaging were evaluated including an effort to use nonflammable materials. Smith et al. (4) describe basic design changes that were implemented, and results from those changes are as follows:

Figure 2. Rehydratable items packaged in four-ply laminate for Apollo missions.

- The meal overwrap material (four-ply aluminum foil/plastic laminate) was replaced with polytrifluorocloroethylene copolymer (Kel-F-82), which is a nonflammable material. This new material was the primary cause for an increase in food system weight of approximately 0.25 lb/person/day or 14% of the baseline weight. Material thickness was found to vary from 4 to 8 mils, with corresponding variation in flex strength. Relatively minor manipulations and abrasion of the meal overwraps frequently resulted in the formation of pinholes and loss of vacuum. However, the Kel-F-82 manufacturer improved the quality of the material through a process change resulting in improved product strength and more uniform thickness. The improved reliability of this material resulted in a highly reliable food-package material that was used with increasing frequency as a primary food package for each succeeding Apollo mission.
- The Bea-cloth lanyard used to attach sequential meals was coated with Teflon®. Flaking of the Teflon® coating presented a potential hazard of inhalation of the resultant aerosol, even in one-g conditions. As a result, Beta-cloth lanyards without Teflon® coating were used.

  During the second day of the Apollo 7 mission, the crew reported a messy failure of a side seam of a package of chocolate pudding (rehydratable). Ground based operations were modified to ensure that heat seals were at least 0.25 in. wide.
- Several water valves leaked food or water around the outside the valve. A section of Teflon® shrink tubing was used to form a leakproof friction fit of the water valve to the package.
- For rehydratable foods, a frequent point of package failure was caused by the attachment of a germicidal-tablet pouch to the outside of the finished package by a heat-seal process. The germicidal tablet was used to prevent microbial growth and subsequent odor development. The germicidal pouch was relocated as a portion of the basic-package blank cutout. The time and effort required for fabrication were reduced.
- Inefficiencies were present for packaging material usage and processing. The length of the package for semisolid foods was reduced resulting in a weight reduction of 2 g for each package and of approximately 1 lb for a mission set of food. This also resulted in a reduction of exposed combustible surface area by 7 in^2. for each package and 1470 in^2. for a mission set of food. The length of the rehydratable-beverage package was increased. This change enabled provisioning of 8-oz servings instead of 6-oz servings increasing the amount of beverage per unit weight and volume of packaging material. Automated package fabrication was instituted resulting in a package production increase from approximately 12 to 100 packages per hour.
- Pressure stresses at the package shoulder when food was squeezed from the package were higher than

Figure 3. Easy open can used for Skylab missions.

necessary. The angle of the package shoulder was lowered from 45° to 30°.

- The texture and flavor quality of rehydratable foods was lower as a result of the diameter of the mouthpiece for rehydratable foods. The diameter for the mouthpiece was increased form 0.75 in. to 1.25 in.

Skylab (1973–1974). The 1973 Skylab food system was the most palatable and varied food system to be used in space to date. All the planned food for the Skylab program was launched with the first mission, making it over 2 years old when the last crew consumed it. Therefore, most of the food was packaged in aluminum cans to maintain the 2-year shelf life. Frozen food, which required heating, and some the thermostabilized items were packaged in aluminum cans with a membrane under the lid to prevent spilling while heating and to facilitate opening in microgravity. All aluminum cans were sealed in canisters designed to withstand the pressure changes from 14.7 to 5.0 psia between the ground and the spacecraft (Figure 3). The primary package for beverages was a clear plastic pouch with a reconstitution valve attached. Expandable polymeric beverage containers were used (Figure 4).

Figure 4. Expandable beverage container used for Skylab missions.

CURRENT FOOD PACKAGING

The current state-of-the-art food packaging materials employed for International Space Stations (ISS) (2000–present) and Shuttle (1981–present) missions include Smurfit Stone's LCFLEX 70466 (LCF), Rollprint's RPP36-1080 (RPP), and Bayer's Combitherm XX115 (COM115) and XX230 (COM230). Figure 5 illustrates three of these materials.

LCF is a multilayer film that is ideal for current missions because it is lightweight, flexible, and durable. LCF includes an aluminum layer that allows the foods to be processed after packaging without sacrificing its high moisture and oxygen barrier properties. It is currently used for packaging of thermostabilized (retorted) and irradiated items. However, LCF cannot be thermoformed, is opaque, and the aluminum layer presents a solid waste issue for long duration missions.

COM115 and COM230 are clear polymers currently used for packaging bitesize (COM115 only) and freeze-dried items. COM230 is currently thermoformed into a tray to hold freeze dried items, and COM115 is used as a lid. Thermoforming COM230 results in areas with decreased thickness and thus reduced barrier capability. Freeze-dried and bite-size items packaged with COM materials are vacuum packed to 29 or 21 in. vacuum.

The COM only provides a 1-year shelf life, which is only adequate for shuttle missions. Therefore, for ISS, menu items packaged using COM materials are overwrapped using RPP to provide additional barrier capability (Figure 6). Use of this additional packaging layer creates additional upmass and trash aboard the ISS, and crewmembers have commented on the inconvenience of having to open two separate packages for each food item.

NASA DESIGN REFERENCE MISSIONS (DRM)

NASA's Exploration Systems Architecture Study (ESAS) identified seven design reference missions (5). They include three DRMs for ISS-related missions, three for lunar missions, and one for an 18-month surface mission to Mars. The timelines relative to food packaging requirements associated with these DRMs vary from 7 days plus travel for Lunar Sortie missions, to 6 months plus travel for ISS and Lunar Outpost missions, to 18 months plus travel for Mars Exploration missions.

These mission timelines can affect provisioning approach and influence the packaging material's primary requirement driver. For Mars Exploration missions, the primary driver is shelf life longevity. For Lunar Sortie missions, the primary driver may shift from shelf life longevity to an ability to safely handle cabin depressurization. However, for any mission, efficiency will always play a role in material selection.

VEHICLE DESIGNS

Temperature, relative humidity, and pressure fluctuations in the vehicle as well as exposure to radiation will

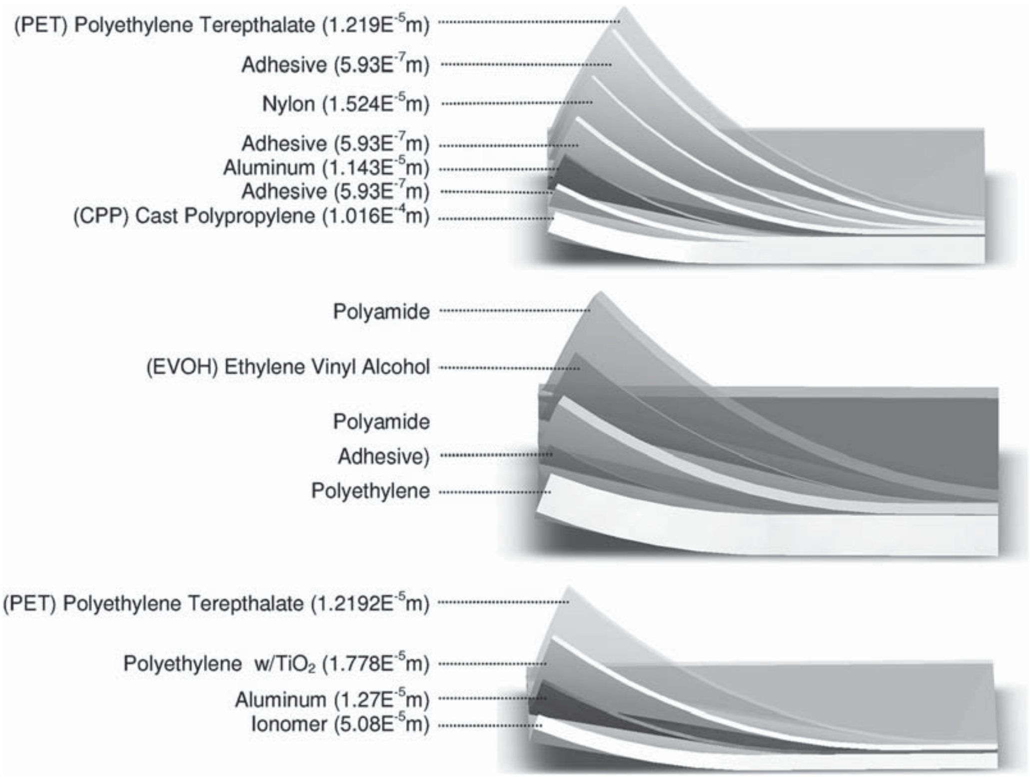

Figure 5. Composition, order and thickness of layers within LCF (top), COM115 (Layer thicknesses are proprietary, therefore are not provided), and RPP (bottom) packaging materials. COM230 is composed of the same materials as COM115, but the thickness of individual layers is not relative to overall thickness.

influence the effectiveness of any packaging material in preserving food quality. A vehicle's design can mitigate or increase the affect of these conditions. A vehicle design can also affect the required interface characteristics of the package. For example, a vehicle may possess a hydration interface, which will affect the design of packaging interface (currently a septum for freeze-dried and beverage items).

SHELF LIFE

Packaging materials are currently used to prevent ingress and egress of mass. Of primary concern to NASA is the ingress of oxygen and water vapor. Packaging materials can decrease the oxygen available for chemical reactions by slowing the transmission of oxygen to the food product. If oxygen is not minimized, the resulting compounds from

Figure 6. Freeze-dried item in primary COM packaging (left) and with RPP overwrap (right).

autoxidation and lipid oxidation will impart a variety of sensory notes that will likely be objectionable to the consumer. This will generally result in lower acceptance of the food product and hence influence shelf life.

To prevent unacceptable oxygen quality degradation effects over a specified mission timeline, the required oxygen transmission rate of a particular packaging material must be defined. In some instances, certain assumptions must be made or at minimum, a range of values should be provided. For example, the assumptions for mission timelines may add 180 days for prepositioning of food provisions. Or, the area of the packaging material may change as packaging conformation changes.

Water vapor transmission through the packaging material is also of concern to NASA as it affects the hydration characteristics of dried food items, which can lead to unacceptable texture characteristics. Packaging materials can pose a safety concern if transmission rates are sufficiently high enough to raise water activity (A_w) above 0.65 (mold growth) or 0.86 (*Staphylococcus aureus*) (6) within food items not undergoing a sterilization process.

NASA PACKAGING RECOMMENDED ATTRIBUTES

Several common attributes for food packaging materials cross over between missions as well as ground-based operations. Because water and oxygen transmission recommended rates are related to required shelf life of the food, these attributes are listed under the specific missions.

Light Transmission. In many cases, the food packages are stowed in an opaque container. Hence, light induced reactions are minimized within the food product.

Offgas Properties. Because the vehicle is a closed environment, NASA has a unique off-gassing requirement for all materials flown. The packaging material should not produce volatiles that would prove harmful to crewmembers. Off-gas levels for compounds will not exceed levels set forth by the Toxicology Laboratory at NASA's Johnson Space Center.

Processing. No refrigerators or freezers for the food are available onboard the NASA vehicles. Hence, the food must be shelf stable. Packaging materials should accommodate the processing method used for microbial and enzymatic stabilization. For example, a material may need to be able to withstand the heat extremes present in retort/thermostabilized processing without loss of integrity. Or, a material may need to allow microwaves to pass.

Puncture Strength. Puncture strength is important for the NASA food packaging materials. Damage to many food packages on board the vehicle can result in a compromised food system, which can compromise the crew health. To measure the puncture strength of each material, a TA-XTPlus (Texture Technologies, Scarsdale, NY) texture analyzer is used. A TA-108 tortilla test rig is used to fix the samples for testing. TA-52 (2-mm cylinder) and TA-55 (5-mm cylinder) probes are used to penetrate the samples. A test speed of 2.0 mm/s is used to a distance of 25 mm.

In general, punctures from food contents can be identified during ground-based operations by loss of packaging integrity. An in-to-out puncture strength of 2.5 kg is required. An out-to-in puncture strength of 1.5 kg is required.

Radiation. Packaging materials can potentially reduce or mitigate the effects of radiation on food items. As radiation effects on food require additional research and the amounts and types of radiation will be mission specific these requirements are still to be determined.

Seal Strength. Packaging materials should withstand specified environmental and stowage conditions without degrading or losing barrier integrity. Periods of reduced or zero pressure will place additional strain on package seals. Periods of increased pressure can also occur. To withstand these conditions, a seal strength of 3 kgf/in. is required.

To measure the tensile strength of seals a TA-XTPlus (Texture Technologies, Scarsdale, NY) texture analyzer is used. A TA-96 tensile test fixture is used to fix the samples for testing. A test speed of 1.5 mm/s is used to a distance of 75 mm. Seal tensile strength is measured using a 1.25 in. length by 1 in width attached on each side of the seal to the clamp.

Material Transmission Rate Calculations. Current space food products were grouped into two main categories: freeze dried/natural form food items and thermostabilized food items. The average mass was determined for each category, and the worst case scenario for O_2 ingress and H_2O ingress/egress was used for calculating the required material transmission rates. The transmission rates required to maintain the proper shelf life were determined for various mission lengths.

The following formula was used to determine the maximum allowable oxygen ingress for a specific product using information obtained from Table 1 below.

$$V_{O_2} = \frac{\text{Productmass(g)} * \text{MaxO}_2\text{(ppm)} * K}{C} \qquad (1)$$

$K = 22\,400$ cc = 1 mole ideal gas at 1 atm and 20°C

$C = 32$ g = Molar mass of O_2

Oxygen transmission rates (OTR) were calculated using information from Table 1 and equations (1) and (2). For example, the required oxygen transmission rate for freeze-dried and natural form food items on lunar sortie missions was calculated using the following information: a VO_2 value of 0.0875 cc determined using a maximum O_2 ingress value of 5 ppm (Table 1), a food mass value of 25 g, which is the average mass of our current products, a T value of 195 days, and an A of 0.0232 m^2, which is the area of the current bite size pouch. Values for determining rates on thermostabilized items were modified to use a VO_2 value of 0.112 cc determined using a maximum O_2 ingress value of 1 ppm (Table 1), a food mass value of 160 g, which is the average mass of our

Table 1. Maximum allowable ingress of O_2 loss or gain of moisture in shelf-stable products

Foods	Max O_2 ingress, (ppm)	Max H_2O gain (+) or loss (−)%
Canned milk, meats, fish, poultry, vegetables, soups, spaghetti, catsup, sauces	1–5	−3%
Canned fruit	5–15	−3%
Dried foods	5–15	+1%
Carbonated soft drinks, fruit juices	10–40	−3%
Oils, shortenings, salad dressings, peanut butter	50–200	+10%
Jams, jellies, syrups, pickles, olives, vinegar	50–200	−3%

current products, a T value of 195 days, and an A value of $0.0387\,\mathrm{m}^2$, which is the area of the current 8-oz retort pouch. Oxygen transmission rates for other missions were determined using the same values above and mission specific T values.

$$\mathrm{OTR_{atm}} = \frac{\mathrm{V_{O_2}}}{\mathrm{A} * \mathrm{T}} \tag{2}$$

Water vapor transmission rates (WVTR) were calculated using information from Table 1 and equation (3). Table 1 states that for freeze-dried and natural form food items, the max allowable moisture ingress is 1% of the product mass, which is 0.25 g for our products. For thermostabilized food items, the max allowable egress is 3% of the product mass, which is 4.8 g for our products.

$$\mathrm{WVTR_{atm}} = \frac{\mathrm{M_{H_2O}}}{\mathrm{A} * \mathrm{T}} \tag{3}$$

When films are converted into pouches, their transmission rates tend to increase because of abuse from processing and other factors. Therefore, the rates in the following sections are only a guideline and are the bare minimum when evaluating materials. The rates were calculated using assumptions that the atmosphere on each vehicle will be 20.9% O_2, 73°F, and 50% RH (relative humidity). Also, they are configured to be comparable with the standard testing parameters of 100% O_2 at 73°F for OTR and 100% RH at 100°F for WVTR. This was done by multiplying the required transmission rate by 100% O_2 divided by 20.9% O_2 for OTR and 100% RH divided by 50% RH for WVTR.

LUNAR SORTIE

Lunar sortie missions are nominally designed for 7 days plus travel (8 days) plus a preflight positioning time of 180 days for food required for transit. The total mission time then equates to 195 days, which is about 6 months.

Oxygen Transmission Rate. The oxygen transmission rate for packaging materials used for freeze-dried and natural form food items shall not exceed $0.0925\,\mathrm{cc/m^2 \cdot day}$ or $0.0060\,\mathrm{cc/100\,in.^2 \cdot day}$. For thermostabilized items this value shall not exceed $0.0710\,\mathrm{cc/m^2 \cdot day}$ or $0.0046\,\mathrm{cc/100\,in.^2 \cdot day}$.

Water Vapor Transmission Rate. The water vapor transmission rate for packaging materials used for freeze-dried and natural form food items shall not exceed $0.1105\,\mathrm{g/m^2 \cdot day}$ or $0.0072\,\mathrm{g/100\,in.^2 \cdot day}$. For thermostabilized items this value shall not exceed $1.2721\,\mathrm{g/m^2 \cdot day}$ or $0.0820\,\mathrm{g/100\,in.^2 \cdot day}$.

ISS AND LUNAR OUTPOST

ISS and lunar outpost missions are nominally designed for 180 days plus travel (8 days), plus a preflight positioning time of 180 days. The total mission time then equates to 368 days, which is about 1 year.

Oxygen Transmission Rate. The oxygen transmission rate for packaging materials used for freeze-dried and natural form food items shall not exceed $0.0490\,\mathrm{cc/m^2 \cdot day}$ or $0.0032\,\mathrm{cc/100\,in.^2 \cdot day}$. For thermostabilized items this value shall not exceed $0.0376\,\mathrm{cc/m^2 \cdot day}$ or $0.0024\,\mathrm{cc/100\,in.^2 \cdot day}$.

Water Vapor Transmission Rate. The water vapor transmission rate for packaging materials used for freeze-dried and natural form food items shall not exceed $0.0586\,\mathrm{g/m^2 \cdot day}$ or $0.0038\,\mathrm{g/100\,in.^2 \cdot day}$. For thermostabilized items, this value shall not exceed $0.6741\,\mathrm{g/m^2 \cdot day}$ or $0.0434\,\mathrm{g/100\,in.^2 \cdot day}$.

MARS EXPLORATION

Mars exploration missions are designed nominally for 540 days plus travel (360 days), plus a preflight positioning time of 180 days. The total mission time then equates to 1080 days, which is about 3 years.

Oxygen Transmission Rate. The oxygen transmission rate for packaging materials used for freeze-dried and natural form food items shall not exceed $0.0167\,\mathrm{cc/m^2 \cdot day}$ or $0.0011\,\mathrm{cc/100\,in.^2 \cdot day}$. For thermostabilized items, this value shall not exceed $0.0128\,\mathrm{cc/m^2 \cdot day}$ or $0.0008\,\mathrm{cc/100\,in.^2 \cdot day}$.

Water Vapor Transmission Rate. The water vapor transmission rate for packaging materials used for freeze-dried and natural form food items shall not exceed $0.0200\,\mathrm{g/m^2 \cdot day}$ or $0.0012\,\mathrm{g/100\,in.^2 \cdot day}$. For thermostabilized items, this value shall not exceed $0.2297\,\mathrm{g/m^2 \cdot day}$ or $0.0148\,\mathrm{g/100\,in.^2 \cdot day}$.

FORENSIC PACKAGING

JACK L. ROSETTE
Forensic Packaging Concepts,
Inc., Del Rio, Tennessee

Forensic packaging is a legal term describing the science of determining the cause of package function as intended. Most people think of forensics as being associated with criminal investigation (especially homicide), when in reality there are many areas of forensic specialization. Forensic medicine involves the cause of disease, forensic pathology is related to the cause of death, forensic psychiatry seeks the cause of mental disorders, forensic engineering is used to determine the cause of accidents such as train or automobile, forensic accounting identifies procedures used to hide illegal accounting such as embezzlement, and forensics in law enforcement refers to scientific physical evidence such as latent prints, ballistics, handwriting, fiber analysis, and similar sciences.

Walter Stern, a packaging consultant in Wilmette, Illinois, was the first person known to use the term *forensics* in defining the science of determining the cause of a package to fail to function that resulted in injury. Forensic Packaging was recognized as a forensic science by the American Academy of Forensic Sciences in 1997.

Determining the cause of package failure may be as simple as discovering that liners are missing from a closure or as complicated as duplicating actual environmental factors such as (a) temperature and humidity present during the time the package was in transport and storage and (b) measuring the effect the conditions have on the subject package. Determining the cause of package failure may fall on the shoulders of any person involved in the sale, manufacture, or use of the package. If the salesperson is unable to readily identify the cause, production may be asked to determine the cause. If production determines that the package was produced in spec (specification), the packaging engineer may analyze whether the spec was sufficient to meet the objectives of the package under the changing conditions. If the engineer is unable to determine the cause, a specialist in forensic packaging may be needed to identify all factors related to the package and conduct extensive tests to determine the cause and recommend solutions to the problem.

The concepts of forensic packaging are most useful in identifying weaknesses in the package design, so that a better package or component can be made and the possibility of package failure can be reduced. Improvements resulting from proper application of forensic packaging concepts are not limited to materials or designs but may also involve manufacturing processes.

The science of forensic packaging requires an objective analytical process, where the results can be replicated by others using the same procedure. Many of the procedures used are found in ASTM 15.06, such as vibration, torque retention, and drop tests. Others may have been developed by various manufacturers, packaging schools, or independent laboratories. The source of the procedure is not as important as its relationship to the problem, reliability of its results, and ability to be replicated by others.

Many improvements in packaging have been the result of identifying the cause of a package failure such as new media for corrugated cartons to increase stacking strength, easier-to-open child-resistant closures, improved lettering on labels, and better barrier properties in films. Identifying and correcting any weakness in a package before the package fails results in savings in tooling, fewer claims of defective products, higher customer satisfaction, and improved profits.

In today’s litigious atmosphere, forensic packaging becomes most useful in legal actions. The science of forensic packaging, when properly applied and explained, can be used to objectively explain the process used in developing a package so that it will function as intended, that any weaknesses known would not affect package performance, or that the cause of package failure was not foreseeable and reasonable for the package to encounter. It is reasonable to expect that the package would survive transport and storage in the high temperatures of the summer, but is it reasonable to expect it to withstand abuse by the consumer? The level of abuse the package would withstand should be determined by testing, including normal use and extreme abuse.

In some cases the package was designed with several safeguards, functioned as intended, but the consumer ignored indications of prior opening and died after consuming an adulterated product that resulted in severe injury or toxicity. Should the company have been liable for the failure of the consumer, when the physical evidence of the package remains indicated that it functioned properly?

A qualified forensic packaging consultant or scientist can explain in either technical or lay terms the cause of and solutions to any problem so that the problem can be understood. The results of all tests performed by the consultant or in-house scientist should be verifiable and replicable by others. While the consultant's findings may be based on experience, results based on objective scientific reasoning may carry more weight. The consultant should be capable of developing evidence for use in litigation and testifying in court if necessary.

In forensic engineering, it is possible to determine whether a turn signal was on at the time of impact even though the light is broken when examined. In forensic packaging, similar results can be obtained by examining the remaining components, duplicating environmental and physical conditions, and conducting tests related to the function of the package. Through the use of objective test-duplicating the package components and conditions, it is possible to determine the probability that a package would or would not leak under similar circumstances. The same analysis combined with variations of the package can identify the cause of the package failure.

What is the value of forensic packaging to management? Proper use of the principles of forensic packaging can prevent the use of manufacture of a package that is likely to fail to function and thereby result in injury to the consumer. It can also ensure that the package is the most effective for the specific application, provided that accurate information on intended use and environmental conditions are known.

FORM/FILL/SEAL, HORIZONTAL

R. F. Bardsley
Bard Associates

A variety of packages can be made on horizontal form/fill/seal equipment. This article deals primarily with pouch making, but similar concepts are applied to thermoform/fill/seal (see the Thermoform/fill/seal article) and bag-in-box packages (see the Bag-in-box, dry product article). Pouch styles include the following: three-sided fin seal, four-sided fin seal, single gusset, double gusset, pillow pouch (lap seal/fin seal), and shaped seal. The package is usually made from rolls of film (see the Films, plastic article) or other "webs" (see the Multilayer flexible packaging article). The sides are normally heat-sealed (see the Sealing, heat article), but other methods such as ultrasonic, laser, or radiofrequency welding can be used to meet specific requirements.

Filling can be done in many ways, depending on the characteristics of the product. Fillers include liquid fillers (see the Filling machinery, still liquid article), paste fillers, augers, pocket fillers, vibratory, orifice-type, and gravimetric units (see the Filling machinery, dry product article). Accessories can be provided with most form/fill/seal equipment to provide registration (feed-to-the-mark or stretch hardware); web splicing ("flying splice" automatic or manual equipment); in-line printing (see the Printing article); coding (noncontact, hot-leaf stamping, or printing units) (see the Code marking and imprinting article); embossing; perforating; notching; vacuum or inert-gas packaging (see the Controlled atmosphere packaging article); aseptic packaging (see the Aseptic packaging article); tear string; cartoning or bagging.

Some machines are small and relatively portable; others are massive and fixed. Some versatile machines can be readily changed over within limits. Other equipment is dedicated to a given size, and any change requires extensive and costly modifications. The cost of equipment varies widely depending on the output required and the extent of the system purchased, and on accessories specified and design requirements (e.g., sanitary criteria and environmental considerations).

This discussion covers pouch, thermoform, and horizontal bag/box machinery according to the outline shown in Table 1. The equipment is classified by type and functional sequence and is further subdivided by design parameters. These are all horizontal form/fill/seal machines, even though the pouch may be horizontal or

vertical (see the Form/fill/seal, vertical article). It would be impossible to mention all the machinery available. Representative equipment is mentioned for clarity, not as endorsement.

POUCH FORM/CUT/FILL/SEAL, POUCH VERTICAL

Inline, Single-Lane, Intermittent Motion. The basic "work-horse" of the pouch machinery group is the single-lane, in-line vertical pouch form/cut/fill/seal intermittent motion machine. It requires some web stiffness to transfer from the cutoff knife to the bag clamps. Size changes, within limits, can be accomplished by adjustments to the machine. Its flexibility includes the ability to handle a wide variety of pouch materials, including most self-supported heat-sealable materials like polyesters, polyethylenes, foils, cellophanes, and paper. Liquids, creams, pastes, granular materials, pills, tablets, and small hard goods, or a combination of these, may be packaged on this type of equipment. Fillers include piston fillers; auger fillers; and vibratory, volumetric, gravimetric, count, and timed-cutoff units. A combination of fillers can be used to permit formulation in the pouch. Gassing and sterilization systems can be provided. The major factor in the selection of this equipment is versatility.

Bartelt Machinery Division of Rexham builds equipment of this type (see Figure 1). Pouch styles that can be produced on this equipment are three- and four-sided fin seal, bottom gusset pouches for greater volume, wrap-around pouches, multiple compartment pouches, and die-cut pouches as well as some combinations of these. Bartelt has been a pioneer in the production of retort pouches, and they can supply automated retort systems from rollstock through cartoning.

Costs for equipment of this type vary widely. For instance, N and W Packaging Systems of Kansas City, MO makes a relatively simple unit that produces 55 packages per minute. Bartelt makes complete systems that take packages from several machines with an "on-demand" feature and cartons them on high-speed equipment.

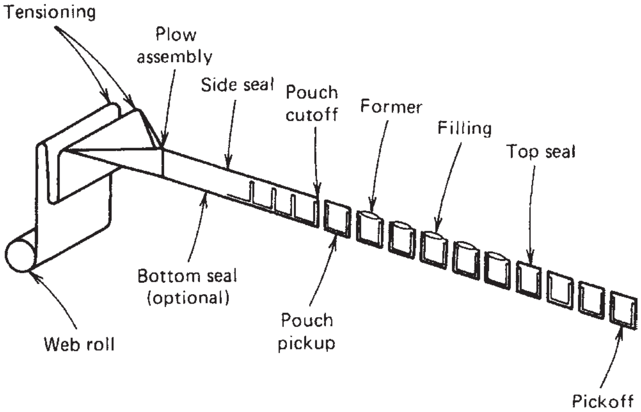

Figure 1. Material-flow diagram of typical Bartelt intermittent bottom horizontal form/fill/seal/machine. Filling of individual pouches allows maximum versatility for multiple component fills and easy pouch-size change. The machine primarily uses supported paper, foil, or laminated film structures.

Hassia, a division of IWK, Germany, builds a flat pouch unit that operates at rates of up to 120 packages per minute. Another German firm that produces inline intermittent-motion pouch equipment is Hamac-Hoeller, a division of the Bosch Packaging Group.

Inline, Single-Lane, Continuous Motion. The sequence of form/cut/fill/seal on a continuous-motion machine entails running a cut pouch into clips attached to a continuously moving chain. Filling is usually accomplished by funnels that move with the pouch to allow time for the fill cycle. Sealing is done either with moving heat sealing bars (see the Sealing, heat article) or band or contact heaters with squeeze rolls at the discharge of the heater elements. Continuous-motion equipment is more complex and expensive than intermittent-motion machines. They are relatively fixed in the pouch size and do not provide the flexibility of intermittent units, but they operate at significantly higher rates.

Delamere and Williams, which is a subsidiary of Pneumatic Scale Corporation, builds a Packetron Pouch Maker that will run at speeds of $\leqslant 500$ pouches per minute. This machine can package products like instant cocoa mix, oatmeal, coffee, seasonings, dairy mix, powdered beverages, and most free-flowing food products. Sealing can be accomplished on three or four sides. A gusseted bottom can be supplied to provide an increased pouch volume.

Rotary Single-Lane, Intermittent Motion. In this design concept, the pouch sides are sealed, then the pouch is cut and transferred to an indexing wheel. Pouch opening, filling, and top sealing take place at various stations around the circumference of the indexing assembly.

Hamac-Hoeller manufactures a unit of this type called the BMR-100. This machine can run up to 120 pouches per minute and produce three- and four-sided fin seals, bottom gusset, standup, and shaped seal pouches. The BMR-200 machine handles two pouches at a time. This unit has a top rate of 200 packages per minute and makes the same style pouches as the BMR-100 plus a twin pouch with a central seal. These machines can be fitted with various type fillers and auxiliaries to meet specific needs.

The Wrap-Ade Machine Company of Clifton, NJ, makes a more economical model of a single-lane rotary pouch machine. This unit produces pouches at a rate of 15–60 pouches per minute. It is a 12-station indexing system with seven possible loading stations.

A somewhat related system is available from Jenco (Germany). This machinery produces a standup bag of relatively large volume. The system can be provided with gas flushing, postpasteurization, or sterilization. Jenco offers complete systems from bagmaking to cartoning. System rates are up to 300 bags per minute.

The machines described above produce relatively small pouches. Horizontal form/fill/seal intermittent motion equipment to make and fill large bags is described below.

POUCH FORM/FILL/SEAL/CUT, POUCH VERTICAL

This area of pouchmaking has advanced significantly. This concept takes the web continuously from a roll, runs it over a forming plough, makes the side seals on a rotary drum (and bottom seal if required), then forms and fills the pouch while it moves around a rotary filling hopper. The top of the web is stretched, and the top seal is usually accomplished by running the web through contact heaters and squeeze rolls. A rotary knife is used to accomplish the pouch cutoff. This type of machine can produce packages at high rates, up to 1300 packages per minute on a single-lane machine. It is an inflexible system and is normally dedicated to one size.

Single-Lane, Continuous Motion. R. A. Jones & Co., Inc., Cincinnati, OH, makes a machine of this type called a Pouch King (see Figure 2). A Japanese firm, Showa Boeki Company Ltd., makes a slower unit called the Toyo type R-10.

The Jones unit was originally developed by the Cloud Machinery Company of Chicago, IL for use on sugar pouches with a paper–poly film (see the Multilayer flexible packaging article). The current capability of the equipment has been greatly expanded. The machine runs a wide range of sizes and flexible heat-sealable structures. These include glassine, cellophane, foil, polypropylene film, and other materials with a variety of sealant materials.

The original machine could fill only relatively small product volumes relative to pouch size, but Jones has developed a system called the “tucked-up-bottom” that holds a significantly larger product volume.

Various types of volumetric fillers that handle free-flowing products can be used on this equipment, including augers, orifice metering, vibratory, and pocket fillers.

Jones now has six models that run a wide range of products including salt, pepper, sugar, beverage mixes, instant coffee, roasted coffee, cocoa mix, and many other free-flowing products. The output is 750–1300 packages per minute.

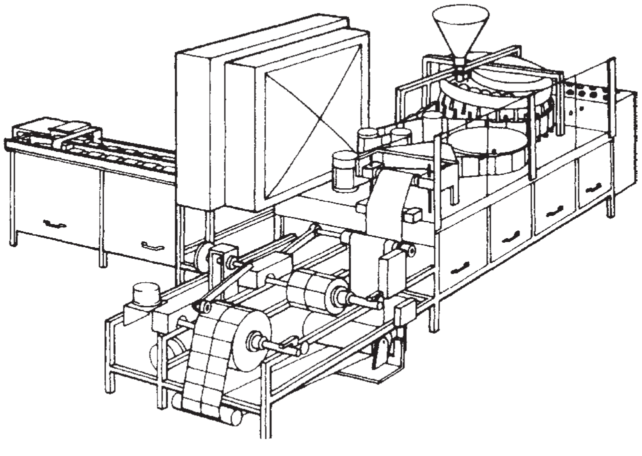

Figure 2. High-speed (700–1200 pouches per minute)—horizontal/fill/seal machine is all-rotary motion to provide long filling and sealing time. Pouches are automatically collated in the count and pattern required. (Courtesy of R. A. Jones & Co., Inc.)

Multilane Continuous Motion. An example in this category is the Matthews Industries (Decature, AL) “Ropak” machine. This equipment was also originally designed to run sugar pouches at rates up to 2000 packages/min. This rate is obtained by running two lanes at 1000 packages/min per lane. Previously, the only structure run on this unit was a paper-poly combination, but a paper—poly—foil—poly web is now being successfully packaged. Machines are currently running sugar, pepper, and instant coffee. Most of the product is bulk packed in drums or cases for institutional use. The machine is equipped with a predetermined counter-and-swing spout for bulk packing by count.

Single-Lane, Intermittent Motion. Simplicity, economics, versatility, and space saving were the criteria for this approach to form/fill/seal pouches. Semirigid packaging material is drawn from rollstock across a vertically mounted tension control. It then passes over an adjustable guide roller into a horizontal and flat position. At this point, the packaging material is folded in half vertically by passing through two round guide bars. In its horizontal direction of travel, the package material passes the bottom seal station (not required for a three-sided seal pouch). A pouch-opening device separates the folded packaging material for entry of the filling funnels before the side seals are completed. After the product is filled, the packaging material passes the top sealing station, followed by the pouch-cutting device. The final station is the packaging material transport station. The machine is adjustable to a maximum pouch of $5\frac{1}{8}$ in. × $5\frac{1}{8}$ in. (130 mm × 130 mm) at output speeds of ≤ 120 pouches/min (240 for duplex operations). The machine is manufactured by Kloeckner Wolkogon, a division of Otto Haensel (Germany).

POUCH FORM/FILL/SEAL/CUT, POUCH HORIZONTAL

In this wrapper-type equipment, the product is fed horizontally into a web that is wrapped around it and sealed. The product can be fed onto the moving web or the web can be formed around the product being carried on an indexing conveyor. The web is longitudinally sealed to form a tube around the product and the ends are sealed and cut off. The machinery is normally single lane, but dual lanes can be run on some equipment. Machines are available that use automatic product feed, manual product feed, run registered web, and they can be equipped for inert gas packaging. A wide range of films and sizes can be run on this equipment. Products such as cookies, candy bars, cheese, and other rigid-type products can be packaged. The pouch is basically a pillow pouch style with a lap- or fin-longitudinal seal. Gussets can be added to handle increased product volumes. Four-sided fin-seal packages can also be produced on this equipment. Machinery can be supplied that operates on either an intermittent or a continuous basis. Speeds of $\leqslant 300$ packages per minute are available. The equipment is relatively flexible and change overs are normally made by adjustments. An interesting innovation offered by Weldotron Corporation on its wrapper is a computer-controlled changeover system. Simply by pressing a button, the machine will adjust itself to any one of six preset sizes. This system was developed by Omori Machine Co. of Tokyo and is distributed in the United States by Weldotron's OMC Packaging Division. Machinery of this type is supplied by Hayssen Package Machinery, Sig, Bosch, Doboy and Oliver, to name a few. Many of these companies specilize in wrapping a given type of product.

Another category of horizontal form/fill/seal equipment is the pouch strip-packaging unit. This machine is basically used to package low-profile products such as flat candy bars, tablets, hardware, medical, and novelty items. The machinery can run two different webs and can run multiple rows of the same or different products.

THERMOFORM/FILL/SEAL EQUIPMENT

Thermoform equipment takes the horizontal-packaging concept further. In this machine concept, a thermoplastic web is heated and formed. The cavity is filled, lidded, and cut from the web. In some machines, a pressure-forming die can be substituted for the heat-form station to form a soft aluminum tray (see the Thermoform/fill/seal article).

A wide variety of packages can be made on intermittent and continuous motion machines of this type. Liquids, solid foods, pharmaceuticals, medical devices, hardware, and beauty aids can all be packaged on thermoform machines. Packages can range from small blisterpacks to deep drawn cups. The product can be gas, vacuum, or aseptically packaged. Films are available today that provide excellent forming characteristics and barrier protection for sensitive food products.

A wide range of thermoforming machines is available. The method of transporting the web through the machine depends on the characteristics of the package and product requirements. There are die machines where the film is formed into a die and the die train moves through the machine, supporting the web at every station. By far the most prevalent is the dieless clip machine where the film is carried on its sides by means of clips. Some machines do not use clips but rely on the strength of the web to pull the packages through the machine. The film is heated, prior to forming, by contact or radiant heaters, then formed at the same station or indexed to a separate forming station. Accessories for film forming such as plug or pressure assists can be supplied to obtain deep draws with a uniform wall thickness.

HORIZONTAL BAG-IN-BOX FORM/FILL/SEAL EQUIPMENT

There are several types of equipment that produce this type of package. One is a system that uses a rotary indexing mandrel to form the inner and outer container. The inner container is usually a flexible film with barrier requirements to meet the needs of the product. The outer packaging material is usually for package appearance or structural requirements and can be either a printed web or a box. Another system forms the box inline with the rest of the system, then the inner liner is formed and inserted in the box and the container is filled. A variation on this is that the container is filled while the inner liner is being inserted in the box (see the Bag-in-box, dry product article).

Some of the major manufacturers of this type of equipment are Pneumatic Scale Corp., Hesser, and Sig Industrial Company. Only Sig and Hesser provide a vacuum system. They also provide a package with a valve system that will allow a product such as coffee to outgas without causing the package to rupture or balloon (see the Vacuum coffee packaging article).

Hesser also makes a system that produces a container similar to a composite can. This machine takes a laminate from rollstock and forms a rectangular body. It then attaches one end, fills the container, and seals a lid to it. This equipment has the capability to make an aseptic package.

Horizontal form/fill/seal is an extremely dynamic segment of the packaging industry; materials and equipment are continually improving and presenting new opportunities. New coextruded structures offer barrier and machining possibilities that are expanding the range of food products that can be packaged in flexible film (see the Coextrusions for flexible packaging article and the Coextrusions for semirigid packaging article). Aseptic packaging is another growth area that will add new dimensions to food packaging. In conjunction with the advance in these technologies are equipment developments that will provide a basis for expansion and cost reduction.

FORM/FILL/SEAL, VERTICAL

EDWIN HO
OSI Industries, Lisle,
Illinois

The term form/fill/seal means producing a bag or pouch from a flexible packaging material, inserting a measured amount of product, and closing the bag top. Two distinct principles are utilized for form/fill/seal packaging: horizontal (HFFS) (see Form/fill/seal, horizontal) and vertical (VFFS). Generally, the type of product dictates which machine category applies. This article deals specifically with VFFS equipment, which forms and fills vertically. It is used to produce single-service pouches for condiments, sugar, and so on, as well as bags for retail sale and institutional use. The range of products and sizes is very large.

PACKAGE STYLES

VFFS machines can make a number of different bag styles (see Figure 1):

- A pillow-style bag with conventional seals on the top and bottom and with a long (vertical) seal in the center of the back panel from top to bottom. The long seal can be a fin seal or a lap seal (see Figure 1a,b).
- A gusseted bag with tucks on both sides to make more space for more product and maintain the generally rectangular shape of the filled bag (see Figure 1c). This style is used inside folding cartons for cereal and other dry products (see Bag-in-box, dry product).
- A three- or four-sided seal package is similar to those made on HFFS machinery (see Figure 1d).
- A standup bag (flat-bottom, gabletop) of the type that used to be common for packaging coffee.
- Other special designs such as tetrahedrons, parallelograms, and chubs (see Chub packaging).

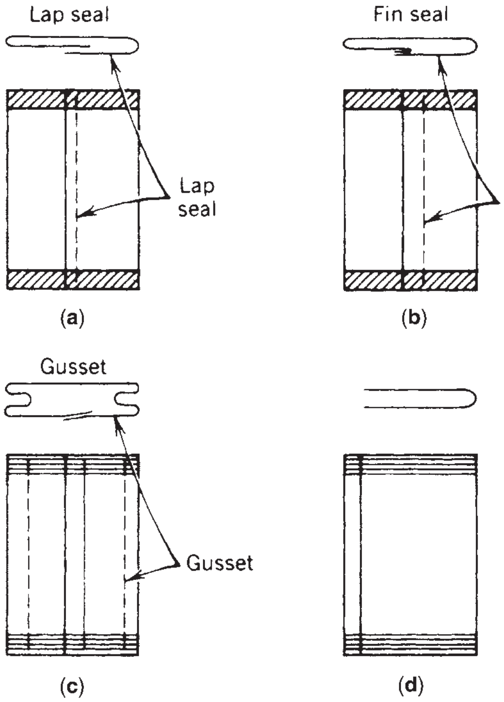

Figure 1. Selected package styles on VFFS machinery: (**a,b**) pillow style; (**c**) gusseted style; (**d**) three-sided seal.

A flat-bottom bag needs a relatively stiff material to hold its desired shape, but any type of machinable material can be used to make a pillow-style bag. Various options are available, such as a hole punch for peg-board display, header labels that are an extension of a standard top of a bag, carry handles for large consumer-type packages, and special sealing tools for hermetic seal integrity.

MATERIALS

Two types of packaging materials are suitable for VFFS: thermoplastic and “heat-sealable” materials. Polyethylenes (thermoplastics) require a special bag-sealing technique. Polyethylene films must be melted under controlled conditions until the areas to be attached to each other are fused. The operation is analogous to welding metals. Heat is applied to fuse the materials, and then a cooling process allows the seal to set. The sequence for making good seals requires careful control in order to get quality-seal integrity. Impulse sealing is used to seal thermoplastics on VFFS machines. A charge of electricity is put into a Nichrome wire that heats to a preestablished temperature (governed by material thickness) that will melt and fuse the materials. Since thermoplastics become sticky when melted, the Nichrome wire is covered by a Teflon (DuPont Company) sheath. The principle of impulse sealing does not require any specific tooling pressure.

Thermoplastic materials are generally used when a high degree of product protection is not required and low material cost is important. Polyethylene materials have some porosity (low gas barrier such as O_2, CO_2) and are not ideal for applications where hermetic seals are necessary for good shelf life, product freshness, gas flushing, and so on. They are used, for example, for frozen foods, chemicals, confectionary items, fertilizers, and peat moss.

The class of “heat-sealable” materials or “resistance seal films” includes paper and cellophane as well as some coextrusions and laminations. Because these materials do not melt at sealing temperatures, or do not melt at all, they require a heat-seal layer that provides a seal with the right combination of time, temperature, and pressure. The sealant layer can be on one or two sides of the web, depending on the desired package configuration (see Multilayer flexible packaging).

A fin seal (see Figure 1) can be made of materials with sealing properties on one side only, because the “heat-sealable” surface seals to itself. This seal is effective for powder products that need the seal to eliminate sifting. It is also a good seal if hermetic-seal integrity is important, as in gas-flush packaging. A lap seal uses slightly less material, but it requires sealing properties on both sides because the lap is made by sealing the inner ply of one edge to the outer ply of the other edge.

MACHINE OPERATION

A VFFS machine produces a flexible bag from flat rollstock. Material from a roll of a given web dimension is fed

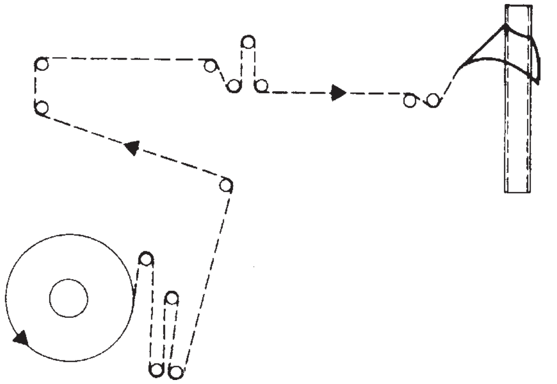

Figure 2. Typical film feed path through a vertical form/fill/seal machine.

through a series of rollers to a bag-forming collar/tube, where the finished bag is formed (see Figure 2). The roller arrangement maintains minimum tension and controls the material as it passes through the machine, preventing overfeed or whipping action. The higher the linear speed of the film, the more critical this handling capability becomes.

The bag-forming collar is a precision-engineered component that receives the film web from the rollers and changes the film travel from a flat plane and shapes it around a bag-forming tube. The design of the bag-forming collar can be engineered to get the optimum efficiency from metallized materials, heavy paper laminates, and so on. As the wrapping material moves down around the forming tube, the film is overlapped for either the fin or lap seal. At this point, with the material wrapped around the tube, the actual sealing functions start. The overlapped material moving down (vertically) along the bag-forming tube will be sealed. The packaging material/film advances a predetermined distance that equals the desired bag-length dimension. The bag length is the extent of the material hanging down from the bottom of the tube. The bag width is equal to half of the outside circumference dimension of the tube. After the film advance is completed, the bag-sealing and -filling completes the remainder of one cycle (film advance/fill/seal). There are two sets of tooling on the front of the machine. One of the sealing tools, the vertical (longitudinal or back) seal bar, is mounted adjacent to the face of the forming tube. Its function is to seal the fin- or lap-longitudinal seal which makes the package material into a tube.

The other set of tooling, the cross (end) seal, consists of a front and rear cross-sealing jaw that combines top- and bottom-sealing sections with a bag cutoff device in between. The top-sealing portion seals the bottom of an empty bag suspended down from the tube, and the bottom portion seals the top of a filled bag. The cutoff device, which can be a knife or a hot wire, operates during the jaw closing/sealing operation. This means that when the jaws open, the filled bag is released from the machine. All vertical bag machines utilize this principle to make a bag (see Figure 3).

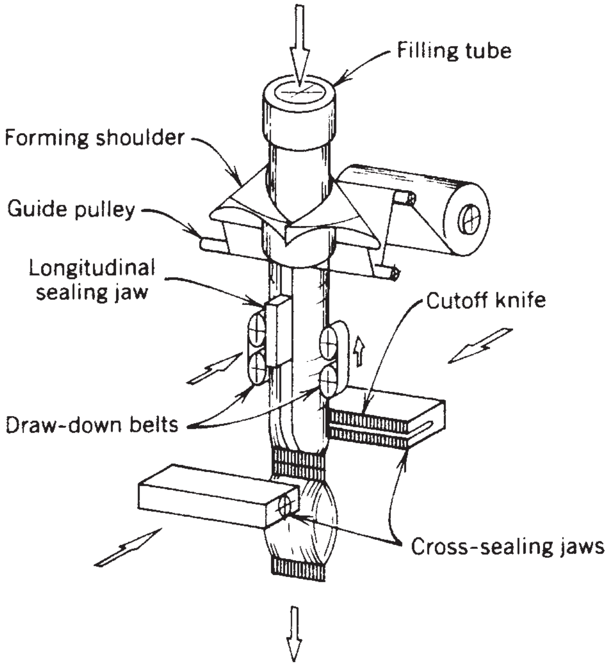

Figure 3. Typical VFFS configuration.

MACHINE VARIATIONS

Film Transport

Two distinct machine designs are used for transporting the packaging material/film through the machine. The traditional design clamps the material with the cross-seal jaws and advances the material by moving the cross-seal jaws down. This is called a “draw bar” (reciprocating up–down cross-seal jaws). The other is a drive-belt principle for film advance, which leaves the cross-seal bars in a fixed horizontal position with only open–close motion. The belt-drive film-advance principle has been shown to be the most versatile design for high–speed packaging and simplicity of operation, and a number of companies have converted to this principle.

Power

There are several approaches to providing power for material/film transport and the filling and sealing operations: all electromechanical; electromechanical/pneumatic; and electromechanical/pneumatic/vacuum.

The electromechanical vertical-bag machine incorporates a cam shaft with a series of cams to operate the various functions. The package material/film drive motion works off a motor/reducer/clutch/brake arrangement. The long-seal and the cross-seal tooling are operated by cams. This allows cycle-to-cycle repeatability of machine settings. This is a very basic principle that has fixed timing on all components and is generally accepted as a heavy-duty, low-maintenance design.

The most common VFFS design incorporates electromechanical power and pneumatics. This combination offers a manufacturing cost advantage in a highly competitive industry; but the tradeoff is the need to control air supplies carefully in order to keep the performance of the machine up to its top efficiency. The use of solenoid valves, pneumatic valves, flow controls, and air lines increases the maintenance requirements somewhat.

The electromechanical/pneumatic/vacuum principle is quite unique. The design is similar to the types utilizing air, with the addition of vacuum material/film transport belts. This principle locks the film to perforated drive belts by means of a vacuum pump. It works quite well, but generally imposes limitations on speed and minimum bag-width dimensions due to the design requirements for utilizing vacuum draw-down belts. Also, the vacuum pump adds another power requirement and noise factor.

BAG-FILLING FACTORS

The product being packaged is generally the limiting factor regarding production rate capabilities on any of the machine designs. Machine operation is affected by product characteristics such as dust, fines, and stickiness, as well as by piece size, piece weight, and product volume. Some products create a piston effect when dropped down inside a bag-forming tube, by pushing air down into the sealed end of the packaging material. This air must escape somewhere. There are various controls such as inner fill tubes and snorkel tubes, to release air pressure before the product drops down the tube. Some machine uses sponge attached to seal jaw to push air out prior to sealing the bag. The perforated or slitted film can be also used to form the bag so that the release of air through the holes helps to reduce bag puffiness prior to packing into corrugated case.

All of these factors affect the end result. Too often, cycle capabilities of the bag machine and of the product measuring system are calculated independently, without considering what happens when the product moves from the measuring system down through the tube and into the bag. Achievable production rates are based on the compatibility of the three components: bag machine, filler, and product(s). Users of VFFS machinery should supply complete information concerning the products to be packaged to the manufacturers of the equipment so that they can factually evaluate the achievable speed, weight accuracy, and efficiency capabilities.

PRODUCT FILLERS

There are several different choices of measuring/filling equipment: net weigh scales, auger fillers, volumetric fillers, counters, bucket elevators, and liquid fillers.

Net weight scales provide the most accurate means of measuring products for packaging. The invention and marketing of the multiple-head computer scale system in the past few decades has literally revolutionized the product-weighing industry. Package weight controls can be held to $\pm 1\,\mathrm{g}$ regardless of the size of the piece or particle being packaged.

Next in line for accuracy is the *auger filler*. This is applicable to products that are powdery in form and can be handled through a screw contained inside a tube. Most chemicals, baking products, and other powdery forms use an auger filler. The accuracy is dependent on bulk density control of the product throughout the augering system as well as the cycle repeatability of the chosen auger filler.

A *volumetric cup filler* fills by volume and is generally used for inexpensive products where high production rates are desirable and product overweight giveaway is unimportant. Counters (see Filling machinery, by count) apply to applications such as hardware, confectionary items, and other items that must be packaged by count. The counter(s) can be mounted directly over the bag machine, or they can work in conjunction with a bucket elevator.

The *bucket elevator* can be an intermediate between any of the other product fillers, but it should be utilized only where space restraints or other impractical reasons dictate needs. The shortest distance between two points is the rule of thumb on VFFS systems, so mounting the filler directly above the vertical bag machine is the best and should be first choice where applicable.

A few major VFFS equipment suppliers to the United States market are General Packaging Equipment Corporation Inc., Hayssen Manufacturing Company, Heat & Control Processing & Packaging Machinery Company, Ilapak Packaging Machinery Company, Package Machinery Company, Pneumatic Scale Barry-Wehmiller Company, Rovema Packaging Machines Inc., Triangle Package Machinery Company, and The Woodman Company.

GAS BARRIER PROPERTIES: EFFECTS OF SMALL LEAKS

KIT L. YAM
Department of Food Science,
Rutgers University,
New Brunswick, New Jersey

How much do small leaks affect the barrier properties of a package and the shelf life of the product it contains? This question is frequently asked by companies concerned with product quality and safety. Here are some real-life examples: A food company found significant weight gains in their packages containing a dry food product, despite the fact that the package was made with a high water barrier material; another company found that the shelf life of their food product was shortened by the onset of oxidative rancidity, although a high-barrier metallized film protected the food product; a researcher abandoned the data of a major experiment, because he found unexpected loss of volatile compounds from the packaged samples used in the experiment. In all of those cases, small leaks were found in the packages.

Small leaks sometimes occur in packages because of the mechanical abuses encountered during processing and transport and the limited mechanical resistance of the packages. The major concerns with the small leaks in packages that contain sensitive food or pharmaceutical products are (a) microbial penetration that can lead to health risk; and (b) disruption of the gas barrier property of the package, causing accelerated transfer of oxygen, water vapor, and flavors through packages, which can greatly shorten the shelf-life of the contained gas- or flavor-sensitive products.

The two types of small leaks commonly found in packages are pinholes and channel leaks (Figure 1). Pinholes are usually found in the package wall, and their depths are approximately equal to the package thickness. Pinholes may be caused by the package wall being accidentally punctured by a sharp object. Channel leaks are usually found in the seal area of the package, and their depths are equal or slightly longer than the seal width. Channel leaks may be caused by contaminants (such a small food particle) or wrinkles in the seal area. It is important to note that a channel leak typically has a longer depth than pinhole; the longer depth poses a higher resistance to microbial penetration and gas transport, and thus a pinhole is usually more detrimental than a channel leak of the same diameter. The diameters of pinholes and channel leaks typically range from 50 to 300 μm.

GAS TRANSPORT THROUGH LEAKS VERSUS PERMEATION

Besides going through leaks, a gas or vapor can also go through a polymeric package wall through the mechanism of permeation. As shown in Figure 2, gas permeation through a polymeric package wall involves a three-step process: adsorption of gas onto one surface of the package wall, diffusion of gas through the package wall, and desorption of gas from the other surface of the package wall. In comparison, the transport of a gas through a pinhole or channel leak (Figure 1) involves only the step of diffusion, and the diffusion of the gas is through the air column in the pinhole or channel leak, not through a solid package wall as in the case of gas permeation.

PREDICTIVE EQUATION

Equation (1) has been developed to estimate the effects of leaks on the barrier properties of packaging materials. The equation assumes a polymeric packaging material with a permeability P ($\mathrm{cm}^2\,\mathrm{s}^{-1}$). A new parameter "effective permeability," P_{eff} ($\mathrm{cm}^2\,\mathrm{s}^{-1}$), is introduced to include the additional effects of leaks in the material. Hence, P accounts for only gas permeation, whereas P_{eff} accounts for both gas permeation and gas transport through leaks.

$$\frac{P_{\mathrm{eff}}}{P} - 1 = \mathrm{B} \cdot \frac{n\delta^2}{\lambda + \kappa \cdot \delta} \tag{1}$$

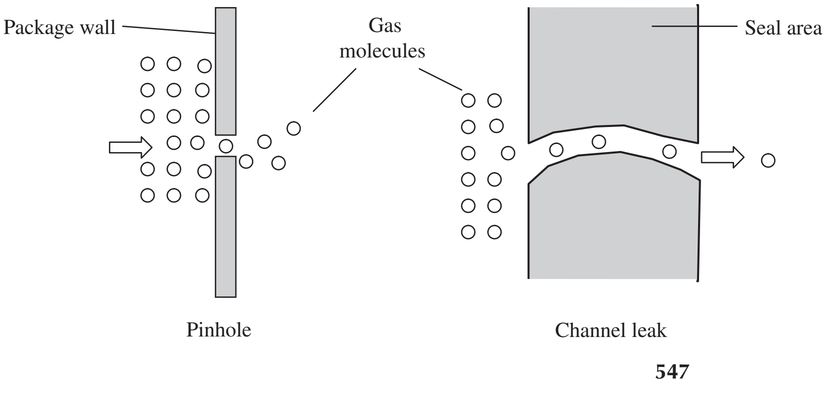

Figure 1. Transport mechanism of gases or vapors through pinhole and channel leak in package.

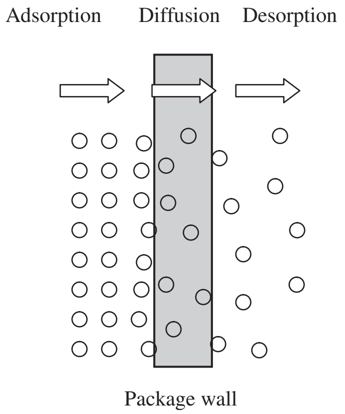

Figure 2. Mechanism of gas permeation.

where

$$B \equiv \frac{D_{1A}\pi \cdot L_P^2}{4A_P P} \tag{2}$$

and

D_{1A} = diffusion coefficient of gas 1 in air ($cm^2\,s^{-1}$)
L_l = length of leak (cm)
L_p = thickness of package (cm)
$\lambda = L_l/L_p$ dimensionless length of leak
$\delta = d/L_p$ dimensionless diameter of leak
κ = proportionality factor to account for end correction of diffusive path length (literature values ranges from 0.5 to 0.11)
A_P = surface area package wall (cm^2)
n = number of leaks

The derivation of this equation may be found in the original paper [1]. It is sufficient to mention here that the equation is based on Fick's law of diffusion, accounting for both the gas leakage across small leaks and the gas permeation across the package wall. The equation takes the effects of the leak into account using an effective permeability that depends on leak size, type of diffusing gas, type of packaging material, and gas status around at leak ends. The leaks are approximated as cylindrical pores in the model. At $\lambda = 1$, the leak is a pinhole; as λ increases, the leak is becoming a channel leak. At $\delta = 0$, there is no leak; as δ increases, the leak becomes bigger.

For a gas-sensitive food packaged with a permeable film, P_{eff}/P obtained from equation (1) may be used for correcting the shelf life estimation for errors caused by leakage:

$$\frac{t_{s,cor}}{t_s} = \frac{P}{P_{eff}} \tag{3}$$

where $t_{s,cor}$ is the shelf life corrected for leakage and t_s is the shelf life in the absence of leaks.

APPLICATIONS OF PREDICTIVE EQUATION

Three practical cases are shown below to illustrate the application of equation (1) to examine the significance of leaks on a gas-sensitive food packaged in low-density polyethylene (LDPE) or an aluminum film. P_{eff}/P is used to compare the barrier properties of packages with and without leaks. The term ($P_{eff}/P-1$) represents the effect of

Case 1: Effect of Leaks on Water Vapor and Oxygen Transport. This case compares the effect of leaks on water vapor transport and oxygen transport through LDPE at 25°C. An LDPE package with one leak ($n = 1$) was considered with a surface area A_P of 500 cm^2 and a thickness L_p of 25 μm. For water vapor transport, the permeability $P = 6.64 \times 10^{-7}\,cm^2\,s^{-1}$, when the relative humidities inside and outside the package are 0% and 90%, respectively, and diffusion coefficient $D_{1A} = 0.260\,cm^2\,s^{-1}$. For oxygen transport, $P = 2.39 \times 10^{-8}\,cm^2\,s^{-1}$ and $D_{1A} = 0.203\,cm^2\,s^{-1}$.

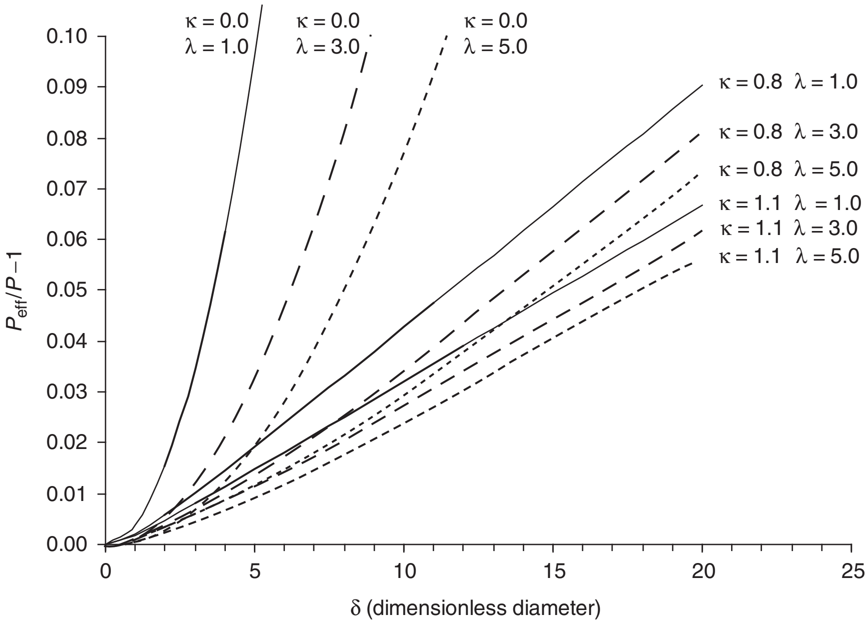

Figure 3. ($P_{eff}/P-1$) versus δ with κ and λ as parameters for water vapor transport through LDPE at 25°C. Simulations were conducted using equation (1) with $P = 6.64 \times 10^{-7}\,cm^2\,s^{-1}$, $D_{1A} = 0.260\,cm^2\,s^{-1}$, $A_P = 500\,cm^2$, $L_p = 25$ μm, and $n = 1$.

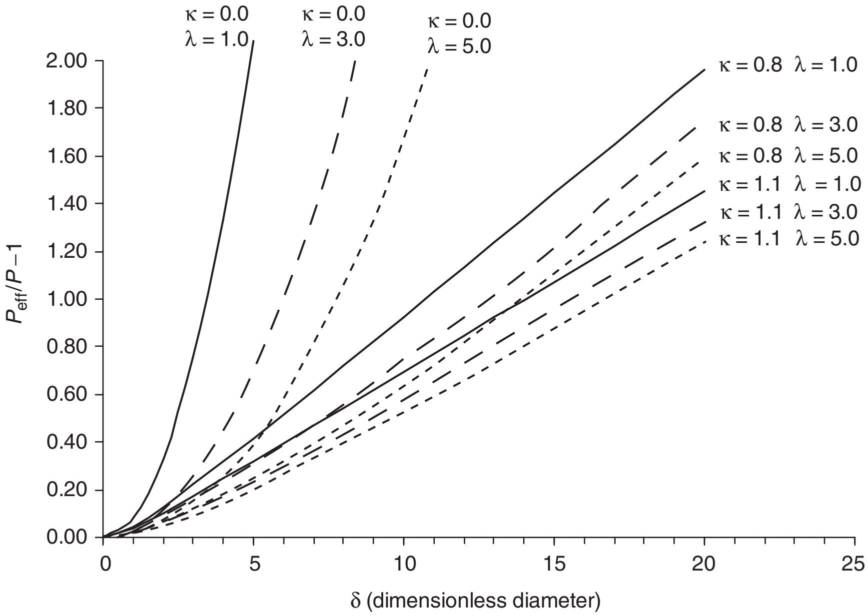

Figure 4. ($P_{eff}/P-1$) versus δ with κ and λ as parameters for oxygen transport through LDPE at 25°C. Simulations were conducted using equation (1) with $P = 2.39 \times 10^{-8}\,\text{cm}^2\,\text{s}^{-1}$ and $D_{1A} = 0.203\,\text{cm}^2\,\text{s}^{-1}$, $A_P = 500\,\text{cm}^2$, $L_p = 25\,\mu\text{m}$, and $n = 1$.

Figures 3, 4 show the plots of ($P_{eff}/P-1$) as a function of dimensionless diameter δ with κ and λ as parameters for water vapor transport and oxygen transport, respectively. In each figure, the range of δ is between 0 ($d = 0$) and 20 ($d = 500\,\mu$m). Three κ values were selected; zero for the case of no end correction, 0.8, and 1.1. At each κ value, three values (1.0, 3.0, and 5.0) for λ were considered. The leak is a pinhole when $\lambda = 1.0$ and becomes a longer channel leak as λ increases. In Figures 2 and 3, three bands of curves are observed; each band corresponds to a value of κ and the smaller variation within the curves of each band is caused by the different λ.

At any given κ and λ, the increase of ($P_{eff}/P-1$) with δ is steeper for oxygen (Figure 4) than for water vapor (Figure 3), which indicates that leaks have greater effects on oxygen transport than on water vapor transport. This observation can be explained by the fact that for LDPE the value of D_{1A}/P for oxygen is about 20 times larger than that for water vapor, which makes the dimensionless parameter B in Equation (1) about 20 times larger.

For an illustration of the effect of leaks on the shelf life of foods, a moisture-sensitive food stored at 25°C was considered, packaged with a LDPE film that had a surface area of $500\,\text{cm}^2$, a thickness of $25\,\mu$m, and one pinhole ($n = 1$ and $\lambda = 1$). The relative humidities inside and outside the package were assumed to be 0% and 90%, respectively. The calculations were carried out with $\kappa = 0.8$. For $d = 100\,\mu$m ($\delta = 4$), the calculated $P_{eff}/P = 1.015$, which indicates the pinhole increases the water vapor transport rate by 1.5%. For $d = 300\,\mu$m ($\delta = 12$), the calculated $P_{eff}/P = 1.052$, and the increase is 5.2%. The relative reductions in shelf life calculated using $100(1-P/P_{eff})$ were 1.5% for $d = 100\,\mu$m and 4.9% for $d = 300\,\mu$m. Under the given conditions, one pinhole does not seem to be important for water vapor transport. However, if the food is oxygen sensitive so that its shelf life depends on oxygen transport, even a single pinhole becomes a serious matter under the same conditions. For $d = 100$ and $300\,\mu$m, the calculated P_{eff}/P values were 1.318 and 2.133, and the calculated shelf life reductions were 24% and 53%, respectively.

Case 2: Effect of Leaks on High Gas Barrier Materials. An inspection of equations (1) and (2) reveals that ($P_{eff}/P-1$) is directly proportional to B and that B is inversely proportional to the permeability P. Therefore, the relative increase of the permeability caused by leaks ($P_{eff}/P-1$) is inversely proportional to the permeability P of the material. In other words, the better the gas barrier properties of the material, the more significant the relative increase of the permeability caused by leaks.

Aluminum is often considered as a gas-impermeable material. A thin aluminum layer is often laminated or metallized onto a plastic film for enhanced gas barrier protection. However, the thin layer of aluminum is susceptible to pinhole formation during the manufacturing process and handling. In the following analysis, such a gas-impermeable material is considered in which pinholes are the only means of oxygen transport. For a gas impermeable material, $P = 0$, therefore, the effective permeability becomes:

$$P_{eff} = \frac{D_{1A}\pi \cdot l_P^2}{4A_P} \frac{n\delta^2}{\lambda + \kappa \cdot \delta} \tag{4}$$

Using the equation, a plot of P_{eff} versus leak diameter d (Figure 5) was constructed at different values of n and λ for oxygen transport through leaks for the gas-impermeable material at 25°C. A package with a surface area A_P of $500\,\text{cm}^2$ and a thickness L_p of $25\,\mu$m was considered and the calculations were carried out with $\kappa = 0.8$. In the same graph, the permeability of LDPE to oxygen at 25°C ($P = 2.39 \times 10^{-8}\,\text{cm}^2\,\text{s}^{-1}$) is shown. It can be observed that even one pinhole ($n = 1$, $\lambda = 1$) with a diameter $d = 270\,\mu$m

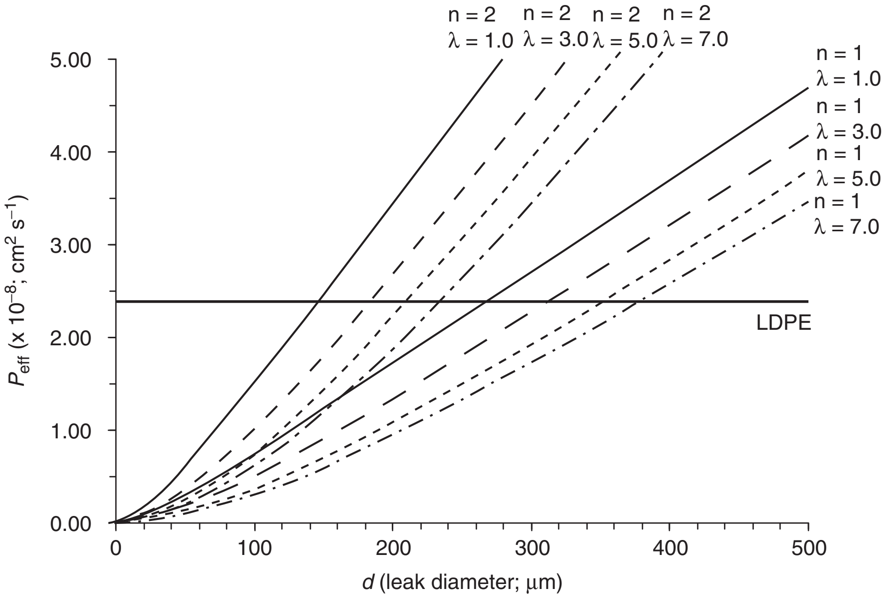

Figure 5. P_{eff} versus leak diameter d at different values of n and λ for oxygen transport through leaks for a gas-impermeable material at 25°C. Simulations were conducted using equation (4) with $A_P = 500$ cm^2, $L_p = 25\,\mu$m, and $\kappa = 0.8$.

can make the otherwise impermeable material more permeable than LDPE. Therefore, it is a waste of money to use expensive high-barrier materials if not enough attention is paid to ensure the package is leak free.

Case 3: Effect of Temperature on the Significance of Leaks. ($P_{eff}/P-1$) varies with temperature because of the temperature dependence of D_{1A} and P in the dimensionless parameter B (equation 2). This temperature effect is illustrated next by considering oxygen transport through LDPE at 25°C and at 35°C. A LDPE package with a surface area A_P of 500 cm^2, a thickness L_p of 25 μm, and one ($n = 1$) leak was considered. Calculations were carried out using equation (1) with $\kappa = 0.8$. At 25°C, we already had $P = 2.39 \times 10^{-8}$ cm^2 s^{-1} and $D_{1A} = 0.203$ cm^2 s^{-1}. The permeability of oxygen through LDPE at 35°C was calculated using the Arrhenius relationship with an activation energy of 10 kcal/mole. The diffusion coefficient of oxygen in air at 35°C was calculated using the Fuller–Schettler–Giddings correlation and the D_{1A} value at 25°C. Thus at 35°C, $P = 4.14 \times 10^{-8}$ cm^2 s^{-1} and $D_{1A} = 0.215$ cm^2 s^{-1}.

Calculations show that increasing the temperature from 25°C to 35°C, P almost doubled whereas D_{1A} increases by only 6%, which results in a decrease of B from 8.34×10^{-2} to 5.10×10^{-2}. These calculations indicate that the relative increase of the permeability caused by leaks ($P_{eff}/P-1$), that is the leak effect, becomes less significant as temperature increases, because the temperature dependence of P is larger than that of D_{1A}. This is illustrated in Figure 6, where the slope of the curves in the plot of ($P_{eff}/P-1$) versus leak diameter (d) is smaller at 35°C than at 25°C.

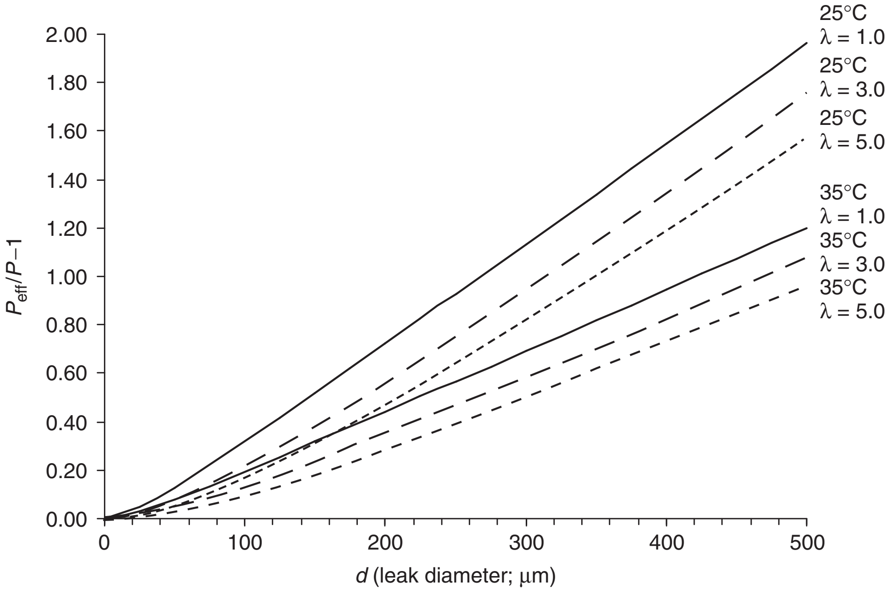

Figure 6. ($P_{eff}/P-1$) versus leak diameter d at various values of λ for oxygen transport through LDPE at 25°C and at 35°C. Simulations were conducted using equation (1) with $A_P = 500$ cm^2, $L_p = 25\,\mu$m, $n = 1$, and $\kappa = 0.8$. $P = 2.39 \times 10^{-8}$ cm^2 s^{-1} and $D_{1A} = 0.203$ cm^2 s^{-1} were used at 25°C and $P = 4.14 \times 10^{-8}$ cm^2 s^{-1} and $D_{1A} = 0.215$ cm^2 s^{-1} were used at 35°C.

GAS PERMEATION OF PACKAGING MATERIALS

KIT L. YAM
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

INTRODUCTION

The transport of gas or vapor through a food package can greatly influence the keeping quality of the packed food. Oxygen ingress into the package can cause oxidation in lipid foods (especially dehydrated meat, egg, cheese, as well as foods cooked in frying oil) that leads to off-flavors, loss of color, and reduction in nutrient value. Water vapor infiltrating the package can cause moisture gain leading to sogginess or microbial growth in food, while water vapor escaping from the package can cause moisture loss leading to undesirable textual changes in food. On the contrary, there are occasions when the transport of gases and vapors is desirable. In modified atmosphere packaging of fresh produce, the exchange of oxygen, carbon dioxide, and water vapor through the package is necessary to accommodate the respiration and transpiration of the still bioactive product and to maintain an optimum gas composition in the package. In packaging of freshly roasted coffee, degassing is necessary to prevent excessive pressure buildup since the product still emits carbon dioxide after packing.

There are two major mechanisms by which gas or vapor may be transported through the package—permeation and leak. Permeation involves the exchange of a gas or vapor (also known as permeant) through a plastic film or package wall. Leak involves the exchange of gas or vapor through pinholes or channel leaks, to be explained at the end of this article. Although permeation is the focus of this article, it is important to realize that leakers from defective packages are often more influential than permeation in determining the overall transmission rate (1).

Permeation and gas barrier are closely related terms. Permeation is inversely proportional to gas barrier; for example, a package which allows gas to permeate quickly is a package of low gas barrier. To protect foods that are oxygen- or moisture-sensitive, high-gas-barrier packages should be used to retard the rate of permeation.

This article is limited to permeation in polymeric packaging materials. It is important to mention that all packaging polymers are permeable to gas and vapor to various degrees. These polymers provide a wide range of permeability for different applications. Hence the study of permeation is important to ensure that adequate gas barrier protection is provided for plastic pouches, plastic containers, and other plastic packages. On the other hand, glass and metal packaging materials are not permeable and paper packaging materials (unless coated with barrier layer) are too permeable. Unlike polymers, these materials do not provide an opportunity for the designer to optimize the barrier property for various applications.

MECHANISM OF GAS TRANSPORT THROUGH PERMEATION

Figure 1 shows that permeation of a permeant through a polymer film (or a package wall) is driven by concentration gradient in the direction from high to low concentration. The mechanism of permeation consists of three sequential steps: adsorption of the permeant onto the high concentration side of the film surface, diffusion of the permeant across the film, and desorption of the permeant from the low concentration side of the film surface.

Diffusion is the movement of molecules from a region of high concentration to a region of low concentration as a result of intermingling of the molecules due to random thermal agitation. The diffusion of a permeant through in a polymer film may be described by Fick's First Law:

$$J = -D\frac{dc}{dx} \tag{1}$$

where J (mol cm^{-2} s^{-1}) is diffusion flux, D (cm^2 s^{-1}) is diffusion coefficient (also called diffusivity), c (mol cm^{-3}) is permeant concentration, and x (cm) is distance in the flow direction. Since the increase in concentration is customarily associated with the positive x direction, a negative sign is needed in equation (1) to denote that diffusion is in the negative x direction or toward a lower concentration.

Adsorption and desorption are related to the solution or sorption behavior of the permeant molecules in the polymer film, which is governed by the relative strengths of interactions between permeant/permeant, permeant/polymer, and polymer/polymer. The simplest or "ideal" sorption isotherm is expressed by Henry's Law:

$$c_s = S_p \tag{2}$$

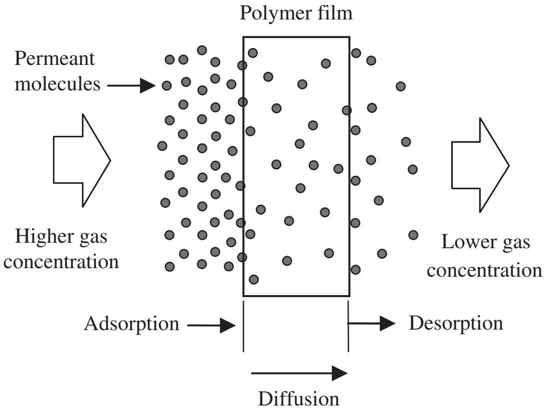

Figure 1. Permeation through a polymer film.

where c_s is permeant concentration at the solid-phase film surface (mol cm^{-3}), p (atm) is the partial pressure of the permeant, and S is solubility coefficient (mol cm^{-3} atm^{-1}). This provides a convenient means for estimating c_s once p and S are known.

Permeation Rate Equation and Its Physical Meaning

A useful equation to describe the gas permeation through a polymer film at steady state is the permeation rate equation:

$$Q = \frac{\bar{P}A}{L}\Delta p \tag{3}$$

where Q is permeation rate, A is film surface area, L is film thickness, and Δp is partial pressure difference of the permant between the two sides of the film. The parameter $\bar{P}$ is known as permeability, which is related to diffusion coefficient and solubility coefficient as follows:

$$\bar{P} = DS \tag{4}$$

The derivation of the permeation rate equation may be found elsewhere [2].

It is instructive to mention that gas permeation through a polymer film, like water through a pipe or electric current through a resistor, may be described by the empirical relationship:

$$\text{flow rate} = \frac{\text{driving force}}{\text{resistance}} \tag{5}$$

Comparing this relationship with equation (3) indicates that Q is the flow rate, the pressure difference Δp is the driving force for permeation, and

$$\text{resistance to permeation} = \frac{\mathrm{L}}{\bar{P}A} \tag{6}$$

Gas permeation through a film may be compared to water flow through a pipe connecting two water tanks of different heights (Figure 2a). Intuitively, the water flow rate is directly proportional to the difference between the water levels (Δh) and inversely proportional to the pipe resistance—this is consistent with equation (5). The pipe resistance increases with the length and friction factor of the pipe but decreases with its cross-sectional area. The similarities are as follows: Water flow rate is similar to gas permeation rate, water level difference between the two tanks (Δh) is similar to pressure difference across the film (Δp), cross-sectional area of pipe is similar to surface area of film, length of pipe is similar to thickness of film, and friction factor of pipe is similar to the inverse of permeability of film.

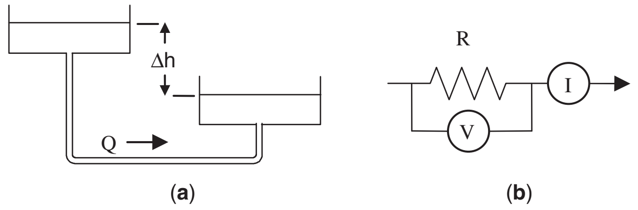

Figure 2. **(a)** Flow of water through a pipe. **(b)** Flow of electric current through a resistor.

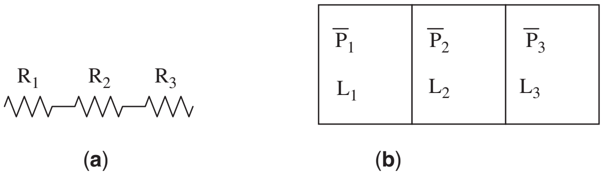

Figure 3. Resistance across **(a)** resistors in series and **(b)** a multilayer film.

Gas permeation is also similar to the flow of electric current through a resistor (Figure 2b). The relationship between electric current I, voltage V, and resistance R across a resistor is described by Ohm's Law:

$$I = \frac{V}{R} \tag{7}$$

which has the same form as equation (5). The total resistance is equal to the sum of individual resistances in series (Figure 3a):

$$R_T = R_1 + R_2 + R_3 + \cdots \tag{8}$$

Similarly, the total resistance in a multilayer film is equal to the sum of resistances in individual layers. Since the resistance to permeation for each layer is shown earlier to be $L/(\bar{P}A)$:

$$\frac{L_{\mathrm{T}}}{\bar{P}_{\mathrm{o}}A} = \frac{L_1}{\bar{P}_1 A} + \frac{L_2}{\bar{P}_2 A} + \frac{L_3}{\bar{P}_3 A} + \cdots \tag{9}$$

or

$$\frac{L_{\mathrm{T}}}{\bar{P}_{\mathrm{o}}} = \frac{L_1}{\bar{P}_1} + \frac{L_2}{\bar{P}_2} + \frac{L_3}{\bar{P}_3} + \cdots \tag{10}$$

where L_{T} is total thickness, $\bar{P}_{\mathrm{o}}$ is overall permeability, and the subscripts 1, 2, 3 refer to the individual layers in the film.

For example, consider a multilayer film constructed of 3 mil PP/0.5 mil PVDC/3 mil PP. Assume that the oxygen permeabilities for the PP (polypropylene) and PVDC (polyvinylidene chloride) layers are 150 and 1.2 (cm^3 · mil)/(100 in.^{2} · day · atm), respectively. The overall oxygen permeability $\bar{P}_{\mathrm{o}}$ of the film may be calculated using Equation (10):

$$\frac{3 + 0.5 + 3}{\bar{P}_o} = \frac{3}{150} + \frac{0.5}{1.2} + \frac{3}{150}$$

where the calculated $\bar{P}_o$ is 14.2 (cm^3 · mil)/(100 in.^{2} · day · atm).

PERMEABILITY OF FOOD PACKAGING POLYMERS

Table 1 shows typical ranges of permeability values for some common food packaging polymers. It can be seen that polymers offer a wide choice of barrier properties,

Table 1. Permeability Values of Polymers

Polymer	O_2 Permeability[a]	CO_2 Permeability[a]	Water Vapor Permeability[b]
Polyethylene (PE)			
Low density	300–600	1200–3000	1–2
High density	100–250	350–600	0.3–0.6
Polypropylene (PP)			
Unoriented	150–250	500–800	0.6–0.7
Oriented	100–160	300–540	0.2–0.5
Polystyrene (PS)	250–350	900–1050	7–10
Poly(ethylene terephthalate) (PET)	3–6	15–25	1–2
Poly(vinyl chloride) (PVC)			
Unplasticized	5–15	20–50	2–5
Plasticized[c]	50–1500	200–8000	15–40
Poly(vinylidene chloride) (PVDC)	0.1–2	0.2–0.5	0.02–0.6
Ethylene vinyl alcohol (EVOH)			1.5–8
0% RH	0.007–0.1	0.01–0.5	—
100% RH	0.2–3	4–10	—
Ionomer	300–450	—	1.5–2
Nylon 6	2–3	10–12	10–20
PC	180–300	—	10–15

[a] Unit in ($cm^3 \cdot mil$)/($100\,in.^2 \cdot day \cdot atm$) at 25°C.

[b] Unit in ($g \cdot mil$)/($100\,in.^2 \cdot day$) at 38°C, 90% RH.

[c] Values depend greatly on plasticizer content.

ranging from low oxygen barrier materials such as polyethylene (PE) to high oxygen barrier materials such as ethylene vinyl alcohol (EVOH). It is noted that polar polymer such as EVOH deteriorates in gas permeability under high relative humidity conditions.

Since the barrier protection against water vapor and oxygen is most important to food, it is useful to compare the oxygen permeability and water permeability together for selecting packaging material. Figure 4 presents the location of polymer material in a two-dimensional matrix of oxygen and water vapor permeabilities. For designing the packaging system for a certain food, its gas and moisture permeabilities should be closely related to the food's sensitivity to oxygen and moisture.

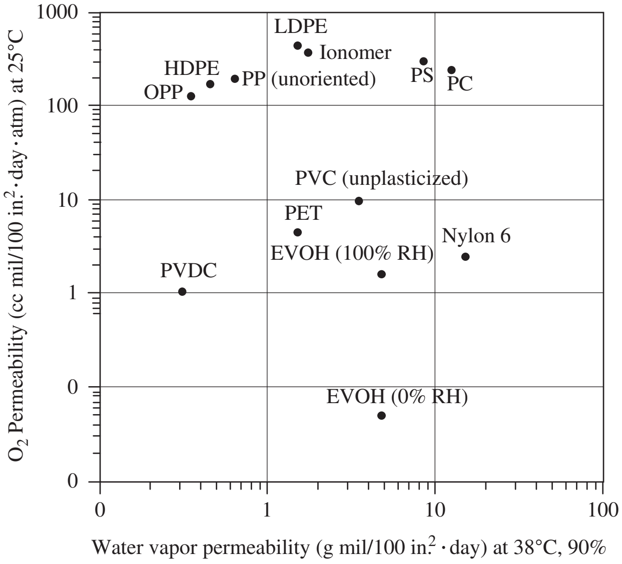

Figure 4. Oxygen permeability versus water vapor permeability.

FACTORS GOVERNING PERMEATION

The major factors governing permeability fall into three categories: nature of polymer matrix, nature of permeant, and ambient conditions. Understanding these factors is helpful for selecting proper materials for barrier protection of food packages.

Nature of Polymer

Generally, the gas and vapor barrier of polymers is improved with increasing polarity of certain types, regularity of molecular structure, and close chain-to-chain packing in the polymer matrix (3). As shown in Table 2, polar functional groups such as OH, Cl, and CN decrease O_2 and CO_2 permeabilities under dry conditions due to strong polymer interactions. High polarity results in high cohesive energy between the polymer chains and consequently lower diffusion and permeability (4).

Figure 5 explains the effects of polymer interactions on the diffusion path taken by the permeant. In situation (a), such as for polyethylene, there is no or very weak interaction between the nonpolar polymer chains, and hence the permeant molecule may diffuse through the polymer matrix via a shorter and more direct path. In situation (b), such as for EVOH, there are strong intermolecular interactions such as hydrogen bonding between the polymer chains. These strong interactions block the passage of the permeant molecule, requiring it to diffuse in the polymer matrix via a much longer path. The longer diffusion path also causes the permeability to decrease.

Permeability also decreases with increasing crystallinity and molecular orientation in the polymer matrix, since regions of crystallinity and molecular orientation are obstacles to the passage of the permeant. Polymers with regular molecular structure and close chain-to-chain packing tend to have higher degrees of crystallinity and

Table 2. Gas or Water Vapor Permeabilities of Selected Polymers

	Permeability for gas (cm^3 mil 100 in.$^{-2}\cdot$ day$^{-1}\cdot$ atm^{-1}) and Water Vapor (g mil 100 in.$^{-2}\cdot$ day$^{-1}\cdot$ atm^{-1})				
Polymer	O_2 (Dry Condition)	O_2 (Wet Condition: 80% RH)	CO_2 (Dry Condition)	H_2O (38°C, 90% RH)	Functional Group
PVOH	0.02	7.00	0.06	10.00	–OH
EVOH	0.05	7.00	0.23	10.00	–OH
PVDC	0.08	0.08	0.30	0.05	–Cl
PAN	0.03	0.03	0.12	0.50	–CN
PET	5.00	5.00	20.00	1.30	–COO–
Nylon 6,6	3.00	15.00	5.00	24.00	–CONH–
PP	110.00	110.00	240.00	0.30	$-CH_3$

Abbreviations: PVOH, poly(vinyl alcohol); PAN, polyacrylonitrile; refer to Table 1 for others.

are more easily oriented in molecular structure. Higher crystallinity also lowers the solubility of permeant in the polymer matrix and thus the permeability. Inclusion of crystallites or inorganic platelets may also increase crystallinity and lower permeation (5).

Permeability generally increases with addition of additives, fillers, and plasticizers in the polymer matrix. Inert fillers such as $CaCO_3$ and ceramic powder have been used to increase the gas permeability of polyolefin films for fresh produce packaging applications.

Nature of Permeant

Permeability also depends on molecular size of the permeant and its chemical affinity to the polymer matrix. Larger permeant molecules generally have lower diffusivity and higher solubility compared to smaller molecules, although solubility also depends on the chemical similarity between the polymer and the permeant (6).

It is interesting to note in Table 1 that the values of CO_2 permeability are typically 3–7 times the values of O_2 permeability. How could the larger CO_2 molecule permeate faster than the smaller O_2 molecule? The answer may be found by recalling (equation (4)) that permeability is the product of diffusion coefficient and solubility coefficient. While it is true that CO_2 diffuses slower than O_2, the solubility of CO_2 is much higher than O_2; the combined effect enables CO_2 to permeate faster than O_2. Although CO_2 molecules diffuse slower, there are more of them diffusing through the polymer matrix.

Ambient Environment

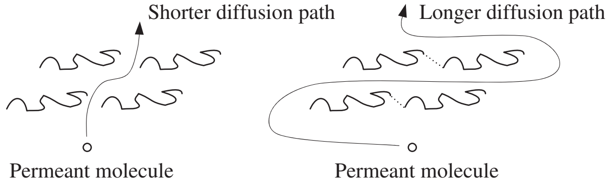
The most important environmental factors are temperature and relative humidity. Temperature generally affects gas permeability by following Arrhenius equation:

$$\bar{P} = \bar{P}_o \exp\left(-\frac{E_a}{RT}\right) \tag{11}$$

where $\bar{P}_o$ is pre-exponential factor, E_a is activation energy, R is gas constant, and T is absolute temperature.

As a rough estimate, a 10°C increase in temperature increases the permeability roughly by a factor of 2. However, the temperature dependence of permeability drastically changes at glass transition temperature; that is, the activation energy changes around that temperature. Many packaging plastics such as PET, PE, and PP show the change of activation energy in a narrow temperature range between 0°C and −12°C.

When water under high humidity is absorbed onto the polymer and interacts with polar group to swell the polymer structure, the gas permeability is greatly increased. Moisture acts as a plasticizer in the polymer structure. This kind of behavior is observed for PVOH, EVOH, and nylon 6,6, but not for polar polymers such as PVDC and PAN (Table 2). Moisture interacts differently with different types of polymers: It is absorbed little onto nonpolar polymers (PP) and certain types of polar ones (PVDC, PAN) and thus does not affect the permeability. The interaction of the polymer with moisture can be seen by high water vapor permeability for PVOH, EVOH, and nylon 6,6 (Table 2). Higher polarity of EVOH resulting with the lower ethylene content increases the water vapor permeability, which means increased sensitivity to moisture.



(a) No interactions between polymer chains
(b) Strong interactions between polymer

Figure 5. Effect of interactions on diffusion paths.

GAS TRANSPORT THROUGH LEAKS

Besides permeation, leak is also an important mechanism of gas transport. Pinholes and channel leaks are two types of leakers occasionally found in defective packages. Pinholes may be found on package walls—for example, on very thin aluminum foils of less than 1 mil thick. Channel leaks are minute channels that may found in defective seal areas caused by improper sealing conditions. Since channel leaks usually have larger depths than pinholes, their leak rates may be much slower.

Figure 6 illustrates that the mechanism of gas transport through a pinhole involves diffusion of gas molecules through a column of stagnant air inside the pinhole.

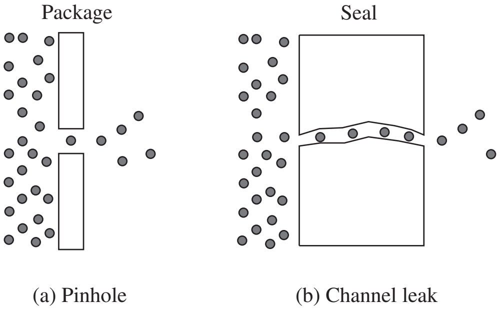


Figure 6. Pinhole and channel leak.

Unlike permeation, the steps of adsorption and desorption are not involved. Also, diffusion through leak occurs in air, while diffusion in permeation occurs in solid. The diffusion velocity in gases, liquids, and solids are generally in the range of 0.00001, 0.5, and 10 cm/min, respectively—hence the transport of gas usually occurs faster through leak than permeation. Both channel leaks and pinholes should be prevented since they can significantly compromise the gas barrier of the package.

GLASS BOTTLE DESIGN AND PERFORMANCE

Michael W. Davis
American Glass Research,
Butler, Pennsylvania

INTRODUCTION

Glass containers continue to be the preferred package for a variety of foods and beverages (1). The reasons behind the long-standing preference are numerous and include that glass containers are made from raw materials that are abundant and inexpensive. Glass containers are rigid and can be easily transported, filled, and stored. They are available in a variety of sizes, shapes, and colors (see Figure 1). Products look better, taste purer, and are secure when packaged in glass. Glass containers are 100% recyclable and are environmentally friendly. Thus, glass would appear to be the ideal packaging material. However, glass is heavy, adding cost to the delivered product. Glass is also fragile and can fail without warning. Thus, there are challenges for glass to remain competitive as a packaging material.

Historically, glass bottles were designed to be heavy and rugged. Conventional wisdom called for additional glass to avoid performance issues. Prior to the 1960s, the majority of the bottles were refillable items that were comparatively heavy. At that time, energy and raw material costs were low and the lack of major competition suppressed the need for change. However, there were two major events in the 1970s that significantly changed the glass packaging industry. The first event was the energy embargo (2) causing a huge spike in both manufacturing and transportation costs. The second event was the introduction of the plastic beverage bottle to the packaging market (3). Competition from a lighter and compliant packaging material was a major threat to market share. Thus, these two events forced the glass packaging industry to consolidate; upgrading to newer and more efficient plants while closing several of the older and less efficient plants (4).

To reduce costs and improve efficiencies, larger and faster IS-forming machines were needed. Changes in forming technology provided the means for faster and more efficient production of bottles. The faster machines required changes in mold technology and cooling methods (5). Improved surface treatments enhanced bottle surface strengths (6). Thus, means for lighter, stronger, and more competitive bottles were now available. However, lighter bottles required more attention to detail since there was

Figure 1. Glass containers come in a variety of sizes, shapes, and colors.

less glass to compensate for quality or performance related issues. Thus, a thorough understanding of the importance of design on performance became critical.

COMPUTER MODELING

To aid in addressing these issues, various computer modeling software packages are being used to develop and analyze new designs (7). Computer-aided design and modeling techniques have provided several important and cost-saving innovations in bottle design. Concept designs are easily created into three-dimensional models (see Figure 2). Many programs offer photo-realistic images to view the finished product, including colors, labels, and closures. Bottle properties such as weight, capacity, headspace, centers of gravity, and moments of inertia are easily determined that once took several hours of manual calculations. Bottle prints including exact dimensions and tolerances can be quickly created. Finite element analyses can be used to determine the stress levels created in the bottle to evaluate the performance of the design. Changes such as reducing glass weight, redistributing the glass, and/or modifying the shape can be readily made in the computer model to ensure that the bottle design is strong, safe, and capable of meeting modern packaging requirements without ever having to create a bottle. Thus, computer-aided design and modeling techniques provide the tools for a fast response to changing tastes and demands in the marketplace.

MARKETING

The competition in the food and beverage industry continues to grow. Both existing and new products require fresh packages with customer appeal and enhanced brand recognition (see Figure 3). Glass container companies have met these requirements by taking advantage of the advances in both technology and marketing. Many existing and stock designs have been given a new and clean look with creative labeling and other decorative treatments. However, most new designs originate from unique and different concepts that provide greater visibility and maximize shelf appeal. Thus, it is the designer's role to convert the concept into a viable design without violating the theme of the package.

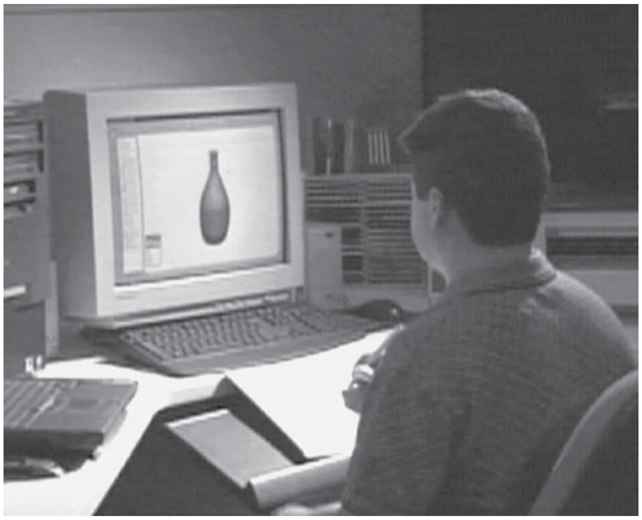

Figure 2. Computer modeling being used to develop new designs.

Figure 3. Labels and decorations promote customer appeal and brand recognition.

REQUIREMENTS

The performance of the glass container is measured against its intended usage. Often, the intended usage is determined by the product and processing requirements. If the container is expected to withstand internal pressure, the shape, weight, and thickness distribution must be selected to provide the safe performance for any internal pressure applied to the bottle. If the product requires special processing after filling, such as pasteurizing or retorting, again, safe performance of the package is required for any loads that might be applied to the bottle. If the container is expected to withstand a top load generated during the capping process or during warehouse storage, the design must exhibit a safe performance for vertically applied loads. And finally, nearly all bottles are expected to receive some level of impacts during the handling or transport of the ware. As filling line speeds increase, safe speeds and gentle handling will be required to achieve good performance. Thus, a thorough understanding of the various requirements is necessitated in order to achieve a design which will exhibit good total performance.

Internal pressures can be generated in bottles either by the product or during the filling process. Many products, such as soft drinks, beers, champagnes and waters, have carbon dioxide (CO_2) dissolved into the product, mainly to enhance the flavour and provide a pleasing sensory effect. The amount of pressure is determined by the level of CO_2 gas and its temperature. With the exception of an inadequate headspace, the approximate pressure levels can be determined from the universal gas laws and CO_2 solubility tables in water (8). Increases in CO_2 and/or temperature cause the pressure levels to increase.

Carbonation levels can vary widely. Beers typically have 2.5 to 3.0 volumes of CO_2, soft drinks have 3.0 to 5.0 volumes of CO_2 and champagnes have 5.0 to 7.0 volumes of CO_2. Normal ranges in temperatures vary from 3°C to 5°C during cold filling to over 60°C during pasteurization or retorting. A typical design pressure level for a beer item during heat pasteurization is 7 bars, whereas the design pressure level for a highly carbonated soft drink item stored in an unvented automobile on a sunny day is 10 bars. Thus, the design pressure will vary with product type and process requirements.

Internal pressures can also be generated in bottles by counter pressures applied during filling (see Figure 4). The counter pressure is used to increase the production speeds and to avoid excessive foaming. Although not exceedingly high, counterpressure levels are typically set in the 3- to 4-bar range. Internal pressures are also generated in bottles during case packing when filled bottles are dropped into cases. The energy of the falling product is converted into a momentary surge pressure. The surge pressure can be as high as 5 bars, depending on the size of container and height of drop. Most bottles for carbonated products have no problems with either counterpressure or surge pressure loads. However, bottles for noncarbonated products or nonround bottles with large flat panels are usually not designed to withstand even these lower pressure loads and may exhibit pressure-related performance issues.

Following filling, bottles are sealed with closures to preserve freshness and protect the product from contaminants. The product will dictate the type of closure necessary to seal the container. For example, crown, twist-crown, or ROPP (roll-on pilfer-proof) closures are necessary for sealing bottles with carbonated products. Lug and/or PT (press-on, twist-off) closures are commonly used with hot-fill items that pull a vacuum when cooled. Screw-on, push-in, or crimp-on closures are commonly used for normal seal applications for wines, liquors, or other food products that do not have pressure or vacuum requirements. In most cases, top loads are required to form a seal between the closure and the finish of the container. For normal seals or vacuum closures, top loads rarely exceed 900 newtons. However, for pressure seals, top loads applied to bottles often exceed 4500 newtons. Again, the design load will vary with product type and process requirements.

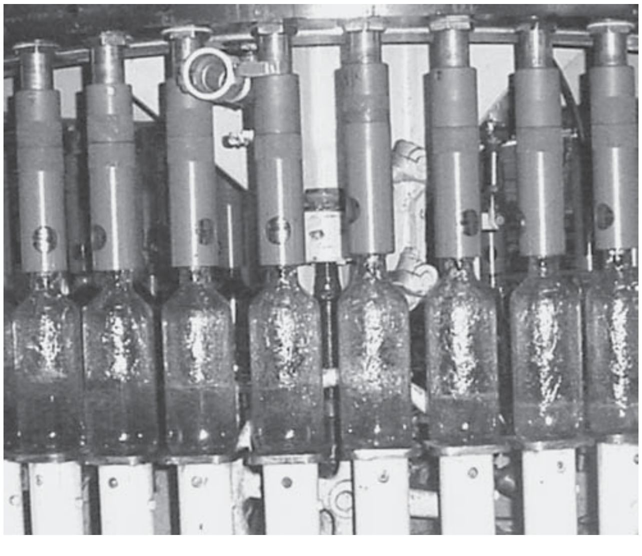

Figure 4. Counterpressures generated during filling.

Figure 5. Uneven loading in the pallet stacks.

Top loads are also generated in stacked pallets of filled containers in the warehouse (Figure 5). Generally, each pallet is topped out at approximately 9 kilonewtons, and they are usually stacked 3 pallets high. In a perfect setting, the weight of the stacked pallets is evenly distributed over the bottles in the bottom row and, on average, each bottle supports approximately 180 newtons. However, storage settings are not perfect; floors are rarely flat; stacking is often uneven; and as the weights shift, the loads are no longer uniformly distributed. A rule of thumb for determining the sustained top force in warehouse storage is to introduce a factor of safety of 10 into the calculations; that is, each bottle on the bottom row must sustain a stacking force 10 times the normal perfect load. Performance-related issues with warehouse stacking are typically associated with nonpressure bottles and jars where the shoulders have not been designed to withstand much top loading.

Many food and beverages are heat-treated either prior to or after filling. The purpose of the heat treatment is to destroy microorganisms and bacteria that may spoil the product or alter the flavor or appearance. This requires that the product be exposed to a specific temperature for a given length of time. The most common heat treatment of product in a container is heat pasteurization, typically used in the beer industry. After cold filling, bottle and product are typically 5°C when they enter the pasteurizer.

The combination is quenched in heated water until the product achieves a temperature of approximately 60°C and then held at the elevated temperature for 6 minutes. The heated bottle and contents are then cooled in stages. The entire heat process takes approximately 20 minutes. It is not the rapid heating of the container that is cause for concern but rather it is the sudden cooling of the container's outer surface. To ensure good thermal performance, a limit on the level of the down shock is required.

Finally, nearly all bottles will receive impacts during their intended usage regardless of whether they are pressure, nonpressure, or vacuum items. Although impact loading is the most commonly applied load, it is perhaps the least understood. Of all the major loads applied to a container, the applied forces created during an impact will be mostly dependent on the properties of the container. In fact, for a given striking velocity, the impact forces will increase with increasing mass and contact stiffness (9). The stiffness or rigidity of the container will vary with impact location and design, while the mass will be dependent on the weight of the container and product (if filled).

In general, the stiffness will be higher at the shoulder and heel contact points than in the sidewall. This is due to complex curvature of the shoulder and heel design. The sidewall, which is cylindrical in shape, is far more flexible and exhibits a lower stiffness. Basic design parameters, such as body diameter and wall thickness, will also affect the stiffness. Decreasing body diameter and increasing wall thickness will increase the stiffness. The total mass will obviously be higher in filled bottles than in empty ones. Similarly, the mass will be greater in larger capacity bottles than in smaller ones, and the mass of refillable bottles will be greater than for nonrefillable bottles. Thus, higher-impact forces will be created in filled versus empty, in larger versus smaller capacity, and in refillable versus nonrefillable ware. The performance requirements for impact loading will vary with bottle size, design, and usage.

The maximum striking velocity that a container can survive greatly depends on the forces created during an impact. Again, these forces depend on the container size and shape and the location of the impact site. Such information is useful in selecting belt speeds and equipment settings in handling and transport of the ware. Differences in expected impact forces are the reasons that empty ware is transported faster than filled ware, small capacity ware is transported faster than larger capacity ware, and lightweight nonrefillable bottles can be transported faster than heavier refillable bottles. As demands for improving efficiencies increase, knowledge of safe handling and transport speeds will be critical for achieving good line performance (see Figure 6).

STRENGTH OF GLASS

The strength of pristine glass is considerably higher than any other packaging material. However, design strengths are compromised because glass is susceptible to surface damage and prone to static fatigue (10). Surface damage in glass bottles can result from the manufacturing process or it can be created by mechanical contact during handling, filling, or distribution of ware. The damage creates stress concentrators in the surface, and any increase in severity of the damage results in lower surface strengths. Various strengths exist for different parts of the bottle. Also, strengths for momentary loading, such as for impacts during handling, are significantly different than those for long sustained loads, such as pressures produced by a carbonated product. Thus, in order to achieve light and efficient designs without compromising performance, an understanding of the surface strengths of a glass container is critical.

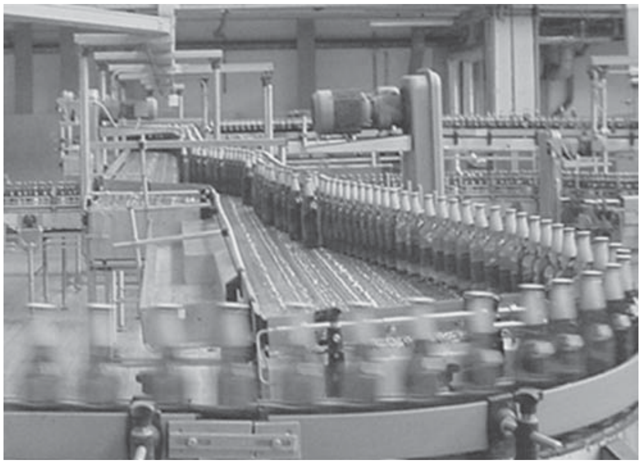

Figure 6. High-speed transport of filled bottles.

There are natural contacts or "touch" points on the outer surface of a glass bottle where the majority of handling damage is generated. These regions include the shoulder contact, heel contact, and bearing surface. Each of these regions will exhibit lower surface strengths according to the degree of damage sustained. Noncontact regions on a glass bottle are generally protected from mechanical damage and will exhibit higher surface strengths. These regions include the shoulder, neck, heel, and bottom. The parts of the bottle are illustrated in Figure 7.

The degree of damage created during handling is also strongly related to the market. For the nonrefillable market, the degree of handling is limited by the single trip through the process. In addition, surface treatments are applied to the outer surface of bottles as a thin metal oxide film that is overcoated with a polyethylene, oleic, or stearate compound. These surface treatments increase the lubricity and scratch resistance of the bottles (11). With limited handling and protected outer surfaces, the bottles exhibit higher surface strengths that can be utilized for lightweighting purposes.

For the refillable market, the degree of handling extends over multiple trips, with most refillable bottles surviving 25 trips or more. Obviously, the degree of handling damage is significant from repeated usage as evidenced by the visible wear bands created at the touch points. Although surface treatments have been used on refillable bottles, their effectiveness is lost following 3 to 5 trips due to the caustic washes employed between cycles. Once the surface treatments have been removed, the

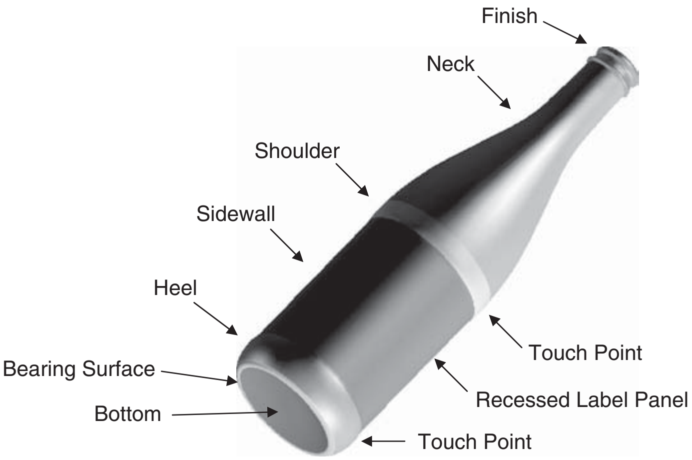

Figure 7. Parts of a bottle.

bottles will then again become susceptible to scuffing, resulting in lower surface strengths. It is noteworthy that some limited success has been achieved with scuff-free coatings applied to refillable ware (12) that is paving the way for lightweight returnable bottles.

The strength of the outer surface of bottles can also be affected by the presence of labels or decorations and may need to be taken into account in the evaluation of the design. Shrink wrap labels that encapsulate the bottle can protect the outer surfaces from handling damage that may, in turn, result in higher surface strengths. Applied Ceramic Labels (ACLs) are silk-screened ceramic paints that are fired onto the glass surface and become a permanent part of the bottle. The strength of the labeled glass depends on the voids and cracks in the ceramic label which can lower the glass strength. Although the ACL label was cost effective when applied on heavier refillable bottles, its strength lowering characteristics can limit the degree of light-weighting in nonrefillable ware. Also, frosted surfaces, which are created with an acid etch or sandblasting, exhibit a pitted surface. These processes remove the surface treatments, and the pitted surfaces become more prone to handling damage.

Also, the strength of the inside surface of a container is significantly higher than the outer surface. This is due to its pristine nature and lack of any mechanical contact. However, there are differences in inside surface strengths that depend on the manufacturing process. The inside surface of blow-and-blow ware is stronger than that for either press-and-blow or NNPB ware. Air is used to create the internal cavity of the parison for blow-and-blow ware, whereas the metal plunger used to create the internal cavity of the parison in either the press-and-blow or NNPB process can deposit small foreign particles into the molten glass surface. These particles, often referred to as “black specks,” can act as stress concentrators and lower the strength of the glass. Thus, these differences must be taken into account when evaluating the design for performance.

Although glass is considered to be chemically inert, freshly formed surface flaws will react chemically with moisture in the environment. This reaction will cause stressed cracks to grow slowly, which in turn lowers the breaking strength of the glass. This slow crack growth mechanism is commonly referred to as “static fatigue” and is responsible for delayed failures, such as pasteurization or warehouse breakage. Because of its chemical nature, increases in either moisture content or temperature will accelerate this process. Thus, wetted glass is weaker than dried glass and hot glass is weaker than cold glass.

When the flaws are only momentarily stressed, such as during an impact, there is very little time for any reactions; and thus little, if any, crack extension or strength loss occurs. However, when flaws are subjected to sustained stresses, such as those produced by a carbonated product stored inside a beverage bottle, there is ample time for cracks to react and extend, provided that the stress levels are sufficiently high. The time-to-failure depends on the initial flaw size and level of stress (see Figure 8). In general, as the stress levels increase, times-to-failure decrease. Also, as the initial flaw size decreases, times-to-failure increase when subjected to the same stress level. Nevertheless, if the length of the extending flaw becomes critical, spontaneous failure can occur without warning. A thorough and prudent design review takes these factors into account to avoid any issue involving static fatigue.

PERFORMANCE

The first step in evaluating the performance of the design is to gather the facts. Identifying the product and any special characteristics will dictate which load types will be applied to the bottle. It is important to identify the magnitude of each load type, since it may change depending on product, processing, or warehouse conditions. It is important to identify the duration in which loads will be applied to account for differences in static fatigue strengths. Identifying the intended market is also important because strength and weight requirements for refillable markets are distinctly different from nonrefillable markets. Determine whether any special labels will be applied that might alter the performance characteristics—for example, shrink wraps or ACLs. And finally, determine the manufacturing process that will be used to produce the bottle since it may affect glass weight, thickness distribution, and inside surface strength. This information will help determine the targeted weight, strength

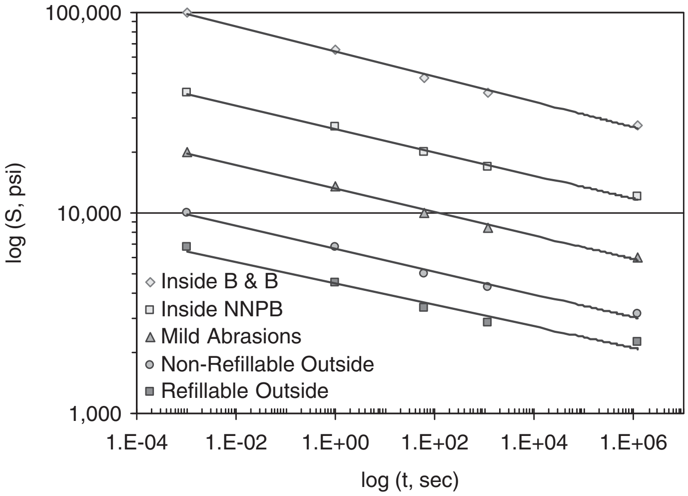

Figure 8. Approximate fatigue strength of soda lime container glass.

criteria, and complexity of modeling. Furthermore, this information is necessary to establish the criteria against which the design is judged for acceptable performance.

The next step is to create a computer model of the design. This can be achieved by various methods. However, the outer surface profile is usually predefined with all the drawing parameters listed on a bottle print. These profiles may be completely new or a modification to a preexisting design. In most cases, the profiles can be directly imported into the model software from a CAD drawing file. Otherwise, the outer surface is manually created to match the concept drawing. The inside surface is initially created by using thicknesses that are equal to industry minimum specifications in the sidewall and bottom regions. Adjustments to these thicknesses may become necessary following the analysis. Some software packages will automatically define the inside surface from simulations of the glass-blowing process (13). In addition to glass weight, other bottle properties, such as overflow capacity, percent headspace, tip angle, and centers of gravity, are readily determined in the solid model. Any changes to the geometry of the bottle can be quickly made with these software packages to correct for any deficiencies with bottle properties and/or weight.

The third step is to select and construct the appropriate finite element model for determining the stress distribution resulting from applied loads. There are generally two types of finite element models used to evaluate the performance of the design. An axisymmetric model can be used if the bottle is round and the applied loads are axisymmetrically applied, such as pressure or top loading. Such models are easily created and greatly reduce computational time. However, if the bottle is nonround or the loading is nonaxisymmetric, such as impact, a three-dimensional model is necessary. To reduce the size of the three-dimensional model and the computational time, axes of symmetry are often used. In most cases, either half-bottle or quarter-bottle symmetry will suffice.

Once the model is selected and the boundary conditions are set, mainly for axes of symmetry, the loads are applied to either individual nodes (special locations on the model) or to surfaces. For internal pressure loading, the inside of the bottle is defined as a surface over which the pressure is uniformly applied. In the case of impact or vertical loading, individual forces are applied to the impact site or along the sealing surface in the finish region of the bottle, respectively.

The magnitude for the load is usually set to one. Thus, for pressure, the load is 1 bar. For top loading, the total load is 1 newton and for thermal shock, the temperature difference is 1°C. The corresponding stress results are then indexed per unit load. Since glass is linearly elastic, the total stress can simply be determined by multiplying the stress index by the actual load. This approach also conserves time and effort. For example, the stress distribution plot shown in Figure 9 corresponds to a 12-oz long-neck beer bottle subjected to a unit internal pressure load. It is obvious that the stresses are not uniformly distributed throughout the bottle but vary from location to location. In general, regions of the bottle most susceptible to pressure performance problems are the contact points where the strengths are the lowest. Regions of maximum stress in the noncontact region are also susceptible to performance problems; however, the surface strengths are higher. This also includes the inside surface where surface strengths are the highest.

Because these results are indexed, the total stress generated from the counter filling pressure during heat pasteurization and/or during storage in a warehouse can be easily determined in spite of the fact that the pressure levels and durations are different. The pressure levels are determined from the (filling) machine settings or from the expected carbonation levels and temperatures in the pasteurizer or warehouse. The strength criteria are determined from the durations of the loads and locations on the bottle. Thus, one analysis is quickly turned into three evaluations. The performance is determined by ensuring that the stress levels do not exceed the expected strengths in the various areas of the container for each of the load conditions.

This same bottle will require a sealed closure for the carbonated product. In general, the applied top force will cause a compression or shortening of the bottle. Even though glass does not break in compression, two bands of tensile stress are generated at the touch points. As illustrated in Figure 10, one band is at the shoulder contact

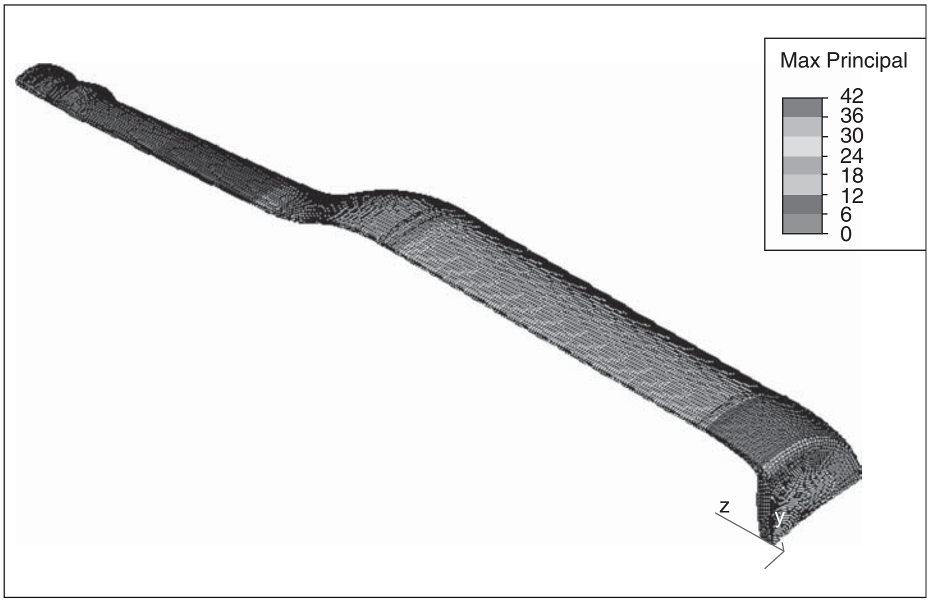

Figure 9. Internal pressure stress indices in a 12-oz long-neck beer bottle (psi/psi).

and extends upward into the shoulder. The other band is at the heel contact and it extends into the lower heel. Since the results in Figure 10 are indexed, the total stress can be determined by multiplying the index values by the expected top loads. In the case of the capper, the indices are multiplied by the total capping force. In the case of warehouse storage, the indices are multiplied by the enhanced stacking force. The strength criteria are determined from the durations of the loads and locations on the bottle. Thus, one analysis is quickly turned into two evaluations. Again, acceptable performance is determined by ensuring that the stress levels do not exceed the expected strengths in the various areas of the container.

An example of where the stresses are not axisymmetrically distributed is shown in Figure 11, where an impact is delivered to the heel contact of a supported 12-oz long-neck beer bottle. In this case, a three-dimensional model with quarter symmetry is employed due to the bottle and loading conditions. There are three types of stress generated during an impact (14). The first and by far the largest are the contact or Hertzian stresses. These stresses are localized and created on the outer surface at the impact site. They are mainly dependent on the hardness and geometry of the contacting object (15). The second highest stress is the flexure stress, which occurs on the inside surface at the impact site. These stresses are also localized and become more of a performance-related issue with NNPB or Press & Blow ware due to the lower inside surface strengths. The third and lowest of the three stresses are the hinge stresses as shown in the figure. They occur on the outer surface and away from the impact site. For the heel impact, there are hinges on either side of

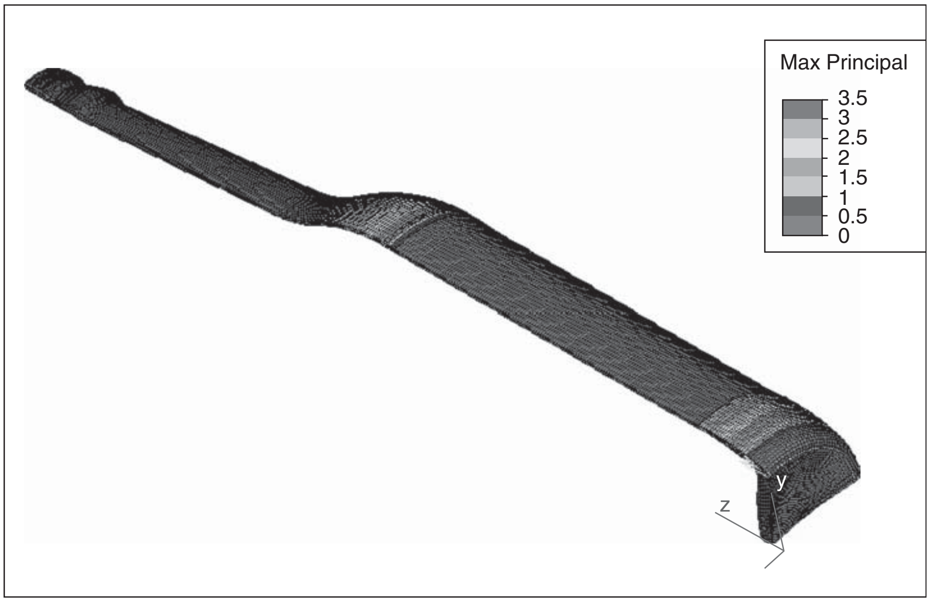

Figure 10. Vertical load stress indices in a 12-oz long-neck beer bottle (psi/lb$_f$).

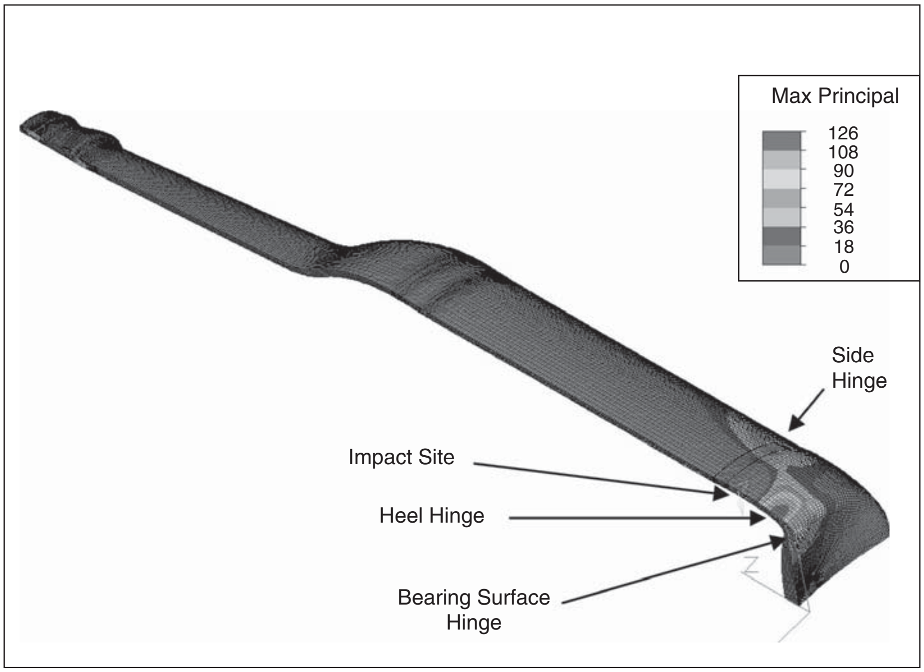

Figure 11. Heel impact stress indices in a 12-oz long-neck beer bottle (psi/ips).

the impact site. There are also heel hinges that occur directly beneath the impact site, which often extend downward into the bearing surface where the surface strength are lower.

As shown in Figure 11, the results are also indexed. However, the unit force is taken as a unit striking velocity, where the results are expressed for a filled bottle striking a rigid object. As such, the performance of the bottle is measured against a severe trade impact. The maximum striking velocity that filled containers can survive is then determined by dividing the expected impact strengths by the various stress indices for the severe impact loading. Such information is useful in selecting belt speeds and equipment settings in the handling and transport of the ware. Alternatively, if the transport velocities in a filling line are known, the total stresses generated in the filled bottle subjected to a severe impact can be determined by multiplying the stress indices by the line velocity. Again, acceptable performance is determined by ensuring that the stress levels do not exceed the expected strengths in the various areas of the container.

Obviously, total performance is dependent on the individual performances for the various loading conditions. To ensure that the design will be a safe package for the consumer, the stresses generated for all of the various loads at all locations in the bottle must be less than the expected surface strengths associated with the glass bottle. If any of the stresses equal or exceed the surface strengths, the entire design is then considered questionable or unacceptable until all of the performance criteria are met for the expected usage. Modifications to the design are then necessary to lower the stresses into an acceptable range. This may involve adjusting the thickness distribution by moving glass into more sensitive regions without changing the glass weight. It may involve altering the shape of the shoulder or heel of the bottle without violating the theme of the package. Finally, the suggested or targeted weight may simply be insufficient, and additional glass has to be added to the design. Whatever approach is taken, the goal is still to offer the consumer an appealing and safe container package.

MODIFICATIONS

Failure to meet a performance requirement is no reason to abandon a design. One of the advantages of computer modeling is the ease and quickness of changing a design. However, to utilize the efforts of marketing research in developing the look and feel of the concept design, changes must be made thoughtfully so that the theme or flavor of the design, which is often used for brand recognition, is maintained. Consider the changes made to the Michelob bottle as shown in Figure 12. When viewed together, the changes may not appear as modest; however, these design changes occurred over a 30-year span. However, during that time, 127 g of glass were removed from the original design, making today's bottle a true lightweight. Even at a lighter weight, the design has better performance characteristics than the original design due to computer modeling and evaluation. It is worth noting that the shape still exhibits the long tapered neck and pinched waist associated with the original Michelob bottle style.

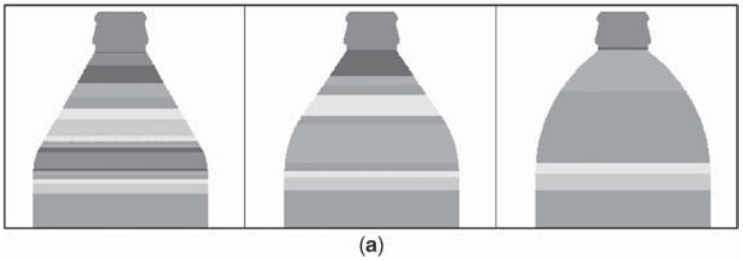
Obviously, all designs cannot afford 30 years to evolve into high-performance lightweight bottles. With markets and tastes rapidly changing, responses must be quick and direct. The quickest approach to improve a design's performance is to shift glass into sensitive regions without changing the total glass weight. No changes are required to the outer surface, leaving the theme of the design untouched. By keeping the weight fixed, there are no changes to overflow capacity or head space with only

Figure 12. Evolution of the Michelob bottle.

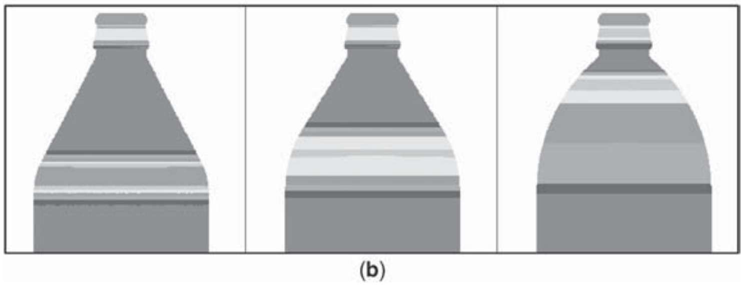
slight changes occurring in the center of gravity and tip angle. This obviously requires removing glass from other areas of the container. In many designs, the bases are under designed while the upper shoulder and neck regions are over designed. Thus, shifting glass from the neck and shoulder regions into the base is often recommended. In fact, a study by Davis and Shott showed that the shift in glass into the lower heel region is one of the best ways to enhance the pressure performance of lightweight glass bottles (16).

Improvements to the performance of a design can also be achieved by changing its shape. However, in many instances, shape changes in the design can lead to compromise. For example, the effect of increasing the contact radius of a simple shoulder design is shown in Figure 13 where the conical shape is transformed into a rounded or bulb-like design. The stress distribution plots in the upper half of the figure show that for internal pressure, stress at the shoulder contact increases with increasing shoulder contact radius. Also, the maximum stress in the shoulder region decreases as the shoulder contact radius increases. If the shoulder contact stress is too high, reducing the radius will help lower its value. Keep in mind that as the shoulder contact radius is reduced, the maximum stress in the shoulder is also increasing. Thus a compromise may be needed on the radius change in order to maintain both levels of stress in an acceptable range.

There may be other compromises to consider. The results for the same shoulder contact radius changes for vertical loading are shown in the lower half of the figure.

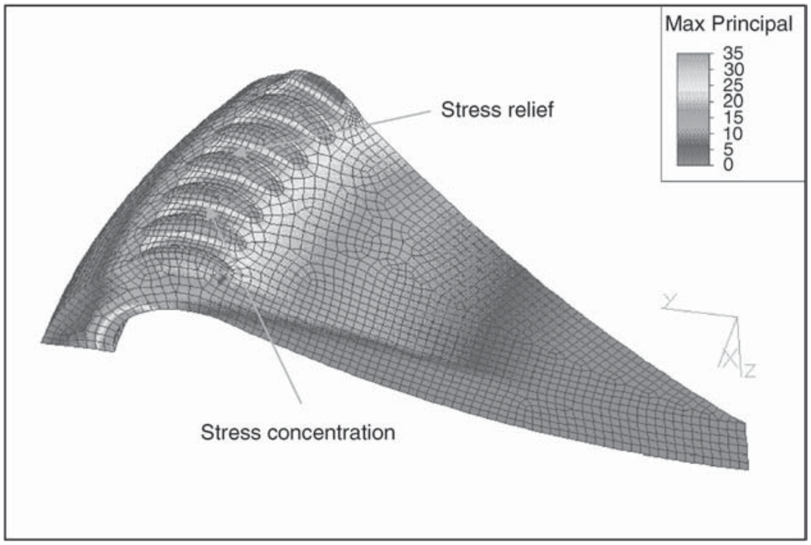


(a)



(b)

Figure 13. Effect of shoulder shape on bottle performance: (**a**) Internal pressure (4–18 psi/psi) and (**b**) vertical loading (0–1.4 psi/lb).



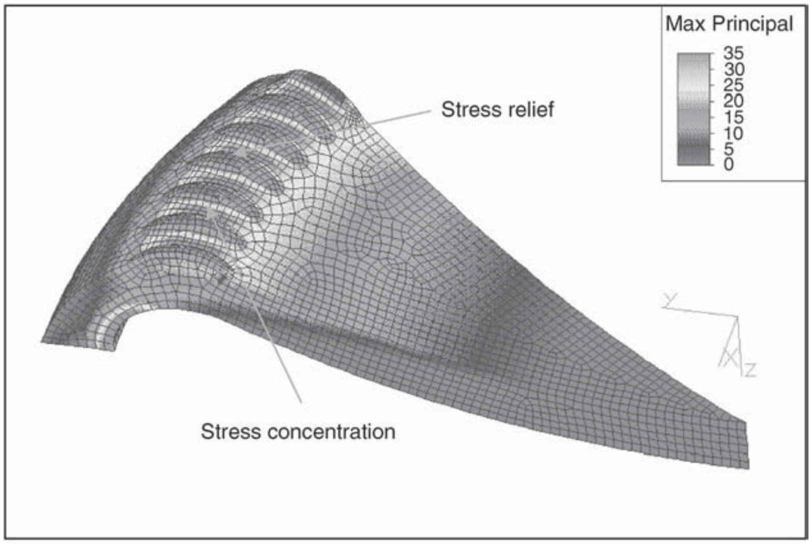


Figure 14. Effect of bearing surface knurling on bottle performance (psi/psi).

These results are opposite to those found for internal pressure loading. As the shoulder contact radius increases, the stress at the shoulder contact decreases while the maximum stress in the shoulder region increases. Thus, while making shape changes to the design, it is important to consider the effect of any shape change on the stresses created by all of the applied loads, thus preventing the introduction of a new issue while attempting to resolve another. Similar compromises may be required when altering the push-up, heel contact height or toe-in of the design.

Lightweighting is perhaps the most important innovation in keeping glass packaging competitive. The rules for performance of lightweight designs are no different; stresses generated from the applied forces must not exceed the surface strengths. However, as glass is removed from the design, the stresses will increase with decreasing wall thickness and there will be a limit to lightweighting when the surface strengths of the bottle are exceeded. Additional lightweighting can only then be achieved by reducing stresses and/or increasing design strengths. Attempts have been made to increase strengths by tempering glass bottles (17) or enhancing the surface strengths with acrylate coatings (18).

The design strength can also be enhanced through creative design methods. Since the design strength is dependent on the degree of handling abuse, containers can be designed to focus the handling damage to lower stressed regions and protect the higher stressed regions from handling abuse. Including recessed label panels in a bottle design will help protect both the label and the sidewall from normal bottle-to-bottle handling damage. Having a higher design strength in the sidewall paves the way for removing glass in this region. In fact, the most efficient place to remove glass is from the sidewall. The recessed label panel also focuses any handling damage at the shoulder and heel touch points where the stresses decrease with increasing label panel depth (19). Also, including knurling on the bearing surface in the design concentrates any handling damage to the knurl tips. The knurls act as stress relievers, exhibit lower stresses, and protect the base glass from becoming damaged (see Figure 14).

CONCLUSION

The glass container industry has come a long way since the wake-up call of the 1970s. Following an initial decline in the market, the industry has stabilized. In fact, the industry has been steadily growing (1). Today, nearly 300 billion containers are produced worldwide on an annual basis. This is due in part to the numerous new designs and markets. However, a weight reduction of more than 30% in the past 20 to 30 years has led glass packages to be economical and competitively priced. The task of achieving lightweight containers was not straightforward, and many factors had to be taken into consideration. Investments into technology for improved melting, forming, and coating were required. This provided larger and more efficient furnaces. Larger and faster IS forming machines that utilized the NNPB technology replaced the smaller, less efficient machines. Improvement to the surface treatment technology provided higher design strength. Investments into new equipment, plants, and warehouses were necessary. However, it is unlikely that the successes in the glass container industry could have been achieved without the understanding of the importance of design on performance.

ACKNOWLEDGEMENTS

HAZARD ANALYSIS AND CRITICAL CONTROL POINTS

Barbara Blakistone

ORIGIN AND HISTORY OF HACCP

Concepts underlying the Hazard Analysis and Critical Control Point (HACCP) system originated in the 1960s to establish risk in quality assurance systems of the National Aeronautics and Space Administration (NASA) (1). The concept was presented to the public at the 1971 National Conference on Food Protection (1, 2). The Pillsbury Company, in response to the food safety requirements imposed by NASA for space foods produced for manned space flights, pioneered using HACCP principles for food protection and published the first text on the subject in 1973 (3). While interest was strong in the early 1970's, HACCP was not widely incorporated into the food industry, in part due to lack of guidance and difficulties industry encountered in implementation. The 1970s were a decade of trial, error, and debate between the regulatory agencies and industy. However, in 1985 a Subcommittee of the Food Protection Committee of the National Academy of Sciences (NAS) resolved the frustrations of all with a report (*An Evaluation of the Role of Microbiological Criteria for Foods and Food Ingredients*) that included a strong endorsement of HACCP as a preventive system for control of microbiological hazards (4). As a result of this recommendation, the National Advisory Committee on Microbiological Criteria for Foods (NACMCF) was formed in 1987 to advise the Secretaries of Agriculture, Commerce, Defense, and Health and Human Services (5). In 1989 NACMCF published its first major document eventually entitled *HACCP Principles for Food Production* (6), which was updated in 1992 and published as an article with the title "Hazard Analysis and Critical Control Point System" (7). Another revision of the document took place in 1997, and the document was published in 1998 as an article with the title "Hazard Anlaysis and Critical Control Point Principles and Application Guidelines" (8).

The NACMCF documents have formed the basis for HACCP application in the United States. On the international level, the Codex Alimentarius Committee on Food Hygiene has worked in concert with the NACMCF to develop HACCP principles and guidelines for application worldwide. In 2003, Codex adopted the latest version of its HACCP document (9), which shares many similarities with the 1997 NACMCF document. The NACMCF documents were used by the USDA Food Safety and Inspection Service (FSIS) in promulgating HACCP regulations for meat and poultry products (10) and by the Food and Drug Administration (FDA) in promulgating HACCP regulations for seafood products (11) and for juice products (12).

The first commodity to be regulated by HACCP was seafood based on final regulations published in the Federal Register on December 18, 1995, which became effective on December 18, 1997. The regulations require processors of fish and fishery products to have on file a HACCP plan for their operations. Based on the final regulations, FDA publishes *Fish & Fishery Products Hazards & Controls Guidance* every two to three years (13). A new Seafood Hazards Guide is expected in 2008 which will include a number of additions and modifications, a few of which are expected to be:

- Addition of a chapter on post-harvest processing technologies (i.e., hydrostatic pressure, Individually Quick Frozen (IQF) with extended cold storage, mild heat, and irradiation) affecting pathogen survival in mollusks.
- Information will be detailed on time–temperature indicators (TTIs) and how they must function.
- Implementation of HACCP comments from the Seafood HACCP Alliance for Education and Training based on their program for the seafood industry and federal, state, and local inspectors.
- More guidance on how to address allergens.
- Recommendations on calibration of temperature-sensing devices.

HACCP CONCEPT

HACCP is a preventive system for assuring the safe production of foods. It is based on a common-sense application of technical and scientific principles to the food production process and system of distribution. The principles of HACCP are applicable to all phases of food production, including basic agriculture, food preparation and handling, food processing, food packaging, food service, distribution systems, and consumer handling and use.

The most basic concept underlying HACCP is the prevention of occurrence of hazards rather than the inspection of finished products for the hazards. A grower, processor, or distributor, when they have gathered sufficient information concerning that segment of the food system, should be able to locate where and how a food safety problem may occur. If the "where" and "how" are known, prevention is simplified. A HACCP program deals with control of food safety hazards originating from the ingredients, product processing, and packaging. The goals of the program are to make the product safe to consume *and* be able to prove that the product presents minimum risk to consumers. The where and how are included in the *HA* (hazard analysis) part of HACCP. The focus on control of processes and conditions is included in the second

Table 1. Examples of Chemicals Used in Food Production and Processing

Point of Use	Types of Chemicals
Growing crops	Pesticides, herbicides, defoliants
Raising livestock	Growth hormones, antibiotics
Production	Food additives, processing aids
Plant maintenance	Lubricants, paints
Plant sanitation	Cleaners, sanitizing agents, pesticides
Packaging	Adhesives resins, surfactants, defoaming agents, slimicides, polymers

principle of identifying the *CCP* (critical control point). Documentation and verification are integral to hazard analysis and establishing CCP. Flowing from this basic concept, HACCP is simply a methodical and systematic application of the appropriate science and technology to plan, control, and document the safe production of foods.

HACCP covers three types of potential food safety hazards that could lead to a health risk—biological, physical, and chemical—whether they are naturally occurring in the food, contributed by the environment, or generated by something in the manufacturing process. Chemical hazards will be of primary interest to packagers, although, of course, chemicals are used at numerous points in the food production chain (see Table 1). While these types of chemicals do not usually represent health hazards when used properly, some of them are capable of causing illness or even death when used improperly. Another potential hazard of interest to packagers is a physical hazard such as glass shards associated with the use of glass bottles as packaging.

PRINCIPLES OF HACCP

NACMCF (8) recommends that the HACCP system should be built upon a solid foundation of prerequisite programs (e.g., Good Manufacturing Practices, Sanitation Standard Operating Procedures, supplier approval program). In preparation for developing an HACCP plan, NACMCF recommends that five preliminary tasks be accomplished to facilitate the application of HACCP principles to a specific product and process. These preliminary tasks are: (a) assemble the HACCP team, (b) describe the food and its method of distribution, (c) identify the intended use and consumers of the food, (d) develop a flow diagram that describes the process, and (e) verify the flow diagram.

According to the NACMCF 1997 document (8), HACCP is a systematic approach to food safety consisting of seven priciples:

Principle 1: Conduct a Hazard Analysis

With information from the preliminary tasks, the HACCP team conducts a hazard analysis to (a) determine significant food safety hazards associated with the product and (b) identify appropriate control mesaures for those significant hazards. The hazard analysis consists of two stages: hazard identification and hazard evaluation. In the hazard identification stage, the HACCP team prepares a list of potential biological, chemical, and physical hazards that may be introduced, enhanced, or controlled at each of the steps in the flow diagram, including potential hazards associated with ingredients and packaging materials. The HACCP team then conducts a hazard evaluation, based on the severity of the potential hazard and its likelihood of occurrence, to determine which of the potential hazards are significant and must be addressed in the HACCP plan. In other words, the hazard anlysis identifies the steps in the process where hazards of potential significance can occur and thus warrants control in the HACCP plan. Table 2 enumerates examples of packaging questions that may be considered during the hazard analysis.

For inclusion in the list of significant hazards and thus the HACCP plan, a hazard must be of such a nature that its prevention, elimination, or reduction to an acceptable level is essential to the production of a safe food (8, 14). Potential hazards that are of a low severity and/or not likely to occur (i.e., low risk potential hazards) would not require further consideration when developing the HACCP plan. Low-risk hazards, however, should not be dismissed as insignificant to the operation and may need to be addressed by other means, for example, by the total quality management (TQM) team.

The HACCP team must then consider what control measures, if any, exist that can be applied for control of each significant hazard. If a significant hazard is identified in the hazard analysis but no control measure exists in the process, the HACCP team must modify the process and product so that a control measure can be applied. Control measures are physical, chemical, or other factors that can be used to control an identified significant health hazard. More than one control measure may be required to control a specific hazard. More than one hazard may be controlled by a specified control measure. Potential chemical hazards

Table 2. Examples of Packaging-Related Questions to Be Considered in a Hazard Analysis

Does the method of packaging affect the multiplication of microbial pathogens and/or the formation of toxins?
Is the package clearly labeled "Keep refrigerated for safety" if this is needed for safety?
Does the package include instructions for the safe handling and preparation of the food by the end user (e.g., validated cooking instruction)?
Is the packaging material resistant to damage, thereby preventing the entrance of microbial contamination?
Are tamper-evident packaging features used?
Is each package and case legibly and accurately coded?
Does each package contain the proper label?
Could the packaging materials contribute any potential physical hazard (e.g., glass) to the product during processing?
Could the packaging materials contribute any chemical compound to the product that may make the product unsafe to consume?

applicable to packaging that the HACCP team may consider during the analysis include the inks, indirect additives, and prohibited substances in packaged ingredients and packaging materials if the intended use is food packaging. The points of control may be, for example, prior to receipt, and the control measures may be compliance with specifications, letters of guarantee, vendor certification, and/or approved uses listed in the Code of Federal Regulations. In a food plant producing canned salmon, a significant biological hazard is a pathogen such as *Clostridium botulinum* in the salmon. Retorting (a point of control) using the appropriate scheduled process is a control measure that can be used to eliminate the pathogen hazard. In the packaging step (a point of control), proper double seaming will prevent recontamination of the product with potential pathogens from the processing plant environment, as well as during distribution, storage, and retail and in the consumer's home. The control measure is forming a proper double seam to prevent leakage and recontamination.

Principle 2: Determine the Critical Control Points (CCPs)

A *critical control point* is defined as a step in the process at which control can be applied and is essential to prevent or eliminate a food safety hazard or reduce it to an accpetable level. The HACCP team determines CCPs based on the outcomes of the hazard analysis. An ideal CCP has the following characteristics: (a) critical limits that are supported by scientific data from research and the technical literature; (b) critical limits that are specific, quantifiable or otherwise measurable, and provide the basis for a yes/no decision on acceptability of product; (c) technology for controlling the process at a CCP that is readily available and at reasonable cost; (d) adequate monitoring (preferably continuous) and automatic adjustment of the operation to maintain control; and (e) historical point of control. All significant hazards identified by the HACCP team during the hazard analysis must be addressed with at least one CCP.

Examples of CCPs may include cooking, chilling, acidification, packaging of processed foods, labeling, specific sanitation procedures, product formulation control, prevention of cross-contamination, and certain aspects of employee and environmental hygiene.

Principle 3: Establish Critical Limits

A *critical limit* is defined as maximum and/or minimum value to which a biological, chemical, or physical parameter must be controlled at a CCP to prevent, eliminate, or reduce to an acceptable level the occurrence of a food safety hazard. As HACCP evolves, a critical limit can also include the presence of an attribute that is not necessarily a quantitative value (e.g., products passing through a functioning metal detector). Each CCP will have one or more control measures that must be properly controlled to assure prevention, elimination, or reduction of hazards to acceptable levels. Each control measure has associated critical limits that serve as boundaries of safety for each CCP. Critical limits may be set such as temperature, time, physical dimensions, sealing conditions, humidity, moisture level, water activity (a_w), pH, titratable acidity, salt concentration, available chlorine, viscosity, presence or concentration of preservatives, and sometimes attributes such as presence of an intact screen of appropriate pore sizes and a functioning metal detector with appropriate sensitivity (14). Critical limits may be derived from sources such as regulatory standards and guidelines, literature review, experimental studies, and experts. The food industry is responsible for engaging competent authorities to validate that the critical limits will control the identified hazard.

Canning operations offer an example of a critical limit for packaging. The Low Acid Canned Food Regulations (Title 21, Code of Federal Regulations Part 113) require that cans should be examined for presence of visual defects, and cans should be periodically removed from the line and torn down to verify that can seam measurements are within specifications (15). If the HACCP team determines that recontamination of product by pathogens due to seam defect and leakage is a hazard reasonably likely to occur after retoring, then a control measure must be identified to address the hazard, for example, in the form of proper seams on cans to protect consumers from foodborne illness, and a CCP would be established at the sealing machine. The monitoring activities are the visual observation and the seam teardown and double-seam measurements. The seam measurement would be compared to the minimum acceptable dimensions (critical limits) specified by the container supplier. Another example of a critical limit is the time and temperature for the retorting of canned salmon. At the retorting CCP, the process must be designed to eliminate the heat-resistant spore-forming pathogen, *Clostridium botulinum,* which is reasonably expected to be present in the incoming raw salmon. Technical development of the appropriate critical limit(s) requires accurate information on the operation of the retort, heating rate of the product, and heat resistance of *Clostridium botulinum*.

A partial hazard analysis for canned salmon is shown in Table 3, which also illustrates how the first three principles of HACCP may be documented by the team.

Principle 4: Establish Monitoring Procedures

In the monitoring process a planned sequence of observations or measurements is conducted to assess whether a CCP is under control and to produce an accurate record for future use in verification. Monitoring serves three main purposes:

1. Monitoring is essential to food safety management in that it tracks the operation of the system. If monitoring indicates that there is a trend toward loss of control (i.e., exceeding a target level), then action can be taken to bring the process back into control before a deviation from a critical limit occurs.
2. Monitoring is used to determine when there is loss of control and a deviation occurs at a CCP–that is, exceeding or not meeting the critical limit. When a deviation to a critical limit occurs, corrective action must be taken.
3. Monitoring provides written documentation for use in verification of the HACCP plan.

Table 3. Partial Hazard Analysis, CCP and Critical Limits for Canned Salmon[a]

Critical Control Point (CCP)	Hazard(s) to Be Addressed in HACCP Plan	Control Measures	Critical Limits
Processing—processes designed to provide commercial sterility	*C. botulinum*	Retorting	Minimum 250°F for 3 min for product Other critical factors as specified by processing authority
Sealing of containers[b]	*C. botulinum* due to recontamination[c]	Creating and maintaining hermetic seal	No visible cutovers, seam sharpness, false seams, deadheading, product overlapping the flange, product leakage, or other visual defects Cover hook: minimum 0.70 in., body hook 0.072–0.088 in.; width: maximum 0.125 in.; thickness 0.052–0.058 in.; tightness minimum 70%
Cooling of containers—applies to water-cooled cans only	Pathogens due to recontamination	Chlorination	Measurable residual chlorine at discharge

[a] *Note*: The partial HACCP plan in this table is for illustrative purposes only and it is not intended to replace the processor's hazard analysis and HACCP plan development.

[b] Source for crticial limits at this CCP: FDA's *Fish and Fishery Products Hazards and Controls Guidance*, 3rd edition (June 2001), except that the tightness value (i.e., the percent of the cover hook that is free of wrinkles) is based on an industry guideline.

[c] Some processors may conclude in their hazard analysis that recontamination with *C. botulinum* due to can defects is a hazard likely to occur in the absence of control, in light of at least two botulism outbreaks associated with recontaminated canned salmon. In this case, critical limits are established for the CCP at the sealing step to control the hazard.

Examples of monitoring activities include:

- Visual observations
- Temperature
- Time
- pH
- Moisture level
- Can teardown and seam dimensions

Principle 5: Establish Corrective Actions

The HACCP system for food safety management is designed to identify health hazards and to establish strategies to prevent, eliminate, or reduce their occurrence. However, ideal circumstances do not always prevail, and deviations from established processes may occur. Corrective actions are designed to prevent products that may be hazardous from leaving the process facility. When monitoring indicates that there is a deviation from an established critical limit, corrective actions must be taken. The first step is to bring the process and the CCP under control by determining and correcting the cause of noncompliance. Second, put all product on hold until determination has been made on the safety of the product to facilitate appropriate product disposition. A third component is to prepare records that document the corrective actions taken. Because of the diversity of possible deviations in a food process, specific corrective action procedures cannot always be developed for every incident. However, a plan should be developed that addresses the process, the product, and the recordkeeping components, with procedures developed in advance for those deviation scenarios that are likely to occur or are expected. The actions taken must demonstrate that the CCP has been brought under control. Individuals who have a thorough understanding of the process, product, and HACCP plan are to be assigned responsibility for taking corrective actions. The corrective action plan should be documented in the HACCP plan.

Principle 6: Establish Verification Procedures

Verification is defined as those activities, other than monitoring, that determine the validity of the HACCP plan and that the HACCP system is operating according to the plan. Monitoring is a distinct activity from verification. For example, verification may be calibration of a thermometer once per day while an example of monitoring is continuous chart recording of the temperature of the scheduled process. The NAS (4) pointed out that the major infusion of science in a HACCP system centers on proper identification of the hazards, critical control points, critical limits, and instituting proper verification procedures. An example of a verification activity is the scientific or technical process to ensure that critical limits at CCPs are adequate and effective. This is sometimes referred to as *validation* of the HACCP plan. Verification activities should take place during the development and implementation of the HACCP plan (14). There are a few aspects involved in the verification process. An important aspect of verification is the initial validation to determine that the HACCP plan is scientifically and technically sound and that the HACCP plan, when properly implemented, will be effective in controlling food safety hazards. The validation process ensures that the HACCP plan in the facility is functioning effectively. Another aspect of verification is evaluating whether the HACCP system is implemented according to the HACCP plan. This aspect includes ongoing verification of CCPs that involves evaluating that day-to-day compliance of the monitoring and other activities specified in the HACCP plan at each CCP as well as a periodic HACCP system compliance audit. A third aspect of verification consists of periodic validations or reassessments, independent of audits or other verification procedures, that must be performed to ensure the accuracy and adequancy of the

HACCP plan. A fourth aspect of verification deals with the government's regulatory responsibility and actions to ensure that the HACCP system in the facility is functioning satisfactorily. FSIS and FDA conduct risk-based inspections of facilities producing meat and poultry products and seafood and juice products, respectively, which include verification of the HACCP plan.

Principle 7: Establish Record-Keeping and Documentation Procedures

Record-keeping provides written confirmation of the hazard analysis, the HACCP plan, and the implementation of the HACCP plan. HACCP records provide written data for review, and records must be maintained for the required period of time. Well-maintained records substantiate that the HACCP plan is being followed and that requirements in the HACCP plan are being met during production; HACCP records help document the safety of the products being produced.

The approved HACCP plan and associated records must be on file at the food establishment. Generally, HACCP records include the following:

1. Summary of the hazard analysis.
2. The HACCP plan. NACMCF (8) recommends that HACCP plan records include:
   a. A list of the HACCP team and assigned responsibilities.
   b. A description of the product, its distribution, intended use, and customer.
   c. A verified flow diagram for the manufacturing process with CCPs indicated.
   d. A HACCP plan summary table that contains information tabulated in Table 4, including the CCPs, the hazards to be addressed in the HACCP plan at each CCP, critical limits, monitoring procedures, corrective action plan, verification procedures, and record-keeping.
3. Supporting documentation.
4. Daily operational records.

HACCP AND PACKAGING

HACCP plan requirements in the manufacture of packaging materials cannot be known until a hazard analysis has been conducted. Methodical steps of the HACCP process will prove most helpful in assessing the safety versus the quality needs of the manufacturing plant. The supplier may need records for its buyers that such an assessment has been conducted even if no hazards have been found during the hazard anlysis. Critical steps in quality may come under different programs—for example, ISO. Grocery Manufacturers Association and the National Fisheries Institute favor interpreting HACCP as a program that focuses only on food safety hazards. Thus, in the case of milk carton manufacture, paperboard stock is

Source: Scott and Stevenson (14).

required by the Pasteurized Milk Ordinances (16) to have no more than 50 bacterial colonies per 8 square inches. By our interpretation, this would be a quality specification and not a HACCP CCP, if historical data show that these are spoilage microorganisms rather than pathogens that are likely to cause illness.

End use of the packaging materials may lead to an exception to the above rule that HACCP is not needed in package manufacture. Some examples follow:

- Active packaging is now a very viable area of research, and much of that research has focused on incorporating into the material types of antimicrobials that are efficacious against microorganisms. If such a compound/product is used in commercial packaging and is itself an allergen to some populations, the labeling step may become a CCP, if the HACCP team concludes in their hazard analysis that the undeclared allergen is a hazard likely to occur. In this case, the CCP is the label, the hazard is the undeclared allergen, and the critical limit is the proper notation on the label with visual monitoring by the label operator or label scanner for the correct label each time the labels are loaded. In some cases, the HACCP team may conclude that the hazard of an undeclared allergen is not reasonably likely to occur due to a labeling prerequisite program in place; in this case, no CCP would be needed.
- Gas combinations in modified atmosphere packaging (MAP) may also prove critical in outgrowth of pathogens because oxygen concentrations below 2–3% allow or enhance the growth of anaerobic organisms such as *Clostridium botulinum*. Oxygen concentration would be a CCP in the MAP-packaging of mushrooms where growth of *Clostridium botulinum* is a hazard reasonably likley to occur, for example. A special case in fresh seafood packaging is vacuum packaging. As noted in the Seafood Hazards Guide (13), packaging material with an oxygen transmission rate (OTR) of 10,000 cc/m^2/24 h has permeability sufficient to allow aerobic spoilage to occur before toxin can be produced. Selection of proper gas combinations and OTRs are CCPs in the cases of certain commodities, where growth of anaerobic pathogens such as *Clostridium botulinum* is a hazard reasonably likely to occur in the absence of control.

SUMMARY

HACCP is a systematic approach to assuring the safety of food products based on the concept of prevention. The HACCP program is widely used in the food industry in the United States as well as worldwide. Although the seven HACCP principles are well-developed and application guidelines have been developed and revised based on experience gained during HACCP implementation in the last several decades, there is no universal formula for putting together the specific details of a HACCP plan. The plan must be specific to each facility and be dynamic, allowing for modifications to production, substitution of new ingredients and new materials (including specialized packaging materials and packaging steps), and development of new products. The plan is participatory at all levels of management, both in formulating and managing the plan. The strength in an HACCP program is in providing a risk management framework that a company can use effectively to organize and manage the safety of the products which are produced.

HIGH-VOLTAGE LEAK DETECTION (HVLD) TECHNIQUE FOR HERMETICALLY SEALED PACKAGES

Yoon S. Song
United States Food and Drug Administration, Office of Food Safety (OFS), Process Engineering Branch,
Summit-Argo, Illinois

INTRODUCTION

High-voltage leak detection (HVLD) is one of the emerging technologies for inspecting package defects and tampering. HVLD operates by applying a high-voltage potential to electrically conductive products inside non- or semiconductive package materials. Pinholes are identified when electrical discharges are detected between products and device electrodes. The HVLD system with different frequencies has been successfully validated and used for years to test the integrity of glass ampoules and vials in the pharmaceutical industry (1, 2) and recently was introduced into the food industry within the United States. It has been demonstrated that this detection system is a powerful tool to detect pinholes in vacuum pouches containing frankfurters. Therefore, the applicability of this high-voltage technique to various containers of different types and compositions is of great interest to the industry.

PRINCIPLES

The HVLD system is composed of four unique elements: high-voltage power generator, support electrode, inspection electrode, and a detector (Figure 1). The power generator subjects the outside of a test package to a certain predetermined high voltage (0.1–25 kV). In typical HVLD systems, a package wall is nearly nonconductive and thus can be regarded as the dielectricum of a condenser. When high voltage is applied to the support electrode on which a test package is placed, it electrifies product particles inside the package. While high voltages are applied, the surface of a test package is scanned with an inspection electrode as shown in Figure 2. In the presence of a leak, electrons are discharged through the hole. The detector can then measure current and/or voltage discharges through the inspection electrode. A data acquisition system in connection with an oscilloscope is used to measure voltage or current profiles discharged from a package. When voltage discharges are measured, V_{10} (kV) value, a high-voltage applied to the supporting electrode when voltage discharge measured from the inspection electrode exceeds the threshold value of 10 V,

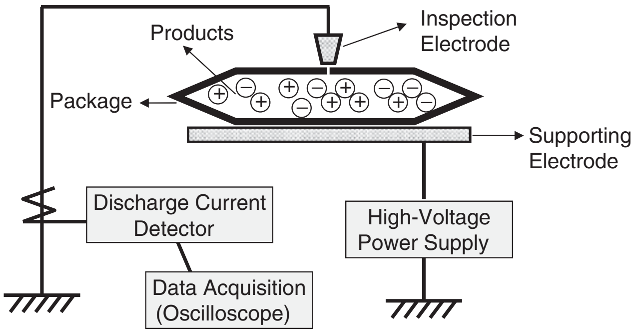

Figure 1. Schematic diagram of HVLD system setup.

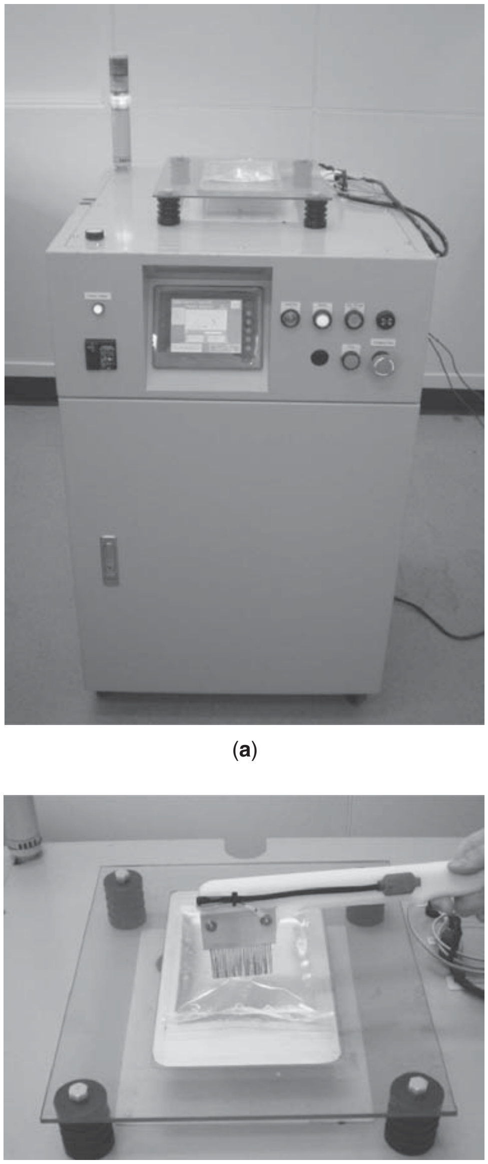

(a)

(b)

Figure 2. (**a**) The front and (**b**) top views of the Type-JH manual HVLD unit (see text for explanation of operation).

can be used as an indication of the detection. When discharge current is monitored, the ability of the HVLD to detect a leak is largely dependent on the gain setting. With the gain control, a minimum current measured at a constant high voltage applied can be adjusted and optimized to within a measurable range to accommodate the most important factors that could influence the detection limit during a leak test.

FACTORS OF INFLUENCE

The ability of the HVLD system to detect leaks can be dependent upon various factors of product, package, and defect. Jain and Song (3, 4) conducted a set of experiments to evaluate the significance of various processing variables on detection of pinholes in flexible pouches using a manual HVLD unit (Model DCC-1-AC, Jovan Electronics Corp., Japan) (Figure 2). Several critical variables, such as thickness (2.5, 4.5, 6.0 mil), structure (plastic, paper and metallized laminates), height (0.3, 0.7, 1.1 in. from a top of the support electrode where a package is placed on), contact surface area (5, 11, 22, 33 in^2), and dielectric constant (ε) (1.63, 1.87, 2.01, 2.34) of pouches, volume (100, 200, 300 mL), electrical conductivity (κ) (0.7, 1.5, 8.5, 10.8 mS/cm), and type (liquid, semisolid (10% pectin), solid (0.85A_w pectin)) of model products, and location (0, 1.9, 3.7 in. from a package center) and diameter (10, 20, 30, 40, 50 μm) of laser-drilled pinholes, were tested.

Effects of the critical variables on detection of 50-μm pinholes in polypropylene (PP)/Nylon/PP laminated pouches containing liquid model products are presented in Figures 3 and 4 (3). In general, the greater the contact surface area of packages and the higher the electrical conductivity of products, the voltage required to detect package defects is lower ($p < 0.05$). The statistical analysis of data revealed that height and dielectric constant of packages, product volume, and defect location were not significant factors affecting detection by the HVLD unit within the ranges tested ($p > 0.05$), but HVLD responses were significantly affected by thickness and surface area of packages and by electrical conductivity of products ($p < 0.05$). Results from a full factorial design experiment with two levels and four factors (surface area, 5 and 33 in.^{2}; film thickness, 2.5 and 4.5 mil; product conductivity, 1.5 and 10.8 mS/cm; pinhole size, 10 and 50 μm) indicated that, among the independent variables, surface area had the most significant effect followed by film thickness, pinhole size, and product conductivity

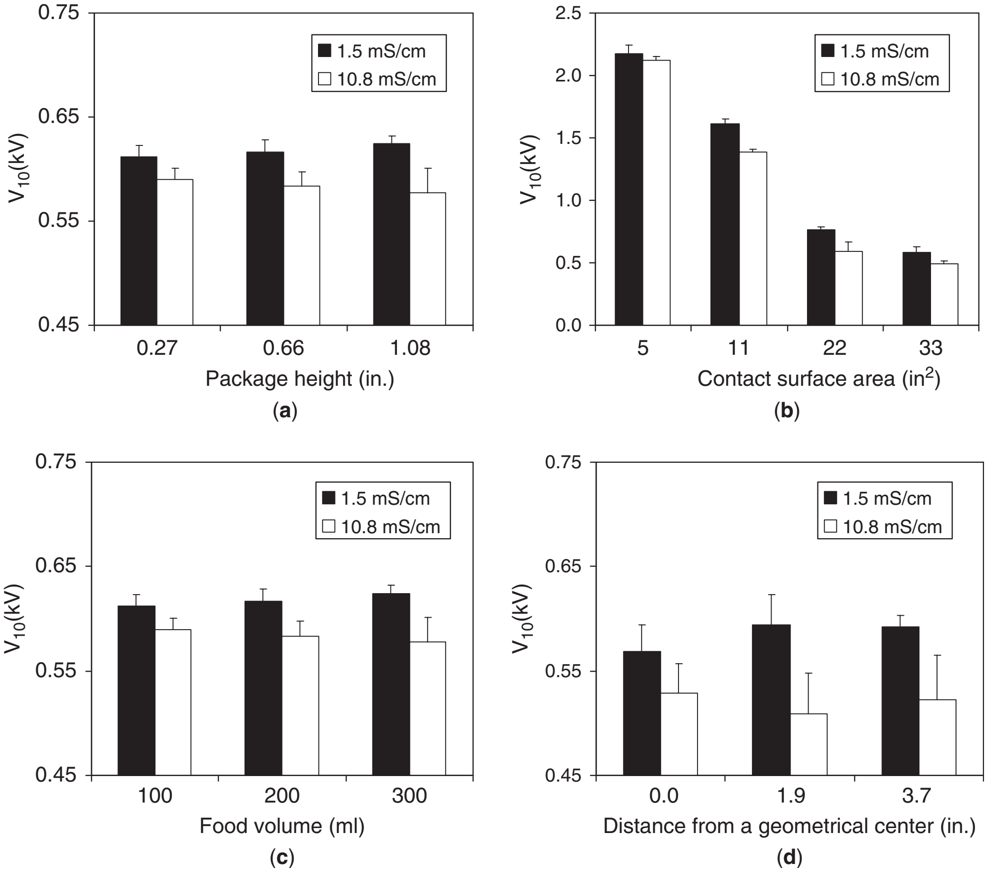

Figure 3. Effects of (**a**) package height, (**b**) package contact surface area, (**c**) product volume, and (**d**) defect location on V_{10} values for PP/nylon/PP laminated pouches ($\varepsilon = 2.01$) with 50-μm pinholes, containing 100, 200, and 300 mL of liquid model products ($\kappa = 1.5$ and 10.8 mS/cm).

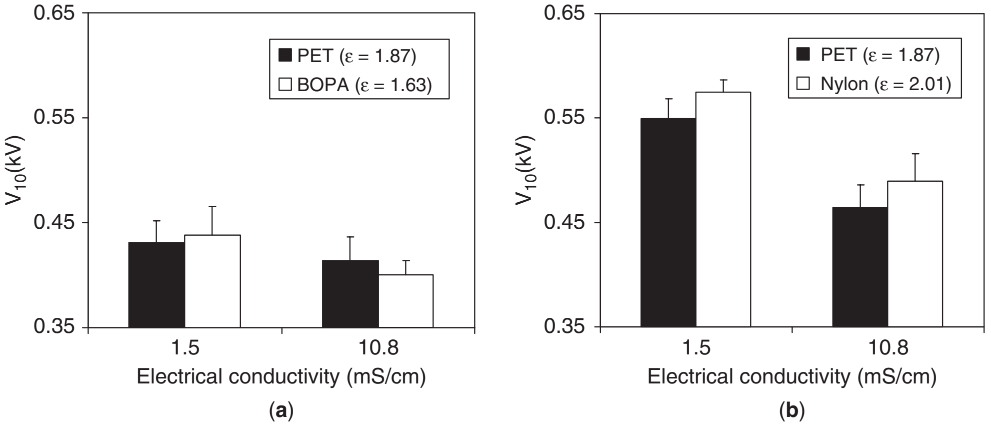

Figure 4. Effects of dielectric constant (ε) and electrical conductivity (κ) on V_{10} values for (**a**) 2.5- and (**b**) 4.5-mil-thick plastic pouches (PET = PET/PE; BOPA = BOPA/PE; Nylon = PP/nylon/PP) with 50-μm pinholes, containing 100 mL of liquid model products.

($p < 0.01$) (4). Strong interactions between those variables were also observed ($p < 0.01$). In particular, two evident interactions—between film surface area and film thickness and between product conductivity and film thickness—contributed to the factorial model at a significant level. HVLD responses to both paper/PP laminated pouches and metallized pouches for different processing variables were comparable with those from plastic laminated pouches containing liquid model products. Similar results were also reported for semisolid and solid model products.

Moll et al. (5) validated the HVLD technique for 100% inspection of low-density polyethylene (LDPE) ampoules by using a fully automated online unit (Model 920-004, Rommelag, Germany). Factors such as detector geometry, electrical conductivity of semisolid model products (7.8–8.5 mS/cm), and wall thickness of ampoules (20–30 mil) were found to be critical in detecting defective ampoules with 5- to 200-μm pinholes. They also suggested that the temperature and relative humidity at the site of testing, along with the speed of conveyor belt carrying ampoules, may have an influence on equipment sensitivity.

LIMIT OF DETECTION

It has been reported that for plastic pouches, the HVLD can detect pinholes as small as 10 μm, even under worst-scenario conditions, such as 4.5-mil film thickness, contact surface area of 5 in.^{2}, and electrical conductivities of 0.7 and 1.5 mS/cm for semisolid and liquid products, respectively (3). Limits of detections for liquid, semisolid, and solid products were 10, 10, and 50 μm, respectively. For metallized pouches, the HVLD can also detect pinholes as small as 10 μm, even under worst-scenario conditions, such as 6.0-mil film thickness, contact surface area of 5 in.^{2}, A_w of 0.85 for solid products, and electrical conductivities of 0.7 and 1.5 mS/cm for semisolid and liquid products, respectively. The limit of detection was 10 μm for liquid, semisolid, and solid products. The HVLD technique can also reliably detect 5- to 10-μm pinholes in LDPE ampoules containing a medium-viscosity hydrogel with conductivity of 7.8 mS/cm (5).

CONCLUSIONS

The HVLD is an innovative testing system for fully automatic detection of package leaks and tampering. It requires that products inside a package be in direct contact with packaging material's surface where the inspection electrode is applied. The site on the package at which leaks and/or tampering have occurred can be instantly and effectively identified when electrical discharges are detected between a product and device electrodes. Due to high voltages applied, however, a defective package may be further damaged, as evidenced by post detection results where 5- to 10-μm pinholes were widened to 50–60 μm (5). The HVLD technique is capable of detecting pinholes less than 10 μm in diameter. Package surface area, thickness and geometry, headspace, product type, and electrical conductivity are parameters requiring testing to determine the necessary system configuration. Parameters that do not appear to be significant barriers to the use of HVLD were height and dielectric constant of package, produce volume, and location of pinhole. It can be concluded that the HVLD technique is a promising nondestructive and online method to detect pinhole defects, which may be applicable to a wide range of hermetically sealed packages.

HOT-FILL TECHNOLOGY

Raymond A. Bourque
Ocean Spray Cranberries, Inc.,
Lakeville, Massachusetts

Food processors use a variety of processing, formulation, and storage methods to assure that food products do not spoil due to microbiological activity throughout their shelf life. Products such as cereals, breads, and confectionaries are formulated with sugars and/or salts to lower water activity (a_w). Water activity below ~ 0.90 will not support the growth of most food-spoilage bacteria (1). Chemical preservatives, such as benzoate or sorbate, are added to many products to inhibit microbiological growth. Many dairy products, fruit juices, fruits, vegetables, meat, fish, and prepared meals are distributed under refrigeration or frozen conditions. Shelf-stable, low-acid foods—such as vegetables, meat, and fish, with a $\text{pH} \geq 4.6$—rely on a thermal process. Thermal processing of low-acid foods is achieved in a retort at pressures of 10–20 psi (7–14 kg/m^2) and temperatures of 240–260°F (116–127°C) (2,3). Food products with a $\text{pH} \geq 4.6$ will support bacteria, yeast, and mold growth. Commercial sterility is defined as the elimination of all microorganisms that can grow and metabolize in a product. To achieve commercial sterility in foods with a $\text{pH} \geq 4.6$, bacteria must be destroyed as well as yeast and mold. The destruction of many bacteria requires temperatures in excess of 212°F (100°C). To achieve temperatures above the boiling point, overpressurization in a retort process is necessary. The high temperature achieved not only destroys micro-organisms in the food but also sterilizes the package. Packages historically used for retorted low-acid foods include metal cans, glass jars, and to a lesser extent, retortable pouches.

High-acid foods with a $\text{pH} < 4.6$ support the growth of yeast and mold but, unlike low-acid foods, only a limited number of bacteria. Yeast, mold, and the types of bacteria that can metabolize in high-acid foods are more temperature-sensitive than those that grow in low-acid foods. Temperatures in the range of 170–200°F (77–90°C) are usually adequate to destroy these microorganisms. Commercial sterility of high-acid food products and the sterilization of the containers in which they are packed is achieved with temperatures of <212°F (100°C). Therefore, retorting with overpressure is not required. High-acid foods are thermally processed in one of three different ways: hot filling, postfill pasteurization, or pasteurization with aseptic filling. This article focuses on hot filling.

HOT-FILL PROCESSING

Foods such as fruit juices, fruit sauces, jams, jellies, tomato sauces, ketchups, and barbeque sauces are often hot-filled. The hot-fill process consists of heating the food product to an adequate temperature to destroy the yeast, mold, and limited types of bacteria that can grow in the food, and then holding the food at that temperature for an adequate time to destroy these microorganisms. The temperatures required range from 170 to 212°F (77–100°C), and the hold times vary from 30 to 60 s depending on the food product. The hot product is then filled directly into the container or package. The headspace in the package may then be nitrogen- or steam-flushed to reduce headspace oxygen. The package is then hermetically sealed and inverted to sterilize the lid or closure. The hot product sterilizes the package. To accomplish package sterilization, the product must be at or above the minimum temperatures [170–200°F (77–93°C)] for an adequate time (usually 1–3 min) (4). Thus, the control points for a hot-fill process are the *minimum fill temperature* and the *minimum hold time* (see Figure 1). Depending on the heat sensitivity of the specific food, the products may or may not be quickly cooled after the minimum hold time is achieved. Cooling is usually accomplished in a water-spray tunnel or immersion bath. Fruit juices and preserves are examples of products that require cooling directly after hot filling to protect product color, flavor, and nutrient content (vitamin C). Barbecue sauce is an example of a product that is not heat-sensitive and can be allowed to cool under ambient conditions after being packed in corrugated shipping containers.

Historically, high-acid products have been packaged primarily in metal cans and glass jars. However, in the 1980s and 1990s, several rigid and flexible plastic packages were developed for hot filling.

TINPLATE CANS

The traditional metal cans used for hot-filled foods are made of tinplate. Some are enameled inside to protect the food from the migration of iron or tin from the can into the food, which may cause a loss of color or off-taste. Other tinplate cans are not enameled inside; these are referred to as plain tinplate cans. The lack of an inside enamel allows the tin to migrate into the product. The color of some canned products, such as white grapefruit juice, is preserved by tin salts. Tinplate cans are also enameled to protect the can itself from the corrosive effects of some high-acid products. High-acid products, such as tomatoes and cranberries, can corrode tinplate cans, which results in perforations and leaking cans. The hot filling of tinplate cans consists of hot-water washing the cans to remove dust or other foreign contamination, hot filling the cans with the high-acid food, flushing the headspace with steam or nitrogen, double-steaming a metal lid onto the can, inverting the can to sterilize the lid, and conveying the hot can for an adequate distance to provide the necessary hold time prior to entering a water-spray cooler. The cans are cooled to approximately 90–110°F (32–43°C). The maximum cooler exit temperature is specified according to the product's heat sensitivity. The minimum cooler exit temperature is established to ensure that the cans are not too cool to prevent the evaporation of remaining water beads. If the can is not warm, then rust will occur, staining the label and distracting from the general appearance of the can. If the can is too cool, then labeling may be difficult as the hot melt used in labeling will set up too quickly, which causes misapplied labels. A vacuum is generated in

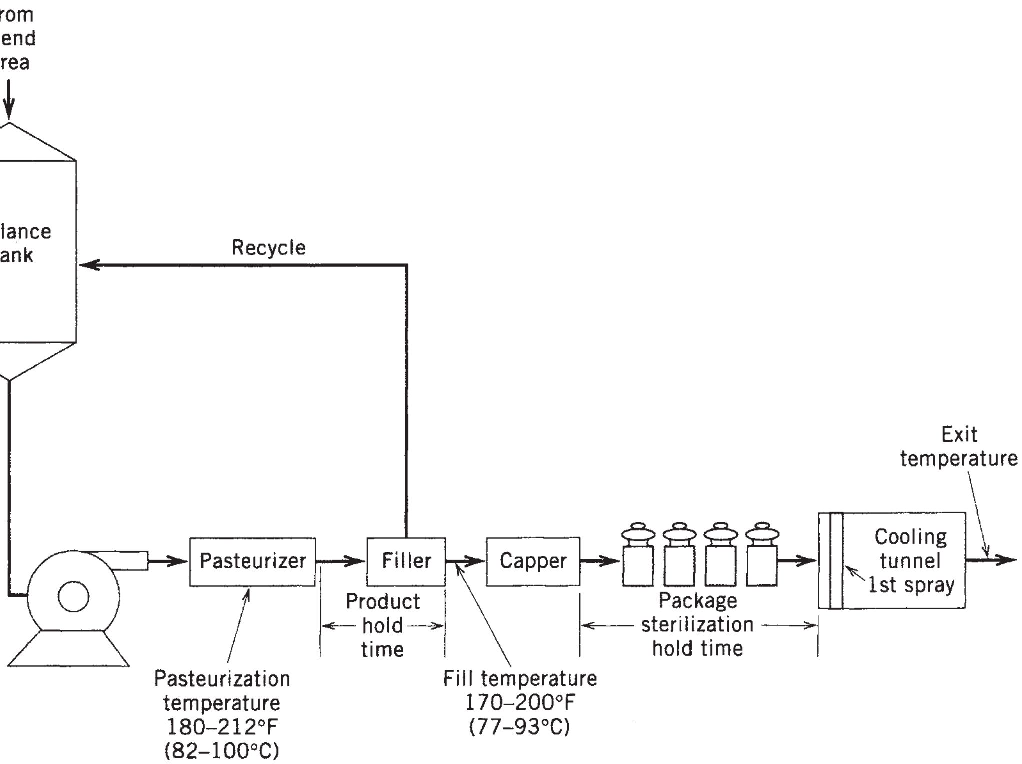

Figure 1. A typical hot-fill process for high-acid food or beverage products.

the can as it cools. The vacuum at the exit of the cooler ranges from approximately 16 to 25 in. of mercury (41–64 cm Hg) depending on the headspace, product density, and size of the can. The vacuum is formed by a combination of the condensation of the steam in the headspace and the contraction of the product as it cools. The vacuum is important as it provides integrity to the can by pulling the ends inward and not allowing them to flex during distribution. The concavity of the end caused by the vacuum also provides visual evidence to the consumer that the can is properly sealed.

LIGHTWEIGHT ALUMINUM CANS

In the 1980s, a new hot-filling process was developed that allowed the hot filling of lightweight aluminum cans. This technology is now used extensively for hot-filled fruit juices and juice drinks in $11\frac{1}{2} = fl = oz$ cans. Lightweight aluminum cans could not be hot filled with traditional processes because the aluminum cans would panel as a result of the vacuum created when the product cooled. The new hot-fill process includes dosing the filled cans with liquid nitrogen immediately prior to applying and double-seaming the can end. The cans consist of a drawn and ironed aluminum body with an E-Z open aluminum end. Directly following the dosing of the liquid nitrogen and the application of the end, the nitrogen vaporizes and creates internal pressure. In the case of hot fruit juices, this nitrogen dosing creates an initial pressure of approximately 45–50 psi (31.6–35.1 kg/m^2) prior to cooling and 25–35 psi (17.6–24.6 kg/m^2) after cooling. Thus, the nitrogen overpressure more than compensates for the vacuum created by the product as it cools, and the final package is overpressured to compensate for its lightweight construction. The hot-fill nitrogen dosing process for juice and juice drinks consists of cleaning the cans with hot water or air, hot filling with juice, leaving a headspace of approximately 0.3–0.4 in. (7–10 mm), dosing liquid nitrogen, applying the can end, double-seaming the can end to the can body, and finally cooling the product to approximately 90–110°F (32–43°C). This hot-fill process allows the use of lightweight aluminum cans for fruit juice and offers the potential for hot filling a variety of other food products. (See also Cans, aluminum.)

GLASS CONTAINERS

Hot-filling technology has been used for many years for, not only tinplate cans, but also for vacuum-packed glass jars and bottles. The hot-fill process used for glass packages is very similar to that used for tinplate cans. One main difference is that glass packages must be preheated prior to hot filling to prevent breakage caused by thermal shock. This problem is particularly troublesome in the winter, when glass is either stored in cold warehouses or filled directly off delivery trucks. It is generally believed that thermal-shock breakage is not a problem if the glass temperature after preheating is no more than 75°F (24°C) less than the hot product. Thus, if the product fill temperature is 185°F (85°C), then the glass must be preheated to at least 100°F (43°C) before filling. The preheating process is usually accomplished with hot water and also serves the function of cleaning the jars or bottles. Cleaning is particularly important with glass, as glass is often received in corrugated shipping and, thus, may be contaminated with carton dust. After cleaning and preheating, glass containers are filled with hot product, ranging from approximately 170 to 200°F (77–93°C). A small headspace is maintained. The headspace is usually flushed with steam in the capper. Metal twist-on, lug-style caps are usually used. These caps contain a gasket compound used to seal the jar or bottle. The caps are preheated in the cap shoot to soften the compound. A small initial vacuum is generated directly following the capper by the condensation of the steam in the headspace. This initial vacuum varies depending on the size of the headspace and the amount of steam in the headspace. An initial vacuum of at least 4–5 in. Hg (10.2–12.7 cm of Hg) is necessary prior to cooling to ensure that the seal between the glass jar or bottle and the cap compound is secure prior to generating the larger vacuum created by product contraction as it cools. Conveyors are designed to allow for at least a 60-s hold after capping prior to entering the cooler. This hold provides time for the hot product to sterilize the jar or bottle. The first zone of the cooler uses a preheated water spray to prevent glass breakage due to thermal shock. The 75°F (24°C) temperature differential, important in the preheating operation, is also critical in cooling. The water-spray temperature should be no more than 75°F (24°C) less than the product temperature. Often the cooler is designed such that cold water enters the discharge end of the cooler and is transported to the infeed end. Thus, the water is warmed as it cools the product throughout the cooler, which prevents thermal shock glass breakage while minimizing energy cost. The product temperature at the end of the cooler is usually 90–110°F (32–43°C). The final vacuum depends on the viscosity characteristics of the product and on the size of the headspace, but usually it is 16–22 in. Hg (41–56cm Hg).

As mentioned, barbecue sauce is not cooled after filling. Products such as this are packed in corrugated shipping containers, palletized, and cooled over several days in normal warehouse storage. As containers in the center of the pallet are insulated by the product stacked on the outside, top, and bottom, they may cool at a much slower rate than product on the outside. To reduce the variation in cooling rates, pallet patterns with ventilation chimneys are used to facilitate heat removal from the center of the pallet.

As hot-filled glass jars and bottles contain a vacuum, they must be handled carefully after cooling. Glass containers, particularly those filled with highly viscose products, break as a result of a phenomenon commonly known as “water hammer” breakage, which occurs when a glass jar or bottle containing a vacuum is dropped or otherwise impacted. On impact, a vacuum bubble forms and collapses quickly. This results in the creation of a hydraulic action that concentrates forces on any defect in the container causing breakage (5).

Care must be taken to properly adjust drop case packers to prevent water-hammer breakage. Corrugated shipping containers are designed to cushion the bottom of glass jars and bottles to minimize the impact of dropping. Partitions are used to minimize glass-to-glass impact. See also Glass container design.

PLASTIC PACKAGES

Historically, the hot-fill process has required packages that can withstand the hot-fill temperatures and are sufficiently rigid to withstand the vacuum developed after cooling without paneling or otherwise distorting. Until recently, these packaging material requirements have limited the use of materials for hot-fill packages to metal and glass. During the 1980s, packaging material and hot-fill technology developments occurred that allowed the use of, not only lightweight aluminum cans as already discussed, but also plastics (6).

Many plastic package technologies were developed in the 1980s that resulted in the commercialization of several hot-fill plastic packages that replaced traditional glass or tinplate packages. These technologies included plastic squeeze bottles with dispensing closures for ketchup and barbeque sauce, plastic table-ready bowls with peelable membrane seals for fruit sauces, plastic cans with double-seamed metal ends for a variety of products, and clear plastic bottles for fruit juices, juice drinks, and isotonic sport drinks (see also Blow molding).

Poly(Ethylene Terephthalate). The late 1970s and most of the 1980s was an era of rigid plastic food-packaging development. Nearly all the major U.S. packaging companies were actively developing plastic packaging technologies. Several Japanese and European packaging companies were also focusing their research and development activities on rigid plastic package developments for food and beverages. In the mid-to-late 1970s, polyethylene terephthalate (PET) was commercialized for carbonated soft-drink bottles. The initial application was the 2-L carbonated soft-drink bottle. Carbonated soft drinks contain preservatives and, thus, are cold-filled. They require a high gas-barrier to retain CO_2 but do not require the high heat resistance or physical strength necessary for hot filling. PET, as used in soft-drink bottles, softens at temperatures too low for hot filling or retorting. However, the success in the market of PET soft-drink bottles proved the consumer acceptance of plastic, and it confirmed the business potential that supported other major plastic food and beverage R&D programs.

Acrylonitrile. At the same time as PET was being developed for cold fill, another plastic resin—acrylonitrile (AN)—was under development for food and beverage packaging. Although AN, like PET, was clear and provided an adequate gas barrier for carbonated soft drinks and oxygen-sensitive foods and beverages, it had a significantly higher melting point and, thus, could be hot-filled and potentially even retorted. In the 1970s, AN was test-marketed for carbonated soft drinks. In addition, several hot-fill containers were developed and test-marketed. A squeeze bottle with a dispensing closure and an induction aluminum-foil seal was test-marketed with barbeque sauce. At least two fruit-juice processors introduced into test markets apple- and cranberry-juice products in $5\frac{1}{2} = fl = oz$ (162.6-mL) AN cans with seamed-on metal ends. Several other developments were under way. In 1977, the U.S. Food and Drug Administration FDA banned the use of nitrile polymers in direct contact with beverages because of the potential migration of AN monomer from AN packages into beverages and the possibility that it could be a carcinogen. AN was reapproved in 1984 with limitations (7).

Polypropylene. Polypropylene containers were also being developed for food and beverage applications in this period. Polypropylene can be thermoformed or extrusion blow-molded and, thus, made into bowls, tubs, and bottles. It has a high melting point and, thus, is well suited for hot-fill applications. Polypropylene is not crystal-clear, like PET and AN, but it is semiclear (contact-clear). The oxygen-barrier properties of the polypropylene are relatively poor. This limited polypropylene's application to foods and beverages, until coextrusion technology was developed in the 1980s to allow the addition of small amounts of high-barrier materials to polypropylene packages. Coextrusion technology resulted in the production of multilayer extrusion, blow-molded bottles and thermoformed containers containing 5 to 7 layers. Figure 2 shows a typical 6-layer, hot-fillable, high-oxygen-barrier polypropylene container. The inner and outer layers consist of virgin polypropylene. Ethylene—vinyl alcohol (EVOH) is used in the middle layer to provide a high-oxygen barrier. Polypropylene regrind is incorporated to use the scrape generated in the extrusion blow-molding process. Two adhesive tie layers are required for proper bonding of the EVOH to the polypropylene. Containers made of this material are hot-fillable, are abuse-resistant, and provide a high-oxygen barrier and contact clarity. In the 1980s, several food processors modified traditional hot-fill processes to allow conversion to polypropylene/EVOH containers from glass and tinplate. Examples include 4-oz apple-sauce cups as well as 12–16-oz cranberry-sauce containers, ketchup and barbecue sauce bottles, and some fruit-juice containers. Most of these hot-fill packages were sealed with heat-sealed or induction-sealed aluminum-foil laminates.

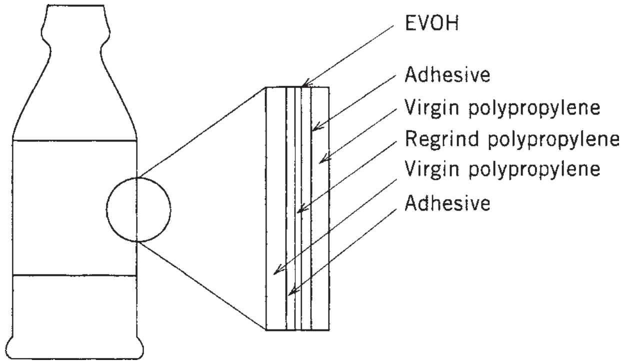

Figure 2. A typical hot-fillable polypropylene/EVOH/polypropylene bottle.

Heat-set PET. Polypropylene/EVOH co-extrusions provide an excellent hot-fill food and beverage packaging material with the possible shortcoming, for some products, of a lack of glasslike clarity. Although PET provides the clarity of glass, it was not hot-fillable until advances in injection blow-molding technology were made in the mid-1980s. Heat-setting technologies were pioneered, primarily by the Japanese, in the early-to-mid-1980s. More advances were made shortly thereafter by U.S. PET bottle manufacturers in conjunction with global injection and blow-molding equipment suppliers. The first commercial application of hot-fillable PET bottles, technologically possible because of the heat-setting process, were for fruit juice and juice drinks. In September 1985, 64-fl-oz (1.89-L) heat-set PET bottles were commercially introduced with a line of cranberry-juice drink products using the Japanese technology. Shortly thereafter, U.S. bottle manufacturers commercialized alternative thermally stable technologies for PET, and the commercial use spread beyond fruit juices and juice drinks to isotonics. Ketchup also converted from contact-clear polypropylene/EVOH bottles to hot-fillable PET/EVOH.

Heat-set, or otherwise thermally stable, PET provides an adequate oxygen barrier for many products, excellent abuse resistance, good recyclability characteristics, hot fillability up to 180–185°F (82–85°C), and the clarity of glass. By the mid-1990s, hot-fillable PET became a prevalent and popular packaging material for several categories of hot-filled foods and beverages (e.g., fruit juices, juice drinks, isotonics, and ketchup) that traditionally were packed in glass.

SUMMARY

In summary, hot-fill processing and packaging is a basic traditional method of preserving high-acid foods and beverages. It has been practiced since the early days of commercial food processing and before that in home canning. It is one of the food-processing technologies that has allowed nutritious foods to be available year-round in all parts of the nation. Historically, its application has been limited to rigid metal and glass containers.

However, technological development of new materials, new package manufacturing processes, and hot-fill methods in the 1980s have resulted in the commercialization of a variety of new hot-fill packages that provide the product protection benefits of metal and glass with additional consumer benefits.

I

INDICATING DEVICES

Dee Lynn Johnson
3 M Company

One summer in the 1930s, Eastman Kodak Co. received a telegram from the Kitt Observatory in Arizona stating that a shipment of photographic plates had no light sensitivity. Each of these plates was developed completely and was uniformly black. A new set of plates was carefully packed and shipped to the remote observatory. Again, all of the plates were black when developed. A well-respected Pinkerton guard accompanied the next shipment. He never let the box of plates out of his sight, and the mystery was solved at a small siding in Arizona. The rail clerk received the box clearly marked “FRAGILE GLASS PLATES,” and methodically opened the box, took out each plate in the bright afternoon sun, removed the black paper cover, and examined each one. “All in perfect shape,” he said to the guard as he rewrapped the plates and returned them to the carton.

A shipper must know what happens to a package after it leaves the shipping room, but it is impossible to send a security guard with every carton. Instead, a variety of indicating devices have become the security guards for the packages.

Perishable products may speak for themselves by their physical condition or their odor. Damage to other products from inappropriate handling may not be evident until actual use. As an example, whole blood stored below 50°F (10°C) is stable for months. If the temperature rises above that point for 20 min, however, enzymatic changes could occur that would make it life threatening if transfused. The potency of vaccines is lost by exceeding critical temperatures; an even greater hazard may result by presuming that it is effective. Because microcircuits are sensitive to mechanical shock and electrical potential, individual components and wired circuits must be monitored.

TIME AND TEMPERATURE INDICATORS

The fully integrating monitoring device can indicate the temperature gradient to which it has been exposed, as well as the amount of time that it has been at that temperature. Many inventors and their companies have focused on developing such devices, which operate on the following principles: physical change, chemical change, electrochemical indication, electromechanical indication, electronic readout, and others. The devices monitor perishable foods such as fish, fruit, and vegetables, as well as pharmaceuticals and vaccines. Table 1 lists the U.S. Food and Drug Administration’s (FDA) temperature limits for various biological preparations.

Table 1. Biologics, Shipping Temperatures[a]

Product	Maximum Temperature, °F (°C)
Cryoprecipitated antihemo-philic factor[b]	<0 (−18)
Measles, mumps, and rubella virus vaccine, live	<50 (10)
Measles and rubella virus vaccine, live	<50 (10)
Measles-smallpox vaccine live	<50 (10)
Measles virus vaccine, live, attenuated	<50 (10)
Mumps virus vaccine, live	<50 (10)
Poliovirus vaccine, live, oral, type 1	<32 (0)
Poliovirus vaccine, live, oral, type 2	<32 (0)
Poliovirus vaccine, live, oral, type 3	<32 (0)
Poliovirus vaccine, live, oral, trivalent	<32 (0)
Red blood cells,[b] frozen	<(−85) (−65)
Red Blood cells,[b] liquid	34–50 (1–10)
Rubella and mumps virus, live	<50 (10)
Rubella virus vaccine, live	<50 (10)
Single-donor plasma,[b] frozen	<(−18)
Smallpox vaccine, liquid	<32 (0)
Source plasma[b]	23 (−5)
Whole blood[b]	34–50 (1–10)
Yellow fever vaccine	<32 (0)

Indicators that show time only are also available in many styles. These are used primarily on shipping containers, not on consumer packages. Life-dated products, such as photographic film and some foods, can have greatly extended salable time by refrigerated storage. A time indicator would benefit the manufacturer and retailer as well as the consumer.

The Andover Laboratories manufactures a time–temperature integrator called the Tempchron, which is formerly known as the Ambitemp (see Figure 1), which functions with a fluid that has a specific melt temperature for the product to be monitored. This device can be described as an integrator because it provides information

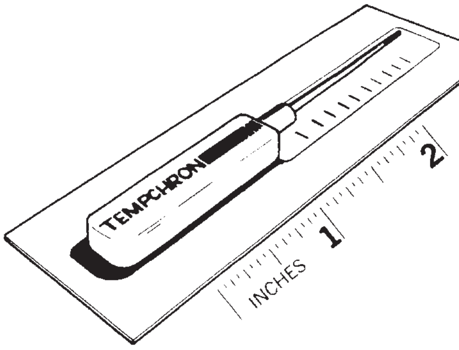

Figure 1. Integrated time–temperature indicator. The Tempchron (Andover Laboratories) uses the melt temperature of the product to be measured. To convert in. to cm, multiply by 2.54.

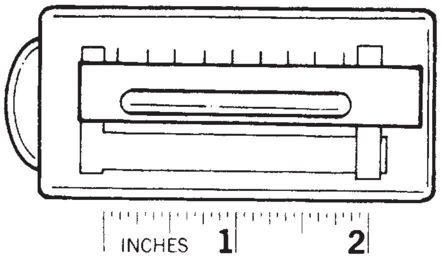

Figure 2. Integrated time–temperature indicator. The TTI (Honeywell Corp.) used an ampul of electrolyte between metal plates. To convert in. to cm, multiply by 2.54.

on the multiple of the time and temperature, giving a readout in degree minutes that can be interpreted from a chart. A wide range of temperatures can be monitored by selection of the liquid that is to be frozen in the tube.

Figure 2 shows an interesting concept of a time–temperature integrator (TTI) that was at one time manufactured by Honeywell Corp. This device, comprised an electrolytic battery that was activated by breaking an ampul of electrolyte between copper and cadmium strips. An electrochemical color reaction that was accelerated at higher temperatures ensued.

Kokum Chemical in Malmo, Sweden, manufacturers a time–temperature monitor (TTM) that uses an enzyme to bring about a color change. This product (see Figure 3), the I-Point TTM, is intended to match the enzyme reactions of the product it is monitoring. A progression of color changes occurs.

Another time–temperature integrator functions by the use of a selective gas-absorption plastic membrane and leuko (colorless) dyes that are sensitive to oxygen (2). The leuko dye is converted to the colored form inside the pouch in proportion to the rate of oxygen penetration through the membrane and the time. The rate of penetration of the oxygen through the membrane is also related to the temperature. The storage life of foods for emergency survival has been studied as a function of the temperatures at which they were stored. With the accurately calibrated barrier films (see the Barrier polymers article) now available, this may prove a valuable area of investigation.

Allied Chemical Co. has a patent (3) on work in which combinations of conjugated acetylene compounds irreversibly change color when heated. After finalizing the above design, the Program for Appropriate Technology in Health (PATH) in Seattle, WA., has marketed a product called the PATHmarker, which indicates the change in color.

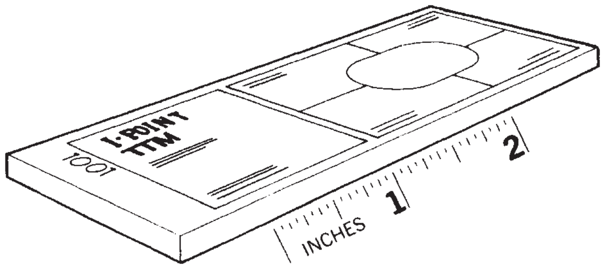

Figure 3. The I-Point TTM (Kokum Chemical) is an integrating time–temperature monitor utilizing enzyme-produced color change. To convert in. to cm, multiply by 2.54.

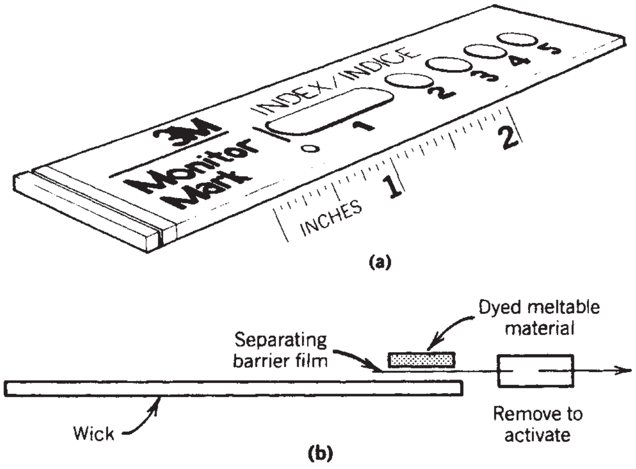

Figure 4. (**a**) The Monitor Mark Time Temperature Tag (3 M Co.), an integrator available in many temperature ranges. To convert in. to cm, multiply by 2.54, (**b**) Cross section.

There are two patents (4, 5) for time–temperature integrators under the name Monitor Mark [see Figure 4(a)]. In this product, a dyed meltable solid travels down a porous wick when heated above its melting point. The time interval is a function of the travel of the color down the wick. The device is activated by removal of a barrier film that is positioned between the wick and the meltable solid [see Figure 4(b)]. The product is available in several response temperature ranges.

The Therma-Gard recorder (Impact-O-Graph Corp.) monitors temperatures on a cassette and functions for 30 days. The TSI International Corp. has introduced a recorder that operates for up to 90 days in the indicating range of −20 to 100°F (−29 to 30°C).

Two workers (6), following the lead of another (7), have fabricated two styles of electronic recorders with built-in memories (see Figure 5); however, they are not commercially available. Workers at 3 M Co. have invented a Thermal History Indicating Device (THID)*. Another product that interfaces with a computer for its readout is the Tattletale thermograph (Onset Computer Co.) (see Figure 6). This thermograph reports temperature transients to a memory and can be programmed to record at 5-s intervals for 5.5–6-h intervals for 32 mo. The functional temperature range is −41 to 185°F (−41 to 85°C).

TEMPERATURE INDICATORS

Temperature-measuring devices are numerous. In the simplest form, a sphere of ice is frozen with one half clear and the other red (see Figure 7). If the product thaws, the

---

* The author and F. R. Parham, 3 M Co., Saint Paul, MN, have been active in microprocessor monitors.

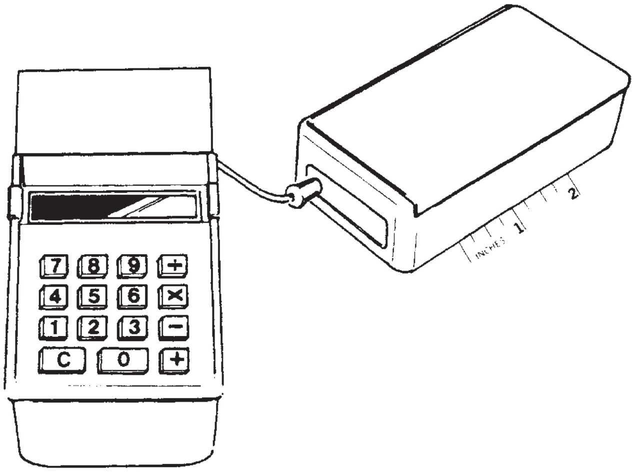

Figure 5. Electronic recorder (6, 7). To convert in. to cm, multiply by 2.54.

sphere becomes pink. High-technology temperature indicators include thermistors, circuits, and liquid-crystal displays (LCD).

Most temperature indicators depend on a chemical color change. These compact units provide direct, reliable information on the temperature to which the product was exposed. They are widely used for materials with critical temperatures such as pharmaceutical and biological preparations (Table 1) and fresh and frozen fish. Table 2 lists some of these indicators; Figure 8 is representative of these devices.

There are two other types of indicators not listed in Table 2: the Criti-Temp (Schobl Enterprise, Inc.), which is a bimetallic spring-loaded monitor, and the Precision Digital Thermometer (TSI International Corp.), which functions from a thermistor to give a temperature display.

FREEZE AND THAW INDICATORS

The main purpose of the indicators listed in Table 2 is to show a response to a rising temperature well above room temperature. Devices to indicate temperatures near the freezing point of water require special design because they must be unbroken before use and function at low temperatures.

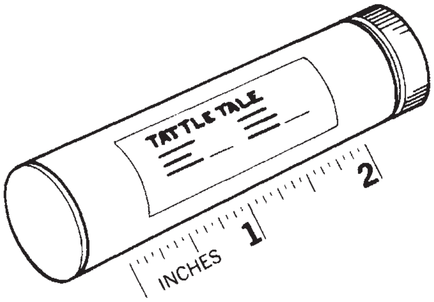

Figure 6. Tattletale thermograph electronic recorder (Onset Computer Corp.). To convert in. to cm, multiply by 2.54.

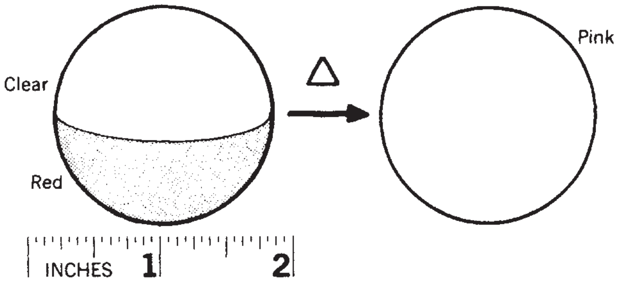

Figure 7. Thaw indicator. Half-colored sphere of ice becomes homogeneous when thawed. To convert in. to cm, multiply by 2.54.

Akzo N.V. of the Netherlands has exerted a strong influence in the monitor area through its subsidiary, Organon, heir to the BMS disposable-thermometer technology, and through its Info-Chem Protective Products Division. Info-Chem manufactures the Thaw-Watch and the Freeze-Watch. These products utilize an ampul filled with a colored fluid. Freezing breaks the ampul, which spills the contents onto a paper indicator (see Figure 9).

Biosynergy, Inc. manufacturers a liquid crystal Hemo-Temp II for use on blood-collection bags. This device, after being frozen, indicates the temperature of the blood (see Figure 10).

The Check-Spot (Check-Spot, Inc.) (8) functions at 3–32°F (−16 to 0°C) and is based on a solid emulsion (see Figure 11).

The Monitor-Mark Button (3 M Co.) [see Figure 12(a)] operates by means of a meltable, dyed compound contained in a porous reservoir. In the inactivated form, a domed indicator paper is separated from the reservoir by a small distance. When the dome is pressed, the two materials come in contact, allowing wicking to occur when the melt temperature is reached [see Figure 12(b)]. This product has many different applications, including irreversible monitoring of bags of whole blood. The specifications for blood banking have been outlined (9).

Other styles of freeze indicators are manufactured by 3 M Co. (10–12), including the Monitor-Mark Cold Side Indicator, model 32F (see Figure 13). When temperatures fall below 32°F (0°C), there is an irreversible color change. In the past, the irreversible warmup indicator (IWI), was manufactured by Artech Corp. (13).

HUMIDITY INDICATORS

Many items are sensitive to moisture in ways that are irreversible. Simply drying out or humidifying does not restore the original function, and the damage that may have occurred during shipping or storage may not be evident to the recipient. To protect the manufacturer and the customer, humidity changes must be monitored. A humidity monitor based on a color change is available from Herrmann Chemie and Packmittel (see Figure 14).

A U.S. patent has been granted for a time/history humidity indicator (14). This device comprises a salt

that absorbs moisture from the air, a water-soluble dye, and an absorbent material. After activation by removal of a barrir film, the dissolved dye migrates into the absorbent material as the humidity increases. This product resembles the product shown in Figure 4.

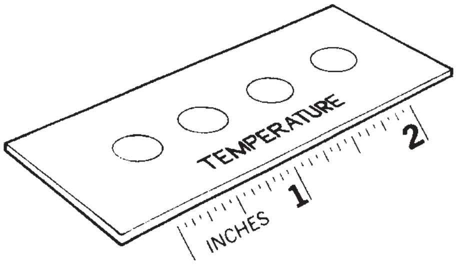

Figure 8. Temperature indicator representative of devices listed in Table 2. To convert in. to cm, multiply by 2.54.

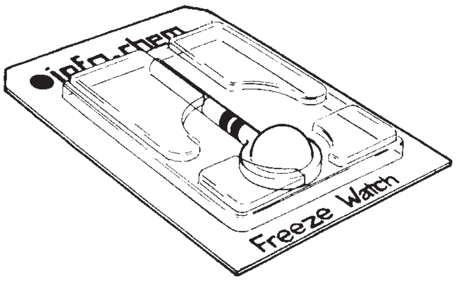

Figure 9. Freeze-Watch (Info-Chem Protective Products).

GRAVITATIONAL-FORCE INDICATORS

Gravity is a useful force in packaging because it keeps containers in place. Many times the normal force of gravity may be applied to a product in shipping and

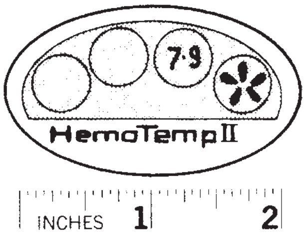

Figure 10. HemoTemp II (Biosynergy, Inc.). To convert in. to cm, multiply by 2.54.

handling. This abusive treatment can cause hidden damage. The Hump-Gard (Impacto-Graph Corp.) is a 30-day monitor for the high *G* forces encountered in railroad shipping.

The Shockwatch is a compact device for measuring high gravitational forces (15). The active element is a capillary tube with surface-energy differences in each end (see Figure 15). A colored fluid is placed in the -philic end, and when forces exceed a predetermined value, the liquid is forced into the -phobic end where it is visible. Once distributed by 3 M Co., it is now available from Media Recovery Co.

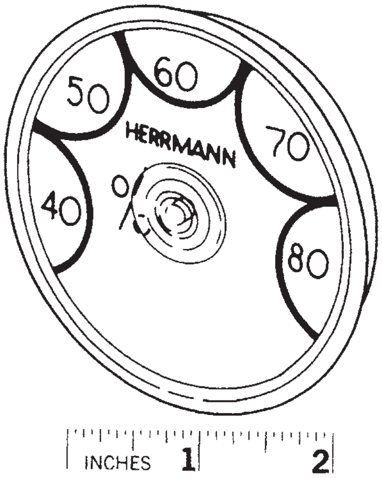

Figure 14. Humidity indicator (Herrmann Chemie and Packmittel of Sod-Chemie AG). To convert in. to cm, multiply by 2.54.

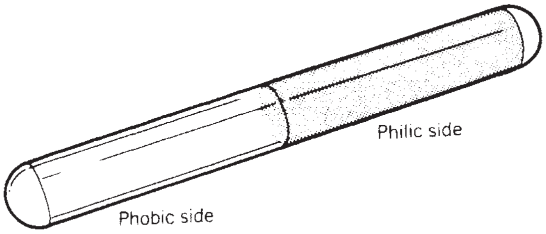

Figure 15. Capillary tube of Shockwatch.

This article has discussed only a few of the hundreds of indicating devices available[†]. A low cost indicator is still needed, preferably one that could be imprinted as part of the label of consumer products such as frozen foods.

INJECTION MOLDING FOR PACKAGING APPLICATIONS

LARRY PASCUCCI
Negri Bossi Inc., Mississauga,
Ontario, Canada

The art of making a form out of a crude mold dates back centuries in the civilization of mankind. In the 20th century the technology of mold-making and materials science in the production of plastic forms evolved together with the invention of the injection molding machine (see Figure 1). Manually operated at first, the injection molding machine evolved into a fully automatic machine capable of faster and faster "cycle times" in the production of plastic parts. This article will take you into the 21st century and explain the art, science, and technology of today's injection molding technology.

This article consists of the following sections:

The Process of Thermoplastic Injection Molding
The Thermoplastic Injection Mold
The Thermoplastic Injection Molding Machine
Automation for Injection Molding Machines
Monitoring and Servicing the Machinery

THE PROCESS OF THERMOPLASTIC INJECTION MOLDING

There are two types of injection molding processes. The most predominant is thermoplastic molding, which consists of injecting melted/heated plastic resin that must be "cooled" by the mold to solidify. The second process involves a thermoset material that requires a "heated" mold to solidfy. The machinery is essentially the same for both processes except for the control of the heating or cooling phases of the material processed. This article will concentrate on the thermoplastic molding process that is most common for packaging applications.

Thermoplastic material in the form of small "pellets" (resin) each about the size of a small pea are placed into a conical steel "hopper" ready to be fed by gravity into the "injection unit" of an injection molding machine. The pellets are then drawn through a "feed throat" into a horizontally mounted "screw "which revolves at a certain speed, driven by an electric or hydraulic motor. The screw resides in a "barrel" that is heated on its outer perimeter by electric "heater bands." As the screw rotates it mixes and induces work energy into the resin and together with the heated barrel melts the plastic. The plastic resin is conveyed to the front of the screw down its shaft. At this point, "injection" into the mold is ready to take place.

The mold is clamped in the vice-like grip of the machine ready to keep the mold closed under extreme injection pressures that can climb to 30,000 pounds-per-square-inch (psi) or more. The screw, on commands given by a central computer that directs all machine functions, then bolts forward to inject the melted resin into the mold. A device on the end of the screw called a "check valve" stops the plastic from backing up into the screw during injection.

Controlled screw speed, injection velocity, and melt pressure are crucial to making a quality finished part. The mold is cooled via water channels to solidify the thermoplastic resin. When the plastic part cools and "sets," the mold is opened by the injection molding machine and the part is "ejected" by the action of both mold and/or machine. At this point the part is left to free-fall to a conveyor that guides the part out of the machine or an automated robot enters and extracts the part for

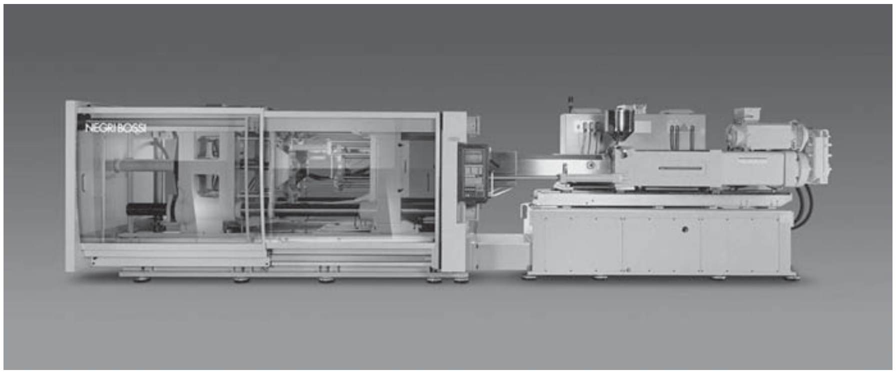

Figure 1. This modern 700-ton clamp force injection molding machine illustrates a HYBRID machine design. Electric screw drive with Hydro-Toggle clamp. PC-based control and DIGITAL Canbus architecture. (Photo courtesy of Negri Bossi.)

packaging or any downstream handling requirements. This point in the process now defines the "cycle" completed.

Let's review the sequences in a more detailed way: The first molding sequence is to "plasticize" the solid thermoplastic pellet into a hot molten condition. The second is "mold-close," where the machine clamps the mold under high forces to withstand the opening forces of high injection pressure. The third is "injection forward," where the screw bolts forward to inject the molten thermoplastic resin into the mold and "hold" the injection forward while the part is cooling. The fourth is "part cooling," where the mold via water-cooled channels cools the thermoplastic part to solidify it. The fifth is "mold open" as the mold opens to ready the part for extraction. The sixth is "part ejection," where the machine and/or mold ejects the part either by free-fall or into the clutch of a robot's grip. The final stage is the to repeat the "cycle" to produce another thermoplastic part(s). To summarize: the seven stages in the cycle of thermoplastic injection molding are:

1. Plasticize or melt the thermoplastic into a molten state.
2. Close the mold under high force to withstand high injection pressures.
3. Inject the thermoplastic into the mold under high speed and pressure and "hold" the injection forward while cooling.
4. Cool the part by extracting heat by a water cooled mold
5. Open the mold to ready part extraction.
6. Eject the part into free-fall or automated robot removal.
7. Repeat the "cycle" to produce another part(s).

THE THERMOPLASTIC INJECTION MOLD

The mold design has a tremendous impact on system productivity and product quality, and therefore on the overall economics of the injection-molding operation. The design of a mold is heavily influenced by characteristics of the part. A thorough understanding of the various mold classifications is also critical in the specification of the right type of mold best suited to your application. The mold classifications section of this article identifies each mold type and the criteria for each.

Most injection-molded parts for packaging have relatively large length-to-thickness (L:T) ratios. The length is defined as the maximum flow length in the cavity and is measured from the point where plastic enters the mold to the furthest point it travels. The thickness is the average wall thickness of the part. Early molds had L:T ratios of up to 200:1, but today they can be as high as 500:1. For such thin-wall parts, design emphasis must be placed on the hot runner system, part ejection, mold cooling, alignment, and mold material selection. A typical mold for thin-walled containers is shown in Figure 2 (also see Figure 3).

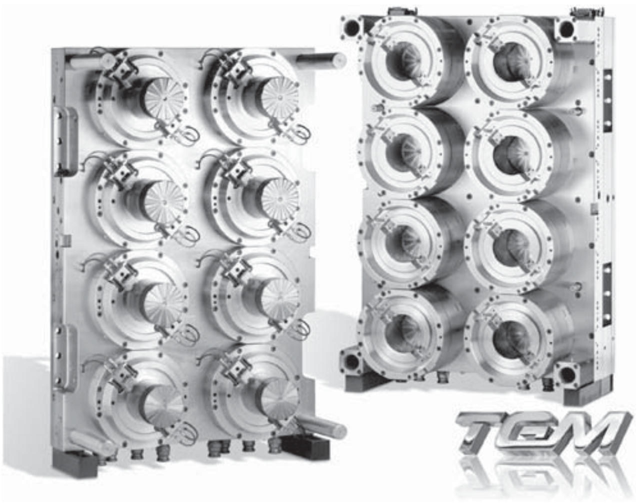

Figure 2. An eight cavity thin-walled container mold with hot runner technology. The part is a one-gallon paint can. (Photo courtesy of Top Grade Molds.)

Mold Classifications

Molds are classified into different SPI (Society of Plastic Industry) mold categories based on expected mold lifetime measured in cycles. The different classifications dictate significant differences in mold design and material which will impact tooling costs. It is important to review and identify the production requirements when specifying the type of mold to be constructed. See Table 1.

Operation. As the mold closes, the cores and cavities are aligned by some form of tapered mating interface. Plastic melt (i.e., melted resin), is injected by the injection unit of the molding machine into the sprue bushing and forced through a network of flow channels called the runner system. In Figure 2, the runner system is heated by electric heaters, hence the term "hot runner." The hot runner system maintains and controls the temperature of

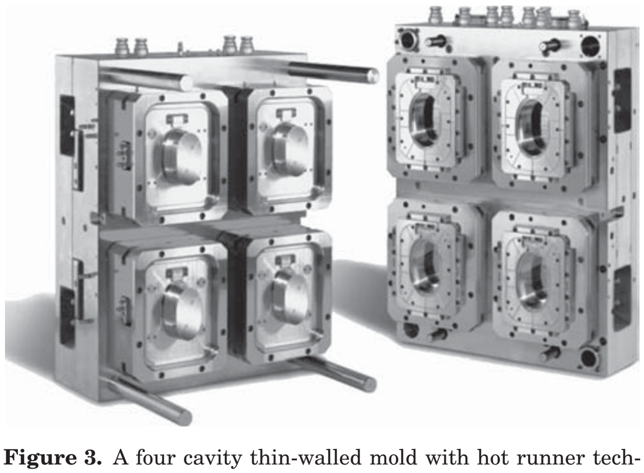

Figure 3. A four cavity thin-walled mold with hot runner technology. The part is a tamper-evident container. (Photo courtesy of Top Grade Molds.)

Table 1. Classification of Molds

Lifetime Cycles	Definition	SPI Classification	Estimated Build Time (weeks)
Greater than 1 MM	Super high production	101	12–20
Less than 1 MM	Medium production	102	8–12
Less than 500 M	Low production	103	6–8
Less than 100 M	Low production	104	6–8
Less than 500	Low production	105	5–6
Low cavity high cycles	Pilot mold (class 101)	PM	8–12
Less than 500	Prototype	PT	<6

the melt right up to the gates by use of a sprue heater, manifold heaters, and nozzle heaters. Past the gates, the melt flows into the cavities. As the molten plastic solidifies during cooling, the parts typically shrink 1–2% of their diameter, causing them to adhere to the cores. When the mold opens, parts are ejected from the cores and drop between the mold halves.

Runner System. There are basically two types of runner systems: cold and hot. In cold runner systems, the melt in the flow channels between the nozzle and the gates is allowed to cool and solidify during each cycle and must be ejected along with the parts before the next cycle begins. Cold runner systems are simpler to design and are less expensive than hot runner systems. A disadvantage is that the plastic of the cold runner must be reprocessed or scrapped, which adds costs and environmental concerns. The introduction of scrap material to virgin resin can adversely affect process repeatability and part quality. Also, the cold runner can significantly slow the cycle at which the mold operates, since the cold runner must be cooled before ejection. For these reasons, hot runner systems have been extensively used in packaging applications.

To ensure consistent quality, the hot runner system should be balanced so that it supplies melt to each cavity at the same pressure and temperature. Flow balance is maximized by ensuring that each flow channel from the nozzle to the cavity gates has an equal length and an equal number of turns. True balance can only be achieved through engineering of the hot runner system with the use of material software to help identify problamatic areas of flow through computer simulation. This allows the engineer to test out various processing and design scenariors before any manufacturing commmences. In cases where the material characteristics or part requirements inhibit an engineered approach, artificially balanced systems can use sequence controls and shut-offs to control the material flow. Temperature balance is achieved through uniform heating and insulation. Hot runner molds with up to 128 cavities operate reliably with this balanced approach. The hot runner system should also have manifold flow channels with smooth, radiused corners to reduce friction and pressure drop. As a result, there should be no dead spots where plastic can be trapped and degrade.

Cooling. Cooling time is a key variable in the total molding cycle. To decrease cooling time and thus increase productivity, gun drilled cooling channels are located near the molding surface. High coolant flow rates are necessary to achieve high heat-transfer rates. In addition, metals with excellent heat-conductivity properties such as beryllium copper can be used for inserts to improve heat transfer where high heat is generated, such as around the gates. Beryllium copper has approximately 10 times the coefficient of thermal conductivity of steel. With a well-designed cooling system, typical thin-walled packaging parts can be cooled rapidly. Total cycle times as short as 1.5 s are now possible. It is also important for the cooling system to maintain the cores and cavities at approximately the same temperature. This prevents excessive wear between interlocking faces due to differences in thermal expansion between the mold halves.

Traditionally, gun drilling of channels has been used to allow for water flow around the cores and cavities. As demands have increased for increased productivity, reduced cycle times, improved part quality, and reduced mold maintenance, new mold cooling technologies have emerging.

A proven approach has been the use of evaporative cooling technology to simplify the design and manufacturing requirements of mold cooling by replacing gun-drilled water lines. Evaporative cooling is achieved through a “cooling chamber” or water pocket that completely envelops mold cooling surfaces. The water chamber ensures even heat distribution without the engineering compromise often associated with gun drilling. Using heat exchangers, evaporative cooling condenses the water, which in turn is recycled throughout the sealed chamber. The turbulent flow of the water reduces any buildup of sludge within the chamber that may impede mold cooling. To reduce or eliminate corrosion issues, air is removed from the cooling chamber prior to production. Use of a mold temperature controller automatically senses and adjusts water flow to regulate heat levels during processing. The advantages of evaporative cooling are both environmental (reduced waster water, reduced energy costs) and design-oriented (reduced engineering costs, reduced manufacturing costs, simplified mold construction), resulting in improved reliability. See Figures 4 and 5 for a detailed view of evaporative versus gun-drilled cooling.

Part Ejection. There are two basic methods of part ejection: mechanical and air. Mechanical ejection commonly uses stripper rings or pins surrounding each mold core, or a moving core cap to physically push the parts off the cores. The stripper rings can be activated by hydraulic cylinders

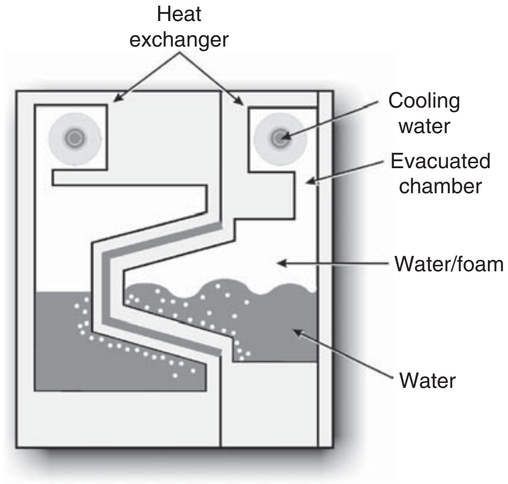

Figure 4. Evaporative cooling. (Photo courtesy of Ritemp Pty. Ltd.)

attached to the machine platen, air cylinders in the mold, or a mechanical linkage tied to the motion of the machine platen. Air ejection uses blasts of air to loosen and blow the parts off the cores. Air ejection is the more popular method because it involves fewer moving parts and, hence, less maintenance. The mold can also be more compact.

Alignment. The proper alignment of core and cavity is critical in thin-wall molding. Slight misalignment leads to preferential filling of the thicker part of the cavity, which causes a pressure imbalance around the core and cavity, thus further shifting the core. The overall result is uneven wall thickness in the molded part. In extreme cases, it can result in (a) incomplete filling of the cavity (i.e., a short shot) and (b) rejected parts. To achieve satisfactory part quality, center-to-center alignment of the core and cavity within ±0.2 mil (±0.005 mm) may be necessary.

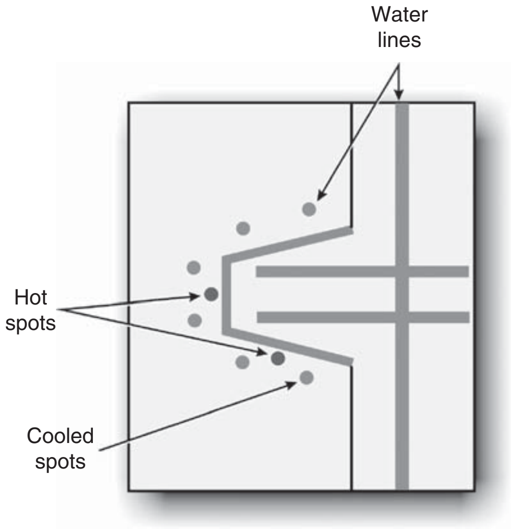

Figure 5. Gun-drilled cooling. (Photo courtesy of Ritemp Pty. Ltd.)

There are different methods of aligning the cores and cavities of packaging molds. One common method is a stripper ring that uses tapers on the stripper ring to align the core and cavity. This popular method of alignment has disadvantages for thin-wall molding, where alignment forces cause relatively rapid wear of the stripper rings. Since the stripper rings form part of the molding surface, excessive wear in this area reduces part quality. To avoid a drop in part quality, frequent mold maintenance is required. Wear is not critical if the locking rings are not part of the molding surface. Either air or mechanical ejection can be used with this approach.

The floating-core method is a more recent design that is suitable for some packaging applications. The cores and locking rings are not rigidly fixed to the core plate, but are allowed to float to more easily align themselves with the cavities. Easier alignment results in less wear on the aligning tapers. This method can also be used with either air or mechanical ejection.

Mold Materials. High-quality mold materials are of the utmost importance. Most mold components are made of through-hardened high-quality tool steel. Hardness ranges from RC 49–51 (Rockwell C scale) for the cores and cavities to RC 30 for the mold plates. Only periodic rebuilding of wear items, such as stripper rings and leaderpin bushings, is required.

Stack Molds. A two-level stack mold typically has identical sets of cores and cavities on each mold face, which are then stacked together back-to-back. In the case of a family stack mold, the cores and cavities differ between the two faces, allowing similar or matched pieces (compact-disk jewel case, floppy-disk shell, etc.) to be produced during each cycle. Use of a stack mold almost doubles the productivity of a machine. For these reasons, stack molds are increasingly popular. Three- and four-level stack molds have recently been introduced for thin-wall lids and containers to further increase machine productivity (see Figure 6).

THE THERMOPLASTIC INJECTION MOLDING MACHINE

A thermoplastic injection molding machine for Packaging Applications can be described in seven parts:

1. The machine control and control architecture
2. The power plant
3. The injection unit
4. The clamp unit
5. The ejector mechanism
6. The base unit
7. Features specific to packaging applications

There are many different configurations of horizontal clamp machines based on how they are powered. Horizontal clamp machine varieties include:

- Hydraulic-operated machines with hydraulically driven clamps

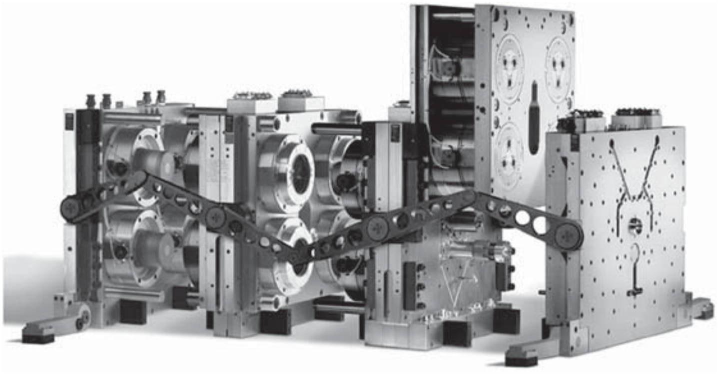

Figure 6. A three-level, 12-cavity mold for 5-qt containers utilizing a patented modular mold change feature. (Photo courtesy of Top Grade Molds.)

- Hydraulic-operated machines with toggle-driven clamps
- All-electric machines (only with toggle clamp)
- Hybrid machines utilizing hydraulic clamp and electric screw drive (see Figure 7)

Add to the above the vertical clamp design and there are quite a lot of models to choose from depending on the molding application. This article will address the horizontal machine group that is most common for packaging applications.

The Machine Control and Control Architecture

The injection molding machine performs all functions to operate a mold in a fully automatic way. The machine control and the control architecture sets the way in which all machine devices perform together in the operation of the mold. There are various control architectures, depending on the manufacturer. Modern control solutions center on "bus-type" controls that provide fully digital control operation of smart devices like smart pumps, smart valving, and digital transducers (see Figure 8). "Smart" means that devices carry their own electronics on-board to communicate with the central industrial PC-based controller. Wiring and overall machine complexity is drastically reduced over traditional "analogue" not-smart device control architectures. Diagnostics and maintenance too is greatly simplified. The machine control carries all the software programs of sequences and finite machine control in the operation of the mold. Screen pages are separated into their specific functions such as clamp, injection, and ejection phases. Controls are intuitive and user friendly.

The Power Plant

The power plant is very important to the effective and efficient operation of the injection molding machine (see Figure 9). Modern trends toward the All-Electric machine configuration is telling of the great need to reduce power consumption and energy costs associated with injection molding. The all-electric design, although more expensive than its fully hydraulic machine counterpart, allows for great power savings. Typically, as much as or more than 50% power savings is attributed to the All-electric design versus hydraulic machine designs. Digital Bus-Type control architectures (even in hydraulic clamp/injection machines) as well provide energy savings due to the

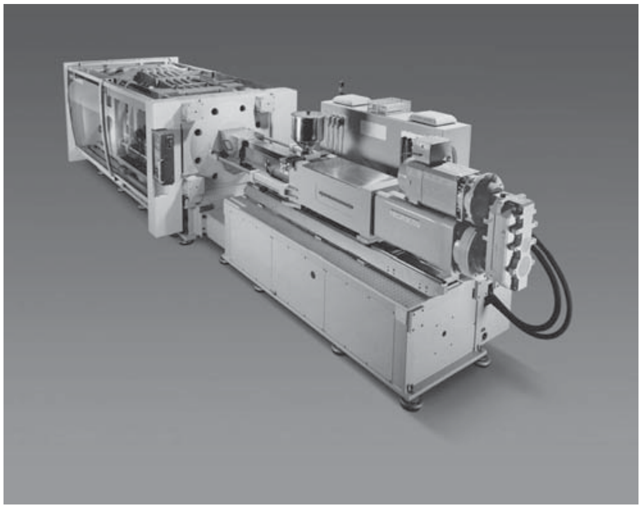

Figure 7. Electric screw drive and hydraulic toggle clamp are the main features of the machine shown. (Photo courtesy of Negri Bossi.)

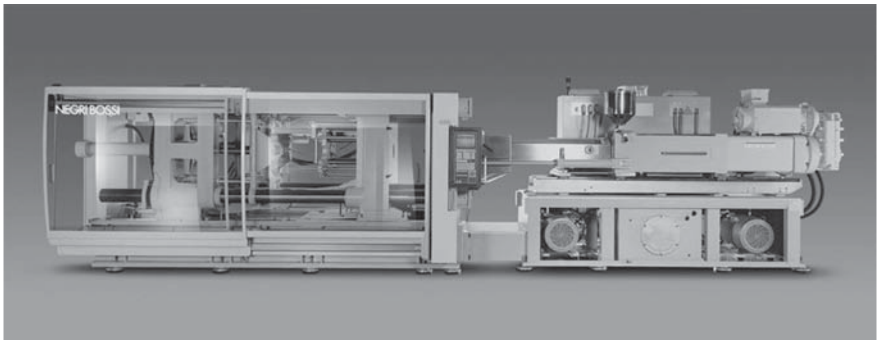

Figure 9. The power plant under the injection unit displays a double smart pump and motor system on this 700-ton electric–hydraulic hybrid machine. The oil tank is located between the smart pumps. The guarding is partially removed from the injection unit for this photo. (Photo courtesy of Negri Bossi.)

reduction of machine components required. A "smart" hydraulic pump that controls its own pressure and flow eliminates the need for a separate hydraulic manifold block to perform the same function. This reduces not only energy usage but also the number of components, allowing for very cost-effective operation.

The Injection Unit. Raw plastic material from the resin maker is processed by the injection unit of an injection molding machine. It is the most critical device in the control of the final plastic part's quality. The process is organized in sequences of the operation of the injection unit as follows: injection shot size, speed, injection and hold pressures, plasticizing recovery rate (melting/shearing rate of the plastic as a function of screw rotational speed), and backpressure (as a function of the resistance pressure on the screw to melt the plastic during plasticization). The injection unit also functions to move the nozzle and apply pressure onto the mold. It does this via "carriage" hydraulic cylinders operating on both sides of the injection unit (see Figure 10).

Determination of the injection pressure will depend on the wall thickness of the part (t), the length of flow (L) of the plastic resin from gate entry into the part to its final stopping point, and the force of injection created by the injection unit. The higher the L/t ratio (called the aspect ratio), the greater the injection forces and pressures required for injection. Typically, thin-walled packaging applications require injection forces greater than 30,000 psi and very fast plasticizing rates. Most packaging applications hover between 5 and 10 s of cycle time (even $<$5-s cycle times) so rapid actions of the injection unit are vital in meeting this requirement. The type of injection unit used most commonly is the reciprocating screw driven rotationally by an electric motor and linear movement driven by hydraulic cylinders. To reach the high speeds of injection, hydraulic accumulators (energy storage devices) are used to instantaneously drive the cylinders and therefore screw forward. The hydraulic power plant of the machine is engineered to allow mold opening and hydraulic ejection during the screw plasticizing mode. These "overlapping" motions in the sequence are designed to reduce the cyle time to its minimum, thereby maximizing machine and mold production output.

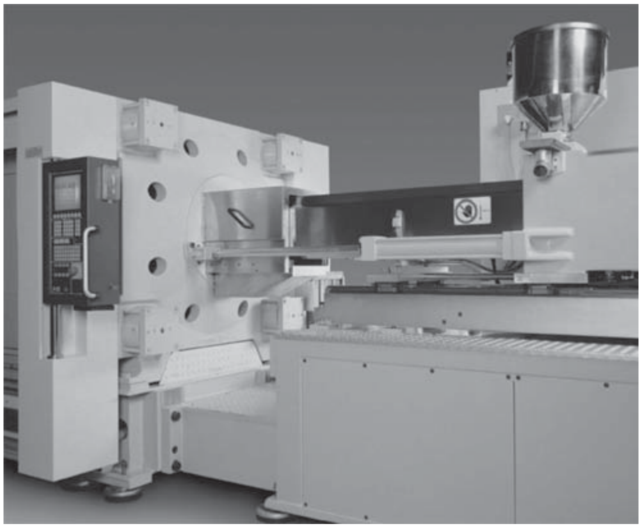

Figure 10. The injection unit displayed here shows a stainless steel purge guard over the heated barrel and hydraulic carriage cylinders (both sides). (Photo courtesy of Negri Bossi.)

Every aspect of machine design is tailored to maximize production output. Most often it is not the machine which creates delays in the production of plastic parts. The mold construction, quality, and the rate of part/mold cooling will determine the final production output. Advances in mold cooling technology as described in Figure 4 greatly reduce cycle time and increase part production.

The Clamp Unit

The main purpose of the clamp unit is to hold the mold closed under the force of plastic injection pressure that is trying to force the mold open (see Figure 11). Its design takes into consideration the objective of fast and precise operation while protecting the mold from damage should a plastic part get trapped from improper ejection or some part of the mold somehow interferes with the proper and complete mold closing sequence. This feature is called simply "mold protection."

Clamp units come in two different operating types: the toggle clamp (hydraulic or electrically operated) and the fully hydraulic clamp. The toggle clamp's advantages are its fast operating speed and natural geometric motion of high-speed acceleration, maximum velocity, controlled deceleration to final mold closing, and sensitivity on mold protection. The fully hydraulic clamp features capabilities to mold deep-draw parts such as extra large

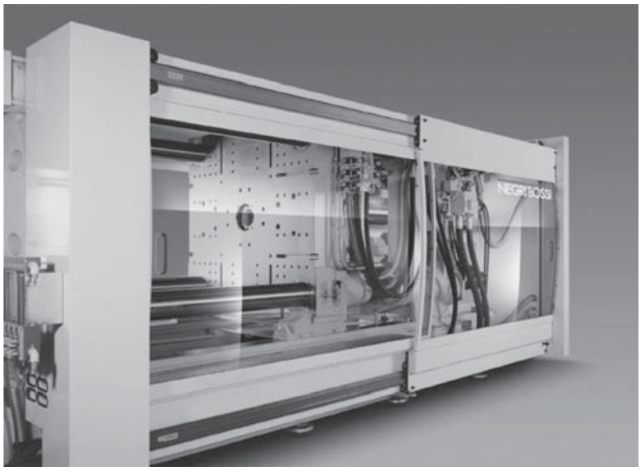

Figure 11. The clamp unit displayed here shows the moving platen with T-slots for ease of mold mounting. (Photo courtesy of Negri Bossi.)

deep-draw containers and is usually engineered into larger machines.

Clamp rigidity, precise alignment/parallelism, and operation is of prime importance because of the extreme forces generated to hold the mold closed during injection. The machine's stationary platen and moving platen's deflection is of great concern; as a result, the most advanced metals, casting methods, and machining processes are typically used in their construction in order to minimize it.

The Ejector Mechanism

Molten thermoplastic resin, when cooled, shrinks onto the "core" of the mold and requires some force to eject it. This can be done in two ways: (a) via an air blast originating from the mold itself or (b) this in combination with mechanical ejector rods operated by the machine which in turn operate mold ejection surfaces. By their very nature, packaging applications produce ultra-thin parts. These ultra-thin parts in a relatively "warm" condition fixed to the mold core can create a problem during ejection. The part could deform if only mechanical ejection is used. Most thin-walled parts take advantage of the mold air eject feature to break the vacuum created between the part and the metal surface of the core.

The Base Unit

The importance of this part of the machine's construction should not be underestimated. The base unit houses all of the major components described above. It carries the weight of these large components and connects them into one cohesive structure.

The base unit can be engineered in different ways, but almost all designs center on the "box tubular steel" welded constuction. This provides the necessary rigidity, strength, and stage for the operation of all components.

Features Specific to Packaging Applications

Thus far the machine description has been universal. Packaging applications demand features of the mold and machine dedicated to it. The packaging mold has been described in detail in this article. The packaging machine needs further clarification on design features which separate it from universal applications. Here is a summary and description of those features required by packaging applications:

- *Hydraulic Accumulator-Assisted Injection*. As described earlier in this article, this feature increases the velocity of injection in order to fill the cavity completely in a thin-walled mold. Instantaneous energy is directed to the injection unit to affect <0.5- to 1.0-s injection times.
- *Positive Nozzle Shut-off.* This feature allows the screw to rotate and plasticize resin while the clamp is opening. It prevents drool out of the nozzle during screw recovery/plasticizing.
- *Independent Plasticizing (Mold Opening During Plasticizing Phase)*. This feature allows faster cycle times of the machine/mold operation.
- *Independent Ejector Motion (Mold Opening and Ejection Simultaneously)*. This feature also allows faster cycle times of the machine/mold operation.
- *High-Pressure Injection (30,000 psi or Greater)*. Pressure is the result of restriction to flow. Due to the thin-wall restriction of the mold, greater forces and speeds of injection are required to completely fill the cavity. The forces here are created by the accumulator assisted injection described above. Keeping the screw size as small as possible also aids in higher injection pressures (pressure = force/area).
- *Barrier Screw for Higher Plasticizing Rates.* This type of screw is sometimes called a "double-wave" screw. The flights of the screw are doubled for greater shearing capacity and therefore greater plasticing/melting output. Another benefit is the greater mixing of the melt which aids in better part quality and processability. Typically, barrier screws are best suited for the polyolefin materials such as polyethylene. A thermoplastic material in high use for packaging applications.
- *High-Flow Check Ring.* The objective is to minimize any restriction to the flow of plastic material. High-flow check valves located on the tip of the screw do just that.
- *Magnetic Resin Filter under Hopper.* Entry points of the plastic into the mold are very small, in the area of 0.04 in. (1 mm) and smaller. Any foreign matter and especially metal can damage the mold or get trapped in the mold, creating flow restrictions. The magnetic filter assists in removing these contaminants.
- *Air Ejection Valves (for Mold Air-Eject Sequence)*. As described earlier in this article, the plastic part shrinks onto the mold core due to cooling and creates an air-lock that needs to be broken for safe and effective ejection of the part.

- *Hot Runner Temperature Controls*. The hot runner system in the mold requires temperature controls to affect the heat energy directed to the molten plastic.
- *Possible Hot Runner Valve Gate Hydraulic Valve and Control*. Periodically, a type of hot runner system known as a Valve Gate System is required to positively shut off the plastic flow directly at the cavity entry point (gate). This is done by a metal pin in the flow of the plastic operated by a piston in the mold. The control of the valve gate piston can be done pneumatically or hydraulically. The machine would then be fitted with a pneumatic or hydraulic valve to activate the valve gate piston.
- *Possible Parts Blow-Down after Ejection*. Multicavity molds eject parts that fall at the speed of gravity. In order to quicken the speed of the machine/mold operation (reduce cycle time), a blast of air directed downward on the parts can be beneficial in reducing the time it takes for the parts to clear the mold and allow it to close unhindered.
- *Increase Power Plant Horsepower.* In order to supply the instantaneous power requirements for packaging applications, the machine's power plant needs to be engineered accordingly. Pumps, motors, and valves must be sized properly and integrated with the machine control architecture to create conditions for ultra-fast and ultra-precise operation.

AUTOMATION FOR INJECTION MOLDING MACHINES

The process of injection molding does not end with the part being ejected from the machine. Somehow the part must get from the ejection sequence to the carton box in which the part will be shipped, or on to a secondary process such as subassembly with other parts. This process is called "downstream part handling," and there are many ways to do this. Parts could drop directly into the shipping box if there are no cosmetic abrasion concerns. It is certainly the least expensive way without need of any handling equipment. An operator could manually take parts off a conveyor belt and stack them into the shipping box? Or a better, more cost-effective way would be to automate the process fully and eliminate the need for costly manual labor while protecting the quality of the part molded.

Automation can take on many different forms. It can start right at the mold with specialized mold chutes designed to carry the parts to another station that packs them into boxes. It could be various robotic equipment such as three-axis or six-axis robots programmed for sequenced action (see Figure 12). These robots could stage a secondary process where parts are wrapped or stacked or printed or any other process required. Automation can perform quality control procedures such as weighing, inspecting, dimensioning, and so on. Indeed, every approach to automating plastic-molded part production is a creative process, and the choices available are extensive, impressive, and worthy of investigation.

Figure 12. Floor-mounted 6-axis articulating robot. Models also come in platen-mounted designs. End of arm tooling not shown. (Photo courtesy of KUKA Robotics.)

MONITORING AND SERVICING THE MACHINERY

Every second of production downtime costs money and valuable resources in a molding company. There is a great need to diagnose and monitor the machine operation including visual imagery from wherever the production manager is located, be it in the plant or out of town on business or even at home in critical situations. It is identically vital that the machine maker's service technician access real-time machine data and visual imagery from wherever they are in the name of responsive service and uptime for their customer, the molder.

Internet technology has made the above scenario possible. Real-time data on the machine process is now available via secure networks with access to any internet location worldwide. This 21st-century technology is revolutionizing the service, monitoring, and control of injection molding machines. It makes the job of servicing machines easier, faster, and better like never before. Problems get diagnosed immediately via the internet through secure levels of access. The manpower, tools, and parts needed to make the fix are prepared ahead of the travel to the machine's location. The jobs are done effectively, efficiently, and at minimum cost to the service company and/or molder, depending on cause. For the first time in the evolution of the injection molding machine, the customer and machine maker have the power over every aspect of machine operation in realtime. One system made by a well-known machine maker also allows real-time changes to be made to machine parameters/settings remotely via any internet location worldwide. This is by far the most powerful service tool ever devised for injection molding machines. See Figure 13 for a graphical explanation of a unique remote teleservice system that works with a

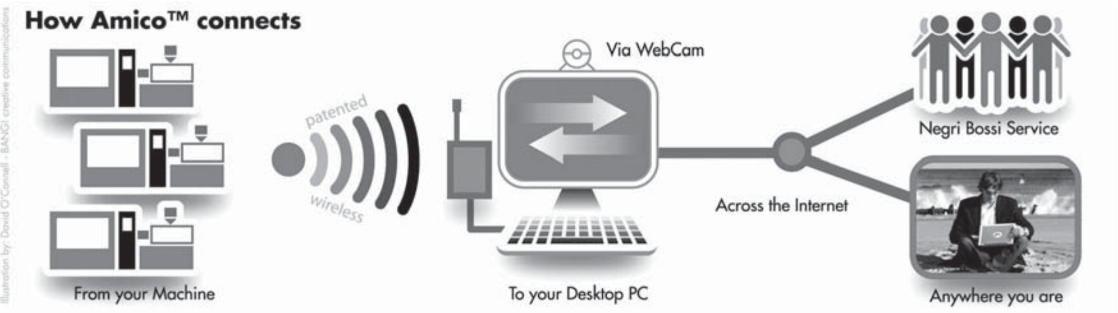

Figure 13. A graphical representation of a remote teleservice system utilizing patented wireless connectivity between machine and central PC. Sun Chemical Corporation

INTRODUCTION

Printing ink is a mixture of coloring matter dispersed or dissolved in a vehicle or carrier, which forms a fluid or paste that can be printed on a substrate and dried. Printing inks are used to decorate the exterior of virtually every package and substrate used in packaging. Since there are various substrates, a number of different printing methods are required to satisfy the needs of this entire market (1). In general, the inks required may be subdivided into two classes: liquid inks and paste inks. The liquid inks include those printed by the flexographic, rotogravure, and screen process methods; the paste inks include those printed by lithographic offset, letterset, and letterpress (see Decorating; Printing).

Basically, all printing inks consist of a colorant (see Colorants), which is usually a pigment but may be a dye, and a vehicle that acts as a binder for the colorant and a film former. Vehicles generally consist of a resin or polymer and a liquid dispersant, which may be a solvent, oil, or monomer. Many other additives are used to provide some specific property or function to the ink or ink film. Approximate viscosities and film thicknesses used in different printing processes are given in Table 1. The four key properties of ink are drying, rheology, color, and end use.

LIQUID INKS

Flexographic Ink

Flexographic printing utilizes a rubber or plastic printing plate and is essentially a typographic process, printing from a raised area. The inks used are very low in viscosity (see Table 1) and dry rapidly because of their relatively high volatility. Since the printing press used has a very simple ink distribution system, these volatile inks do not cause problems in drying on the inking rollers. The thickness of the ink film is controlled by the depth of engraving used on the anilox inking roller. The commercial speeds used for this type of printing range from 500 to 1000 ft/min (152–305 m/min). Flexographic ink accounts for more than half of the ink utilized in decorative packaging.

Flexographic inks may be subdivided into two general classes: solvent-based and water-based. The volatile solvents selected for the formulation must be chosen with care, since they are in constant contact with the plate elastomer. It is important to screen these ink solvents with the plate and roller elastomers to ensure that no swelling

Table 1. Ink Viscosity and Film Thickness by Process

Process	Viscosity, Poise (Pa · s)	Printed Film Thickness (μm)
Lithography	50–500 (5–50)	1–2
Letterpress	20–200 (2–20)	3–5
Flexography	0.1–1 (0.01–0.1)	6–8
Gravure	0.1–0.5 (0.01–0.05)	8–12
Letterset	30–300 (3–30)	1.5–3
Screen	1–100 (0.1–10)	20–100

or attack of the surface takes place. In most cases, alcohols are the material of choice for solvent-based flexographic inks, with additions of lower esters and small amounts of hydrocarbons. These are used as needed to achieve solubility of the vehicle resin and proper drying of the ink film at press speed. Solvent blends are required to achieve the best balance of viscosity, volatility, and substrate wetting and must also take into account EPA (Environmental Protection Agency) requirements.

Water-based inks have increased in popularity because of air pollution concerns and are being used in increasing amounts for both absorbent and nonabsorbent substrates. The solvent used in these inks is usually not 100% water. They may contain as much as 20% of an alcohol to increase drying speed, supress foaming, and increase resin compatibility. The wetting of plastic substrates is also greatly aided by the lower surface tension of the alcohol–water mixture.

The resins and polymers used in the flexo-ink vehicles cover a wide range of chemistry and are selected to achieve adhesion to various substrates or to confer resistance properties to the dried ink film. A number of resin classes and the substrates upon which they are generally used are shown in Table 2. Note that the water-based vehicles are listed in a separate portion of the table, since they are generally emulsions or colloidal dispersions rather than true solutions.

A generic formulation for an aqueous flexographic ink (components amounts are in %, w/w) is as follows: pigment dispersion, 35–50; emulsion vehicle, 25–35; solution vehicle, 10–20; amine neutralizer, 0.5–1.5; wax emulsion compound, 2–5; wax powder, 0–2; surfactant, 1–1.5; cross-linking additive, 0–2; silica additive, 2–5; corrosion inhibitor, 0–1; defoamer, 0–1, other additives, 0.25–0.5 (2).

Gravure Ink

Gravure printing utilizes an etched or engraved cylinder to transfer ink directly onto the substrate. Because of the mechanics of filling the very small cells, the viscosity of gravure inks must be relatively low (see Table 1). This is also required in order to transfer ink from the engraved cells at high speeds. The rotogravure press uses a simple inking system, where ink is applied directly to the gravure cylinder and excess ink is scraped off with a doctor blade. The ink-film thickness is determined by both the depth of engraving and the area of the cells, because these two factors determine the volume of ink transferred. Commercial speeds vary from 800 to 1500 ft/min (244–457 m/min) or more. Gravure ink is the second-largest category of packaging inks. Together with flexographic ink, these two liquid inks account for more than 80% of all packaging ink.

Rotogravure inks can also be classified as solvent-based or water-based types. The solvent-based inks are not as restricted by plate compatibility problems as are the flexographic inks because the plate is metal and resistant to nearly all solvents. Since a wider variety of solvents can be utilized in manufacturing a rotogravure ink, a much wider range of resin types and resin molecular

Table 2. Liquid Ink Applications for Packaging: Flexographic and Gravure

weights can be utilized in achieving the desired ink properties. This means that gravure inks for packaging can be tailored for good adhesion to the widest selection of substrates. Historically, there are 10 gravure inks categorized by the binders or solvents used: A, aliphatic hydrocarbons; B, aromatic hydrocarbons; C, nitrocellulose; D, polyamide resins; E, SS, nitrocellulose; M, polystyrene; T, chlorinated rubber; V, vinyls; W, water-based; and X, miscellaneous. Many of these classifications are blurring as blends of these materials are becoming more common (1).

The resins and polymers used in packaging gravure vehicles cover a wide range of chemistries and are chosen to achieve adhesion to various substrates or to confer specific properties to the finished ink film. These are listed in Table 2.

Approximately 50% of all flexographic inks use water as their primary solvent and diluent. Water-based gravure inks are used widely for printing paper and paperboard substrates, and their use for nonpaper substrates is growing because of concern about air pollution. The formulation of these inks is very similar to those used in water-based flexography and the polymers are also very similar. These are listed in a separate section of Table 2. Main advantages of water inks include excellent press stability, printing quality, heat resistance, absence of fire hazard, and convenience of water for reduction and wash-up. The main disadvantage of water inks is the increased energy required for drying due to the high latent heat of water. A significant problem that can occur with water-based inks in gravure is the drying of the vehicle polymer or resin in the engraved cells. This can occur during shutdowns of the press. Some of these materials are not readily resoluble once they have dried because they are usually emulsions or colloidal dispersions in water. To assist in the drying of water-based inks, the gravure cylinders are usually engraved or etched with shallower cells. A thinner ink film is applied, which contains less water to evaporate. This also means, however, that the amount of pigment in the press-ready ink must be higher in concentration to achieve the same relative printing density as the solvent-based ink.

Uses. Type C inks are the dominant group used in packaging gravure. Type C is used for printing on foil, paper, cellophane, paperboard, coated and uncoated paper, glassine, acetate, and metallized paper. Type A and B are used for gift wrapping paper. Type D inks have excellent adhesion to many plastic films. This type ink is used in foil, paper, and paperboard. Type E includes a wide variety of inks and lacquers and some dye inks. They are often used on paper and paperboard, some grades of cellophane shellac, or nitrocellulose primed foil pouch stock glassine and other coated speciality products. Type T inks show extremely good resistance to alcohol and soap. They are considered high-quality inks. Type W gravure inks, primers, and lacquers are used to comply with VOC emission standards. Water inks are primarily used in packaging gravure on board and paper. Type V inks are used for printing vinyl films and Saran (1).

Screen Ink

Screen printing, which accounts for a relatively small percentage of ink used in the packaging market, is used on low-volume specialty items or where very thick films are desired (see Table 1). Screen ink is included in the liquid-ink section because of its paintlike rheology and chemistry.

Screen inks are applied by squeegeeing the ink through a stencil screen with a rubber blade. The inks must have adequate flow to pass through the screen, but must also have enough body to resist dripping and stringing when the screen is lifted. For many years this was a hand-printing operation, but has now become largely mechanized due to the development of rotary screen technology which allows screen units be inserted in-line with other printing technologies on web-fed combination presses. The two largest classifications of screen inks are solvent types and plastisol types, although water-based, radiation-curing, and two-part catalytic systems are also available. Substrates need not be flat, because oval and round forms can be printed.

Lamination Inks

These inks must not interfere with the bond that is formed when two or more films are bonded together to obtain a structure that provides more resistance than is found in a single film. Laminations are used in candy and food wrappers. Resins used for this ink cannot exhibit any tendency to retain solvent because this would contaminate the product. In addition to polyamides, these inks contain modifiers such as polyethylene resins, plasticizers, and wax. Laminations are usually reverse-printed and end up sandwiched between films. Water-based inks are being tested for their functionality and ability to meet U.S. EPA emission standards.

PASTE INKS

Offset Lithographic Ink

Lithographic printing uses a planographic plate in which the ink-receptive image is chemically differentiated from the nonimage area. Since these plates are constantly wetted with a dampening solution, the inks must resist the chemicals contained in these solutions without changing in their printing characteristics. The thickness of the ink film in this process is 1–2 μm, which is the thinnest film in any commercial process. Because of this, the colorant concentrations in lithographic inks are generally higher than those found in inks for other processes. Lithographic inks generally have relatively high viscosities due to the ink-distribution systems used on the press equipment for this process. It is also common to find a gelled consistency in the body of these inks because of the need to obtain high printing resolution and faithful reproduction of the plate image. Image quality of half-tone reproduction is extremely high.

Sheetfed Offset Lithography. A large segment of commercial prinitng is done on sheet-fed presses almost entirely by the litho process. Inks for these presses are based on vehicles containing phenolic-modified, maleic-modified, or unmodified rosin-ester resins dissolved in vegetable-drying oils and diluted with hydrocarbon resins. Special acrylic resins have been developed for use in quickset inks, and they offer nonskinning properties and excellent press stability. This process is widely used for printing on packaging board, paper, metal, and plastic sheets. The use of the offset blanket permits excellent reproduction even on surfaces that are not entirely flat owing to the compressibility of the blanket material. The inks used for most conventional sheetfed printing are dried by an oxidative process and may also be accelerated by the use of infrared radiation. These inks set rapidly in a matter of seconds, but are not truly dry for several hours. In the case of metal, the inks are usually reactive only at high temperatures of ≥300°F (≥149°C), which are achieved by passing the metal sheets through a heated oven after removal from the press.

Drying of sheet-fed lithographic inks can be done with ultraviolet radiation, which is applied by means of high-powered mercury arc lamps immediately after printing. This process is widely used in the production of packaging that must be die cut and finished in-line, such as cartons for cosmetics and alcoholic beverages. Ultraviolet drying of the ink offers significant energy savings in metal decorating where it replaces long, energy-consuming ovens.

Web Offset Lithography. In web offset, the same lithographic principles that are used in sheet-fed lithography are applied to the printing of the substrate in the form of a web. The web of the substrate is fed into the printing press for decoration from a large roll. The printed substrate, upon exiting the press, must be dried immediately so that the finished product can either be rewound, sheeted, or finished in-line. The most common method to dry the printed ink immediately is the utilization of a high-temperature oven that employs recirculated hot air at a temperature of about 250–350°F (121–177°C). For this reason, the handling of plastic substrates is generally not possible because of the distortion of the substrates at these high temperatures. Drying inks with ultraviolet or electron beam radiation allows the printing of temperature-sensitive substrates. Generally, web offset printing in packaging is confined to paper and board printing. However, drying technology utilizing radiation curing promises to offer the packaging market the advantages of high-speed printing, the quality of offset lithography, and the lower cost of offset plates compared to gravure cylinders. Typical speeds for web offset printing are 800–1200 ft/min (244–366 m/min).

Letterset Ink

This printing process, formerly known as dry offset, is a combination of letterpress and offset in that the printing plate uses raised images, but the printing on the substrate is accomplished with a rubber blanket. Therefore, the inks used in letterset generally have the viscosity and body of a letterpress ink. The predominant use of letterset printing in packaging is for the decoration of two-piece metal cans (see Metal cans, fabrication). Plastic preformed tubs and containers are also printed utilizing the letterset process on a mandrel press. Two-piece can printing is accomplished on special presses that produce at the rate of 1200 cans per minute with up to five colors and a clear varnish. The inks for beverage cans are generally dried by heat.

Ultraviolet drying is used by several metal-decorating printers, primarily for beer cans. Ultraviolet is widely used for curing plastic containers where thermal sensitivity is a serious problem and heat curing cannot be used. The metal-decorating ovens used for thermal curing have recently gone to short cycles that use temperatures of 600°F (316°C) for only a few seconds to cure the inks. These inks are used primarily for ecological reasons (3).

Letterpress Inks

These inks are used primarily for printing corrugated packaging (see Boxes, corrugated), although small amounts are still used for folding-carton and multiwall-bag (see Bags, paper) printing. Since letterpress uses raised images, the inks are fairly heavy in body (Table 1), and the primary mechanism for drying is oxidative or absorptive. The inks are generally formulated in a manner similar to sheet-fed offset inks but with a slightly lower viscosity. This printing method has been losing market share to the other printing processes for a number of years because of high preparatory and labor costs. This is particularly true in corrugated printing, which is going primarily to water-based flexography.

ENVIRONMENTAL CONCERNS

Speciality inks are a sector of the chemical industry. Federal regulations fall under the auspices of the United States Environmental Protecion Agency and the Department of Labor and to a lesser degree the Food and Drug Administration. Some states and voluntary guidelines also impact ink.

In general, environmental concerns affect various industries involved with ink. These include the converting industry that uses inks to produce packaging and printed matter of all types and even extends to issues related to the ultimate end-user companies whose printed or packaged products are often distributed around the world.

Common environmental aims such as reducing air pollution, use of renewable resources rather than crude-oil based chemistries, biodegradable inks and coatings, and the pressure to recycle waste materials back into the raw materials supply impact the printing ink industry. Over the past 20 years, new ink products have been developed and will continue to be developed in response to environmental issues.

The United States has been among the most highly regulated countries in the world. Beginning in the 1970s and continuing through the 1990s, there was a persistent flow of regulations governing not only printing processes but also the use and disposal of printed matter. A clear historical account of the effect of antipollution laws and the ink industry can be traced. Since the late 1980s, Canadian, Asian, and European markets have had a heightened perception of environmental issues, and regulations in these countries are being formulated at a faster rate than in the history of the United States. As printing ink becomes a global business, the successful marketing of ink technology now requires attention to an expanding body of worldwide regulations.

INTELLIGENT INKS IN PACKAGING

Andrew Mills
Department of Pure and
Applied Chemistry, University
of Strathclyde, Glasgow, UK

INTRODUCTION

The traditional roles fulfilled by packaging are protection, containment, communication, and convenience, and the ability to address these different roles has improved enormously over the years (1). In packaging, the role of communication is largely affected using printed inks, which provide such diverse information as product and producer names, ingredients, price, sell-by date, and bar code. Although it is possible to print directly on plastics, as well as paper, the latter is usually cheaper; thus, on primary packages such information is usually conveyed via an exterior self-adhesive label, comprising inert inks (i.e., oblivious to their environment) and providing information that does not change during the lifetime of the package.

Nowadays, there is increasing interest across the food packaging chain—from packager to wholesaler and from retailer to end-user—for reactive, printable inks, that is, intelligent, smart, or diagnostic inks that do respond to their environment, for example, by exhibiting a change in color or luminescence intensity to a change in the temperature outside the package or the level of oxygen or carbon dioxide inside and, in so doing, provide important information, that is, intelligence (1–7). Such intelligent inks are a key aspect to intelligent packaging (see Intelligent Packaging), recently defined as "capable of carrying out intelligent functions, such as detecting, sensing, recording, tracing, communicating and applying scientific logic" (1).

Just like inert inks, intelligent inks are usually printed on a surface that is applied to the package in the form of sticky labels for ease of application and incorporation. Because they are more than a normal label, such intelligent labels are often called "smart package devices" (SPDs) (1). For internal applications, SPDs often have an outer cover, usually a polymer membrane, to allow transmission of the analyte under test (e.g., oxygen) to the reactive ink in the label and prevent direct contact between the package contents and printed ink. There are a large number of patented SPDs that utlize intelligent inks and cover a wide range of chemical and physical processes. However, most of these are unlikely to have any significant commercial future, usually for reasons of cost, especially when considered for use in the food and beverage packaging industry, the largest of the packaging industries. As a consequence, this limited overview will illustrate the emerging area of intelligent inks in packaging by focusing on the different intelligent inks and SPDs which are now commercially available for use in the food and beverage packaging industry.

TEMPERATURE

Inks that change color with temperature are thermochromic (8, 9). Such inks are fairly commonplace, especially in the novelty toy market and textiles, and have been used for a variety of applications including: a safety feature for baby spoons, cups or kettles (warning of a hot surface), authentication devices on restaurant tickets, pre-paid phone cards, and store coupons and a method to prevent color copying of sensitive documents. In almost all these cases, these thermochromic inks used exhibit a reversible response, albeit with some hysteresis, and are indirect systems—that is, ones in which the chromophoric material reacts to changes in its environment brought about by heat, involving composite thermochromic pigments.

The use of thermochromic inks is not unusual in packaging and is a common feature of product labels and advertising specialities. For example, they are currently used as follows: to show when pancake syrup has been microwave heated to the desired temperature (10); in the lids of disposable coffee cups to indicate the coffee is still hot and the lid is correctly placed (11); and on beer cans to indicate when they are fully chilled (12). As an illustration of the latter, the beer manufacturer, Grolsch UK, recently featured a thermochromic ink on their cans so that the consumer could identify when the beer had been sufficiently chilled, as illustrated by the pictures in Figure 1.

Figure 1. Photographs of a can of Grolsch™ beer (**a**) before and (**b**) after correct chilling, the ink in the label becomes lighter.

The key component of most thermochromic inks used in packaging are polymer microcapsules, 1–10 μm in diameter, containing three interacting chemicals responsible for the overall temperature-dependent color in an ink, which also comprise a resin and a solvent. The first of the three components in the microcapsules is a leuco (i.e., colorless) dye, such as a fluoran, triphenyl methane lactone, and spirolactone. The ring-closed forms of these dyes are colorless—thus their "leuco" epithet, from the Greek "*leukos*" meaning white. In contrast, the ring-opened forms of these dyes are highly colored and generated by protonating the leuco form using a proton donor. The protonation of the leuco dye, Crystal Violet Lactone, to create its highly colored, protonated form is illustrated in Figure 2. Not surprisingly, the second microcapsule component is a weak acid that acts as a solvent and proton donor to the leuco dye (i.e., a "color developer") such as bisphenol A, alkyl *p*-hydroxybenzoate, and derivatives of 1,2,3-triazole and 4-hydroxycoumarin. The third component is a polar co-solvent, such as lauryl alcohol or butyl stearate, with a low melting point that controls the temperature at which the color change will take place (8, 9). The dye is usually protonated (i.e., highly colored) when this solvent is a solid, but colorless, (i.e., in its leuco form) when it is melted. Interestingly, although many combinations of dye-developer-solvent are known, the exact mechanism by which such thermochromic dyes operate is still the subject of some debate (9); however, a popular explanation is that the color of the solid form of the material is due to an ion-pair interaction between the dye and the developer—an interaction that breaks up when the solvent melts, thereupon returning the dye to its protonated, leuco form.

There is a temptation to include in this section details of the most advanced of all the SPDs, in terms of commercialization and product integration, namely time–temperature indicators (TTIs, also see Time Temperature Indicators), that is, devices that integrate over time the exposure of the package to temperature (13). However, most TTIs do not utilize a reactive, printable ink, but rather are diffusion/melting point-based with a mechanical activation element—for example, the breaking of a seal separating one reservoir from another (13–15). There are some chemical-reaction-based TTIs, such as FreshCheck™ indicator (TempTime Corp.) based on a lattice-controlled, solid-state reaction, proceeding through a 1,4-addition polymerization route, of colorless diacetylenic monomers, such as that shown in Figure 3 (14, 16, 17). These compounds polymerize thermally to give very dark, conjugated polymers. The kinetics of the polymerization depends upon the type of substitution and thus provides a route by which TTIs with different

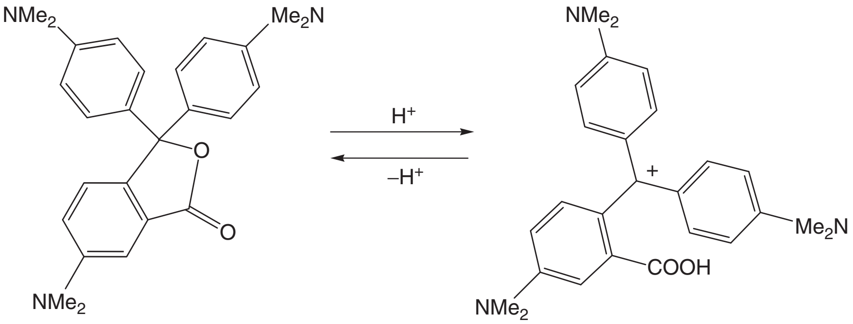

Figure 2. Reaction scheme illustrating the protonation of the well-known thermochromic dye Crystal Violet Lactone. The lactone form of this dye (left-hand-side structure) is colorless, whereas its protonated, ring-opened form is bright blue.

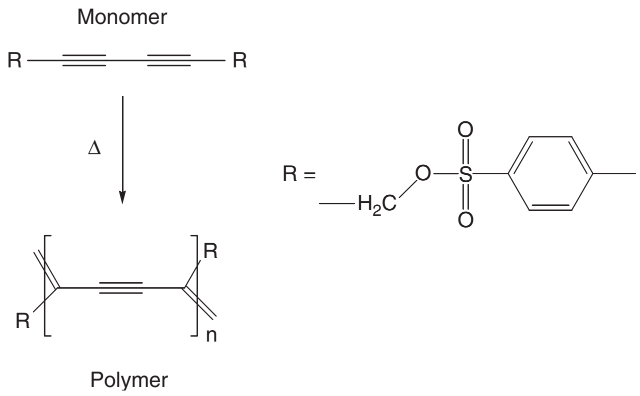

Figure 3. Polymerization of a diactetylenic monomer (colorless) that leads to a dark product; this chemistry underpins the FreshCheck™ indicator (14).

temperature sensitivities can be produced. In a typical indicator the polymerization takes place in the center of a bull's-eye pattern, with the outer part of the bull's-eye acting as reference color ring. FreshCheck™ indicators are used by some supermarkets, such as Trader Joe's in the United States and Monoprix in France, on selected refrigerated products. Another, similar TTI is the irreversible thermochromic colorless (to deep magenta) ink, developed for use as a TTI bar code by SIRA Technologies as part of their Food Sentinel System™ (18). Details of this latter ink are sparse, but, like the FreshCheck™ TTI, the Food Sentinel System™ indicators appear to be full history TTIs that are temperature-only activated (i.e., no mechanical activation) and so require deep-freeze storage prior to use—a feature that, although clearly an essential for all temperature-only-activated TTIs, is costly and a major limitation to any global product implementation.

The Cryolog company has recently developed an irreversible, novel, temperature-activated, printable TTI label that utilizes food-grade microorganisms to simulate the real deterioration of food products—called Traceo® technology (19). The growth of these microorganisms parallels that of the microorganisms naturally present in the food and produces a pH change in the indicator which is revealed using a pH-sensitive dye and/or a pH-sensitive obscuring agent, such as casein. This initially colorless, transparent Traceo® technology is used to cover barcodes, turning pink and concealing the barcode if the product is no longer fresh due to improper temperature storage. As with FreshCheck™ and Food Sentinel™, the Traceo® TTIs are full-history, temperature-only-activated indicators, requiring deep-freeze storage prior to use.

The above TTIs are compatible with label technology but not with direct printing as reactive inks. However, more promising is OnVu™, recently promoted by Ciba Specialty Chemicals and FreshPoint as a printable, *irreversible* thermochromic ink that is UV-activated and thus able to act as a TTI (20). The key ingredient is a colorless, valence isomerization photochromic, such as a spirobenzopyran, that is rendered dark blue (indicating formation of a meta-stable state) upon exposure to UV light and remains in this form when held at temperatures $\leq 1^{\circ}$C, but reverts thermally to its colorless, more stable form in about 7 days when held at 25°C. Thus, exposure to temperatures higher than those prescribed accelerates the lightening process of the color; and when the activated color attains the same shade as the reference, the product is deemed to have reached the end of its shelf life. Evaluation of the status of the indicator is made by reference to printed colors within the label. The OnVu™ label is currently printed as simple labels using water-based flexo inks, but the slight, negative feature of this label appears to be its continued sensitivity to UV light once activated (since the latter reactivates the pigments). This is addressed in the label by a UV filter flap, which needs to be placed over the label, *after UV activation*, to protect it from recharging by ambient UV light. An online labeling device has been made for this technology to allow the basic indicator to be UV-activated and then protected from re-activation by the overprinting of a UV filter. Although initially developed for use by the meat and dairy industries, plans are in place for OnVu™ indicators for fresh salads, chilled prepared dishes, and juices and to serve the medical industry, for blood, vaccines, and medication (20).

LIGHT

Dyes that change color upon exposure to light—that is, photochromics (8)—are sometimes used to protect products from overexposure to light, especially UV light. Because their main role is to respond to the environment in such a way as to protect the product, rather than provide information, they are best considered as an example of *active*, rather than *intelligent*, packaging (21) and thus will not be detailed here.

OXYGEN

At first it may not be clear why the detection of oxygen is important, especially in food packaging. However, oxygen is the main cause of most food spoilage, since its presence allows a myriad of aerobic food-spoiling microorganisms to grow and thrive. Oxygen also spoils many foods through enzyme-catalyzed reactions, as in the browning of fruit and vegetables, destruction of ascorbic acid, and the oxidation of a wide range of flavors. An increasing popular method of packaging food is modified atmosphere packaging (MAP, see also Modified Atmosphere Packaging), a process in which the atmosphere within the food package is flushed with an inert gas, such as nitrogen or carbon dioxide, reducing the oxygen content to typically 0.5–2% (7, 13, 22, 23). Unlike nitrogen, carbon dioxide is an *active* gas in food packaging, since it affects most food-spoiling microbes, reducing significantly their growth, even if some oxygen is present (22). Both carbon dioxide and nitrogen slow the rates of respiring foods, such as fruits and vegetables, and retard oxygen-based spoilage. As a consequence, MAP is very effective at extending the shelf lives of many foods, typically by a factor of 3–4, and is widely used in food packaging; indeed, it is estimated that 52 billion food packages were MAPed in 2007 (23). An intelligence ink for oxygen has great potential with regard to MAP, since it would provide the packager with a method

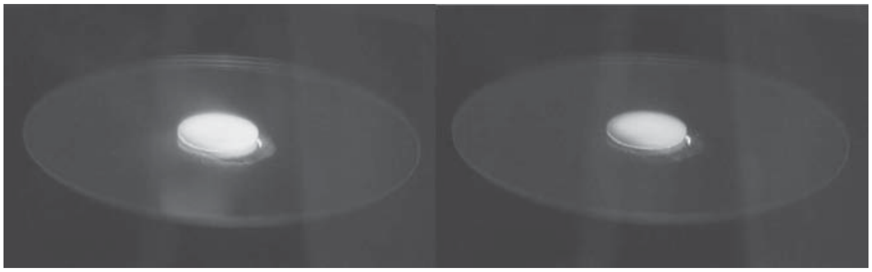

Figure 4. An O_2xyDot™ in the presence (left-hand-side image, higher level of luminescence intensity) and absence (right-hand-side image) of oxygen.

of ensuring 100% quality assurance, help the retailer identify packages of compromised integrity (e.g., damaged in transit or subjected to tampering), and reassure the consumer that the quality of the contents inside has not been compromised by damaged packaging.

Intelligent ink oxygen indicators fall into two categories—luminescence or colorimetric—and most are luminescence-based, comprising a lumophore, L, dissolved in a solvent along with a solvent-soluble resin, such as a fluoro-silicone polymer. The luminescence associated with the electronically excited lumophore, L^*, is quenched irreversibly by molecular oxygen, that is,

$$L^* + O_2 \underset{k_Q(O_2)}{\longrightarrow} L + {O_2}^* \qquad (1)$$

where k_Q (O_2) is the bimolecular rate constant for the quenching process.

Although many different lumophores have been tested, one of the most popular is tris(4,7-diphenyl-1,10-phenanthroline) ruthenium (II) perchlorate, that is, $[Ru(dpp)_3](ClO_4)_2$, where dpp is the complexing ligand, 4,7-diphenyl-1,10-phenanthroline; $[Ru(dpp)_3](ClO_4)_2$ is a highly luminescent complex (probability of luminescence $\cong 0.3$) with a long-lived excited state ($\sim 5.3\,\mu s$), that is readily quenched by oxygen (k_Q $(O_2) \cong 2.5 \times 10^9\,dm^3\,mol^{-1}\,s^{-1}$) (24, 25).

The luminescence of a commercial luminescence-based oxygen indicator, the O_2xyDot™, comprising $[Ru(dpp)_3](ClO_4)_2$ in a silicone polymer dot (5-mm diameter, 0.2 mm thick) with a glass (or nowadays acetate) backing support, is illustrated in Figure 4. The O_2xyDot™ is attached inside the package under test using typically an RTV silicone rubber adhesive. It is possible to assess the level of oxygen surrounding such a luminescence oxygen indicator (i.e., $\%O_2$) by measuring its luminescence intensity. However, such measurements require significant calibration and a very stable excitation light source and detector. As a consequence, with such indicators it is generally preferred to determine $\%O_2$ via the measurement of luminescence lifetime, τ—that is, the time taken for the luminescence to decay to 1/*e* of its initial value—although the equipment costs associated with this technique are significant. This is certainly how the O_2xyDot™ is used, and Figure 5 illustrates a typical set of luminescence decay curves for the O_2xyDot™ as a function of increasing oxygen partial pressure (26). From these results it can be seen that τ decreases with increasing $\%O_2$, and further work shows that $1/\tau$ is proportional to $\%O_2$; thus these indicators can be used for quantitative analysis of O_2. Although the major current, commercial oxygen sensor system used in food packaging, OxySense™, uses lifetime measurements and luminescence-based oxygen indicators, this approach is still too expensive, in terms of equipment and indicators, for incorporation in all MAPed packages and so its use is limited to mainly package research (24, 26).

Luminescence is often hard to discern and requires analytical equipment to assess the degree of quenching. This represents a major disadvantage of luminescence-based intelligent inks. In contrast, colorimetric indicators can be assessed, semi-quantitatively at least, by eye; as a result, there is much more interest in intelligent inks based on color. A commercial, colorimetric ink that responds to oxygen has recently been reported and comprises the following: a UV-only absorbing semiconductor photosensitizer, TiO_2; a redox indicator, methylene blue (MB); a mild reducing agent, glycerol; and a polymer encapsulating material, hydroxyethyl cellulose (27, 28).

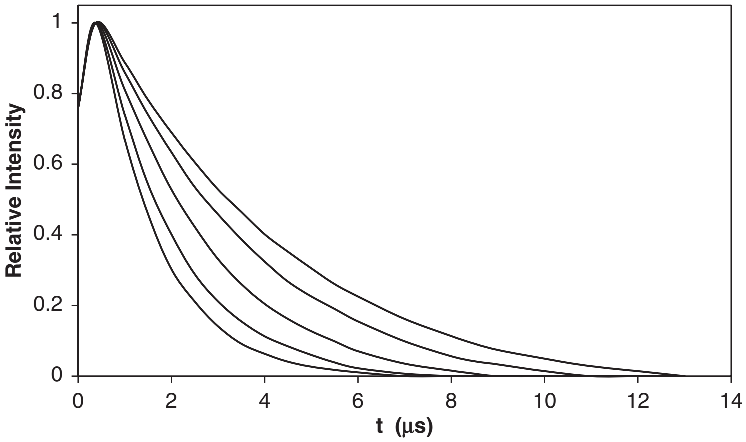

Figure 5. Luminescence decay profiles, produced using a pulsed excitation light source, for the oxygen-quenchable lumophore $[Ru(dpp)_3]^{2+}$ in an O_2xyDot™ indicator under different levels of oxygen (i.e., from slowest to fastest decay: 0%, 2.1%, 6.3%, 12.6%, and 21.0%, respectively).

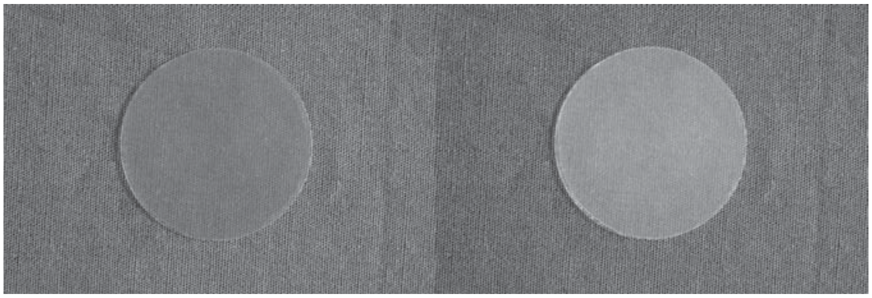

Figure 6. Photographs of a typical colorimetric, oxygen-sensitive, TiO_2/MB/glycerol/HEC ink before (left-hand side) and after (right-hand side) UV activation (3 min, 4 mW cm^{-2}). After UV activation the ink recovers its initial blue color within 10 min in air, but remains colorless in the absence of O_2.

All of the indicator components are soluble, or easily dispersed, in water and can be used to create a water-based, oxygen-intelligent ink that can be printed on a variety of common substrates used in food packaging.

The above MB/TiO_2/glycerol oxygen indicator is activated with UV-light; and Figure 6 illustrates a typical indicator film, made from such an ink, before (blue-colored) and after (colorless) UV activation. Before UV activation, the ink is inert, but upon activation it acts as an oxygen indicator, returning to its original color upon exposure to air, or remaining colorless in the absence of oxygen. The UV-activated oxygen indicator works via the simple mechanism illustrated in Figure 7. In brief, upon UV excitation of the nanocrystalline, finely dispersed titania (TiO_2) pigment powder particles encapsulated in the polymer film, electron–hole pairs are generated. The photogenerated holes are able to oxidize readily and irreversibly the glycerol present, allowing the photogenerated electrons to accumulate on the semiconductor particles, $TiO_2(e^-)$. These electrons reduce the highly colored redox-indicator (MB) to its usually bleached form (LMB). This latter species is readily oxidized back to MB by oxygen, thereby regaining its original color. However, if no oxygen is present, the film remains bleached. The Finnish-based label manufacturer, UPM-Raflatac, has recently launched an oxygen-indicating label based on this technology (29).

CARBON DIOXIDE

The popularity of CO_2 as a MAP gas has been an important driver in the development of an appropriate intelligent ink to show up leaks in packages. The chemistry that is usually employed to sense CO_2 is based on its ability to acidify water (30, 31), that is,

$$CO_2(aq) + H_2O \Leftrightarrow H_2CO_3 \Leftrightarrow H^+ + HCO_3^- \qquad (2)$$

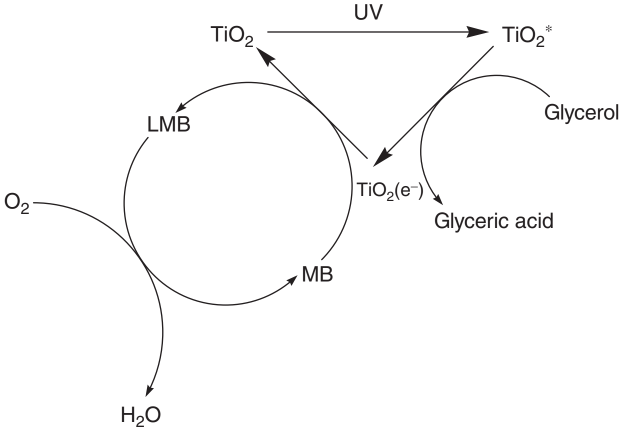

Figure 7. Schematic illustration of the primary processes involved in the functioning of the TiO_2/MB/glycerol/HEC ink.

The detection of the protons released by carbonic acid, H_2CO_3, is easily achieved using a pH-indicating dye, such as *meta*-cresol purple, which is blue when deprotonated (MCP^-) and yellow when acidified (MCPH). Thus, an aqueous solution containing MCP^- is blue in the absence of CO_2, but yellow when saturated with CO_2. Reaction (2) highlights the need for water in the formulation, but, ideally, a solvent-based (i.e., largely hydrophobic), intelligent ink for CO_2 is desired. This is achieved by coupling the anion of the pH-indicating dye with a phase transfer cation, Q^+, such as the tetraoctyl ammonium cation, to create a solvent-soluble ion pair, $MCP^-Q^+xH_2O$, which, as indicated by its molecular formula, usually retains a few molecules of water. As a consequence, when incorporated into an ink, the following reversible colorimetric process can be effected (30, 32):

$$\underset{\text{Blue}}{MCP^-Q^+xH_2O} + CO_2 \Leftrightarrow \underset{\text{Yellow}}{HCO_3^-Q^+(x-1)H_2O \cdot MCPH} \qquad (3)$$

The Trufflex GS carbon dioxide SPD, which has been promoted by Cryovac-Sealed Air Ltd., is an example of this technology (3).

FRESHNESS INDICATORS

Freshness indicators are designed to respond to chemicals released by food as a result of spoilage; usually an oxidative process is effected by bacteria, yeasts, and fungi, which break down food carbohydrates, proteins, and fats to a wide variety of low-molecular-weight molecules, such as lactic and acetic acids, aldehydes, alcohols, sulfur-containing species and nitrogen-containing molecules, such as ammonia and amines. For example, when proteins are bacterially decomposed, the products are amines that are related to the original amino acids that make up the protein. Thus, arginine is converted to putresceine, lysine, to cadaverine while histadine is converted to histamine. Putrescine, cadaverine, and histamine are volatile amines, responsible for the smell of rotting protein, such as meat and seafood. In much the same way that the

Figure 8. Typical bromophenol blue in poly(vinyl butyral)/tributyl phosphate film-coated sample bottle inverted over a sample bottle cap containing putrescine. The images were recorded after 0-, 10-, and 20-min exposure to the vapor above the sample bottle cap (33).

presence of CO_2 can be detected using an intelligent ink based on pH-sensitive dyes that respond to its slightly acidic nature, we note that intelligent inks, incorporating pH-sensitive dyes, DH, can be created that respond to the basic nature of volatile amines and ammonia, that is,

$$\underset{\text{Color A}}{\mathrm{DH}} + \mathrm{RNH_2} \Leftrightarrow \underset{\text{Color B}}{\mathrm{D}^-} + \mathrm{RNH_3^+} \tag{4}$$

For example, the pH indicator dyes bromophenol blue, bromocresol blue, and chlorphenol red have been used to create a range of ammonia intelligent inks, comprising dye, resin (poly(vinyl butyral)), plasticizer (tributyl phosphate), and solvent (methanol) (33). In the absence of ammonia or volatile amines, such as putrescine, the films are yellow, but in their presence they are either blue or purple. Figure 8 nicely illustrates the response of such a typical film coating a sample bottle when it is placed over a sample bottle cap containing a few milligrams of putresceine (a solid); within 20 min the initially yellow film is blue. This approach to sensing ammonia and volatile amines has been adopted by COX technologies, with their Fresh Tag™ indicator which is attached to the outside of the package as a small adhesive label and monitors the freshness of seafood products inside, via a barb on the backside of the tag that penetrates the packaging film, allowing any volatile amines to be wicked to the color-based indicator outside, turning it from yellow to blue if spoilage amines are present (2, 34). More recently, Food Quality Sensor International Inc. (FQSI) has used similar pH-sensing technology in their SensorQ™, a label that detects the freshness/spoilage level of packed meat and poultry (35, 36). The SensorQ™ label, illustrated in Figure 9, has an orange-colored center in the "Q" when exposed to fresh meat, which turns dark green if the meat is spoiled. The pH indicator dyes used in this sensor appear to be anthocyanins, such as betanin or flavonoid dyes (36, 37). The SensorQ™ system is a stick-on label that is used on the inside of packages (35).

As noted above, decaying foodstuffs, especially poultry meat, can produce sulfur-containing compounds, such as hydrogen sulfide and/or dimethyl disulfide. This feature has been exploited by UPM-Raflatac with their volatile sulphide indicator, comprising metallic silver and/or copper particles, typically <10-μm diameter (pale pink), which reacts to produce the dark gray/black colored metal sulfide; for example,

$$2\mathrm{Ag} + \mathrm{H_2S} \rightarrow \mathrm{Ag_2S} + \mathrm{H_2} \tag{5}$$

The metal layer, 1–5 μm thick, can be screen or flexographically printed on paper, board, or plastic, using an ink containing 70–90% dry weight of metal particles. Films of different sensitivity can be created because the sensitivity of the indicator decreases with increasing metal film thickness. The indicator is placed inside the food package and is promoted as a shelf-life indicator (38, 39).

The detection of volatile decomposition gases is the most likely and practical approach to the assessment of food quality/freshness on a global basis and very compatible to printing technology. However, these are effectively indirect indicators of the presence of spoilage bacteria or pathogens; and the possibly more attractive direct measure of such species, using immunochemical indicators,

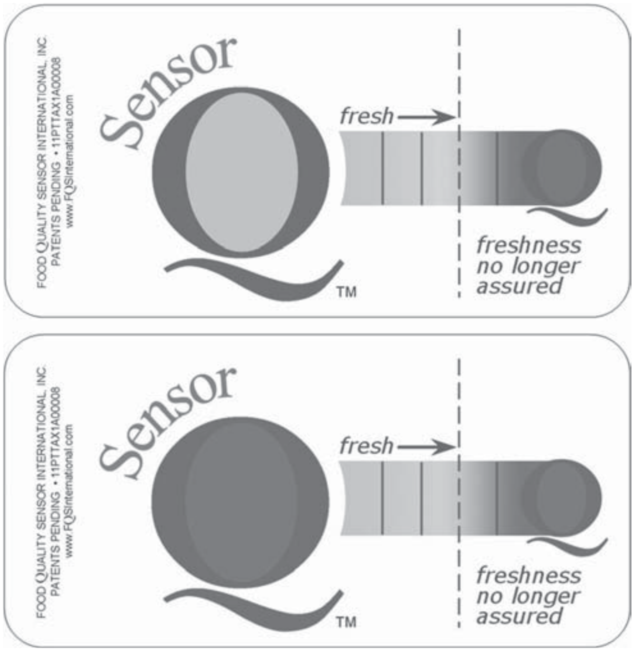

Figure 9. SensorQ™ indicator label from FQSI, before (left-hand side) and after (right-hand side) exposure to amine containing spoilage gases from meat (35). (Photographs courtesy of FQSI.)

has been reported in recent years—for example, by Food Sentinel System™ (SIRA) and Toxin Guard™ (Toxin Alert) (40–42). These indicators require direct contact with food and the use of colored or fluorescent labeled antibodies. The combination of tough food contact regulations with regard to direct food contact and a likely high cost of production represents a major barrier to the widespread implementation of these indicators in food packaging.

Finally, the RipeSense™ label, developed in New Zealand, appears to address the problem of knowing when fruit is ripe and was identified by TIME™ magazine as one of its 36 greatest inventions for 2004 (43). As shown in Figure 10, the indicator is red colored for unripe (crisp) fruit, but yellow when the fruit is very ripe (juicy); the indicator responds to the volatile gases emitted by many fruits as they ripen—not ethylene, but probably aldehydes and ketones. Developed initially for pears, and currently sold in New Zealand, Australia, USA, Canada, Mexico, Belgium, and France, work is in progress to develop similar indicators for: kiwifruit, melon, mango, avocado, and stone fruit, such as cherries and peaches. An ethylene-based ripeness sticker, RediRipe™, has been reported by researchers at the University of Arizona. It has yet to be released commercially, but it is estimated that each sticker will cost less than 1 cent (44, 45).

CONCLUSIONS

The number of commercial intelligent inks is still relatively small, but their diagnostic range is impressive and is a reflection of the significant and growing number of patents and articles published on intelligent inks and sensors. There is still some way to go before these indicators are a global feature of packaging, but few can doubt that that time will come, given increasing demand from the packaging industry customers for better, more secure packaging, a need that can be addressed via the information provided by intelligent inks.

It is encouraging to note that EU legislation is now in place to allow intelligent and active packaging in Europe (46). EU regulations No. 1935/2004 and 2023/2006 authorize market placement of packaging which acts intelligently when in contact with foodstuffs, either by providing information on the quality (freshness) of the product or preserving it for longer by introducing favorable modifications. However, this same legislation also stresses that such active or intelligent packaging must not mislead the consumer. Thus, indicators that give wrong information concerning the food that could mislead the consumer are not allowed. This quite reasonable condition may be a factor in the slow take up of the technology by many brand names, given the possibility that most indicators could be misinterpreted by consumers, even though such indicators provide greater customer reassurance (e.g., via tamper evidence, sterilization indicators, freshness indicators), prevent illness (time–temperature indicators), reduce costs (through less waste), and enhances brand differentiation (47).

With respect to the general initial reaction and subsequent perception of the consumer with respect to intelligent indicators, much can be learned from the few established intelligent indicators that exist, such as Monoprix in France, who has been using TTIs for more than 10 years. Initially, leaflets and posters were used to raise awareness and educate the consumer, but now most are comfortable and familiar with “La Puce Fraicheur.” Current surveys show that French consumers now perceive the TTI as complementary to the “use by” date and that the TTI is a more reliable guide than the “use by” date and are prepared to pay a little more for the reassurance of freshness and quality (48). Most surveys of intelligent indicators show the consumer to be a keen advocate, given sufficient education and an associated modest increment in price, provided the indicator concerned is reliable, clear, and easy to interpret. With the gradual removal of legislation barriers and growing customer interest in information and reassurance with regard to food, the conditions appear promising for a major breakthrough in the use of intelligent inks in the food packaging industry.

INTRODUCTION

To understand intelligent packaging, it is helpful to review the historical development of packaging. Traditionally, the basic functions of packaging have been classified into four categories (Figure 1), as follows: protection, communication, convenience, and containment (1, 2). The package is used to protect the product against the external environment, communicate with the consumer as a marketing tool, provide the consumer with greater ease of use and time-saving convenience, and contain products of various sizes and shapes. Nevertheless, these functions are not totally exclusive; for example, the communication function of the package through warning labels and cooking instructions can also help to enhance food protection and convenience.

Although traditional packaging has contributed greatly to the early development of the food-distribution systems, it is no longer sufficient because today's society is becoming increasingly complex. Innovative packaging with enhanced functions is constantly sought in response to the consumer demand for minimally processed foods with fewer preservatives, increased regulatory requirements, market globalization, concern for food safety, and more recently, the threat of food bioterrorism. How can the existing functions of a mature, and sometimes taken for granted, technology be enhanced? It probably requires rethinking and shifting in the existing paradigm (3). Active packaging and intelligent packaging are the results of "thinking outside the box."

During the past two decades, the popularity of active packaging (AP) has signified a major paradigm shift in packaging; namely, the protection function of packaging has been shifted from passive to active. Previously, primary packaging materials were considered as "passive," which means that they functioned only as an inert barrier to protect the product against oxygen and moisture. Recently, a host of new packaging materials have been developed that provide "active" protection to food products. AP has been defined as a system in which the product, the package, and the environment interact in a positive way to extend shelf life or to achieve some characteristics that cannot be obtained otherwise (4). It has also been defined as a packaging system that actively changes the condition of the package to extend shelf life or improve food safety or sensory properties, while maintaining the quality of the food (5).

All AP technologies involve some physical, chemical, or biological action for altering the interactions between the package, the product, and the package headspace to achieve a certain desired outcome (6, 7). Gas absorbing/emitting packaging (5, 8) is a group of technologies that uses packaging films or sachets to absorb gases (such as oxygen, water vapor, or ethylene) from the package headspace or to emit gases (such as carbon dioxide or ethanol) to the package headspace, so that a favorable internal package environment and thus an extension in shelf life are achieved. Controlled-release packaging is a group of technologies that uses packaging materials as a delivery system to release active compounds (such as antimicrobials, antioxidants, enzymes, flavors, and nutraceuticals) to protect against microbial spoilage and enhance food quality. Most attention in this group has been focused on antimicrobial packaging (9, 10) and antioxidant packaging (11, 12). Recently, an additional step forward was made by developing antimicrobial packages that contain natural instead of synthetic additives (13). Smart films are breathable films that enable the control of oxygen, water vapor, and carbon dioxide permeation at rates beneficial to modified atmosphere packaging of fresh produce (14). Microwave susceptors (15, 16) are metallized polyester-based structures that interact with microwaves to provide crispness and browning of foods during microwave heating.

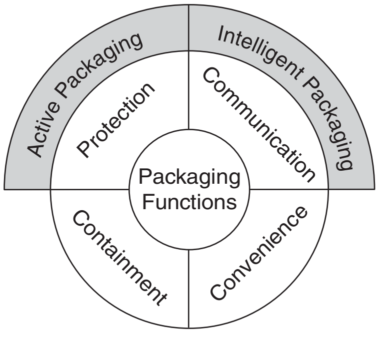

Figure 1. Model of packaging.

Active Packaging is placed above the protection function in the model of Figure 1. The placement reflects the situation that most AP technologies are aimed at and limited to enhancing the protection function of the package. This is not to say that AP does not provide other functions: For example, the microwave susceptor is an active packaging technology that provides convenience and food quality. Why were these technologies not simply described as a packaging system with enhanced protection functions, instead of inventing the term active packaging? An answer to this question is that this term has inspired researchers to develop innovative technologies by thinking packaging in a new way.

In recent years, the terms intelligent packaging (IP) and smart packaging (SP) have also begun to appear with increasing frequency in conferences, journals, and magazines. Unfortunately, clear and unequivocal definitions are not yet available in the scientific/technical literature. IP and SP are often used interchangeably at conferences and symposiums. Brody et al. (7), however, defined IP as a packaging system that senses and communicates, and they define SP as one that possesses the capabilities of both AP and IP. Clarke (17) defined smart packaging as one which communicates and intelligent packaging as one that includes logic capability. Rijk (18) defined IP as one that monitors the conditions of packaged foods to give information about the quality of the food during transport and storage. A major deficiency of these definitions is that the authors simply stated them without providing careful justifications.

In this article, we define intelligent packaging based on the historical development of packaging functions and a proposed conceptual framework. Specific examples are also presented to clarify the meaning of the definition.

DEFINITION OF INTELLIGENT PACKAGING

According to the American Heritage Dictionary, the word “intelligent” is defined as “showing sound judgment and rationality” and as “having certain data storage and processing capabilities.” A prerequisite of making sound decisions is effective communication—the ability to acquire, store, process, and share information—and this is where IP can make a significant contribution.

We define IP as a packaging system based on the science and technology that can carry out intelligent functions (such as detecting, sensing, recording, communicating, and applying scientific logic) to facilitate decision making and corrective actions to extend shelf life, enhance safety, improve quality, provide information, and warn about possible problems. We believe that the uniqueness of IP is in its ability to communicate. Because the package and the food move constantly together throughout the supply chain cycle, the package is the food’s best companion and is in the best position to communicate the conditions of the food. Accordingly, we place IP above the communication function in the model of Figure 1, building on the historical development of packaging functions. We have also developed a conceptual framework in the next section to delineate the anatomy of IP and provide more depth to its definition.

As alluded to earlier, the purpose of introducing intelligent packaging is to inspire people to expand the communication function of packaging in an innovative and useful way. The purpose of introducing the conceptual framework is to provide a roadmap to facilitate the systematic study to advance understanding and application in this field. Note that the definitions of AP and IP are not mutually exclusive: Some packaging systems may be classified either as AP or IP or both, but this situation does not detract the purpose of these terms. We have also been careful not to introduce other terms such as “responsive packaging” and “clever packaging,” because too many terms tend to complicate the already confusing terminology.

According to our definition, a package is “intelligent” if it has the ability to sense the environment and communicate with humans: For example, an intelligent package is one that can monitor the quality/safety condition of a food product and provide early warning to the consumer or food manufacturer. It is important to emphasize that IP is a product delivery system that involves not only the package but also the food product, the external environment, and other considerations. We believe that the emergence of IP has signified another paradigm shift in the concept of food packaging—shifting the package from a mediocre communicator to an intelligent communicator.

CONCEPTUAL FRAMEWORK OF INTELLIGENT PACKAGING

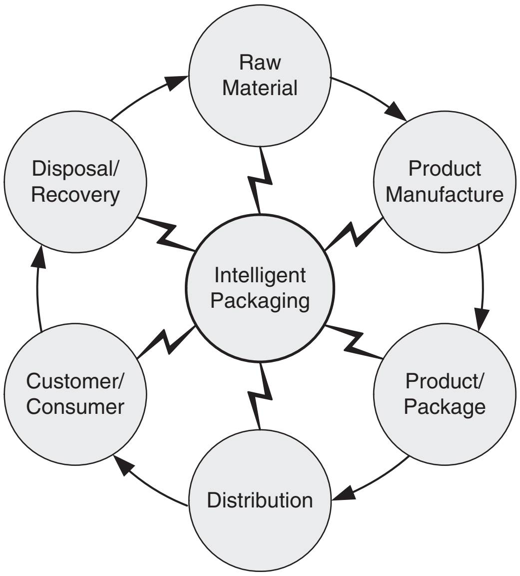

Figure 2. Material flow and information flow in the food supply chain.

Intelligent packaging can play an important role in facilitating the flows of both materials and information in the food supply chain cycle. In Figure 2, the outer circles represent the supply chain cycle from raw material through manufacturing, packaging, distribution, product use, and disposal. The package, in one form or another (such as a pouch, container, or drum, pallet), is traditionally used to facilitate the flow of materials (represented by the arrows in the figure) from one location to another, by performing the basic functions of containment and protection of the product. Furthermore, the package can also facilitate the flow of information (represented by the communication links between the inner circle and outer circles), although this communication function has been largely overlooked. The package can indeed be a highly effective communicator—it can carry actual information in the direction of material flow (e.g., via truck, train, or ship), and it can transmit information visually (e.g., via an indicator) or electronically (e.g., via a barcode or the Internet) throughout every phase of the supply chain cycle.

A conceptual framework describing the flow of information in an IP system is illustrated in Figure 3. The system consists of the following four components: smart package devices, data layers, data processing, and information highway (wire or wireless communication networks) in the food supply chain. The smart package devices are largely responsible for generating the concept of IP, because they impart the package with a new ability to acquire, store, and transfer data. The data layers, data processing, and information highway are collectively referred here as the *decision support system*.

As shown in Figure 3, the smart package devices and the decision support system are designed to work together to monitor changes in the internal and external environments of the food package and to communicate the conditions of the food product, so that timely decisions can be made and appropriate actions taken. From the quality and safety viewpoint, the external environment can be divided into the ambient, physical, and human environments (2), which are factors important for determining shelf life.

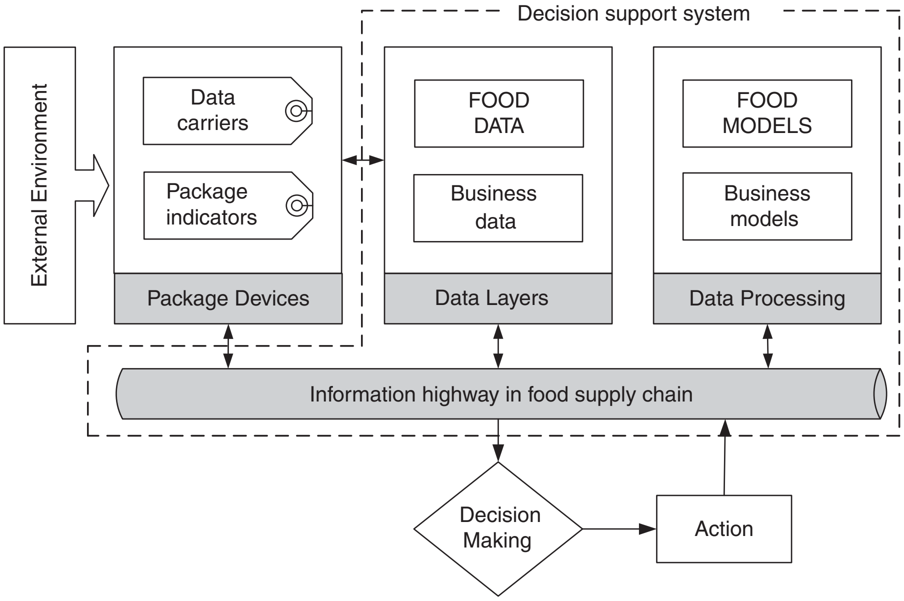

Figure 3. Information flow in the intelligent packaging system.

However, the business environment is also an important factor; in fact, the development of smart package devices (especially data carriers) and the information highway is largely motivated by the desire to increase profit and operational efficiency. Currently, business data (such as product identification, quantity, and price) and business models (rules for processing information to maximize profits) are incorporated into the system to facilitate product checkout, inventory control, and product traceability. It is interesting to note that just a decade ago, IP was not an attractive concept because package devices and computer networks were limited and expensive. Today, more powerful and affordable information technology has created a favorable environment for IP to flourish.

A challenging question to the food packaging scientist or technologist is whether more efficient delivery of safe and quality food products can also be achieved by superimposing an additional layer of *food data* and *food models* (capitalized in Figure 3) on the information highway of the food supply chain, which is the goal of IP. The food data refer to data that are indicative of food quality and safety (such as time-temperature history, microbial count, pH, and water activity), and the food models refer to scientific principles or heuristic rules for processing the food data to enable sound decision making. The answer to this question is likely positive, although significant research and development is needed before the potential of IP for enhancing food quality and safety could be fully realized.

SMART PACKAGE DEVICES

Smart package devices are defined here as small, inexpensive labels or tags that are attached onto primary packaging (e.g., pouches, trays, or bottles), or more often onto secondary packaging (e.g., shipping containers), to facilitate communication throughout the supply chain so that appropriate actions may be taken to achieve desired benefits in food quality and safety enhancement. Two basic types of smart package devices are *data carriers* (such as barcode labels and RFID tags) that are used to store and transmit data and *package indicators* (such as time-temperature indicators, gas indicators, biosensors) that are used to monitor the external environment and, whenever appropriate, issue warnings. As shown in Figure 3, these devices provide a communication channel between the external environment and other components in the system. These devices differ from each other not only in "hardware" (physical makeup) but also in the amount and type of data that can be carried and how the data are captured and distributed. In a typical IP system, multiple smart package devices are employed at several strategic locations throughout the supply chain.

Barcodes. Barcodes are the least expensive and most popular form of data carriers. The Universal Product Code (UPC) barcode was introduced in the 1970s and has since become ubiquitous in the grocery store for facilitating inventory control, stock reordering, and checkout (19). To enable barcodes to communicate with scanners and printers, many standards have been developed over the years into commonly accepted languages known as "symbologies," although less than 20 of them are used today (20). The UPC barcode is a linear symbology that consists of a pattern of bars and spaces to represent 12 digits of data. Its meager storage capacity allows the containment of only limited information such as manufacturer identification number and item number, which leaves no room for encoding additional information.

To address the growing demand for encoding more data in a smaller space, a new family of barcode symbologies called the Reduced Space Symbology (RSS) is recently being introduced (21). Some of those family members are particularly well suited for product identification at point-of-sell and for product traceability in the grocery industry (Figure 4). The RSS-14 Stacked omnidirectional barcode encodes the full 14-digit Global Trade Item Number

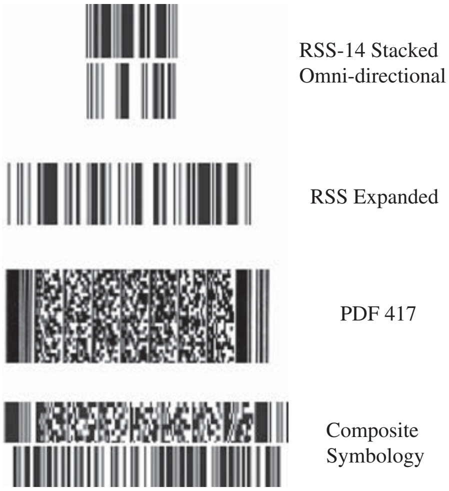

Figure 4. Examples of barcode symbologies.

(GTIN), and it may be used for loose produce items such as apples or oranges where space limitation requires a narrow symbol. The RSS Expanded Barcode (also available in stacked format) encodes up to 74 alphanumeric characters, and it may be used for variable measure products (e.g., meat and seafood that are sold by weight) where larger data capacity is required to encode additional information such as packed date, batch/lot number, and package weight.

As scanners are becoming more powerful and affordable, two-dimensional (2-D) barcodes (Figure 4) are also gaining popularity. The PDF 417 (where PDF stands for Portable Data File) is a 2-D symbol that carries up to 1.1 kb of data in a space of a UPC barcode (22). It allows the encoding of additional information not possible with linear barcodes, such as nutritional information, cooking instructions, website address of food manufacturer, and even graphics. The advantage of portable data is that they are available immediately, without having to access an external database. To provide more versatility, the Uniform Code Council has also introduced a new symbology called Composite Symbology (Figure 4) by combining a 2-D barcode such as PDF 417 with a linear barcode such as UPC (23).

With the advent of wireless handheld barcode scanners, barcode scanning is finding new and innovative applications. In the hospital, barcodes may be used to ensure that the right medication is given to the right patient at the right time and dosage (24). Immediately prior to administrating, the medication barcode and patient's identification tags are scanned, and the information is sent over a wireless Local Area Network (LAN) to check for accuracy.

Radio Frequency Identification (RFID) Tags. The RFID tag is an advanced form of data carrier for automatic product identification and traceability. Although RFID has been available for many years for tracking expensive items and livestock (25), its broad application in packaging has only begun in recent years. In a typical RFID system, a reader (or interrogator) emits radio waves to capture data from a RFID tag, and the data are then passed onto a host computer (which may be connected to a local network or to the Internet) for analysis and decision making (26). Inside the RFID tag is a minuscule microchip connected to a tiny antenna. RFID tags may be classified into the following two types: passive tags that have no battery and are powered by the energy supplied by the reader and active tags that have their own battery for powering the microchip's circuitry and broadcasting signals to the reader. The more expensive active tags have a reading range of 100 ft. or more, whereas the less expensive passive tags have a reading range of up to 15 ft. The actual reading range depends on many factors including the frequency of operation, the power of the reader, and the possible interference from metal objects. At the time of this writing, a passive tag costs between 50¢ and $1 depending on the quantity ordered, but the industry is working to reduce it to 5¢ in the next few years (27). An active tag costs as much as $75, but the cost is expected to decrease rapidly (27).

Compared with the barcode, the RFID tag has several unique characteristics. Line of sight is usually not required: That is, the RFID tag does not need to be oriented toward the reader for data transfer to occur because radio waves travel through a wide array of nonmetallic materials. A significantly larger data storage capacity is available (up to 1 MB for high-end RFID tags), which may be used to store information such as temperature and relative humidity data, nutritional information, and cooking instructions. Read-write operations are supported by some RFID tags, which are useful in providing real-time information updates as the tagged items move through the supply chain. Multiple RFID tags may be read simultaneously at a rapid rate. Nevertheless, the RFID tag is generally not considered as a replacement for the barcode. Because both data carriers have advantages and disadvantages, they will continue to be used either alone or in combination, depending on the situation. A RFID tag may also be integrated with a time-temperature indicator or a biosensor to carry time-temperature history and microbiological data (28, 29).

In recent years, there has been an overwhelming interest from major retailers, companies, government agencies, and researchers in using RFID tags for various applications, such as supply chain management, asset tracking, security control, and feed pattern of live stocks (30–33). An impetus for this technology is that several major retailers, including Wal-Mart Stores and Metro Group, have issued mandates requiring their leading suppliers to use RFID tags on shipping crates and pallets. Such mandates are accelerating the adoption of the technology and future development of the RFID information highway.

A large amount of information on RFID is scattered in online journals (more notably, the Smart Packaging Journal and the RFID Journal), white papers published by technology companies (34–36), and the Internet. On the contrary, limited information on RFID was found in peer-reviewed scientific journals, particularly those relating to food science. This fact does not imply that food science knowledge is not important. It simply reflects that this technology is still at its early stages of implementation, and currently, the focus is on simple tasks such as product identification and tracking, and not on complicated matters that involve the application of scientific food principles. When the RFID technology will become more established, the integration of food science knowledge will be required to develop the necessary decision support system for enhancing food safety and quality.

Time-Temperature Indicators. Temperature is usually the most important environmental factor influencing the kinetics of physical and chemical deteriorations, as well as microbial growth in food products. Time-temperature indicators (TTIs) are typically small self-adhesive labels attached onto shipping containers or individual consumer packages. These labels provide visual indications of temperature history during distribution and storage, which is particularly useful for warning of temperature abuse for chilled or frozen food products. They are also used as "freshness indicators" for estimating the remaining shelf life of perishable products. The responses of these labels are usually some visually distinct changes that are temperature dependent, such as an increase in color intensity and diffusion of a dye along a straight path. Three basic types of commercially available TTIs are critical temperature indicators, partial history indicators, and full history indicators (37). Their operating principles and performance have been reviewed extensively in the literature (38–43).

In the early 1990s, Lifelines Technologies (Morris Plains, New Jersey) demonstrated a concept of using a laser optical wand to scan a TTI/barcode label to obtain product information and temperature history simultaneously (39). The concept was unfortunately not embraced by the industry at that time, because scanners were expensive and the information highway in the supply chain was not ready to support this innovation. Today, powerful and affordable scanner and wireless technologies have provided a more favorable environment for companies to develop advanced TTI systems for tracking and controlling the quality of perishable food products (44). For example, Bioett (Lund, Sweden) has developed a TTI/barcode system in which data may be read by a handheld scanner, displayed on a computer monitor, and downloaded into a database for analysis (45). KSW Microtec (Dresden, Germany) has developed a battery-powered TTI/RFID tag using a technology in which thin-film batteries are printed onto a flexible substrate (46, 47). Infratab (Oxnard, California) is also developing a battery-powered TTI/RFID tag (2003). Unlike the traditional TTI that is based on diffusion or a biochemical reaction, the TTI/RFID tag uses a microchip to sense and integrate temperature over time to determine the shelf life of a product.

Gas Indicators. The gas composition in the package headspace often changes as a result of the activity of the food product, the nature of the package, or the environmental conditions. For example, respiration of fresh produce, gas generation by spoilage microorganisms, or gas transmission through the packaging material or package leaks may cause the gas composition inside the package to change. Gas indicators in the form of a package label or printed on packaging films can monitor changes in the gas composition, thereby providing a means of monitoring the quality and safety of food products.

Oxygen indicators are the most common gas indicator for food packaging applications, because oxygen in air can cause oxidative rancidity, color change, and microbial spoilage. Several oxygen indicators are designed to show color changes caused by leaking or tampered packages (48, 49). Ahvenainen et al. (50) and Smiddy et al. (51) used oxygen indicators to detect improper sealing and quality deterioration of modified atmosphere packages containing pizza or cooked beef. Gas indicators for water vapor, carbon dioxide, ethanol, hydrogen sulfide, and other gases are also useful. For example, Hong and Park (52) used a carbon dioxide indicator that consisted of a carbon dioxide absorbent and a chemical dye in a polymeric film to measure the degree of fermentation in kimchi products during storage and distribution.

It is expected that the future integration of gas indicators into barcode labels or RFID tags will enable gas indicator signals to be transmitted not only visually but also electronically. Advances in smart ink and printing technology will also allow gas indicators to be read automatically using optical systems from a distance.

Biosensors. The broad spectrum of foodborne infections is changing constantly over time as most known pathogens are controlled and new ones have emerged. Rapid, accurate, on-line sensing is needed for *in situ* analysis of pollutants, detection and identification of pathogens, and monitoring of postprocessing food quality parameters.

In general, a biosensor is a compact analytical device that detects, records, and transmits information pertaining to biochemical reactions. This smart device consists of two primary components: a bioreceptor that recognizes a target analyte and a transducer that converts biochemical signals into a quantifiable electrical response. The bioreceptor is an organic or biological material such as an enzyme, antigen, microbe, hormone, or nucleic acid. The transducer can assume many forms (such as electrochemical, optical, or acoustic) depending on the parameters being measured. Some important characteristics of a biosensor are its specificity, sensitivity, reliability, portability, and simplicity. Matrubutham and Sayler (53), Simonian et al. (54), D'Souza et al. (55), and Velasco-Garcia and Mottram (56) have reviewed the principles and potential applications of biosensors. Alocilja and Radke (57) have analyzed the pathogen detection industry and concluded that biosensors are a growing market. This article relates primarily to biosensors that can be placed inside the food package or integrated into the packaging material, although there are also handheld or desktop biosensors.

Presently, commercial biosensors for intelligent packaging are not available, although several prototypes are being developed. For example, SIRA Technologies (Pasadena, California) is developing a biosensor/barcode called Food Sentinel System to detect pathogens in food packages (35, 58). In this system, a specific-pathogen antibody is attached to a membrane forming part of the barcode; the presence of contaminating bacteria will cause the formation of a localized dark bar, which renders the barcode unreadable during scanning. Toxin Alert (Ontario, Canada) is also developing a diagnostic system called Toxin Guard that incorporates antibodies into plastic packaging films to detect pathogens (59–61). When the antibodies encounter a target pathogen, the packaging material displays a clear visual signal to alert the consumer, retailer, or inspector. This system is intended for detecting gross contamination, because it is not sensitive enough for detecting low levels of pathogens that can cause disease.

APPLICATIONS OF INTELLIGENT PACKAGING

Enhancing Food Safety and Biosecurity. Intelligent packaging, especially when integrating with science-based principles, is a useful tool for tracking products and monitoring their conditions, facilitating real-time data access and exchange, and enabling rapid response and timely decision making. These qualities are essential for any food safety or biosecurity strategy. The applications of IP in enhancing traceability systems and Hazard Analysis Critical Control Points (HACCP) systems are discussed below.

Traceability, tracking, and record keeping of product flow through the production process and supply chain is generally considered key in enhancing food safety and biosecurity (62–64). The existing traceability systems vary in breadth, depth, and precision; these terms refer to what data are recorded, how far backward or forward along the supply chain are the data tracked, and how precisely is the product location pinpointed, respectively (64). Because tracing all information with high precision is virtually impossible, only a limited set of variables is usually traced. In tracing beef, for example, variables such as global trade item number, batch/lot number, and country of origin are recommended (65). However, these variables do not provide technical information about the safety and quality of the food product.

Intelligent packaging could be integrated into existing traceability systems to create more effective communication links. Bar codes and RFID tags can enable electronic recordkeeping and information sharing, especially when interfaced with external instruments that can rapidly measure quality attributes and monitor food safety. For example, pH meters, water activity meters, rapid microbial detection devices (66, 67), or nondestructive quality measurement instruments (68, 69) may be placed at strategic locations along the supply chain where they exchange data with read/write bar codes or RFID tags. Nevertheless, increasing the breath and depth of a traceability system alone is not sufficient to improve food safety; science-based food models and user-friendly software are also required to utilize fully the additional food-related data layer available.

In recent years, HAACP has become an internationally recognized system for managing the risk associated with food safety. HAACP is a science-based system that consists of the following seven principles: conduct hazard analysis, determine critical control points, establish critical limits, establish monitoring procedures, establish corrective actions, establish verification procedures, and establish record keeping and documentation procedures (70). The implementation of these principles requires storing, sharing, and processing information so that timely decision and corrective actions could be made.

Figure 5 outlines a system based on the conceptual framework of IP and HACCP principles for managing information flow and ensuring food safety. An important point about this system is that information is shared among multiple devices at multiple locations. Information obtained from multiple devices and multiple locations, especially when the devices are interconnected, is far more useful than information obtained from a single device and at a single location. It is generally recognized that microbial detection alone is not a complete solution to ensure food safety; however, when it is coupled with physical and chemical measurements, timely detection

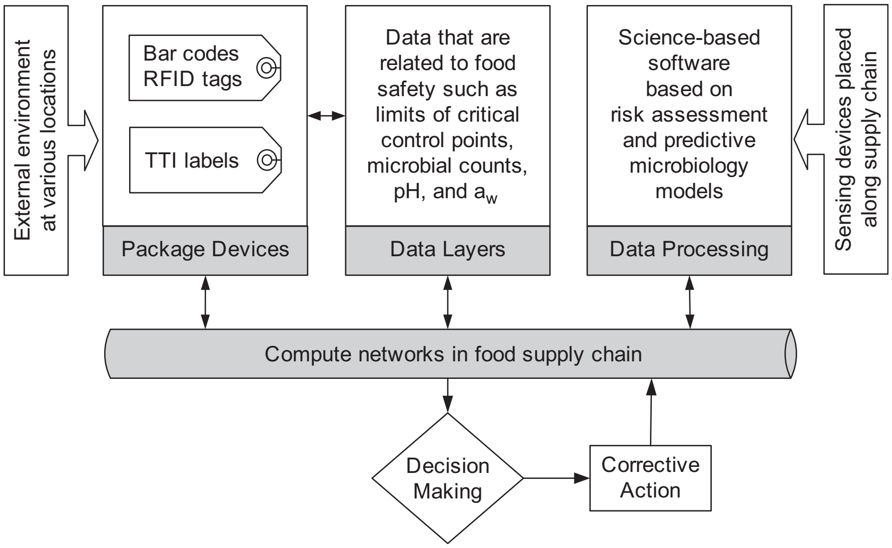

Figure 5. An example of the intelligent packaging and HACCP system.

and correction of safety problems may be achieved more readily. The multiple devices include smart package devices coupled with sensing devices such as pH meters and water activity meters that are placed along the supply chain.

When applying the HACCP principles, special attention should be paid to designing the decision support system. The hazard analysis should determine not only the flow of materials but also the flow of information. The critical control points, as well as the sensing devices required at specific locations, should be identified. The limits of critical control points (such as time and temperature) may be encoded in bar codes or RFID tags to enable electronic data retrieval. Monitoring the critical control points may be achieved by using TTI labels or other sensing devices at strategic locations. Read/write RFID tags and computer networks may facilitate record keeping and documentation. Decision for corrective actions may be facilitated using data processing software, which should incorporate science-based knowledge such as risk assessment and predictive microbiology models (71, 72). The development of an IP-based HACCP system is in the early stages, and significant research work is needed for its future development and implementation.

Enhancing Food Quality and Convenience. The current application of IP has been focused mostly on using TTI labels to monitor temperature, although many other applications are also possible. For example, it may be applied to cooking appliances such as the intelligent microwave oven system shown in Figure 6 (73). The uniqueness of this system is in its use of information sharing to enhance food quality and convenience. The PDF 417 barcode in the package carries data about the food product, and the data processing system generates the proper heating instructions for the microwave oven. Information exchange also occurs through the user interface (such as a touch screen or voice recognition system) and the Internet.

Because microwave ovens come in different sizes and power outputs, the heating instructions printed on microwaveable food packages are obviously vague to accommodate the many different ovens in the market. Using these vague instructions often does not allow for achievement of good food quality. This problem may be overcome by scanning the bar code to enable the decision support system to match the microwave oven and the food package. To achieve a higher level of quality, temperature and moisture sensors may be placed inside the microwave oven to provide feedback for the data processing system.

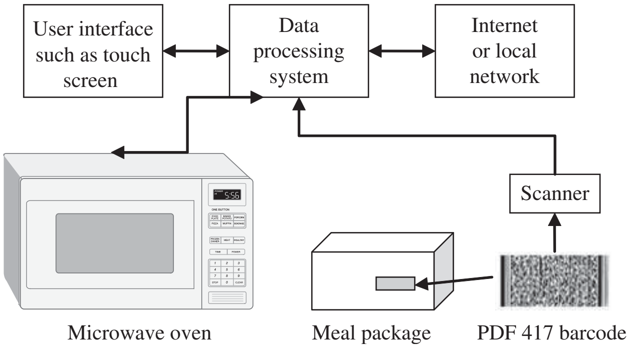

Figure 6. Intelligent microwave oven system.

Scanning the bar code eliminates the need for entering the heating instructions. This technique is particularly useful for microwave/convective ovens that use complicated instructions. These combination ovens can provide higher food quality than the conventional microwave ovens, but their heating instructions involve multiple steps because both microwave energy and convective heat are employed. Scanning the bar code is also helpful for people who are visually impaired or have difficulties in understanding the language. The Internet connection provides convenient access to information relating to the packaged food such as the manufacturer's website, recipes, food allergen information, and product recall.

The development of the intelligent microwave oven system requires the application of scientific knowledge to design the data layers and the data processing system. The data layers should contain information relating to the food, package, and microwave oven. The architecture of the data layers could be rather complicated because data may enter the system in different ways. For example, the food manufacturer may encode the food and packaging information in the bar code, the oven manufacturer may store the oven information in a database connected to the information processing system, the consumer may enter his or her preferences through the touch screen, and information may be exchanged via the Internet. The data processing system should include algorithms that are based on heat transfer principles and heuristic rules relating to food quality and safety to generate instructions for controlling the magnetron and turntable (if available) of the microwave oven. In addition, the algorithms may have also other abilities such as obeying the requirement or preferences of the consumer, warning the consumer against food allergens, and tracking the dietary intake of the consumer.

RESEARCH ROADMAP

Future research is needed to ensure the safe and smooth adoption of intelligent packaging. In developing a research agenda, the conceptual framework in Figure 3 may be used as a roadmap, and the role of IP in relation to AP and traditional packaging in the model of packaging functions (Figure 1) should be considered. Conducting the research frequently requires a system approach involving interactions between researchers in food packaging, food engineering, biotechnology, microelectronics, software engineering, nanotechnology, and other disciplines. Discussed below are some recommended future research areas.

- Development of Decision Support System. In the business world, decision support systems are now available for analyzing data and facilitating decision making. However, those decision support systems are

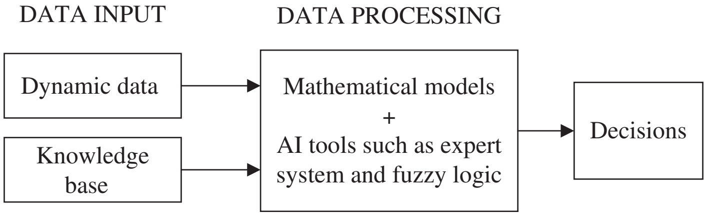

Figure 7. Block diagram for a decision support system.

not adequate for intelligent packaging applications—what is lacking is the scientific knowledge necessary for food quality and safety enhancement. Although a vast amount of scientific knowledge is available in journals such as the Journal of Food Science, more research is still needed to transform it to a form that can be incorporated into the data layer and food models for the IP system. Traditionally, mathematical models (e.g., kinetic models for quality deterioration and microbial growth) have been useful for quantitatively describing the existing knowledge of food systems, but those models alone are often not sufficient to handle complex real-time data from multiple package devices at multiple locations. To compensate for this deficiency, artificial intelligence (AI) tools such as knowledge-based expert systems, fuzzy logic, inductive learning, and neural networks may also be used (74). These AI tools are designed to deal with complex real-life data and transfer expert knowledge, in the form of rules-of-thumb, to quantitative functions that can be processed by computers. The utility of those tools have recently been demonstrated for microbial growth modeling (75), food processing (76), controlling cheese ripening (77), and other food applications (78).

- Yam and Saba (79) has also described a decision support system for modified atmosphere packaging for fresh produce, with the goal of extending the shelf life of product by creating and maintaining a desirable modified atmosphere inside the package. This complicated system involves many variables and the dynamic interactions among the respiring product, package, and distribution environment. The product parameters include the respiration rates for O_2 consumption and CO_2 evolution, the product weight, and the optimum modified atmosphere for the product; the package parameters include the O_2 and CO_2 permeabilities, package thickness, and package surface area; the distribution environment parameters include temperature and relative humidity. A challenge is to deal with these many complex, constantly changing variables. Figure 7 shows the block diagram of a generic decision support system that may be used for this and other food packaging applications. The *data input* consists of dynamic data and data from the knowledge base. Examples of dynamic data are the climatic conditions and respiring rates; the quality of the produce can change daily and are preferably monitored with sensing devices. Examples of data stored in the knowledge base are the gas permeabilities of packaging films, package dimensions, and regulations that are not likely to change daily or weekly. However, the knowledge base will be updated periodically, for example, when the regulation has changed or when a new packaging material is available. The data processing consists of mathematical models and AI tools. The mathematical models are those based on the scientific principles describing the interactions among the respiration of the produce, the O_2 and CO_2 permeabilities of the package, and environment conditions (14). The AI tools may include fuzzy logic sets containing rules or algorithms for dealing with ambiguous and difficult situations that are not easily reduced to mathematical models. The mathematical models and AI tools work together to enable more rapid and reliable decision making.
- Additional Development of Smart Package Devices. Smaller, less expensive, and more powerful smart package devices are needed to meet the market needs. Many advanced smart package devices such as biosensor and biosensor/RFID are still in the prototype development stage. Most existing biosensor prototypes have limitations such as slow response time and short shelf life; however, exciting research opportunities exist in combining biotechnology and nanotechnology to develop biosensors to overcome these and other limitations (80). The integration of TTIs and gas indicators with barcodes and RFID tags requires future research and development. Standards are also needed to enable the efficient communication among smart package devices.
- Integration of IP into Total Packaging System. IP is only one component in the total packaging system (Figure 1), and thus it must be integrated smoothly and efficiently with other system components. Exciting research opportunities exist in combining IP and AP; for example, an active/intelligent packaging system may use a TTI/biosensor to sense the environment, and whenever necessary, release an active compound (such as antimicrobial or antioxidant) to extend the shelf life of the food.

CONCLUSIONS

Intelligent packaging is emerging as a new branch of packaging science and technology that offers exciting opportunities for enhancing food safety, quality, and convenience. The advancement in this technology will require researchers to continue think outside the box and use nontraditional packaging approaches to meet new challenges. For the first time, packaging science, food engineering, biotechnology, information technology, nanotechnology, and other disciplines are coming together to develop a breakthrough packaging technology. As this technology is unfolding, issues such as those relating to legislation, consumer acceptance (relating to privacy, for example), and economics also need to be addressed.

INTERNATIONAL STANDARDS

RICHARD C. RANDALL
International Business
Standards Association,
Littleton, Colorado

International standards are developed and adopted for use by multiple countries. In contrast, a standard developed specifically for use in only one country is considered a National standard. A National standard is controlled (revised and distributed) by an organization (either government or non-government) within a single nation. An International standard is controlled by an organization (typically non-governmental) with participating members representing multiple nations. International standards are often distributed in multiple languages.

WHAT ARE STANDARDS?

Quite simply, a standard is a technical specification or other document created for the purpose of promoting consistency.

A standard may be "open" (available to the public—for use by anyone) or "closed" (usually a technical specification—for use only by those who have obtained permission from the standard's owner or patent holder). Use of a closed standard may involve payment in the form of a royalty to the patent holder. A standard may be intended to promote free-market competition (e.g., an open standard) or restrict competition (e.g., a closed standard). Similarly, a standard may be designed to (a) promote free trade by removing barriers caused by differences in national practices or (b) restrict trade through creating artificial, protectionist barriers to trade. Standards may also be designed, by either government or non-government entities, to promote specific social agendas. Regulatory requirements often create standards, directly or indirectly.

In short, standards may be designed to promote, or restrict, communication, efficiency, quality, safety, health, environmental protection, free trade, and so on.

Compliance with a "legal" standard (e.g., weights and measures, labeling) is required by law. While compliance with a "voluntary" standard is discretionary, a voluntary standard can be incorporated into a contract or regulation where its provisions become mandatory (1).

THE INTERNATIONAL ORGANIZATION FOR STANDARDIZATION (ISO)

The most widely recognized international standards are developed and published by the International Organization for Standardization (ISO). Established in 1947, the ISO (pronounced "*iso*," as in "isometric") is a network of the national standards institutes representing 157 countries, on the basis of one member per country, formed "to facilitate international coordination and unification of industrial standards." A Central Secretariat in Geneva, Switzerland, coordinates the system.

A *member body* of ISO is the national body "most representative of standardization in its country." Only one such body for each country is accepted for membership in ISO. Member bodies are entitled to participate and exercise full voting rights on any technical committee and policy committee of ISO. A *correspondent member* is usually an organization in a country which does not yet have a fully developed national standards activity. Correspondent members do not take an active part in the technical and policy development work, but are entitled to be kept fully informed about the work of interest to them. *Subscriber membership* has been established for countries with very small economies. Subscriber members pay reduced membership fees that nevertheless allow them to maintain contact with international standardization (2, 3). A complete list of each member body and its country may be found online at http://www.iso.org/iso/en/aboutiso/isomembers/MemberCountryList.MemberCountryList.

The work of preparing ISO standards is normally carried out through technical committees (TCs), their subcommittees (SCs), and their working groups (WGs). Each member body interested in a subject for which a technical committee has been established is entitled to be represented on that committee. International organizations, governmental and non-governmental, in liaison with ISO, also take part in the work. Each TC and SC has a secretariat assigned to a ISO member body. Details of each TC, including its secretariat, organizational structure, and scope of responsibility (determined by the ISO Council), are identified in the annual *ISO Memento* (3).

The ISO technical committees directly concerned with packaging and the distribution of goods are shown in Table 1. It is important to note, however, that the work of other TCs often relates to packaging; for example, TC 6 "Paper, board and pulps," and TC 61, "Plastics,"

Table 1. ISO Technical Committees Concerned with Packaging

	TC 51: Pallets for Unit Load Method of Materials Handling
Scope:	Standardization of pallets in general use in the form of platforms or trays on which goods may be packed to form unit loads for handling by mechanical devices
Secretariat:	British Standards Institution (BSI) 389 Chiswick High Road GB-London W4 4AL Tel: +44 208 996 90 00 Fax: +44 208 996 74 00 Secretariat direct: E-mail: bernard.shelley@bsi-global.com
	TC 52: Light-Gauge Metal Containers
Scope:	Standardization in the field of light-gauge metal containers with a nominal material thickness of $\leq 0.49\,\mathrm{mm}$
Secretariat:	Association française de normalisation (AFNOR) 11, rue Francis de Pressensé FR-93571 Saint-Denis La Plaine Cedex Tel: +33 1 41 62 80 00 Fax: +33 1 49 17 90 00 Secretariat direct: E-mail: annick.galpin@afnor.org
	TC 63: Glass Containers
Scope:	Standardization of glass containers made from molded glass used as a means of packaging.
Secretariat:	British Standards Institution (BSI) 389 Chiswick High Road GB-London W4 4AL Tel: +44 208 996 90 00 Fax: +44 208 996 74 00 Secretariat direct: Tel: +44 208 996 71 72 Fax: +44 208 996 77 99 E-mail: mick.maghar@bsi-global.com
	TC 104: Freight Containers
Scope:	Standardization of freight containers, having an external volume of $\geq 1\,\mathrm{m}^3$ ($\geq 35.3\,\mathrm{ft}^3$), with regard to terminology, classification, dimensions, specifications, test methods, and marking
Secretariat:	American National Standards Institute (ANSI) 1819 L Street, NW US-Washington, DC 20036 Tel: +1 212 642 49 00 Fax: +1 212 398 00 23 Secretariat direct: Tel: +1 212 642 49 75 Fax: +1 212 730 13 46 E-mail: isot@ansi.org
	TC 122: Packaging
Scope:	Standardization in the field of packaging with regard to terminology and definitions, packaging dimensions, performance requirements, and tests; excludes matters falling within the scopes of particular committees (e.g., TC 6, 52, 104)
Secretariat:	Japan Packaging Institute (JISC) 4-1-1 Tsukij JP-Tokyo, Chuo-ku 104-0045 Tel: +81 3 3543 1189 Fax: +81 3 3543 8970 Secretariat direct: Tel: +81 3 3543 1189 Fax: +81 3 3543 8970 E-mail: iso-tc@jpi.or.jp

(*Continued*)

Table 1. Continued

	TC 220: Cryogenic Vessels
Scope:	Standardization in the field of insulated vessels (vacuum or non-vacuum) for the storage and the transport of refrigerated liquefied gases of class 2 of "Recommendations on the Transport of Dangerous Goods—Model Regulations—of the United Nations," in particular concerning the design of the vessels and their safety accessories, gas/materials compatibility, insulation performance, the operational requirements of the equipment and accessories
Secretariat:	Association française de normalisation (AFNOR) 11, rue Francis de Pressensé FR-93571 Saint-Denis La Plaine Cedex Tel: +33 1 41 62 80 00 Fax: +33 1 49 17 90 00 E-mail: uari@afnor.org Web: http://www.afnor.org Secretariat direct: Tel: +33 1 41 62 84 50 E-mail: nicole.legent@afnor.org

both address materials, standards, and associated test methods, but do not specifically address their use in packaging. The scope of TC 34, "Agricultural Food Products," and TC 126, "Tobacco and Tobacco Products," includes packaging, storage, and transport of such products but is, in practice, limited to general, practical advice. When necessary, TCs may create liaisons with other appropriate TCs concerned with packaging.

Because international standardization is a lengthy and expensive process, proposals for new standards must be justified by identifying the need, the aim(s) of the proposed standard, and the interests that may be affected. Once a document is developed, it is listed under the relevant Technical Committee in the annual *ISO Technical Programme* (4) as draft proposals or draft international standards (DISs) in increasing degrees of formality. When a technical committee agrees on a draft standard, it is proposed for approval by all ISO members. If 75% of the votes cast are in favor of the DIS, it is sent for acceptance to the ISO Council. This provides an assurance that no important objections have been overlooked.

There is no requirement for ISO member bodies to publish an ISO standard as a national standard, although it is through such action that ISO standards are put into use throughout the world. On occasion, publication of an ISO standard as a national standard is not considered appropriate.

All ISO standards are listed in the ISO Catalogue (5) and on the *ISO Online* web site (at http://www.iso.ch/welcome.html). ISO standards can frequently be purchased from national standards bodies (ISO member bodies) or directly from ISO on-line at: http://www.iso.org/iso/en/prods-services/ISOstore/store.html.

ISO PACKAGING STANDARDS

Six technical committees have developed ISO standards directly concerned with packaging.

TC 51: Pallets for Unit Load Method of Materials Handling. Tasked with standardizing pallets for general use in the form of platforms or trays on which goods may be packed to form unit loads, TC 51 has currently developed nine standards listed in Table 2.

TC 52: Light-Gauge Metal Containers. Through the work of TC 52, the number of different sizes of open-top, general-purpose food cans has been reduced from over 2000 in 1947 to a total of 35 by the time

Table 2. ISO Standards for General-Purpose Pallets (TC 51)

ISO 445	*Pallets for Materials Handling—Vocabulary*
ISO 6780	*General-Purpose Flat Pallets for Through Transit of Goods—Principal Dimensions and Tolerances*
ISO 8611	*General-Purpose Flat Pallets for Through Transit of Goods—Test Methods*
ISO/TR 10232	*General-Purpose Flat Pallets for Through Transit of Goods—Design Rating and Maximum Working Load*
ISO/TR 10233	*General-Purpose Flat Pallets for Through Transit of Goods—Performance Requirements*
ISO/TR 10234	*General-Purpose Flat Pallets for Through Transit of Goods—Phytosanitary* (plant health) *Requirement for Wooden Pallets*
ISO/TR 11444	*Quality of Sawn Wood Used for the Construction of Pallets*
ISO/TR 12776	*Pallets—Slip Sheets*
ISO 12777-1	*Methods of Test for Pallet Joints—Part 1: Determination of Bending Resistance of Pallet Nails, Other Dowel-Type Fasteners and Staples*

Table 3. ISO Standards for Light-Gauge Metal Containers (TC 52)

ISO 90-1	*Light-Gauge Metal Containers—Definitions and Determination Methods for Dimensions and Capacities—Part 1: Open-Top Cans*
ISO 90-2	*Light-Gauge Metal Containers—Definitions and Determination Methods for Dimensions and Capacities—Part 2: General-Use Containers*
ISO 1361	*Light-Gauge Metal Containers—Open-Top Cans—Round Cans—Internal Diameters*
ISO 3004-1	*Light-Gauge Metal Containers—Capacities and Related Cross Sections—Part 1: Open-Top Cans for General Food*
ISO 3004-2	*Light-Gauge Metal Containers—Capacities and Related Cross Sections—Part 2: Open-Top Cans for Meat and Products Containing Meat for Human Consumption*
ISO 3004-3	*Light-Gauge Metal Containers—Capacities and Related Cross Sections—Part 3: Open-Top Cans for Drinks*
ISO 3004-4	*Light-Gauge Metal Containers—Capacities and Related Cross Sections—Part 4: Open-Top Cans for Edible Oil*
ISO 3004-5	*Light-Gauge Metal Containers—Capacities and Related Cross Sections—Part 5: Open-Top Cans for Fish and Other Fishery Products*
ISO 3004-6	*Light-Gauge Metal Containers—Capacities and Related Cross Sections—Part 6: Open-Top Cans for Milk*
ISO/TR 8610	*Light-Gauge Metal Containers—Round Vent-Hole Cans with Soldered Ends for Milk and Milk Products—Capacities and Related Diameters*
ISO/TR 10193	*Round General-Use Light-Gauge Metal Containers—Nominal Filling Volumes and Nominal Diameters*
ISO/TR 10194	*Nonround General-Use Light-Gauge Metal Containers—Nominal Filling Volumes and Nominal Cross Sections*
ISO 10653	*Light-Gauge Metal Containers—Round Open-Top Cans—Cans Defined by Their Nominal Gross Lidded Capacities*
ISO 10654	*Light-Gauge Metal Containers—Round Open-Top Cans—Cans for Liquid Products with Added Gas, Defined by Their Nominal Filling Volumes*
ISO/TR 11761	*Light-Gauge Metal Containers—Round Open-Top Cans—Classification of Can Sizes by Construction Type*
ISO/TR 11762	*Light-Gauge Metal Containers—Round Open-Top Cans for Liquid Products with Added Gas—Classification of Can Sizes by Construction Type*
ISO/TR 11776	*Light-Gauge Metal Containers—Nonround Open-Top Cans—Cans Defined by Their Nominal Capacities*
ISO 11944	*Round General-Use Light-Gauge Metal Containers—Nominal Diameters for Cylindrical and Tapered Cans up to 10,000-mL Capacity*

ISO 3004-1:1986 was issued. This still may be too many, but it represents the best possible compromise at the present time. The range of standards for light-gauge metal containers, following the current program of work, is listed in Table 3.

TC 63: Glass Containers. Concerned with standardizing glass containers used as a means of packaging (excluding containers made from tubular glass), TC 63 developed 15 standards, listed in Table 4. With no further work item under study or foreseen, TC 63 has since been dissolved.

TC 104: Freight Containers. The standards relating to freight containers (Table 5) are perhaps the best possible example of international standardization, because without them, the "container revolution" could never have taken place. Standardized dimensions, maximum gross masses, and, above all, standardized methods of lifting (twist locks and corner fittings) have enabled rapid, safe transfer of the containers from one transport mode to another. These type standards relate not only to box containers but also to tank containers for liquids, gases, and solids.

TC 122: Packaging. The committee with the broadest scope, TC 122, works to standardize packaging terminology and definitions, as well as packaging dimensions, performance requirements, and tests, but excludes matters falling within the scopes of other committees (e.g., TC 51, TC 52, TC 63, and TC 104). These standards are listed in Table 6.

Table 4. ISO Standards for Glass Containers (TC 63)

ISO 7348	*Glass Containers—Manufacture—Vocabulary*
ISO 7458	*Glass Containers—Internal Pressure Resistance—Test Methods*
ISO 7459	*Glass Containers—Thermal Shock Resistance and Thermal Shock Endurance—Test Methods*
ISO 8106	*Glass Containers—Determination of Capacity by Gravimetric Methods—Test Method*
ISO 8113	*Glass Containers—Resistance to Vertical Load—Test Method*
ISO 8162	*Glass Containers—Tall Crown Finishes—Dimensions*
ISO 8163	*Glass Containers—Shallow Crown Finishes—Dimensions*
ISO 8164	*Glass Containers—520-mL Euro-form Bottles—Dimensions*
ISO 9008	*Glass Containers—Verticality—Test Method*
ISO 9009	*Glass Containers—Height and Nonparallelism of Finish with Reference to Container Base—Test Methods*
ISO 9056	*Glass Containers—Series of Pilferproof Finish—Dimensions*

ISO 9897-3	*Freight Containers—Container Equipment Data Exchange (CEDEX)—Part 3: Message Types for Electronic Data Interchange*
ISO 10368	*Freight-Thermal Containers—Remote Condition Monitoring*
ISO 10374	*Freight Containers—Automatic Identification*

TC 220: Cryogenic Vessels. Standardization in the field of insulated vessels (vacuum or non-vacuum) for the storage and the transport of refrigerated liquefied gases of class 2 of "Recommendations on the Transport of Dangerous Goods—Model Regulations—of the United Nations," in particular concerning the design of the vessels and their safety accessories, gas/materials compatibility, insulation performance, and the operational requirements of the equipment and accessories. By the end of 2006, TC 220 had developed 13 standards (listed in Table 7).

ISO 9000: QUALITY SYSTEMS STANDARDS

In 1979, the ISO formed Technical Committee ISO/TC 176 on Quality Management and Quality Assurance to develop a single, generic quality system standard that could be used for external quality-assurance purposes. In 1987,

Table 6. ISO Standards for Packaging in General (TC 122)

ISO 780	*Packaging—Pictorial Marking for Handling of Goods*
ISO 2206	*Packaging—Complete, Filled Transport Packages—Identification of Parts When Testing*
ISO 2233	*Packaging—Complete, Filled Transport Packages—Conditioning for Testing*
ISO 2234	*Packaging—Complete, Filled Transport Packages—Stacking Tests Using Static Load*
ISO 2244	*Packaging—Complete, Filled Transport Packages—Horizontal Impact Tests* (horizontal or inclined plane test; pendulum test)
ISO 2247	*Packaging—Complete, Filled Transport Packages—Vibration Test at Fixed Low Frequency*
ISO 2248	*Packaging—Complete, Filled Transport Packages—Vertical Impact Test by Dropping*
ISO 2873	*Packaging—Complete, Filled Transport Packages—Low-Pressure Test*
ISO 2875	*Packaging—Complete, Filled Transport Packages—Water-Spray Test*
ISO 2876	*Packaging—Complete, Filled Transport Packages—Rolling Test*

ISO 21028-2	*Cryogenic Vessels—Toughness Requirements for Materials at Cryogenic Temperature—Part 2: Temperatures Between −80 degrees C and −20 degrees C*
ISO 21029-1	*Cryogenic Vessels—Transportable Vacuum Insulated Vessels of not more than 1000 Litres Volume—Part 1: Design, Fabrication, Inspection and Tests*
ISO 21029-2	*Cryogenic Vessels—Transportable Vacuum Insulated Vessels of not more than 1000 Litres Volume—Part 2: Operational Requirements*
ISO 23208	*Cryogenic Vessels—Cleanliness for Cryogenic Service*
ISO 24490	*Cryogenic Vessels—Pumps for Cryogenic Service*

on the basis of the work of TC 176, the ISO published the ISO 9001 Standard. No other standard developed by the ISO has had as much impact on a global scale as this ISO 9001.

ISO 9001 was developed by researching a number of national standards from several ISO member countries including Great Britain's BS 5750 and BS 4891, France's AFNOR Z 50-110, Germany's DIN 55-355, the Netherland's NEN 2646, Canada's Z-299, and the United States' ANSI/ASQC Z-1.15, MIL-Q-9858A, ANSI/ASQC C-1, and ANSI/ASME NQA-1 (6).

Each representative member country participating in the ISO has taken ISO 9001 back to their respective country and, after translation, issued it a designation unique to that country. In the United States, ISO 9001 is published by the American National Standards Institute (ANSI), in conjunction with the American Society for Quality (ASQ), and is referenced as ANSI/ISO/ASQ Q9001.

ISO 9001 is a generic, baseline quality standard written with the intent of being broadly applicable to a wide range of varying nonspecific industries and products. With this objective, ISO 9001 establishes the basic requirements necessary to document and maintain a marginal quality system. These quality system requirements are intended to be complementary to specific product requirements. This broad objective is ISO 9001's strength.

For example, the current version of ISO 9001 (2000 edition) contains broad requirements relating to packaging (in section "7.5.5 Preservation of Product"), stating:

> *The organization shall preserve the conformity of product during internal processing and delivery to the intended destination. This preservation shall include identification, handling, packaging, storage and protection. Preservation shall also apply to the constituent parts of a product.*

Therefore, as appropriate to the product, any of the ISO packaging standards listed in this article may be utilized within an ISO 9001 compliant quality management system.

INTERNATIONAL CODES, RECOMMENDATIONS, REGULATIONS, AND TECHNICAL INSTRUCTIONS

Several other international organizations have developed codes, recommendations, regulations and technical instructions that should also be mentioned here:

1. *UN Recommendations on the Transport of Dangerous Goods, Model Regulations*. Prepared by the United Nations "Committee of Experts on the Transport of Dangerous Goods and on the Globally Harmonized System of Classification and Labelling of Chemicals." These *recommendations* may be viewed (14th edition, 2005) or ordered online at

   http : //www.unece.org/trans/danger/publi/
   unrec/rev14/14files_e.html

2. *The International Maritime Dangerous Goods Code (IMDG)*. Published by the International Maritime Organization. For more information on the IMDG, including how to order the latest edition, visit:

IONOMERS

Barry A. Morris*
DuPont Packaging and
Industrial Polymers,
Wilmington, Delaware

Ionomers are premier heat seal polymers that have found use in demanding packaging applications requiring excellent seal reliability, formability, and toughness. The term *ionomers* was coined by the DuPont Company in the early l960 s to describe polymers having both ionic and covalent linkages (1, 2). In particular, ionomers was used to describe the polymers originally sold under the registered trademark of SURLYN®. These polymers are made by high-pressure free-radical polymerization of ethylene with an unsaturated organic carboxylic acid and then partially neutralized with a metal ion (3). The acid groups in these polymers are incorporated randomly along the polymer backbone. While DuPont ionomers are typically made from ethylene–methacrylic acid copolymers, the Dow Chemical Company, and A. Schulman ionomers are made from ethylene–acrylic acid copolymers (4) All four companies supply grades neutralized with either zinc or sodium ions. The ionomers above are composed of ethylene-unsaturated carboxylic acid–carboxylate salt. In addition, DuPont offers some grades that contain a termonomer, isobutyl acrylate. Isobutyl acrylate acts to reduce the polymer's modulus and melting point. It also increases toughness and improves adhesion to certain substrates. Mitsui–DuPont in Japan offers ionomers similar to SURLYN® ionomer resins under the registered trademark of HI-MILAN®.

Recently, DuPont introduced a potassium-based ionomer resin under the tradename ENTIRA™ AS, which is a permanent antistat. It can be blended with polyolefins such as polyethylene or polypropylene to reduce static buildup. Other polymeric materials are also included in the classification of ionomers (5, 6), but the discussion here will be limited to those based on ethylene copolymers that are used as sealants in packaging applications. Structure, physical properties, processing, and selected end uses are covered below.

IONOMER STRUCTURE

The polymer that can be considered the "parent" of these ionomers is low-density polyethylene (LDPE). The structure of LDPE consists of crystalline and amorphous phases, but ionomers contain a third ionic phase composed of metal ions and neutralized carboxylate groups. The structural units of this third phase are called *ionic clusters* and are illustrated in Figure 1. They possess an internal order, the exact nature of which depends on the type of ion present. These clusters are responsible for the unique set of properties of ionomers.

For instance, ethylene-unsaturated acid copolymers exhibit improved toughness compared to LDPE because of hydrogen bonding between carboxylic acid groups on different polymer chains. Ionomers made by neutralizing some of the acid groups in such polymers have not only hydrogen-bonding forces holding polymer chains together but also the much stronger ionic forces from clusters that interconnect polymer chains, as shown in Figure 2. The attractive forces, called *ionic crosslinks*, weaken with increasing temperature, making the polymer more readily processable than an LDPE polymer having comparable melt flow index.

Although the order within the clusters decreases with increasing temperature, the clusters themselves are not destroyed even at temperatures as high as 572°F (300°C). When heated polymer is allowed to cool, reordering of the structure within the clusters and crystallization of short polyethylene segments causes a substantial increase in the modulus of the polymer. The modulus of the cooled polymer and its rate of attaining ultimate modulus depends on the processing temperature, the storage temperature, and relative humidity.

PHYSICAL PROPERTIES

The amount of acid incorporated into the backbones of ionomer chains may range from 7wt% to 30 wt% for commercial products. These acid groups are usually neutralized from about 15% to 80%. Even a relatively low amount of neutralized acid provides significant changes in

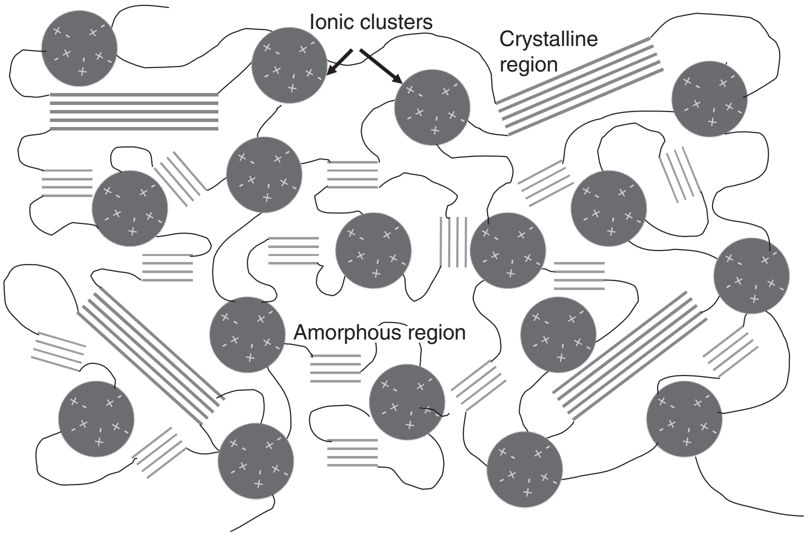

Figure 1. Morphology of ethylene ionomers. Ionomers contain crystalline and amorphous regions similar to LDPE, but also contain "ionic clusters" that impart a unique balance of properties.

physical properties compared to LDPE. Increasing acid content and percentage neutralization causes the following properties to increase: tensile strength, modulus, toughness, clarity, abrasion resistance, puncture resistance, resistance to both mineral and vegetable oils and fats, moisture absorption, and melt strength. Properties that decrease are melting point, haze, surface tack, and notched tear resistance.

Adhesion to polar materials such as aluminum foil, nylon, and paper in coextrusion or extrusion coating is a direct function of the amount of unneutralized acid in the ionomer. Adhesion to nonpolar polyethylene is decreased by increasing amounts of acid and carboxylate salt. Zinc ionomers tend to have a broader range of adhesion than do sodium ionomers and are less hygroscopic. Sodium ionomers offer superior grease resistance and optical properties.

PROCESSING

Unlike LDPE, ionomers are hygroscopic. Manufacturers supply them in a dry state, and they need to be kept dry for proper processing. Ionomers can be processed in typical extrusion and coextrusion equipment that is suitable for extruding LDPE, with the exception that corrosion-resistant equipment needs to be used. For blown-film extrusion, ionomer grades having melt-flow indices ranging from fractional to about 5 dg/min are suitable, although grades having melt flows as high as 14 dg/min can be extruded because ionomers possess exceptional melt strength. The melt strength of ionomers is sometimes used to help carry other layers in coextrusion. For extrusion coating, grades having melt-flow indices ranging upward from about 2.5 dg/min are suitable. Because ionomers have affinity for metal surfaces, grades for extrusion coating benefit from the use of matte chill rolls. Use of a chill-roll release additive also can be helpful, especially if a gloss chill roll is required. Cast-film processing is also suitable for ionomers.

Unlike LDPE, the extrusion temperature should not exceed 590°F (310°C). Good practice calls for maintaining a slow flow of ionomer through the equipment during nonproduction periods. Ionomers need to be purged with a polyolefin resin from the extruder and die prior to an extended shutdown.

APPLICATIONS

Vertical Form/Fill/Seal Packaging

Many of the uses of ionomers in packaging depend on the melt-strength, melt-flow, and adhesion characteristics of this polymer family. As a heat-seal layer especially for vertical form (VFFS) packaging, a property that is extremely important is called "hot tack," which is the capability of a newly formed (still molten) heat-seal bond to resist an opening force. In the case of VFFS packaging, the force is exerted on the end seal by product being dumped into the package. If the hot tack of the seal layer is insufficient, the seal may open partially or completely. Ionomers excel in melt strength, and seal widths of packages can be minimized by their use as the seal layer (see also Form/fill/seal, vertical).

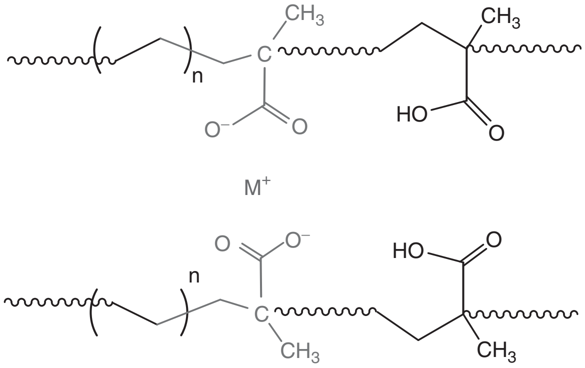

Figure 2. Chemical structure of ethylene ionomers. The interaction between the metal salt (M) and the carboxylic groups on the polymer chain creates "ionic crosslinks."

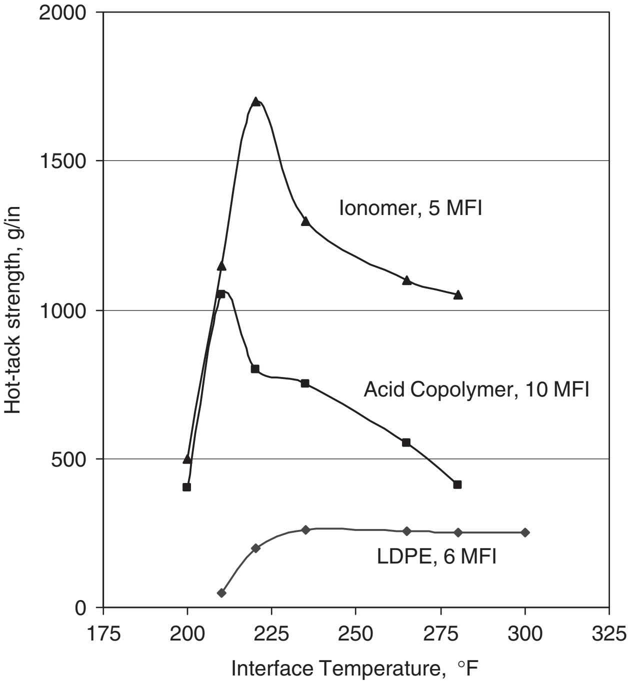

Figure 3. Hot-tack strength comparison, DuPont spring test.

A comparison of the hot tack profiles of a low-performance zinc ionomer, an acid copolymer, and LDPE is shown in Figure 3. For a given hot-tack strength, say, 750 g/in., the operating-temperature window of the ionomer is greater than 75°F, that of the acid copolymer is 40°F, and the LDPE polymer has insufficient hot-tack strength to meet the requirement. The width of the hot-tack window for ionomers contributes to seal reliability and reduced dependence on highly accurate temperature control of the sealing operation.

Ionomers also have low seal initiation temperatures because the crystalline melting point of the parent LDPE has been reduced by copolymerization of acid and/or ester. Since their seal strength is maintained at the high-temperature end of the sealing range, this means that the overall heat-seal operating window is widened and contributes to increased packaging line speeds and seal reliability. The melt-flow characteristics of ionomers also allow them to flow and seal around particulate contaminants that may be in the seal area, also increasing seal reliability. Abrasion resistance of ionomers is a benefit in packaging food products that tend to be abrasive.

Ionomers have greater stiffness than other sealants with similar low-temperature sealability, such as EVA's and polyethylene plastomers. The stiffness of a film affects its ability to be handled in high-speed packaging lines and impacts the package appearance and feel. Because the sealant is one of the outer layers in a multilayer structure, it can have a large impact on the stiffness of the film (7). Sealant stiffness also affects the slow puncture resistance of a packaging film; stiffer ionomer resins impart better puncture resistance than softer plastomers. This is important for many dry food and meat (bone) applications.

Visual Carded Display Packaging

This type of packaging, also called "skin packaging," is used both for retail hanging card displays and for industrial packaging to hold products to a board for shipping. The toughness, optical clarity, and minimal board-curling properties of ionomers make them particularly suited for this use.

Thermoformed Packages

The melt strength of ionomers allows deeper draw depths of packaging webs utilizing an ionomer layer compared to use of other polymers. Coextrusions of ionomers with nylon have been useful in packaging processed meats and cheese. Methacrylic acid-based ionomers also have the property of providing adhesion to the protein of meats and reduce the amount of purge, that is, liquid exudation formed during meat processing. Because of their melt-flow properties, ionomers also have superior properties compared to other polymers for sealing through contamination, as from meat juices. This property gives webs having ionomer seal layers a reduced amount of package leakage, reducing waste and cost.

A specialized type of thermoformed packaging is called "Stretch Pak," in which a film attached to a windowed card is thermoformed, and the product is placed in the cavity. The packaged object is held snugly in the custom-shaped cavity when passing the package through a heated shrink tunnel shrinks the film.

Aluminum-Foil-Based Packaging

Ionomers containing unneutralized acid groups have found wide utility as the seal layer in extrusion-coated aluminum foil structures. The acid groups provide adhesion to the foil, while the superior sealing and chemical-resistance characteristics of the ionomer permit packaging a wide variety of products.

JAPANESE PACKAGING

Andrew W. Streeter
CPS International Pack-Track
Cambridge, United Kingdom

INTRODUCTION

No country in the world is as collectively dynamic with consumer packaging than as Japan. It is a country as much in love with (or certainly with a positive liking for), as well as fully appreciating of, its commercial potential. The phenomenon is not new; we have traced it back some few hundred years, but it has certainly for the past 50 years been a key packaging leader in the world.

Japan is also is a very wealthy country, with one of the highest per-capital values (US$37050 GDP per capita; second only to the United States) of the "big" countries in the world. This huge spending power and a discerning market is a breeding ground for packaging innovation and change, and Japan rises and fulfils this challenge well.

This article explores the different facets of Japanese packaging, where culture is as important as commerce and the science of change. Change is in fact frequent in Japan, with packaging not always technically new but certainly visually new and collectively pushing back boundaries of packaging possibilities. It is a fascinating, seductive, and energetic packaging world that is globally trend setting.

THE UNIQUE JAPANESE PACKAGING CULTURE

We have traced the application of packaging back 200 years or more to when bakeries used to wrap their cakes and confectionery in different ways to distinguish them from rival producers. Over time, this became more interesting and entertaining for the consumer, with more elaborate folding of the wrapping and with clever uses of materials. Materials then were primarily paper, and there is a (much longer) parallel here with origami in the creative use of paper materials.

Out of this value-adding use of paper wraps for cakes evolved three principles that have held good in Japan to this day, which you can observe in even the most advanced pack. First, there is the stated need for differentiation while retaining market sector recognition.

Second, it is a statement of care and a statement of pride on behalf the baker. He or she is saying through the packaging, "Here is my product and I thank you for buying it; I present it to you with care, that you may both enjoy it and enjoy the anticipation of it as you unwrap and use the product."

In that last point lies the third quality; over time, it has evolved that to unwrap a pack should be pleasurable, enhancing expectation, and an integral part of the product experience. The pack is part of the product, true now in the developed regions of the world, but Japan was first in this respect, and in Japan it remains more true and more extensive than anywhere else.

We have evolved a phrase from Robert Louise Stevenson that reflects this quality: "to travel is as important as to arrive." When you see, hold, open, use, and finally throw away a pack in Japan, you are on a journey that should be positive and enhance the experience of the product or brand.

The consequences of these factors are that consumer packs are designed in every aspect to a high degree of functionality, which is finessed for consumer handling and commercial considerations of cost. Packs in Japan are well built; easy to open, dispense, and recluse; and today will have a sustainability dimension about them. All that is undertaken in a way that engages the consumer with the brand.

It is not just the history of packaging application that is a driver, however; the Japanese people have high and typically unshakeable standards. It is about quality, quality, and quality; consumer packaging is a beacon of that way of life.

THE IMPORTANCE OF GOOD PACKAGING DESIGN

The role of packaging design is key in securing these multifunctional needs out of the one pack. But design is visualized, and the sector structure is different in Japan when compared with other regions of the world. Every department in the product manufacturing company will work hard to make the pack work at a profitable margin. There is a cultural acceptance to agree on a proposed pack and then deliver it, whereas in the west, by way of example, we argue and debate.

To an outsider, a visit to a Japanese supermarket would reveal a cornucopia of fascinating packaged brands and products, but that romantic pleasure should not disguise a ruthless commercial approach to a product or brand, by this integral association, or its packaging success. If it does not deliver the expected ROS (rate of sale per linear meter on shelf) straight away, it is delisted, and this can be as little as 4 days after launch. So, packaging has to work hard immediately.

A key driver in this need is in the pack design. It can be segmented into graphics, new structures, and new concepts, and each has to add something more to the past packaging design.

Packaged brands are often created for a short market life, sometimes just a few months. A brand can be the same product but in new or evolved graphic interpretations. Change is part of the brand ethic, so there is a constant desire for a new package and something to smile about, which creates an exciting and/or an inventive graphic design community.

A key strategy in this, ironically, is the Japanese language. Its character script has over 10,000 characters, and it is not until about the age of 10 that a young person would have mastered the language sufficiently. Consequently, symbols are frequently used in packaged brand communication and have reached a high level of evolution. Pack designers are extensive users of symbols and other devices. It is often easy for non-Japanese to understand what is inside a Japanese packaged brand because symbolism has a universal quality.

More than graphics, however, Japan has international fame for its new pack structures and concepts where multi disciplined packaging design skills are required. The expression “holistic design” is very appropriate in Japan. Allied to this is a business ethic of introducing new packaging ideas to the market; packaging ideas that can be groundbreaking like the bottle made from paper pulp (image 2). And like the paper pulp bottle, it is accepted that there is a degree of failure, although this failure could be more often one of timing—often ahead of the market-than anything else and certainly not technical failure. Even during the protracted recession of the 1990s, Japan’s packaging industry continued to create and manufacture innovative new packaging.

Japan is often recognized as being an “overpackaged” society, but this not really the case. First, you cannot compare on a like for like basis, as the standard in Japan is so much higher, in terms of quality expectations, than elsewhere. A simple printed can in Japan is more expensive because its cheaper western counterpart is not made to the same standard. The other aspect to the overpackaging perception is also a value one—the need to protect and to ensure that each product is virgin and clean. Couple this with creating pleasure when using the pack and “unwrapping” and the expectation of being functional, and the difference is one of standards, Japan (brings) to the west. Do these higher standards come at an inappropriate premium? We think not and have the opinion that Japan, on a pack comparative basis, pays 1 1/2% to 5% more in packaging unit cost. The value that is delivered is certainly more than the cost, for the Japanese consumer, but maybe in the west we are not there yet.

From that standpoint, Pack concept design in Japan can often deliver a sought-after feature: value adding while not cost adding, and in some instances, cost reduction as well. By way of an example, the small S&B Raa-yu bottle (image 3) has a (a) one-piece closure that is (b) simple to manufacture, (c) provides controlled drops of oil, (d) in an intuitive way to use, (e) engaging to use, (f) low in unit cost, and (g) functions perfectly. Controlling the dispensing of small qualities of oily substances in the kitchen is tricky and has created many complex, costly and at times inadequate packaging devices, yet the closure on the S&B Raa-yu bottle is simple and effective. It is a good example of value up and cost down.

THE PACKAGING INDUSTRY AND PACK DESIGN

The value and culture of new pack design is not lost on the packaging manufacturing industry, where nearly all types of packaging design are controlled by the packaging industry. There are very few independent packaging designers or consultants in Japan. Every medium-sized and upward packaging company would have its own in-house designers, and outside design houses would typically be allied to packaging companies.

The packaging industry, like nearly all industry in Japan, is rather incestuous. Everything is kept within one giant network of suppliers, which is linked by tradition and trusted by time. Added to this, vertical integration is common; for example, the food company Anjinomoto owns a packaging company, a distribution company, and a retailing arm. Control, a fast decision, and flow of goods enhance the whole ethic of quickly introducing new packaging designs and concepts.

With basic issues like graphic design change, a substantial amount of work is created for everyone within the supply chain; turnover grows, employment prospects are made sound, and there is constant market excitement. The mechanisms involved may be open to criticism, but it does work and it does produce some of the most interesting packaging in the world.

The packaging industry leverages design to match the fast changing market needs, and brands often have a projected life of just a few months, so in graphic terms there are constant print changes as designs come out. By tradition, there are beer brands for the different seasons, each one rotating by graphic design every few months, and each season sees a new design.

THE PACKAGING MANUFACTURING INDUSTRY

Japan has a large packaging manufacturing industry that represents a steady 1.3% of GPD (515,733 billion Yen in 2007). The industry has 18 major players, which include foreign subsidiaries like Nihon Tetra Pack. Some of these companies are international, like Mitsubishi, Toppan Printing Company, and Dia Nippon Printing, and in companies where packaging is part of a wide and, in the case of Mitsubishi, diverse range of materials, goods, and services.

In monetary terms, there has been tiny but steady growth in materials leaving the factory gates; glass is in decline and metal is flat, as is to be expected, but this is offset by plastics growth and small improvement in the total value of paperboard.

In tonnage terms, the movement upward has been modest indeed, reflecting a mature society, and all sectors are more or less flat.

Japan is an important and active producer of packaging machinery. The sales value and machine numbers in the table below reflect, like materials, modest overall growth, except that machines to do with flexible packaging have seen a steady growth in line with market trends in this sector.

As costs increase, the industry has been outsourcing and investing within the wider region. Toppan established a base in China in the 1980s, when the situation there was different than today. Packaging machinery components are manufactured in China and finished, and the machine was assembled in Japan. Principle countries in

outsourcing are South East Asia, South Korea, and China. The Philippines is a major source in Japan of printed flexible packaging for pouches and flow wraps.

The solution to the cost base issue is to continue to value-add packaging, while inventing and exploiting new technologies in the process. Japan's packaging industry innovates with packaging and also commercializes pack concepts from other countries. Toppan's Cart-o-Can originates from Finland; it was developed and commercialized by Lamican oy in Valkeakoski. This is a good example of the Japanese commercial mentality to exploit, improve, and get to market quickly.

The packaging industry leads globally in many consumer pack areas; to highlight this fact, 3 examples are as follows:

- Print quality. The value of good quality print and the exploitation the medium can offer (Image 3) is underappreciated.
- Shaping of paperboard containers. Moving a straight-sided carton into a curvy and feature-rich pack has been a Japanese strength that has given an added dynamic to what was once an unchanging format (image 4).
- Light weighting of PET. This is a popular claim from many countries, and Japan can claim important success here especially with structural design and the use of interlocking panels to create strength (image 5).

Light weighting is a good example of Japan's success with materials application, but part of the pressure to change is to increase savings because of expanding raw material costs. As an example is a brand leader in the bottle water market, "Tennensui" (brand owner & producer Suntory), which was launched in March 2007, introduced a light-weighted 500 mL PET bottle at 25 g with a new (and in some respects novel) shape that was asymmetrical. This design was enhanced by a hewn ice effect, and although it had good visual impact, standout, and brand recognition at the point of sale (PoS), it proved to be structurally weak. This was evident in the all-important vending distribution system, where lateral crushing became very evident. A modification to the bottle structural design was necessary through adding a rib to the base (launched in April 2008) to enhance strength. The net result in weight saved was another 4 g at 21 g for this 500-mL bottle.

Although 21 g is lightweight the current lightest weight 500-mL PET bottle is 18 g for "Pokari Sweat" (brand owner and producer Otsuka Pharmaceutical), which is an 11 g reduction over the previous pack. The values of this bottle through shaping were challenged, and the well-known square cross-sectioned-based bottle was replaced by a conventional cylinder with strengthening ribs added to the perimeter body. Otsuka Pharmaceuticals believes they have reduced PET consumption for this bottle (launched in 2007) by 2700 t per annum.

These weight reductions also demonstrated that the brand values of a pack through shaping and surface treatment are critical, if not paramount. Although serious shape change has taken place to reduce weight, the essence and recognition of the brand has not been lost in these moves. For new brands coming on to the market, we expect more use of surface facets that not only deliver compression and lateral strength in a lightweight container but have the facility deliver light-reflecting highlights to enhance standout at the PoS and add emotional values to a packaged brand.

Changes in other materials have, like PET, been evolutionary more than revolutionary, which is consistent with the packaging industry by and large globally. Important in this evolution has been Toppan, who have continued their vapor disposition process created with GL films (silica oxide) to produce a range of films called GX—hybrid of thin film, disposition, and barrier coatings—with a claimed barrier equivalent to aluminium foil. Toppan have secured over 400 patents in the development of GX films and with a market of some 12,000 t in 2005 and Toppan seeking a 40% share, the prizes are high. This see-through capability when compared with aluminium foil, less heat to incinerate pushing down the dioxin emissions, and other benefits like not infering with metal detection equipment on the production filling line. Toppan's classic Japanese strategy of taking a long-term approach and with GX following on from GL, the disposition and hybrid process approach is set to continue in pursuit of offering a higher barrier on a lower material base.

In the early 1990s, Japan was a leader in two-dimensional (2-D) pouches, and the process is now copied around the world, especially in the United States. Now, Japan has fresh thinking in three-dimensional (3-D) pouches. In image 6, there are two standup pouches with unique bases that give extra stability and enhanced branding opportunities; the pouch to the left has a double skirt, whereas the pouch to the right base is made with a separate film piece. Both approaches provide solutions to the issue of pouch stability and competitiveness in that parameter when compared with rigid containers.

Rigid containers in aluminium and steel have experienced the introduction of shaping especially in three key areas. First, the introduction of surface nonregistered embossing, with aluminium beverage cans, adds enhanced stand-out at PoS and tactile qualities in usage. Second, the introduction of the two-piece bottle can for beverages has been a significant development and is in wide distribution. Paralleling that in steel has been the thee piece bottle can for carbonated beverages, which has a smaller diameter aperture and closure. And in steel, the shaping of three-piece cans with conventional closures, which are used primarily for beverages, especially ready-to-drink (RTD) coffees, and with some skilled surface decoration and embossing to match. (Image 7)

As a vehicle of coordination of developments, training, and activity, the industry in effect sponsors The Japan Packaging Institute (JPI), which is an organization paid for by the industry and not by the members. This economic approach has ensured a lively and active packaging institute in Japan in a decade when many packaging institutes have downsized or even disappeared.

The JPI is the voice of the industry on government bodies; it puts forward plans to meet government regulations, such as on waste, and also promotes its own initiatives, especially this decade, on waste, recycling, and sustainability. In addition, the institute organizes the industry's biannual trade fair, Tokyo Pack and Conference, which can draw in 200,000 visitors over a 5- day period.

JAPAN, PACKAGING, AND SUSTAINABILITY

In some respects, the concept of the three R's (reduce, recycle, and reuse) arrived late in Japan compared with western countries. By the mid-1990s, and again in the mid-2000s, the situation has changed, and Japan leads with a different strategy and plans for packaging waste as part of an overarching national strategy.

Japan's approach to sustainability is embedded in The Containers and Packaging Recycling Act, which was first established in 1995 to meet the increasing need to reduce the volume of solid waste and make full use of recyclable resources by means of sorted collection, and to recycle waste containers and wrapping. The key words at this point in time are *recyclable resources*. A comprehensive reassessment of the Act was started in 2004, with an important contribution from the JPI, and the revised Container and Packaging Recycling Act went into effect just 2 years later in June 2006. The key points of the revised act are as follows:

- Promote the establishment of a sustainable society according to the three Rs of Reduce, Reuse, and Recycle defined in the Basic Act for Establishing a Recycling-Based Society
- Improve cost efficiency throughout society
- Encourage cooperation of all interested parties, including the government, municipalities, business enterprises, and citizens

The key words at this stage are *establishing a Recycling-Based Society*. There are several drivers for this statement, and I want to highlight two. First, Japan is not rich in natural resources (and this, coupled with over 85% of its land being mountainous, plus constant earthquakes, means that there is little to be had from the ground, trees are extensively grown for commercial use). Second, the share of post packaging in the municipal waste stream was high at 60.6% when the original 1995 Act was passed. By comparison, Europe is municipal packaging waste is 5% to 25%.

There has a been a steep change in thinking, and packaging waste is considered to be a resource—a valuable resource—in its own right. The national plan is to harvest that resource.

Operating principles are similar to Europe and North America, where manufacturers and users assume responsibility. The 2004 Act states that there are "specified business entities": These are manufacturers who do the following:

- Use containers and wrapping for shipping their products, including retailers and wholesalers who use containers and wrapping for selling merchandise, manufacturers of containers, importers who import and sell merchandise in containers or wrapping, and importers of containers.
- Have been assigned the responsibility of recycling these containers and wrapping in accordance with the volume that they manufacture or sell.

As in other countries, it is difficult for individual business entities to collect waste containers and wrapping from respective municipalities and recycle them on their own. To provide an alternative, a government designated organization, The Japan Containers and Packaging Recycling Association (JCPRA) was set up to operate the recycling needs of businesses on behalf of the specified business, to meet their statutory obligations. This is paid for by the "business entities" on a fee basis to the JCPRA. The JCPRA has a formidable board structure and is well resourced. The legislation itself can be said to be modeled on the French system of deposit–return and was designed to limit the disruption of these existing systems, including safeguarding the jobs of local government workers employed in waste management.

In addition, the consumer is expected to make a contribution by sorting domestic packaging waste into streams of glass, metal, paperboard, plastics, and PET (as a separate plastics material). This strategy also includes the removal of debris on the container, which, if with water, is a debatable environmental point.

In essence responsibilities can be tabulated as follows:

Consumers	Sort packaging according to municipal criteria
Municipalities	Design and implement a program for source-separated collection of packaging Prepare packaging materials for market
Manufacturers, product manufacturers (includes importers)	Recycling of materials collected by municipalities Meeting the government set targets Develop recycling plants Ultimately recycle all materials from the waste stream

The national plan to implement this strategy is detailed and impressive, and it sets test standards.

How is it working? It is fair to start by saying that the industry fought to limit its responsibility under this system. Yet, nearly two thirds of local governments and municipalities had already implemented systems for separation and collection of recyclable materials from household trash, prior to the law's enactment.

Most municipalities or communities have introduced or expanded curb-side recycling programs to meet these requirements. This is paid for by the Municipal authority. Once they have collected materials, municipalities must prepare them for market. This preparation can include washing collected bottles; removing contaminants, such as caps and labels; and baling. In fact, Japan has some of the most attractive curb-side containers for packaging waste anywhere in the world (even when placed freely on the pavement, it seems always to be neatly bundled and stacked up for collection). Also segmented collection containers are every where, from the small convenience store, to metro stations, to the big supermarkets.

Up-to-date information is not available, but in 2004 the Ministry for the Environment states "that the number of Municipalities conducting sorted collections has increased with regard to every item except for steel and aluminum cans[*] compared with 2002. The volume of waste collected separately and recycled also increased with regard to every item, except for and steel and aluminum cans, of which consumption volume had decreased. This shows that the system under this law is well recognized and has taken root in society.

The volume of used PET bottles collected in 2003 was approximately 110% that of 2002. The recovery rate of used PET bottles, calculated by dividing the volume of sorted collection by the volume of manufacturing, totaled 48.5% in 2003, and this rate steadily increased year by year. Assessing trends[†] regarding the volume of wasted PET bottles, which was derived from the difference between the separately collected volume of used PET bottles

---

[*] The number of municipalities conducting sorted collection and recycling decreased, because the number of municipalities decreased by merger outnumbered the municipalities launched sorted collection and recycling.

[†] The voluntary collection of used PET bottles by businesses is conducted in addition to sorted collection undertaken by municipal governments. The figure here was estimated based on the difference versus the volume of used PET bottles collected by municipalities only. A survey conducted by the Council for PET Bottle Recycling shows that the volume of wasted PET bottles totaled approximately 171,000 t, which decreased by approximately 26,000 t compared with 1997, including approximately 54,000 t (collected rate was 60.9%) of used PET bottles collected by businesses in 2003.

and the manufactured volume, it was found that the recycled volume increased by approximately 6% compared with 2002, whereas the volume of waste decreased by 9000 t compared with 1998 figures.

The used plastic containers and packages other than PET bottles and used paper containers and packages were designated as additional items subject to the law in April 2000. In 2003, 4 years after this designation, the collected volume of used plastic containers and packages and used paper containers and packages increased 140% and 130%, respectively, compared with 2002 figures.

The system is complex, and with the fees, quotas are also imposed on the packaging supply chain at source as part of funding this post consumer collection. The scale of charges is determined by both weight and volume, and this has driven innovation and technical development in response. Reducing package weight has been an example of this. It not only reduces the fees but also cuts other related costs like distribution weight and cube efficiency.

The figures do not tell the whole story. Nearly all Japan's PET is shipped to China and selected South East Asian countries for recycling (undermining some serious new investment in this technology) for cost reasons. Actual recycling rates per household are still below that of the United States. But the system works, has a different objective and ethic than other countries, and is stimulating the packaging industry to create more sustainable packaging and find new ways of meeting product protection needs.

Also, in a move to underline this, in March 2008 the government decided to promote Japan's knowledge and expertise to other countries under the scheme "Sound Material-Cycle Societies".

OTHER DRIVERS OF PACKAGING CHANGE

Japan's economic success has come with a premium; the birth rate has steadily fallen, and the population is living longer. It is now predicted that by 2025 over one third of the population will be 65 or older. Coupled to this the life expectancy prediction (Government 2006) is 79.0 years for a man, second only to Greenland, and 85.8 years for a woman, which is the highest life expectancy in the world.

This society will have packaging issues for a large section of the population. Part of the solution is in the underlining need to value add and to provide packs that match an aging lifestyle. An aging population is likely to consume more pharmacy products, and there are packaging opportunities there.

Another part of the solution is in the concept of universal design (UD). The theory of universal design is advocated by the U.S.-based researcher Ronald L. Mace. refers to the design of products, elements, or spaces that can be used with equal effectiveness by anyone, from the elderly or physically challenged, to children or pregnant women, irrespective of the user's abilities or degree of dexterity.

The packaging industry and their designers are responding. Product manufacturer Kokko has an oblate-shaped cup that is designed to make it easy for the elderly to take medication. At the everyday product level, plastics company Osaka Hososha, in conjunction with flexible manufacturer Gunze, has developed a new sandwich pack made from an easy opening heat seal of OPP film produced by Gunze. This pack features two tabs on either side of the pack, either of which is simply pulled in an upward direction to open. The film separates smoothly from the seal portion, leaving the label intact and enabling the contents to be removed with ease without out the fingers coming in contact with the filling.

There is a strong enough eco-ethic in Japan to have a packaging effect. The application of cellulose-based fiber has been enjoying a renaissance. Pressure-formed paper-pulp compartmentalized trays as replacements for plastics are now well established. They are well decorated and can have an elaborate shaping. When Lion launched a powdered detergent in a paper pulp bottle (image 2) not only was that a remarkable feat but also they were confident enough to supply a refill pouch as well.

Making use of waste packaging, Daiko Sangyo has made a gift-wrapping cloth out of recycled PET bottles.

A company called Yutaka has developed tubs that are edible. They are made from potato or sweet potato starch. The tub can be an alternative for a small packs made from paper or plastics. It can only be used where a barrier is not required and the shelf life is short. Conventionally, this type of edible wafer film becomes fragile when it dries, which makes it difficult to form, but the Yutaka process uses a controlled thickness of starch film and then forms it at narrow temperature bands. The material is claimed to be resistant to oil and moisture. Its potential is seen for small baked goods like muffins and deli foods and for boxed meals. The product is claimed to be sustainable as it is a foodstuff in its own right from renewable plants and does not need to be separated and disposed of.

Behind these developments, the environmental driver is creating new improvements. Packaging company Nagata has a liquid container that can be folded for easy transportation and storage. The Giant paperboard company Oji has developed a board product that uses the leaves from green tea within its structure.

WHAT THE FUTURE MAY HOLD IN JAPAN FOR ITS PACKAGING

Like many other countries and societies, Japan is at something of a crossroads with its packaging. It has a high cost base, a complex but effective recycle packaging resource strategy, a rapidly aging consumer market, and a relatively large packaging sector, all in the context of potentially severe global economic downturn starting in 2008–2009.

A prime key is in value adding with packaging, but in a way that meets the demands of a changing and environmentally aware society with the backing of government sustainability legislation.

We see new packs emerging from fiber. Japan is fortunate in that has a large forestry industry and an inclination to be technologically innovative with cellulose fiber. We predict that Japan will be a global leader in the conversion of cellulose into new pack formats, and that it will continue to perfect machines and paperboard materials that can be shaped and made easy to open, easy to dispense, and easy to reclose. Paperboard materials engineering struggles with incorporating a barrier while retaining some element of biodegradability or avoiding complex, multilayered materials with this material.

Strength is in the packaging design base of paperboard products and with the facility to create value-adding packs without always increasing cost.

On the horizon is the development of high-function resins—aliphatic polycarbonate—from carbon dioxide. This work has been started with the objective to launch the resins onto the market by 2012. The development is a collaboration between the industry and the universities.

When fully commercialized, it is judged to have the potential to replace polyethylene (PE) and polypropylene (PP) materials, which in turn account for 60% of the worlds resin usage. If realized this would have the effect of reducing CO_2 emissions by 30% when compared with resins manufactured from oil.

The Japanese approach to packaging, society, and commerce is different to that of most countries in the world. It is flexible; it embraces and drives change, and accepts constant change as a way of life. It has a culture that can implement change faster than most.

Compared with other countries' packaging sectors, in changing and challenging economic and global warming times, that skill base, with change, has the potential to retain its leading edge with packaging.

L

LABELS AND LABELING MACHINERY

Steve Werblow
Micha Noah

Labels can be affixed to almost anything to indicate its contents, nature, ownership, or destination. Labeling is the art of applying or attaching the label to a particular surface, item, or product (see also Tags).

Originally, labels were used merely to identify a product or to supply information about the properties, nature, or purpose of the items labeled. Today their use is often required by legislation (1), and they are seen as sales and marketing aids in the total design of a package or product. In some cases, the labels have become products in themselves.

TYPES OF LABELS AND MATERIALS

The range and variety of labels used, and the markets and applications for them, are increasingly diverse. Materials include paperboard, laminates, metallic foils, paper, plastics, fabric, and synthetic substrates. These, in turn, may be adhesive or nonadhesive. Even then, the range of label materials can be further subdivided into a variety of different types: coated or uncoated; pressure-sensitive or heat-sensitive; conventional gummed or particle gummed (2). Figure 1 shows the main types of labels and materials.

Of all the different types of labels, nonadhesive plain paper labels applied by wet gluing tend to dominate the total user market throughout the world. In recent years, however, there has been a marked trend toward self-adhesive pressure-sensitive labels. Newer methods of labeling such as shrink sleeve, in-mold, and heat transfer have also gained market acceptance (see Bands, shrink; Decorating).

Overall, the U.S. pressure-sensitive (self-adhesive) roll label market is growing at about 10–15% per year, with some printers and market sectors showing growth of 20% or more. The two main markets showing above average growth are electronic data processing (EDP) labels and prime labels.

Plain-Paper Labels

The conventional wet-glue plain-paper label is widely used, particularly for large-volume items such as beer, soft drinks, wines, and canned foods, where high label application speeds, sometimes in excess of 80–100,000 labels per hour, are required.

Most of the papers used in this type of labeling are one-sided coated grades, which make up the familiar can and bottle labels, but a fair volume of uncoated grades is still used. These tend to be limited to special effects, such as colored papers, embossed papers, or antique laids for wine labels, where particular characteristics are required (3).

Gummed-Paper Labels

Gummed-paper labels have been declining in usage in recent years and are now limited mainly to applications such as address labeling for cartons, point-of-sale displays, and any labeling applications where automation is either difficult or unnecessary. Two main types of gummed labels are in use: conventional gummed and particle gummed (4).

Conventional gummed labels are those that are made up of a base support of paper coated on the reverse side with a film of water-moistenable gum. On particle gummed papers, the adhesive is applied in the form of minute granules. This avoids problems of curling often associated with conventional gummed papers. Most of the

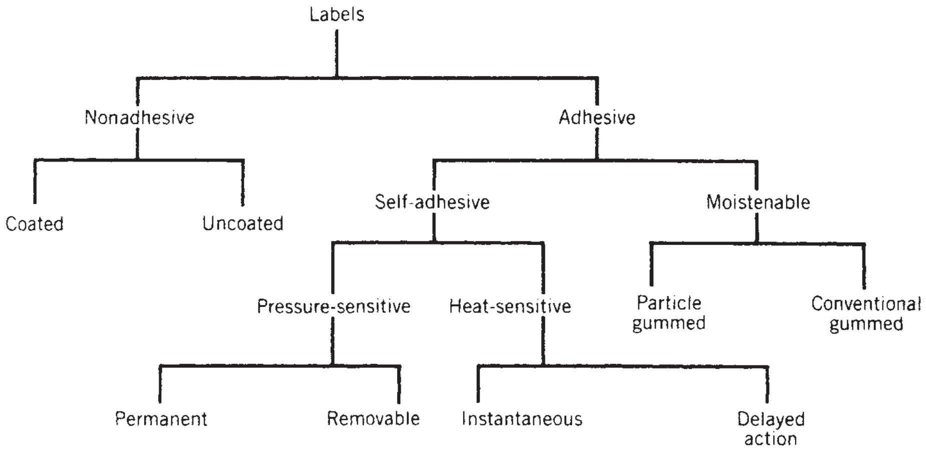

Figure 1. The main types of labels and materials.

newer applications for gummed papers require the properties of high-tack particle gummed papers, which offer many advantages in terms of processing efficiency and security of application.

Self-Adhesive Labels

Self-adhesive label materials (see Figure 2) today range from permanent to removable adhesive types, as well as a whole range of special adhesive materials (see Adhesives).

Permanent adhesives are those that are required to stay in position for a long time or for application to surfaces that are round, irregular, or flexible. Because of the strong adhesive "grab," the label normally becomes damaged or defaced if attempts are made to remove it.

Removable adhesives are those that can be removed after a specified time without damage to the surface on which they have been applied. Uses include short-term food-packaging applications, point-of-sale or advertising stickers, china, and ovenware, where the label should be easy to remove before use.

Within the broad categories of permanent and removable self-adhesive labels, there is a wide variety of special adhesive types to cover requirements such as water removability, low- or high-temperature adhesion, ultraviolet-light resistance, and high- and low-tack properties. Adhesives, which at one time were largely solvent-based, have moved rapidly in recent years to hot-melt or water-based acrylic adhesives (5) (see Acrylics).

For all normal self-adhesive labeling requirements (food and supermarket labels, retail/price marking labels, etc.), surface papers in a variety of weights and finishes, colors, and radiants are available. For special applications, such as outdoor labels, instruction and nameplates for appliances, underwater labels, ampules and vials, and luxury-labeling of cosmetics and toiletries, there is a wide range of nonpaper materials. These include metallic foils and plastic films.

One of the most recent developments in self-adhesive materials is a range of thermal imaging label facestocks, which have become popular for in-store supermarket labeling of meat and fish and fresh produce (fruit and vegetables). These materials contain a surface coating of chemicals that darken under the action of a heated printhead (see Figure 3) (6), thereby providing clear price and weight information and accurate scannable bar codes (7) (see Codebar; Code marking and imprinting).

Almost all self-adhesive label materials are available in sheet form, from paper merchants and suppliers, or, for reel-fed conversion, from manufacturers and specialist suppliers in roll form.

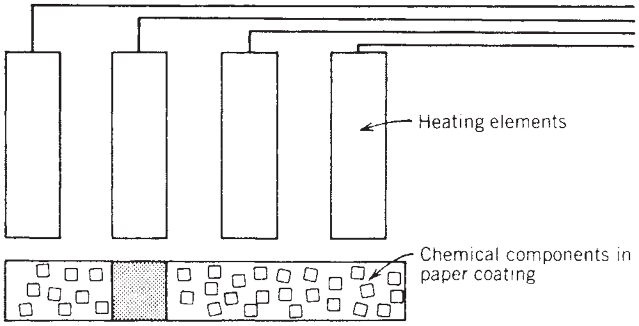

Figure 3. The chemical components in the thermal label paper coating combine and darken when activated by heat.

The main markets for self-adhesive labels in the United States are basically segmented into three areas: industrial labels (or primary and secondary labels used in retail, wholesale, and industrial packaged goods), which make up about 80% of the U.S. self-adhesive label market; EDP labels (those used for marking/imprinting variable information); and price-marking and imprinting (which addresses label applications through handheld dispensers and the whole range of imprint technology). Split into some of the main market application areas, this includes promotional labels, price labels, functional labels, office/retail labels, nameplates, stickers, EDP labels, and prime labels.

Heat-Sensitive Labels

There are two basic types of heat-sensitive or heat-seal labels: instantaneous and delayed-action. In the former, heat and pressure are applied to the label to fix it directly on to the product, whereas with delayed action, applied heat turns the product into a pressure-sensitive item. No direct heat is applied to the goods; and this clearly is vital to some products, such as food.

Typical market applications for delayed-action heat-sensitive label papers include pharmaceutical, price/weigh, some glass-bottle, and rigid or semirigid plastic container labeling. Instantaneous materials are used for applications such as (a) end seals on biscuit or toilet tissue packs and (b) labels on "pleat wrapped" articles (e.g., disinfectant pads, pies, cakes), as well as for some banding applications (8).

In-Mold Labels

In-mold labels are printed on paper or synthetic papers made of polyethylene (PE) or biaxially oriented plolypropylene (BoPP). They are introduced into the container-producing mold before the molten resin is added. The heat

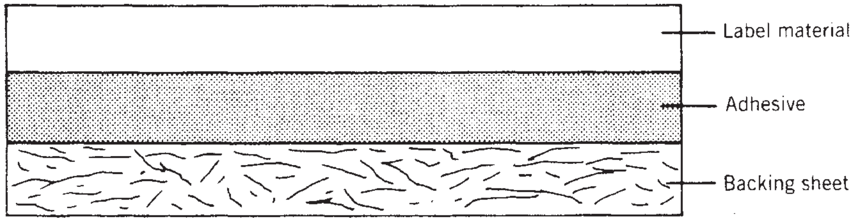

Figure 2. Self-adhesive labels consist of three main layers: the label-face material itself, the pressure-sensitive adhesive coating, and a release coating on a backing material to prevent the adhesive from sticking to the face material in the reel or sheets.

of the resin fuses the heat seal layer of the label to the container, combining label and container to create a sleek, seamless no-label look, as if the graphics were screened directly on the container.

Because they can be produced on high-quality rotogravure or rotary offset presses, in-mold labels can deliver beautifully sharp and nuanced graphics, far surpassing the quality of direct-screened or dry-offset printing.

In-mold labels are typically used where a no-label look is desired, for flexible containers, or for applications in which pressure-sensitive, glue-applied, or heat-seal labels could be challenged by scuffing, freezing conditions, grease, or solvents such as cleansers.

Shrink Sleeves

Shrink sleeves offer full 360-degree graphic space and conform to the shape of nearly any rigid container when heated. Because of their ability to conform to most contours, shrink sleeves have gained tremendous popularity on curved bottles and jars, as well as squeezable containers, all of which have traditionally been very difficult to decorate with conventional labels.

Shrink sleeves are printed, then rolled and sealed into a tube shape. On the packaging line, the tube is placed over the container and sealed in a heat tunnel, where controlled blasts of hot air or steam shrink the film onto the container.

Designing graphics for shrink sleeve labels requires software that compensates for the shape of the container. Graphics look distorted as the sleeve material comes off the press; when shrunk onto the container, it appears as the designer planned.

Managing shrinkage is therefore of the utmost importance in designing and applying a shrink sleeve. The process starts with material selection. High-quality film is critical to obtaining good results, as is selecting film of a material and gauge (thickness) that offers the appropriate amount of shrinkage.

Poly(vinyl chloride) (PVC) tends to yield the most easily controlled shrinkage, the lowest shrink temperature, and the most cost-effective alternative.

Poly(ethylene terephthalate) gly (PETG) is significantly more expensive, but can shrink far more, which makes it appropriate for dramatic contours such as very narrow-waisted or long-necked bottles. Where recycling is important, PETG may be the favored choice, because PVC on a PET container can be difficult to separate from PET during the container recycling process.

Oriented polystyrene (OPS) is less expensive than PETG, but its instability can make it difficult to handle, print, and seal. However, it may be desired for its flexibility and low vertical shrink, which makes it well-suited for squeezable containers.

Poly(lactic acid) (PLA) offers a compostable alternative, but many converters have been wary during PLA shrink sleeves' introductory years because shrink characteristics have not been as well understood as with more familiar films.

Shrink Sleeve Application

Shrink sleeves are applied by setting the tube-shaped sleeve around the container and conveying the sleeve and container through a heat tunnel, where they are exposed to hot air or steam. The heat in the tunnel must be set to a temperature at which the shrink sleeve film shrinks at a controlled rate in order to ensure that the sleeve covers the container evenly and conforms to each contour. Shrink sleeve applicators and heat tunnels often have to be fine-tuned—by adjusting temperature as well as directing the nozzles or heating elements inside the tunnel—to ensure that proper application and shrinkage are occurring.

In most cases, the contours of the container and the tight fit of the film are enough to ensure that a shrink sleeve will remain in place throughout the package's useful life. However, for packages whose shape could allow the sleeve to slip off—for instance, a yogurt cup or a simple jar—a few dots of heat-activated adhesive applied on the inside of the sleeve during the printing process can keep the sleeve in place.

In-Mold Label Application

In-mold labels are applied during the creation of the package itself, fusing the label to the container. In the United States, blow molding is the most popular production process, while injection molding is the dominant technology in Europe.

During the container manufacturing process, a label is held in place in the mold by vacuum or electrostatic forces. Hot resin is injected or blown into the mold, forming the container while fusing the label into its wall. In blow-molding applications, the label contains a heat-activated adhesive. In the injection-molding process, no adhesive is necessary. In both cases, the label is integrated into the wall of the container.

The high cost of molds has been a barrier to the wider adoption of in-mold labeling. However, many companies appreciate the opportunity to decorate packages during the manufacturing process, eliminating the time, labor, and equipment needed for a separate labeling step. The look and performance of in-mold labels also has tremendous appeal.

LABEL PRINTING

The main printing processes in use for label production are flexography, letterpress, gravure, lithography, silkscreen, and, to a lesser extent, hot-foil stamping. This applies for most types of labels whether printed flat or from a reel (see Decorating; Printing).

Although the principles of each process remain the same for reel- or sheet-fed printing, the selection of the particular process and the cost factors in that decision are different for each particular section of the label industry. For example, printing of sheet labels is done primarily by lithography or gravure; but letterpress and flexography are major processes for the production of reel-fed self-adhesive labels.

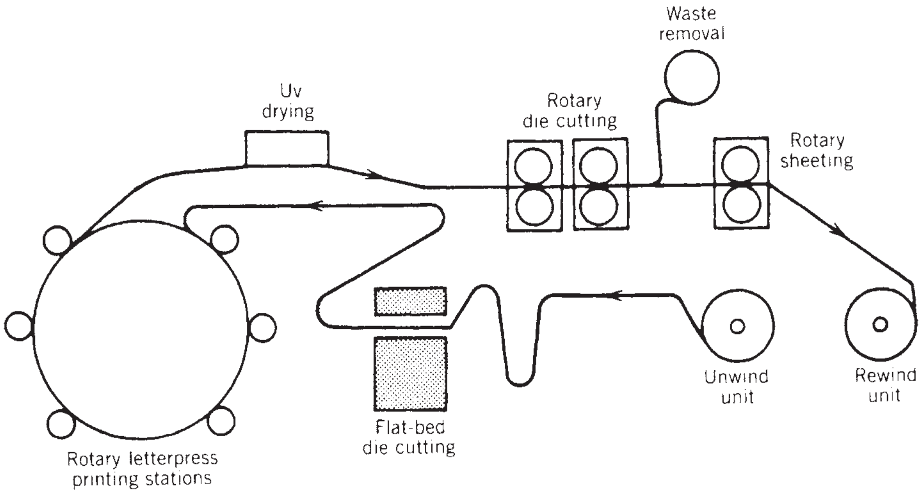

Figure 4. Rotary letterpress roll label press.

The fastest-growing technique of label printing is the narrow-web roll label conversion of self-adhesive materials using presses that may be printing and converting webs as narrow as 2 in. (50 mm), ranging up to 250, 300, or 400 mm wide (9). These presses not only print substrates up to 6, 8, 10, or more colors in one press pass but also undertake flat-bed or rotary die cutting of the labels and possibly UV varnishing, over-laminating with clear synthetic films, removing matrix waste, slitting, fan-folding, sprocket-hole punching, and so on, and, finally, rewinding of the printed reel of labels ready for automatic application (10). A schematic diagram of a typical roll label printing and converting press is shown in Figure 4.

PRINTING METHODS

Flexography

The main advantage of flexography, the most widely used process for reel-fed label printing, is its output speed, which is due to full rotary printing and machine die cutting. In addition, spirit-based inks evaporate quickly, allowing printing on a wide variety of substrates other than paper (see Inks).

Owing to speed of output, flexo labels generally cost less than labels printed by the other major processes. Because presses can be purchased at a relatively low capital cost, many of the smaller label printers use the process. The presses do, however, vary enormously in complexity. Equally important, the quality of the labels produced depends greatly on the skill of the operator.

Letterpress

Although letterpress has declined in usage in the general printing industry, it is a major process in the label industry and gaining in popularity. It is the second most popular process in the roll label industry after flexography, and in some countries it is almost the only process used.

The process has adapted well to the needs of the label industry, giving good-quality reproduction and relatively low-cost origination. Presses are available in flat (platen) form, semirotary, or full-rotary letterpress (9).

The main advantage of letterpress is superior quality and ability to hold accurate print definition throughout the run. Solid- and fine-line printing are no problem, because the inks are fully pigmented with excellent lightfastness and color matching. Printing plates can be metal or photopolymer.

The development of UV-cured inks has meant that previously difficult or even impossible to print substances such as vinyls and polyesters can now be "cured" using polymer inks and UV lamps.

Gravure

The gravure process gives excellent quality and print definition. With a very fast throughput it is best suited to long runs where the high cost of originating printing cylinders can be recovered.

Silkscreen

The unique method of applying ink through a screen gives screen process an ink coverage that cannot be completely matched by any other printing method (9). It will also print on virtually any substrate.

The presses are made as complete screen printing units, or a series of screen printing heads can be added to suitable letterpress machines, giving a combination of benefits.

Hot-Foil Stamping

Hot-foil stamping is generally done in one of two ways: by complete hot-foil presses in their own right and by hot-foil units set in-line onto an existing label press. The process gives striking effects when combined with other processes and is very much a designer's medium (9).

LABELING

Once a label has been produced, it must be applied in the correct position to a particular surface or product. The label must be applied securely enough for it to remain fixed in that position throughout the useful life of the product or container. It must stand up to whatever conditions it is likely to be exposed to and should also maintain a good appearance. In the case of returnable bottles, however, the label must be able to be removed easily during the washing operation.

The labeling operation must also be able to meet production requirements. On packaging lines, the labeling machine must be able to keep pace with the line, often at high speeds, having minimum stoppages and downtime (11).

Some labels are applied to products or containers with a simple handheld gun or dispenser; others are applied by a semiautomatic or fully automatic labeling machine suited to the particular type of label: wet-glue, pressure-sensitive, or heat-seal (heat-sensitive).

Wet-Glue Labeling Machinery

Wet-glue labeling is the least expensive labeling system in terms of label costs. There are many machines on the market from the simple semiautomatic to the high-speed advanced models for speeds of up to 600 containers per minute. Straight line or rotary, vacuum transfer of the label or transfer by picker plate, and allover gumming or strip gumming all have a place and are used in many industries, particularly in food, wine, and spirits plants.

New types of adhesives make glue labeling important for plastic containers as well as glass. Hot-melt adhesive can be used. Large labels are probably cheaper to apply with wet glue than with a heat-seal or pressure-sensitive system, and wet-glue labels are probably superior for applying multiple labels to a range of containers, such as liquor bottles.

Labels may be applied by hand or by semiautomatic or automatic machines (see Figure 5). There are many different types of wet-glue labeling machines, but they all have to perform the following functions:

1. Feed labels one at a time from a magazine.
2. Coat the labels with adhesive.
3. Feed the glued labels on to the articles to be labeled in the correct position.
4. Ensure that the articles are held in the correct position to be labeled.
5. Apply pressure to smooth the label on to the article and press it into good contact.
6. Remove the article when it has been labeled.

If any of these operations are not performed at the right times, with everything positioned accurately, the results will be unlabeled articles, badly positioned, skewed, or torn labels, and machine stoppages. Machines vary mainly in the way they perform the various functions. For example, some machines may use suction to remove labels from the magazine, and others use the tack of the adhesive itself (11).

The adhesives used for wet labeling fall into five main classes: dextrin-based, casein-based, starch-based, synthetic-resin dispersions, and hot melts.

Apart from the hot melts, all these adhesives are waterborne. The speed at which they set depends, therefore, on the rate at which the water phase can be removed by the absorbency of the label stock. If the water cannot get away, they will not set.

Synthetic resin dispersions, of which the most widely used are those based on poly(vinyl acetate) (PVA), have the major advantage of faster setting, owing to the ability of the polymer particles to draw together to form a continuous film for the loss of much less water than is the case with those adhesives based on natural materials. They are used particularly in the labeling of plastic bottles or coated glass, where normal dextrin, casein, and starch adhesives have difficulty in producing a permanent bond. They are limited to nonreturnable bottles, however, as the dried film has considerable resistance to water and cleaning fluids. One advantage is a low initial tack, which restricts their application to certain types of machines with sufficient brushing-on capacity.

Hot melts are 100% solids, melting when heated and setting almost instantaneously on cooling. They have high initial tack, thus labels adhere to surfaces such as PVC and polyethylene (PE) at high speeds, but are not suitable for wet bottles. To select the correct adhesive for a particular application, every factor of the operation must be taken into account: the operating conditions, type, and condition of the articles to be labeled, nature of the label papers, transport and storage conditions, and any particular usage requirements (12).

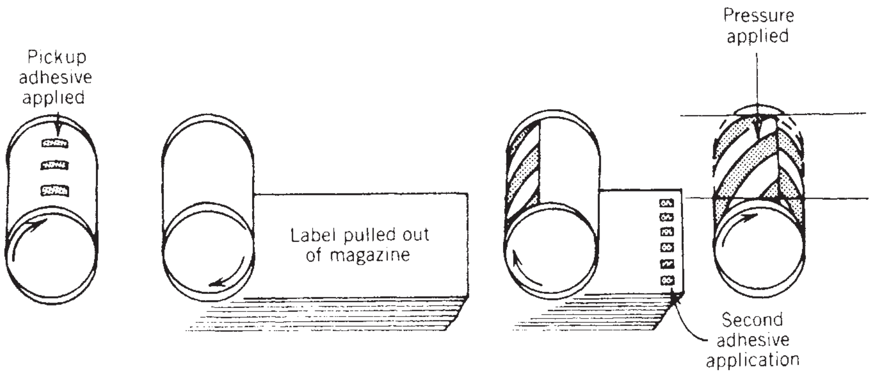

Figure 5. Stages in the labeling of cans. Adhesive is first applied to the container. As the container rotates over the label magazine it picks up its own label, which is then rolled around it. A second adhesive application to the trailing edge of the labels, followed by pressure, completes the labeling operation.

Pressure-Sensitive Labeling Machines

A pressure-sensitive adhesive is one that remains permanently and aggressively tacky in the dry form and has the ability to bond instantaneously to a wide variety of materials solely by the application of light pressure. No water, solvent, or heat is needed to activate these materials.

Because the adhesive is permanently tacky, it would stick to anything it contacted, so a backing sheet is required to protect the adhesive layer until it contacts the article to be labeled. The backing sheet is coated with a release coating to prevent the label from sticking too firmly to it (13).

There are many different types of applicators, but they all have one thing in common: a means of peeling the labels away from the backing (see Figure 6). This is usually accomplished by unwinding a reel of die-cut labels and then pulling them under tension around a stripper plate. As the backing is bent around a sharp angle, the front edge of the label peels away. Once the labels have been detached from the backing, there are various ways of feeding them forward and pressing them onto the containers in the correct position. Containers may be fed forward to an applicator drum where the label is transferred to it under light pressure created by an applicator drum and pressure pad. Alternatively, the label may be held in position on a vacuum box or drum and released onto the article when it is in the correct position, or it may be blown onto the container by releasing the vacuum and applying air pressure. The backing paper is then rewound on a take-up spool (12).

Comparatively simple systems have been devised to apply the label to the product. The choice ranges from a dispenser that releases a label for hand application up to high-speed automatic labelers. Labeling machines for applying pressure-sensitive labels vary in complexity according to the nature of the package to be labeled, the number of labels to be applied at one time, and the speed of application. There are, of course, semiautomatic labelers for single-product medium-volume application. Although pressure-sensitive labelers are available as standard machines, they are usually readily customized to meet special requirements. Generally, they are only about one-third to one-half the cost of most competitive labeling systems.

The advantages of pressure-sensitive labels are said to be numerous. They are cleaner than other methods, less wasteful than wet glue, and more easily controlled because they come in roll form so that labels cannot be mixed up. A wide variety of adhesives for different surfaces is available, and clear acetate, vinyl, or polyester film can be used for “see-through” labels.

Heat-Seal Labeling Machines

Heat-seal labeling has most of the advantages of pressure-sensitive labels but generally offers a lower label cost. Heat-seal describes a plasticized paper which, when heated by the machine, becomes sticky on its underside. Labeling equipment for heat-seal ranges from simple aids to automatic high-speed machines, giving the unique advantage of being able to apply to many varied types of surface labels that can be precision-placed, give allover adhesion, and be perfectly clean when applied.

The machines free the user from mixing and adding glue, selecting grades, controlling viscosity, and so on. The absence of glue eliminates cleaning the machine, and these savings give substantial increases in productivity and reductions in maintenance expenses. The labels offer a high degree of adhesion security that is useful, for example, for bottles subjected to high humidity, or steam of water saturation (14).

Of the two types of heat-seal paper, the delayed-action type is best suited for machine operation. The ability of the adhesive to remain tacky after removal of the heat source allows the machine designer to separate the heat source from the pressure application of the label. Thus the heating plates can be simple whereas the pressure-applying devices can be of complex shapes, enabling a diverse range of articles to be labeled, varying from flat to round or irregular shapes (10).

LABEL OVERPRINTING MACHINERY

For certain label applications there is a requirement to have a plain paper or preprinted label or labels

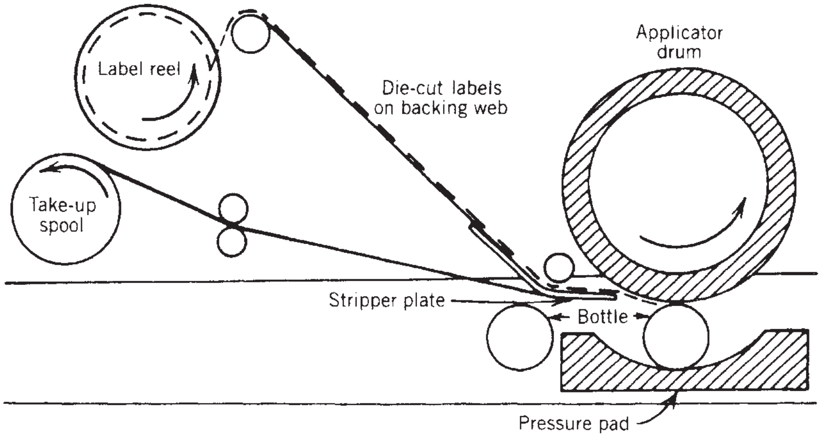

Figure 6. A common type of self-adhesive label applicator.

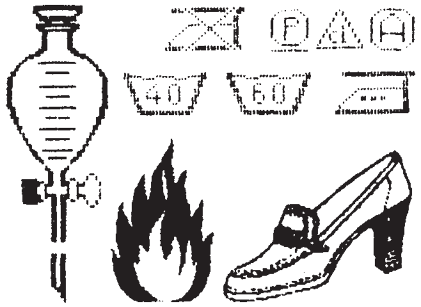

Figure 7. Electronically produced graphics are available on electronic label overprinters.

overprinted with price, price/weight, bar code, or other variable information just prior to or at the point of application. A variety of mechanical, electronic, or computer-based overprinting systems are available for such operations. These are now widely used by department stores, the retail and wholesale trade, industry, and even some label producers.

Mechanical overprinting systems range from small hand-operated machines with one or two wheelsets and two type channels, to hand-operated and electronic versions used for price/description labeling with either conventional or EDP-readable fonts (10).

The current trend in overprinting is away from mechanical to totally electronic overprinters, which can now print labels and tags without any form of marginal or sprocket-hole punching. Free formating and graphics, as well as alphanumeric information and bar codes, are now possible using such overprinting technology, the graphics being keyboard entered and edited. Graphics suitable for reproduction include product outlines, such as shoes, laboratory equipment, small hardware items, safety hazard designs, and laundry symbols. Figure 7 shows examples of such electronically produced and overprinted graphics.

LAWS AND REGULATIONS, UNITED STATES

Ralph A. Simmons
Keller and Heckman
Washington, DC

There is no single body of law or regulations pertaining to all aspects of the manufacture, distribution, and use of packaging in the United States. Many different types of federal, state, and even local laws and regulations affect the packaging industry. These laws and regulations can be separated into two broad categories: (a) those that pertain directly to the packaging itself and (b) those that pertain generally to manufacturing and commercial transactions, including packaging among many other products.

This article focuses on the former category of legal requirements pertaining most directly to packaging. These include health and safety regulations of packaging materials, labeling requirements, and environmental laws and regulations relating to the disposal of packaging.

FDA’S REGULATORY FRAMEWORK FOR PACKAGING

The Food and Drug Administration (FDA) has primary regulatory authority in the United States over the safety of packaging used for food, drugs, cosmetics, and medical devices to the extent the products are in interstate commerce (which they almost always are).* The packaging for these products is regulated by the FDA so that it does not

---

*The U.S. Department of Agriculture (USDA) technically has authority over packaging used in federally inspected meat and poultry processing plants. However, in practice, USDA does not independently evaluate the safety of packaging materials, deferring to FDA on this issue.

cause the products themselves to become contaminated or "adulterated" in violation of the Federal Food, Drug and Cosmetic Act.

The most extensive of FDA's packaging regulations are the "food-additive regulations," which provide official permission for the use of substances as food ingredients (direct additives), and as components of food packaging or other food-contact materials (indirect additives). The FDA does not have regulations clearing specific materials for use in packaging for drugs, medical devices, or cosmetics. In the case of drugs and medical devices, packaging materials are reviewed and approved by the FDA in the context of approving the drug and medical-device products themselves, if such approval is necessary. The FDA does have a general requirement for tamper-resistant packaging for over-the-counter (OTC) drugs. Suppliers of packaging materials to drug and medical-device manufacturers typically assist those manufacturers in obtaining FDA approval by providing information on the packaging to the FDA through a confidential drug or device master file. Neither cosmetic products nor their packaging are subject to premarket clearance by the FDA; it is up to the cosmetics manufacturer and its packaging suppliers to ensure that the products and packaging are safe for their intended use.

Definition of Food Additive. The FDA's regulation of food packaging is based on Section 201(s) of the Federal Food, Drug and Cosmetic Act. Section 201(s) of the Act defines a food additive, in relevant part, as follows:

> [A]ny substance the intended use of which results or may reasonably be expected to result, directly or indirectly, in its becoming a component … of any food … if such substance is not generally recognized … to be safe under the conditions of its intended use; except that such term does not include …
>
> (4) any substance used in accordance with a sanction or approval granted prior to the enactment of this paragraph pursuant to this Act (4)

Section 409 of the Act requires that a food additive, as defined above, must be the subject of an applicable food-additive regulation.[†] Thus, substances used in food-contact applications that, under their intended conditions of use, may reasonably be expected to become components of food are "food additives" and can be used only in accordance with an applicable food-additive regulation unless they are either (a) the subject of a prior sanction or approval granted by FDA or the U.S. Department of Agriculture (USDA) prior to the enactment of the Food Additives Amendment of 1958 or (b) generally recognized as safe (GRAS). If the substance is not reasonably expected to become a component of food under the intended conditions of use, however, it is not a food additive within the meaning of Section 201(s) of the Act, and may be used as intended without the need for consultation with or prior action by the FDA

The Food-Additive Regulations. The FDA's food-additive regulations, found in Title 21, Parts 170–197 of the Code of Federal Regulations (CFR), cover both direct and indirect additives. The term "direct food additive" commonly refers to materials directly and intentionally added to foods to perform a functional effect in the food. The term "indirect food additive" generally refers to substances that are not intended to, but nevertheless become, components of food as a result of use in articles that contact food (e.g., substances used in packaging materials).

Over the years, indirect food-additive regulations have been promulgated in response to individual food-additive petitions with no overall structural scheme. This has led to the existence of three general types of indirect food-additive regulations: those that clear specific polymers (e.g., Section 177.1520, applicable to polyolefins), those that clear substances categorized by function (e.g., Section 178.3400, applicable to emulsifiers and surface-active agents), and those that list substances that may be used in specific types of packaging (e.g., Section 176.170, applicable to components of paper and paperboard). For this reason, a great deal of overlap among different regulations has occurred.

A major limitation on the types of substances that may be listed in the food-additive regulations is the so-called Delaney Clause of the Federal Food, Drug and Cosmetic Act. The Delaney Clause prohibits the FDA from issuing regulations permitting the use as food additives of substances that are "found to induce cancer when ingested by man or animals" (1).

The FDA has mitigated the impact of the Delaney Clause, however, by interpreting it to apply to the finished food ingredient or food-contact material itself, not to constituents or components of the food additive (e.g., the Delaney Clause applies to polymers used to make food packaging but not to monomers used to make the polymers). This "constituents policy" is not set forth in any law or regulations but is applied by the FDA in evaluating food additive petitions, was described by FDA in an Advance Notice of Proposed Rulemaking, and has been upheld by the courts (2).

Prior-Sanction Exemption. The Federal Food, Drug and Cosmetic Act specifically exempts from the definition of a food additive any substance that is "prior-sanctioned," which means any substance permitted for its intended use by an FDA or USDA letter or memorandum written prior to the Food Additives Amendment of 1958. Unfortunately, no authoritative master list exists for the materials covered (3).[‡] If a company has any such letters in its files or knows of any relevant ones elsewhere, they can be relied on, but the FDA interprets such letters narrowly.

"Generally Recognized as Safe" Exemption. Another exemption from the food additive definition pertains to

---

[†] Food that contains an uncleared food additive is considered "adulterated" and would be subject to adverse FDA regulatory action.

[‡] The *Food Chemical News Guide*, commonly known in industry as the "Knife and Fork" book, contains listings of both direct and indirect food additives and their status under the Food and Drug Regulations; the "Knife and Fork" book also documents public "prior sanctioned" status of substances. The *Guide* is regularly updated.

GRAS substances. Section 174.5(d)(1) of the *Food Additive Regulations* states that substances generally recognized as safe "among experts qualified by scientific training and experience to evaluate their safety" are permitted to be used as components of articles that contact food. Parts 182, 184, and 186 of the *Food Additive Regulations* provide a listing of some substances that are considered by the FDA to be GRAS, but the substances actually listed in the regulations by no means constitute all substances that are GRAS.[§] Section 182.1 of the *Food Additive Regulations* makes it clear that the GRAS listings are by way of illustration and do not represent an all-inclusive list. Furthermore, the absence of a substance from the list does not preclude a company from making a self-determination that its products are GRAS, where such a determination is supported by the available information.

The FDA has codified requirements for the classification of food additives as GRAS under 21 *CFR* 170.30(a). As stated in that provision, general recognition of safety must be based on (a) scientific procedures or (b) in the case of a substance used in food prior to January 1, 1958, through experience based on common use in food. The general recognition of safety requires a "common knowledge" about the substance throughout the scientific community about the safety of substances directly or indirectly added to food. For substances not widely used in food prior to 1958, general recognition of safety requires the same quantity and quality of scientific evidence as is required to obtain approval of a food additive regulation for the ingredient. Unlike a food-additive petition, however, general recognition of safety is ordinarily based on published studies that may be corroborated by unpublished studies and other data and information (4).

The exclusion of GRAS substances from the definition of the term "food additive" means that such substances do not require premarket clearance by the FDA. Any manufacturer who determines that a particular substance is GRAS is free to market the substance without notification to, or approval by the FDA. Obviously, if the FDA should consider the manufacturer's determination of GRAS status to be erroneous, then the Agency can take appropriate regulatory action; in such a case, the burden of proof would fall on the FDA to demonstrate that the substance is not GRAS. This is an unlikely consequence unless a real public-health problem is presented.

A manufacturer who pursues a self-determined GRAS position for a substance can also file a GRAS Affirmation Petition (GRASP) with the FDA seeking the Agency's concurrence. In contrast to a Food Additive Petition, if a GRASP is accepted by the FDA for filing, then the petitioner may market the product while the petition undergoes technical review because FDA has been informed of the manufacturer's determination that the product is GRAS and has raised no objection. However, unlike a Food Additive Petition, all materials submitted in support of the GRASP become immediately available in full to the public, and even manufacturing details cannot be kept confidential. The requirements and type of information a petitioner must supply for a GRASP are spelled out in 21 *CFR* § 170.35.

The "No-Migration" Exemption. One of the most important means of establishing satisfactory FDA status for an indirect additive is to establish a rational basis on which to conclude that there is no reasonable expectation of the substance becoming a component of food. If a substance is not reasonably expected to become a component of food under its intended conditions of use, it is not a food additive by definition and, therefore, may be so used without obtaining any FDA "approval." Unfortunately, the FDA has not provided definitive, objective criteria for determining when a substance in a food-packaging material may reasonably be expected to become a component of food. Nevertheless, reliable guidance is available from at least two different sources:

1. *Ramsey Proposal*. The first source of guidance is a proposal circulated by the FDA as its response to widespread criticisms by the food-packaging industry at the National Conference for Indirect Additives held in Washington, DC in February 1968. This so-called Ramsey proposal would have acknowledged in a regulation the propriety of the use, without the prior promulgation of a food-additive regulation, of substances that will transfer from packaging or other food-contact articles to food at levels no higher than 50 parts per billion (ppb); components of articles used in contact with dry, nonfatty foods; and components of articles intended for repeated use in contact with bulk quantities of food. This would have applied to all substances except those known to pose some special toxicological concern, such as a heavy metal, which is a known carcinogen, or something that produces toxic reactions at levels of 40 parts per million (ppm) or less in the diet of humans or animals. Although never formally adopted, the standards in the Ramsey proposal were deemed scientifically acceptable and have been generally honored by the FDA either explicitly or by its having taken no enforcement action in cases where the criteria are met.
2. *Monsanto v Kennedy*. The second source of clarification of the "food additive" statutory definition is provided by a U.S. Court of Appeals decision. In *Monsanto v Kennedy*, 613 F.2d 947 (D.C. Cir. 1979) the FDA argued that any contact of a packaging material with food must result in some transfer of the packaging constituent to the contained food. The Court rejected this argument and stated:

    > Congress did not intend that the component requirement of "food additive" would be satisfied by … a mere finding of any contact whatever with food…. For the component element of the definition to be satisfied, Congress must have intended the Commissioner to determine with a fair degree of confidence that a substance migrates to food in more than insignificant amounts (5).

Role of Extraction Studies. On the basis of the Ramsey proposal and the *Monsanto* precedent, it is widely

---

[§] Idem. The "Knife and Fork" book also documents filings and status of petitions to FDA for listing of substances as GRAS in the regulations.

accepted that if extraction testing properly simulating the intended conditions of use for a potential additive does not yield detectable migration of the additive or its components at an appropriate analytical sensitivity, then the substance is not reasonably expected to become a component of food under these conditions and, thus, is not a food additive within the meaning of Section 201(s) of the Act. The industry generally considers a finding of "nondetected" in a properly conducted migration study using methods sensitive to the equivalent of 50 ppb of the substance in contacted food to be a sound basis for concluding that a substance is not a food additive. However, in some cases, it is necessary to make use of analytical methodology that can detect as little as 10 ppb or even 1 ppb to support a "no-migration" determination because of the sensitive nature of the material being used, such as a heavy metal or a substance for which there will be a high level of use, such as milk or soda containers.

General Adulteration Provision. If the packaging material is not reasonably expected to become a component of food and is, therefore, not a food additive, it is still subject to the nonadulteration provision of the Act. The FDA sometimes refers to this as the general safety clause, contained in Section 402 of the Act. This general prohibition against adulteration is the basis for the FDA's "good manufacturing practice" regulation, which requires that "[a]ny substance used as a component of articles that contact food shall be of a purity suitable for its intended use" (6). Fortunately, the same analysis that demonstrates that a material will not become a component of food will also satisfy the Act's general safety requirements for food-packaging material, specifically, that the packaging will not adulterate the food by rendering it injurious to health.

The "Basic Resin Doctrine" Exemption. A significant characteristic of the *Food Additive Regulations* is that the FDA clears substances on a generic rather than a proprietary basis. In the case of resins and polymers, as long as the basic resin is listed in a regulation, is manufactured in accordance with good manufacturing practices, and complies with applicable limitations such as stated extraction requirements, it is covered by that regulation even though different manufacturers may make the resin by different processes and employ different catalysts, reaction control agents, and the like.

A "basic polymer" is the material that comes out of the polymerization "kettle" or reactor, that is, the product that results when the polymerization process has been carried to commercial completion. Substances such as catalyst residues, chain-transfer agents, minor comonomers, and other materials required to produce the basic resin are considered a part of it and are *not* subject to independent regulatory consideration. The FDA's basis for this principle is that, where a substance is used only in a small quantity and either becomes part of the resin during polymerization, or is washed from the resin at the conclusion of polymerization, its potential for significant migration is minimal. In other words, there is no reasonable expectation of migration, and therefore the substance is not considered an independent food additive.

The basic polymer doctrine also reflects the practical reality that the FDA cannot write generic regulations for food-packaging materials that describe and specifically clear every substance that might properly be a trace component or contaminant of the packaging material as a result of every manufacturing process that yields a suitable resin. Because trace quantities of these "unregulated substances" are not perceived to present a public-health hazard, the FDA has wisely chosen not to subject these substances to the burdensome preclearance provisions of Section 409 of the Act that apply to food additives.

Generally speaking, it is reasonable to consider catalysts and minor comonomers to be covered by the basic polymer doctrine when used at levels of up to approximately 0.5%; between this level and 1%, the substance and use in question must be evaluated on a case-by-case basis. At levels above 1%, the basic polymer doctrine is not considered applicable.

Even if a component of a food-contact material falls within the basic-polymer doctrine, the finished food-contact material must still satisfy the necessary purity requirements of the *Food Additive Regulations;* that is, it must be of a purity suitable for its intended use, as required under 21 *CFR* § 174.5(a)(2). Obviously, if a particular catalyst being used were to render a finished food-contact material unsafe or unfit for its use, that material would not satisfy the purity requirements.

The Housewares Exemption. The components of eating utensils, receptacles, paper towels, or other kitchenware, sold as such, are outside the scope of coverage of the Food Additive Amendments of 1958, and therefore these products do not require premarket clearance by the FDA. This has come to be called the "housewares" exemption. This exemption is grounded on a declaration of intent in the legislative history of the 1958 Food Additives Amendment. The following statement appears in the official record of the debate on the Amendment and was made by the floor manager of the bill, The Honorable John Bell Williams, Chairman of the House Subcommittee on Health and Science:

> I have been asked since the Committee report of the bill what is meant by a substance "holding" food, as mentioned in the bill. An example of what is meant by this would be a plastic film or paper wrapper which surrounds the package of food. This bill is not intended, for example, to give the Food and Drug Administration the authority to regulate the use of components of dinnerware or ordinary eating utensils (7).

The FDA has written many letters affirming this exclusion. The exclusion of housewares from the need for filing foodadditive petitions is a recognition that such products generally do not give rise to any public-health concern. However, the FDA does take action against products falling within the housewares exemption in instances involving migration of a substance, such as lead, which has been proven to pose a true public health concern.

Threshold of Regulation. The exemptions from the FDA's premarket clearance authority discussed so far all have one important characteristic in common—a company is entitled to determine for itself whether the exemptions apply and whether no consultation with or concurrence by the FDA is required. The FDA recently has adopted an additional exemption that only the Agency itself may apply, which is called the Threshold of Regulation.

In 1995, the FDA published the final rule establishing the Threshold of Regulation, which is the FDA's "process for determining when the likelihood or extent of migration to food of a substance used in a food-contact article is so trivial as not to require regulation of the substance as a food additive" (8). The "threshold" level is defined as a dietary concentration of 0.5 ppb or less. The threshold for substances that have been cleared by the FDA as direct additives is that the indirect or packaging use must be limited to 1% or less of the acceptable daily intake established by the Agency for the direct use of the substance. To be eligible for the exemption, the food-contact material must not be a carcinogen and must not contain carcinogenic impurities that are more potent than a certain level defined in the regulation (the impurity cannot have a TD_{50} value of <6.25 mg/kg bw (body weight) per day, with TD_{50} defined as the feeding dose that causes cancer in 50% of the test animals.

The FDA has reserved to itself the authority to grant official exemptions from regulation under the Threshold of Regulation Rule. However, in proposing the Rule, the FDA explicitly recognized the continuing right of a company to determine on its own "that a particular use of a substance does not meet the definition of a food additive" (9). Therefore, companies continue to be entitled to determine for themselves whether the "no migration" exemption or any of the other exemptions from the definition of "food additive" apply to a particular intended use of a food-packaging material.

The Food-Additive Petition Process. If none of the exemptions from the FDA's premarket food-additive regulatory authority is available for a packaging material, then regulatory clearance must be obtained from the FDA through a food-additive petition. Section 409(b) of the Federal Food, Drug and Cosmetic Act permits any person to petition the FDA for a regulation prescribing the conditions under which an additive may be safely used. The Act delineates generally the type of information to be submitted in support of a petition and the procedures and substantive parameters to be followed by the FDA in considering a petition. Additional detail on these information requirements and procedures is provided in Part 171 of the *Food Additive Regulations*.

Reduced to its fundamentals, a food-additive petition must describe the substance to be cleared, provide an estimate of the quantity that will enter the diet, and demonstrate that this quantity will be safe. The Act requires the FDA to act on a petition within 90 days, with one extension for an additional 90 days available to the Agency. In practice, few petitions are acted on in 18 months or less, and most are under review for at least 2–3 years.

In 1995, several industry groups representing food manufacturers and their packaging suppliers revived their efforts to reform the legal system for food-additive regulation by the FDA. The basic goals of this effort are to replace the Delaney Clause with a negligible risk standard based on sound science and to require the FDA to accelerate the process of reviewing food-additive petitions. With respect to packaging materials, the proposed reforms would replace the petition process with a premarket notification system. The FDA would have 120 days to review the data on a new packaging material. The material would be permitted for use at the end of the 120-day period unless the FDA objected on the basis of real safety concerns.

FDA Regulation of Recycled Materials for Food Packaging. A specialized area commanding much attention in the early 1990s has related to the recycling of postconsumer waste materials, which includes their use in some cases to make food packaging. There is no legal requirement to obtain any special or new FDA "approval" for the use of recycled material in food packaging. The FDA has no special regulations governing recycled materials, with the exception of a regulation on recycled paper that merely restates the universal FDA requirement that all food-contact materials must be suitably pure for their intended use (10). The Agency generally regulates food-contact materials on the basis of their composition, not on the specific process by which they are manufactured or the source of the raw materials. Any food-contact material (whether plastic, glass, metal, or paper and whether virgin or recycled) must meet the safety requirements of the Act and the specifications and limitations of any food-additive regulations applicable to the generic type of material (11).

Although no FDA approval is required for recycled content in food packaging, the requirements of food companies for assurance that recycled materials are safe has resulted in a common industry practice of seeking an official blessing from the FDA, particularly with respect to recycled plastics. These blessings take the form of so-called no-objection letters from the FDA. The Agency generally applies the "Threshold of Regulation" analysis to requests for these letters, requiring a showing that any potential contaminants in the recycled material have been reduced to the "threshold" dietary concentration of 0.5 ppb or below.

ENVIRONMENTAL LAWS AND REGULATIONS

The Federal Role: Environmental Protection Agency (EPA). The EPA, which is the primary federal agency responsible for regulating waste disposal, has broad authority over the management of solid waste under the Resource Conservation and Recovery Act (RCRA) (12),[¶] as well as the Clean Air Act (13), the Clean Water Act (14), and the Comprehensive

---

[¶] Under the complex RCRA statute, Congress has divided waste management into two discrete universes: hazardous waste, which is regulated under subtitle C of the statute (42 *USC* 6901), and all other waste, which is regulated under subtitle D. Most packaging waste is subject to subtitle D, which governs MSW. During the past decade, most of EPA's resources have been directed toward toughening standards for land disposal of subtitle C hazardous waste to make them commensurate with pollution controls already in place for air emissions and water discharges under the Clean Air Act and Clean Water Act.

Environmental Response, Compensation and Liability Act (15) (commonly referred to as "Superfund"). This authority includes the power to set standards for the design and operation of landfills and incinerators and other modes of waste disposal.

In general, EPA's modus operandi for dealing with solidwaste management issues, particularly issues concerning packaging, has been to make recommendations, such as on preferred options for waste disposal, but to leave much of the actual regulation of waste to state and local officials.[‖] At this time, the EPA has no specific rules governing the disposal of postconsumer packaging waste.

State Regulation. A few states have adopted bans or other limitations on packaging that does not meet certain standards of "environmental acceptability." The criteria of environmental acceptability in these proposals are typically that the packaging be recycled at a specified rate, be reusable, or be made from recycled materials.

California enacted a law in October 1991 that purported to ban, as of January 1, 1995, rigid plastic containers that (a) are not composed of 25% postconsumer material; (b) do not have a recycling rate of 25% (55% in the case of PET containers, if measured separately); (c) are not source-reduced by 10%; or (d) are not reusable or refillable five times (16).

The statute contains significant waiver and exemption provisions. The state will waive the postconsumer material content requirement if it finds that (a) the containers cannot meet the content requirement and remain in compliance with FDA regulations or other state or federal laws or regulations or (b) the use of containers meeting the content requirement is "technologically infeasible." The statute also exempts containers for food, cosmetics, drugs, medical devices, medical food, or infant formula.

Oregon has a statute nearly identical to California's (17). The Oregon law has a permanent exemption for food packaging, except for beverage containers.

Wisconsin has a law purportedly requiring 10% recycled content in plastic containers (18). However, this law will go into effect for FDA-regulated products only if the FDA has "approved" the use of recycled content through a "formal" procedure. So far, FDA's "no-objection letter" approach to permitting recycled materials has not been recognized by Wisconsin as a "formal" procedure. Wisconsin also has banned recyclable packaging from landfills and incinerators (19), but has been granting a series of 1-year waivers for certain plastic packaging that is not widely collected for recycling.

Nine states have deposit laws that place a surcharge on certain beverage containers, and provide a refund of the surcharge to consumers who return the containers for recycling.[**] California has its own modified form of deposit law, known as AB (Assembly Bill) 2020, under which, in addition to collection and refund of deposits, industry may be assessed fees on the basis of costs of recycling.

CONTROL OF ALLEGED TOXIC SUBSTANCES IN PACKAGING

State Restrictions on the Heavy-Metal Content of Packaging. Eighteen states[††] have enacted statutes restricting lead, cadmium, mercury, and hexavalent chromium in inks, dyes, pigments, adhesives, stabilizers, and other components of packaging. These laws are based on model legislation developed by the Coalition of Northeastern Governors (CONEG).

California's Proposition 65. Perhaps the most far-reaching state environmental law directly affecting packaging and other consumer products is California's Safe Drinking Water and Toxic Enforcement Act,[‡‡] which is popularly known as "Proposition 65." Proposition 65, approved by California voters as an initiative in 1986, is a right-to-know law that requires companies to either establish that their products are not likely to expose any individual to a "significant" amount of any of over 400 chemicals, or to provide a "clear and reasonable" warning that the product contains a known carcinogen or reproductive toxin. To avoid the warning requirement, a manufacturer must establish that exposure to a chemical listed under Proposition 65 from a particular package or other product presents "no significant risk." The state has established "no significant risk levels" for some, but by no means all, of the substances listed under Proposition 65.

LABELING

For most packaging, the requirements pertaining to labeling will depend on the nature of the product contained within the package. Many products require only that the labeling not be false or deceptive. This standard is enforced on a nationwide basis by the Federal Trade Commission (FTC)[§§] and by appropriate authorities in each state, enforcing the so-called "Little FTC Acts."

[‖] EPA advocates, but does not mandate, an integrated waste management approach based, in order of preference, on (a) source reduction, (b) recycling and composting, (c) incineration, and (d) land disposal (EPA, 1989).

[**] The nine states with deposite laws are Connecticut, Delaware, Iowa, Maine, Massachusetts, Michigan, New York, Oregon, and Vermont.

[††] The 18 states that have adopted versions of the CONEG heavy-metals restrictions are Connecticut, Florida, Georgia, Illinois, Iowa, Maine, Maryland, Minnesota, Missouri, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, Vermont, Virginia, Washington, and Wisconsin.

[‡‡] California Health & Safety Code § 25249.5-.13.

[§§] The FTC regulates false, deceptive, or misleading advertising pursuant to authority granted the Agency under section 5 of the Federal Trade Commission Act [15 *USC* § 45(a) (1)], which prohibits unfair or deceptive acts and practices affecting interstate commerce. The Commission has interpreted the act as essentially requiring companies to be able to substantiate the truthfulness of both express claims and any inferences a reasonable consumer is likely to draw from the express claim.

Certain products, however, are subject to special labeling laws and regulations, frequently for health or safety reasons.

FDA Regulation. The FDA regulates the labeling on packaging for foods, drugs, cosmetics, and medical devices. The Federal Food, Drug, and Cosmetic Act prohibits the "misbranding" of FDA-regulated products. A product is "misbranded" if its labeling is "false or misleading," or if it violates other specific statutory or regulatory requirements.

The FDA has issued separate regulations pertaining to the labeling of foods, drugs, cosmetics, and medical devices. The food labeling regulations are the most extensive of the group and now include a requirement for nutrition labeling on most food packages.[¶¶]

Packaging and Labeling of Hazardous Materials. The U.S. Department of Transportation (DOT) regulates the packaging and labeling of hazardous materials for interstate shipment (and has proposed extending its regulations to intrastate shipments as well). The authorized types of packaging and the required labeling vary according to the degree of hazard presented by a particular material (21).

ENVIRONMENTAL ADVERTISING AND LABELING

Federal and State Guidelines. Labeling and advertising claims about the environmental attributes of packaging or products are not subject to special laws or regulations at the federal level or in most states. The permissibility of particular claims generally is tested according to the "false or deceptive" standard of the Federal Trade Commission Act and similar state laws.

Both federal and state authorities have issued guidelines for applying the "false or deceptive" standard to environmental labeling and advertising. In July 1992, the FTC released its *Guidelines for Environmental Marketing Claims*. The *Guidelines* address eight categories of claims: general claims such as "environmentally friendly," degradable claims, compostable claims, recyclable claims, recycled content claims, source-reduction claims, refillable claims, and ozone-safe/ozone-friendly claims. The FTC is currently reviewing its *Guidelines* to determine whether they should be modified to be more effective. The *Guidelines* do not have the force of law but are considered authoritative statements of the way in which the FTC will exercise its enforcement authority. A task force of the state attorneys general also issued guidelines in 1991, known as the *Green Report II*, addressing the same types of claims covered by the FTC *Guidelines*, but taking a more restrictive approach. In the absence of formal regulations issued by the FTC, states can enforce stricter limitations on environmental claims than would the FTC.

State Regulation. A few states have actually adopted laws or regulations limiting environmental claims for products and packaging. Two states, California and Indiana, enacted laws governing environmental advertising, including use of such terms as "recycled" and "recyclable" (22). California's law was challenged in court as an infringement on commercial free speech (23). Although most of the law was left intact when the United States Supreme Court declined to hear the case, California subsequently repealed the essential provisions of the law. Indiana's law as enacted was similar to California's, but the state now defers to the FTC's *Guidelines*.

Some states, such as New York and New Hampshire, specifically restrict use of the terms "recycled" and "recyclable" (24). Both New York and New Hampshire restrict the use of the term "recycled" to products containing a certain minimum percentage of postconsumer material. They also require significant levels of recycling for a package or product to be labeled "recyclable."

LEAK TESTING

George W. Arndt, Jr.
Schreiber Foods Inc., Green Bay, Wisconsin

INTRODUCTION

The function of a package is to protect products from changes brought about by the outside environment. Prior to the development of packaging, food-borne diseases caused by pathogenic microorganisms were one of the most serious problems faced by humans. Microorganisms excrete enzymes that break down materials releasing nutrients that they can absorb. Packaging made from synthetic materials are generally resistant to microbial enzymes and thus can serve as a barrier preventing the attach of microbes. During prolonged dry periods, many microorganisms survive inactively as spores. Bacteria, yeast, and mold require water to feed, grow, and reproduce, so packages need to be maintained in a clean and dry condition. Packages are inspected before they are filled for evidence of water stains, foreign materials, and contamination. Then packages may be washed or blown with compressed air to remove dust-containing spores. Thermal processing and chemical preservatives kill vegetative microorganisms and many, but not all, spores. During filling and closure, care must be exercised to assure minimal contamination of package seals that would create defects. Package defects form a pathway for microbial penetration and infection. The quality control aspects of packaging by processors focus upon sanitation and closure integrity (see also Testing, Permeation and Leakage). There are many ways to assess the microbial barrier of packages. Since package styles, closures, and materials differ widely, there is no universal test method. It is necessary to evaluate various methods to determine one that is reliable under the conditions of use.

DESCRIPTIONS OF TEST METHODS FOR PACKAGE INTEGRITY

Below are brief descriptions of some methods for package integrity testing. For detailed descriptions, see the *Bacteriological Analytical Manual*, 7th edition, published by the FDA.

1. Air-leak testing involves pressure decay or measurement of airflow rates.
2. Biotesting uses solutions with concentrations greater than one million nonpathogenic microorganisms per milliliter. Individual packages are immersed and pressure, vacuum, or mechanical flexing is applied to distort the package. Alternatively, packages contained within a chamber may be sprayed with an aerosol mist containing microorganisms.
3. Burst testing may be used as a dynamic test where the maximum force required to explode a package is used as an index of seal strength, or as a static test where packages are held at a fixed pressure to determine if the package will maintain pressure for a specific period of time.
4. Chemical etching separates or dissolves overlaying materials to expose the sealant layer of packages. This is useful for visual examination of contaminated seals of plastic and paperboard packages.
5. Compression testing is a burst test using pressure applied to the outside of a package. Weak packages will crush or burst, while stronger packages should not.
6. Distribution testing is a simulation of forces that are likely to be incurred by packages during storage and distribution. Tests include vibration, drop testing, and compression in a laboratory having controlled temperature and humidity. Simulated abuse testing is useful for side-by-side comparison of two or more package designs in order to determine if one package design is more fragile than another. Simulation testing is preferred over shipping tests because there are fewer variables and results from simulated distribution testing are generally reproducible.
7. Dye testing is used to determine if holes in packages are present or not present. Water-soluble dyes should be used with plastics or paperboard packages, and solvent-based penetrating dyes should be used with glass or metal packages.
8. Electesting is a nondestructive method for liquid foods that change viscosity as they spoil. A shock wave is created by shaking the package. The amplitude and wavelength of the shock wave is a characteristic of the viscosity of liquids. When the device detects a signal response outside the normal range, the package is rejected. Other tests may be used to examine rejected packages for leaks.
9. The electrolytic test uses electricity to determine whether holes are present in plastic films, coatings, and seals. The detector is an open circuit that uses electrolyte or metal components of the package to conduct electricity. Holes are indicated when the circuit closes activating alarms. Liquid products containing at least 1% salt, or a solution containing 1% table salt (NaCl) in tap water, may be used to conduct electricity through very small holes in packages having plastic layers. Breaks in the

coatings of metal cans may be located using this method. Porous coatings and breaks in coatings expose metal to the product, and these are the locations where corrosion can occur.

10. Gas leaks may be detected by mass spectrophotometer or a gas chromatograph. Helium is a useful tracer gas, because it moves readily through small holes in packages. Sulfur hexafluoride is inert like helium and may be used to detect, locate, and measure small holes in packages in a nondestructive manner.
11. Incubation is a test that encourages the growth of microorganisms that are present within packages. Packages that swell as a result of microbial fermentation of the product may be identified by visual inspection. The test can be performed on large numbers of packages while they are held in a warm warehouse.
12. Light may be used to spot holes in packages. Visible light is used to backlight packages and reveal small holes. Polarized light can reveal areas within transparent plastic heat seals that are not fused or have different amorphous or crystaline compositions. X-rays are used to detect foreign materials such as stones and glass shards within sealed packages. Lasers are used to measure very small differences in package dimensions that indicate a leak has allowed packages to change shape. Laser shearography may be used to measure the effect of stress on packaging materials.
13. Machine vision may be used to measure critical dimensions of packages traveling rapidly along conveyors. Strobe lights stop the action as the video image is digitized. The picture is compared to images stored in computer memory. Parallel networks enable rapid comparison of images to standards. Nonconforming packages are sidelined for inspection by technicians using other tests for integrity.
14. Eddy-current meters sense the position of metal in packages. Concave ends indicate retained vacuum. Flat ends indicate packages have lost vacuum. The profile of container ends is consistent when the package, product, and filling conditions are rigorously controlled. Proximity sensors may also be used to measure the position of metal components of packages when a force is applied. Those packages that respond differently under stress may be identified by this method.
15. Seam scopes are large-format low-power microscopes. Mechanical or electronic measuring devices may be used to measure critical dimensions. Specialized devices are designed for viewing cross sections of metal can double seams. The dimensions of very small holes may be measured using a seam scope as a microscope.
16. Sound is a novel nondestructive testing method. Rigid packages with internal vacuum may have ends tight, like a drum. Tapping on a can end reveals a difference in sound between a normal can and one that has lost vacuum. Electromagnets may be used to pull up can ends, which then snap back. A transducer can register the sound for analysis. Ultrasonics and laser acoustics may be used to measure pressure within packages without contact. Ultrasonic microscopy may be used to evaluate defects between layers and stress patterns in metals, and plastics.
17. Tensile testing is a term applied to laboratory methods that stress packages or materials by pulling to create tension. Plastic ends and metal pull tabs on packages may be peel-tested. Composite materials may be delaminated and the strength of adhesion and cohesion measured. Glue bonds may be evaluated using tensile tests. Pieces of metal or film may be pull-tested to determine elasticity, stretching, and break strength.
18. Vacuum may be used to test packages in many ways. Packages dipped in soapy water to coat the surface before being placed within a vacuum jar will exhibit bubbles revealing the location and approximate size of a leak. If the vacuum chamber is filled with water and the package held below the surface, a steady stream of bubbles in the water may reveal the location of the leak on the package. Vacuum decay within a closed vessel is a useful method for measuring small leaks over a period of time.
19. Visual inspection is the most common method of package inspection. Holes as small as 100 μm may be seen with unaided normal vision under ideal lighting conditions. Unfortunately, inspectors quickly fatigue and the best visual inspection is only 85% effective.

SELECTING THE RIGHT TEST METHOD

Some test methods are specific to materials and others are specific to the design of the package closure. No single test method will work for all applications.

First, begin by collecting as many different package defects as possible and group them according to their public health significance. A three-class system for package defects is used in the United States:

1. Critical defect
   a. Loss of the microbial barrier
   b. Evidence of microbial growth within package holes, fractures, punctures, swelling and leakage
2. Major defect
   a. Might leak, but has not yet leaked
   b. Testing is needed to determine whether packages will leak
   c. Weak seals, deformed double seams, deep scratches, cracks, creases

Table 1. Recommended Test Methods for Food Packages[a]

Package descriptions

1. Paperboard packages
2. Flexible pouches
3. Plastic packages with heat-sealed lid
4. Plastic cans with double-seamed metal end
5. Metal cans
6. Glass bottles and jars

Test Method	1	2	3	4	5	6
1. Air-leak testing	O	O	O	O	O	O
2. Biotesting	O	O	O	O	O	O
3. Burst testing	O	X	X	O	NA	NA
4. Chemical etching	O	O	O	NA	NA	NA
5. Compression, squeeze testing	X	X	O	O	NA	NA
6. Distribution (abuse) testing	O	O	O	O	O	O
7. Dye penetration	X	O	X	O	X	X
8. Electesting	O	NA	NA	O	O	O
9. Electrolytic	X	X	O	NA	NA	NA
10. Gas-leak detection	O	O	O	O	O	O
11. Incubation	X	X	X	X	X	X
12. Light	NA	O	O	O	O	O
13. Machine vision	O	O	O	O	O	O
14. Proximity tester	O	O	O	X	X	X
15. Seam scope projection	NA	NA	NA	X	X	X
16. Sound	X	NA	X	X	X	X
17. Tensile (peel) test	NA	X	X	O	O	O
18. Vacuum testing	NA	O	X	O	X	X
19. Visual inspection	X	X	X	X	X	X

[a] X, recommended method; O, optional method; NA, not appropriate method.

3. Minor defect
   a. Do not leak
   b. Are of economic, not public health, concern
   c. Flex cracks, dents, abrasions, convolutions

Classification of defects has been completed for packages that contain food products that may support the growth of *Clostridium botulinum*, the bacteria causing botulism. Sources of information are listed in the bibliography at the end of this article.

Second, make a drawing of the package for each type of defect. Mark the drawings to show the location of the defects. This graphic summary will reveal where defects occur most frequently on the package. Photos of representative defective packages will also be useful.

Third, select the test method most likely to reveal the defect at the point on the package where it occurs. Methods that test the entire package are preferred to methods that test only a portion of the package. With most test methods for package integrity, the design of fixtures to hold packages during testing is important. Dynamic test methods apply stress to packages, and changes may be measured over a range. Static tests apply pressure at a fixed level, and measurement is made after the package has been under this condition for a specified period of time. Evaluation of packages is needed to determine when a static or a dynamic method provides better results.

Fourth, follow the path taken by packages starting at the point of manufacture, through filling, processing, warehouse, and distribution, all the way to the consumer. Draw this pathway as a flow chart and identify where defects are first detected. The cause is often just upstream

Table 2. Nondestructive On-line Testing Methods for Packages

Method	Nondestructive	Application
1. Air-leak testing	Yes	Empty rigid and flexible containers and sealed packages
2. Biotesting	No	Recommended only for testing new package designs
3. Burst testing	No	Heat seals of flexible and semirigid packages
4. Chemical etching	No	Only a laboratory method for samples
5. Compression testing	Yes	Sealed flexible packages
6. Distribution simulation	Yes	Simulates all modes of distribution and suitable for all types of packages
7. Dye testing	No	A laboratory test useful for locating leaks
8. Electester	Yes	Useful for detecting liquids that separate when spoiled within sealed containers
9. Electrolytic	Yes	A laboratory test useful for locating leaks in films and coatings
10. Gas-leak detection	Yes	Useful for locating leaks through seals and packaging materials
11. Incubation	No	Most useful following simulated abuse and biotesting
12. Light	Yes	Empty formed packages may be examined at high speed
13. Machine vision	Yes	Many commercial devices
14. Proximity tester	Yes	Useful for measuring deflection of metal jar lids, and films containing metal foils drawn down by vacuum on semirigid packages
15. Seam scope	No	Useful for visually observing the overlap between double-seams and the distribution of sealing compound
16. Sound	Yes	Many commercial devices
17. Tensile testing	No	A laboratory method
18. Vacuum testing	Yes	Both empty and sealed packages
19. Visual inspection	Yes	Most common method

from this point. Go to that location and observe for the occurrence of defects on the packages. Proceed upstream until defects are no longer detected. Search for actions that contact the package at the point where defects commonly appear.

Fifth, determine what physical action might form each defect. This is easier to visualize if you are able to locate the source of the defects and observe their formation during production or handling. There may be more than one cause for the same defect, and some defects may be nothing more than different stages of the same defect. Use normal packages to try to reproduce the defects to verify the possible causes of damage. Often testing in a packaging laboratory can help to verify damage mechanisms. Refer to Table 1 to select the appropriate test method for your package defect.

Sixth, conduct validation testing of the method to determine the threshold sensitivity for small holes. Some test methods may be used online in a nondestructive manner.

NONDESTRUCTIVE TESTING METHODS

Most package testing methods may be automated for laboratory testing or for use in manufacturing. The ideal testing method will be nondestructive and fast enough to be performed on the production line. Online nondestructive testing provides the opportunity to individually test packages for hermetic integrity. Table 2 lists some current applications and limitations of on-line nondestructive test methods for packages.

Many of the online nondestructive testing methods available today use sensors that do not contact the package. Examples include light leak detectors, pressure-differential sensors, proximity detectors, and sound and machine vision systems. The ability to perform nondestructive testing to packages using other methods that contact packages is limited by the design of fixturing capable of coupling the package to the sensor at production line speeds

Consumer product companies are facing new challenges in the packaging arena today. The packaging they use must be attractive, keep the product fresh and usable, and provide for the safety of users by being tamper resistant, childproof, or unbreakable. Now, packaging must also be environmentally friendly. Although it is more difficult to claim environmental friendliness than it used to be, the environmental effect of packaging materials is a primary area of concern for many companies. *Life-cycle assessment* (LCA) is a tool that can be used to address this concern by evaluating the potential environmental effects of packaging options. LCA can show companies whether a packaging change is likely to cause more or less environmental burdens than what is in current use.

LCA DEFINED

Life-cycle assessment is the quantitative determination of the resource and energy use as well as the environmental burdens of a given product or process over its entire life cycle. It is often called a “cradle to grave” analysis, because it takes into account the resource and energy use, and the environmental burdens of a given product or package system from the cradle (raw-material acquisition) to the grave (final disposal by the consumer). Life-cycle assessments are generally comparative in nature. Typically, there is a comparison of one or more products or packages that provide the same functional use. The benefit that LCAs provide is that they look beyond the resource and environmental burdens of the immediate production and disposal of the product or package being studied. This is done by including the indirect effects caused by the production processes leading up to the final product or packages. Some of these indirect effects are the mining of raw materials, the energy and emissions resulting from transportation, and the energy and emissions associated with the production of electricity. These added “indirect” effects often result in substantial added environmental burdens of a product.

The first life-cycle study was done on packaging (in 1970), and packaging has been the focus of a high percentage of the LCAs that have been conducted since then. The use of LCAs in this industry has continued to increase over the past 5 years, even as broader uses of LCA are growing in importance. Typically, LCA is viewed as an environmental management tool. More specifically, it has been used as a green design tool, especially in the packaging industry. “Green design” is defined as a product or package design that is compatible with environmental goals.

PACKAGING CHOICES: CHOOSING OPTIMAL SIZE BASED ON ENVIRONMENTAL EVALUATION

For example, a beverage bottler may want to determine what bottle size produces the least environmental burdens for delivery of an equivalent amount of beverage to their customer. The choices in this example are 1-, 2-, or 3-L polyethylene terephthalate (PET) bottles. Each bottle requires the manufacture of a cap, a thin PET bottle wall and bottom, and a thicker bottle neck. The manufacture of the bottle neck and cap requires substantially more resources than the manufacture of the thin PET bottle wall and bottom. All three bottles use the same sized cap. A logical review of these choices may lead one to believe that the 3-L bottle would be the optimum choice. This would seem to be an obvious conclusion because the delivery of 6L of beverage requires six 1-L bottles, three 2-L bottles, or two 3-L bottles and the manufacture of their associated caps and necks (putting them on an equivalent basis). Thus, one would assume that the 3-L bottle would deliver the desired quantity of the beverage with relatively smaller environmental burdens. As expected, the 2-L bottle uses less energy and produces less emissions to the air, water, and land than does the 1-L because of the reduced number of bottle tops manufactured. However, this same logic does not hold for the 3-L bottle. As an LCA would indicate, the 3-L bottle, because it holds larger quantities of liquid, requires a greater rigidity and wall thickness than do the 1- and 2-L sizes. This extra requirement is enough to make the environmental burdens of the 3-L bottle equivalent to that of the 2-L bottle (1). This is illustrated in Figure 1, 2, which show the energy and solid-waste totals generated by a computer model for the delivery of an equivalent quantity of soft drink. Figure 1 shows the total energy usage for the three soft-drink container sizes. The graph illustrates the extra energy necessary for the 1-L bottle and shows that this same advantage between the 2- and 3-L bottles does not exist. This same relationship holds for solid-waste totals, which are illustrated in Figure 2.

So, in actuality, the optimal beverage delivery size is either the 2- or 3-L sizes, and not the 3-L, as logic would indicate. This is not to say that the 1-L bottle is without merit; in fact, all three sizes are strong in the marketplace. For example, the 1-L (or smaller) container is an individual serving size. As this example shows, the value of an LCA is that it takes into account the products entire life cycle, and it provides a comparison with the other packaging options. Often, this cradle-to-grave comparison provides results that are contrary to common opinion.

USES OF LCA

Although LCA is now a tool for green design, its uses have continued to extend into other applications. The areas of LCA usage can be broken down into the following four basic categories: (a) environmental management, (b) ecolabeling, (c) regulatory purposes, and (d) information and education (2–4). The first category is using LCAs as an environmental management tool for internal use within an industry and/or company. Some of these uses include product design (more specifically green design), assistance in meeting ISO 14000 guidelines, and cost effectiveness. The second category of LCA uses also has economic implications, and that is for ecolabeling. Typically, ecolabeling may be used to sway public opinion regarding a product or give environment sanction to a product based on some stated criteria. The label can sway public opinion to increase market share. Ecolabeling based on LCA principles is a very active concept in Europe. However, the ecolabeling approach is fraught with complexities that are not resolved. In the United States, LCA is not viewed widely as a public policy tool for

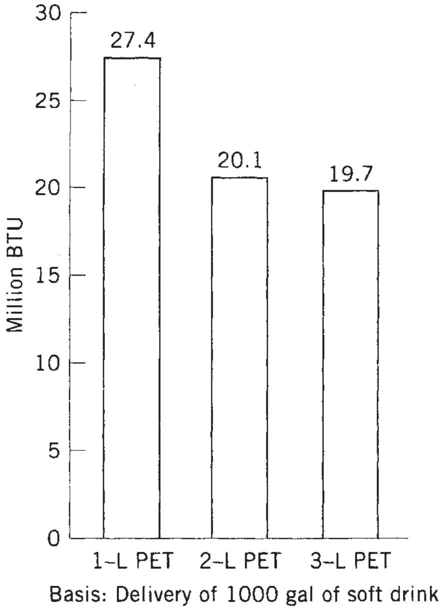

Figure 1. Energy requirement for PET soft-drink containers.

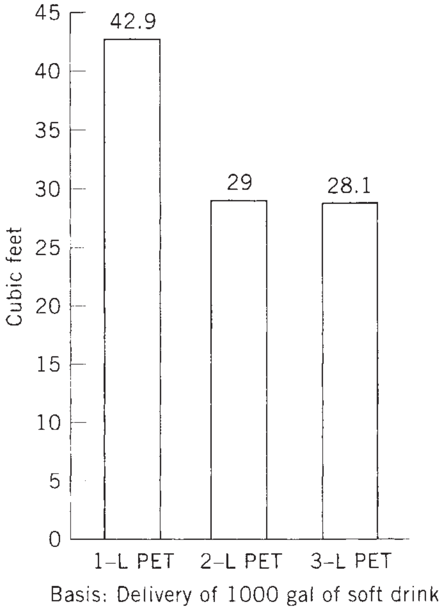

Figure 2. Solid waste for PET soft-drink containers.

labeling or for environmentally preferable products or packages. Nonetheless, this type of initiative is a proposal under public review.

The third category of LCA uses is providing information for regulatory purposes. Both the U.S. Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA) are requiring more environmental information when applying for product approval. For example, applications to the FDA for approval of new packaging that will be in contact with food now require information on the environmental consequences of the new packaging. This information must include a comparison of the new packaging with the packaging it will replace or compete with. This additional information is typically outlined well by an LCA.

The final category of LCA uses is also for information and education. This includes providing information that will be used internally to educate the members of an industry of the extent and complexity of a products production. This same information can be used externally to educate the public or regulatory agencies about an identified product. All of these uses show that LCA utility extends beyond the world of environmental applications. As its utility continues to expand, knowledge of LCA becomes more and more important for those involved in the packaging industry.

LCA COMPONENTS

The LCA can be broken down into four major components: goal definition and scoping, life-cycle inventory (LCI), impact assessment (now defined as inventory interpretation), and improvement assessment (2, 3). To this date, most life-cycle studies have included life-cycle inventories and some improvement assessment. There has been limited success in completing impact assessments because of the lack of quality data and a consistent, accepted methodology.

Goal Definition and Scoping. "Goal definition and scoping" is the task of identifying the purpose and basis of the study. The purpose of the study should be a clear and unambiguous statement of why the study is being pursued. This statement helps to define the system and the processes within the system that need to be analyzed. The "system" under study is defined in the same manner as it is defined in classic thermodynamics.

Thermodynamics breaks a process down into two components: the system and the surrounding environment. The surrounding environment acts as a source of all inputs and a "sink" for all outputs. The description of the system is a description of all flows that go across the system's boundaries. For example, the surroundings provide the raw materials for the system that enters across the boundaries. Conversely, all air, water, and solid-waste emissions along with the desired product cross the boundaries into the surroundings. This is illustrated in Figure 3. Thus, an LCA takes into account all materials and energy that cross or are held within the system.

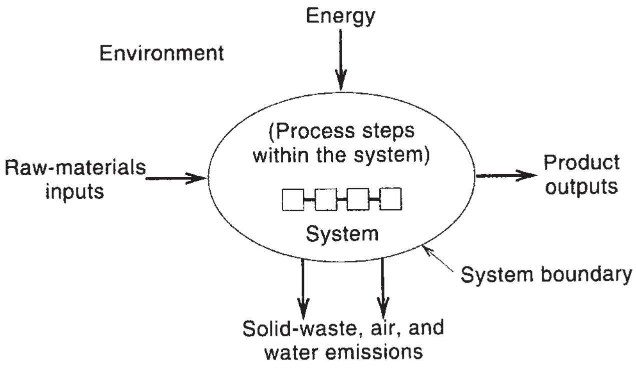

Figure 3. Definition of system in LCA.

The boundaries for an LCA include the acquisition of raw materials, manufacture of intermediate materials and final product, use of product, and final disposition of the product. Also included in the boundaries are any use, reuse, or recycling that occurs; the energy and emissions for each processing step; the energy and emissions to transport from one step to the next; and any energy and emissions necessary to process energy sources into usable fuels. The energy and emissions from extracting the fuels that are consumed often contribute significantly to the LCA results. Therefore, the fuel extraction steps, which include spills and losses, should be included with the data for fuel combustion. In fact, relatively simple flow diagrams such as Figure 3 turn into a complex network of processes when an actual product or package is evaluated. Also, whether the product or package is reusable can be an important consideration. A good example is a reusable glass or ceramic cup. Each reuse requires the washing of the cup with hot water and detergent. Over the lifetime of a cup, it may be washed hundreds of times or it may break and thus have a short life. The burdens from the generation of the hot water and detergent for the reuse of the cup could outweigh the burdens from the generation of the cup from raw materials. In other words, the reuse cycle may create unanticipated burdens compared with a single-use item such as a paper or plastic cup.

One of the most important parts of defining the scope and boundaries of a study is the definition of the functional unit. This identifies the unit of product that is going to be studied and compared. Some examples are the unit surface area covered by paint, the packaging used to deliver a given volume of beverage, or the amount of detergent used for a standard household wash (2). So with these boundary definitions, the product under study is examined from cradle (raw-material acquisition) to grave (final disposition of the product).

Life-Cycle Inventory. The boundaries and scope provide direction into completion of LCA. The LCI is the next stage of the LCA and is the most frequently used and best developed stage. The LCI is often used separately from the other components of the LCA, because the inventory portion of the LCA is more clearly defined. This clearer definition is because the methodology of LCI is based on scientific principles. LCI is essentially based on the law of conservation of mass, the conservation of energy, and thermodynamic definitions of systems. Using these scientific principles, the basis of LCIs can be developed and applied consistently with each LCI regardless of the product analyzed. The LCI consists of seven unique steps: (a) definition of scope and boundaries, (b) identification of unit operations, (c) development of systems and network diagrams, (d) data gathering, (e) creation of a computer model, (f) analysis and reporting of study results, and (g) the interpretation of results leading to specific conclusions.

The definition of scope and boundaries is directed by the scope and boundaries identified by the full LCA. If the LCI is used separately from an LCA, then the scope and boundaries for the LCI need to be defined in a similar manner as was described for the full LCA.

Once the functional unit and the system to be studied are identified, the system must be broken down into individual unit operations from the beginning to the end of the life cycle. This process serves as a blueprint for the process of gathering data (5). For example, to make ethylene from petroleum, each step in the life cycle, from the drilling of crude oil and natural gas, to producing ethylene, needs to be broken down into discrete steps. For each of these discrete steps, a system boundary must be identified, with all the inputs and outputs that cross the boundaries identified as well. For the preceding example, the process of making ethylene would include the inputs of natural gas and/or naphtha as raw materials and energy resources (6). Outputs would include ethylene, propylene, and butenes (coproducts), air, water, and solid-waste emissions to the environment. This process as part of the whole life cycle is shown in Figure 4. Once the inputs and outputs for each individual process are identified in this manner, the entire process is linked according to the functional unit defined in the scope of the study. The difficulty lies in obtaining the data for each individual step within the life cycle.

Data gathering is a resource-consuming process, but its importance cannot be overemphasized. The entire LCI/LCA is dependent on the quality of the data gathered. Each unit operation should have a complete breakdown of all inputs and outputs, both material and energy. With the advent of computer technology, the quantity of data used and the accuracy and complexity of LCIs that can be undertaken have increased tremendously. With the use of spreadsheets or computer programs, the air, water, and solid-waste emissions, as well as the energy usage for each individual unit operation, can be totaled with respect to the functional unit selected in the scoping of the project. The computer model can then be modified to determine how changes in the functional unit, or the process conditions, will affect the overall results. For example, the delivery of peanuts could have two packaging alternatives: a glass jar or a composite aluminum and plastic bag. Once the two packaging alternatives are put on an equivalent basis, an LCA can identify the environmental burdens and resource consumption for each packaging alternative. From the LCA comparisons of the two packages, a choice can be made as to which of the two alternatives produces the least potential environmental burden.

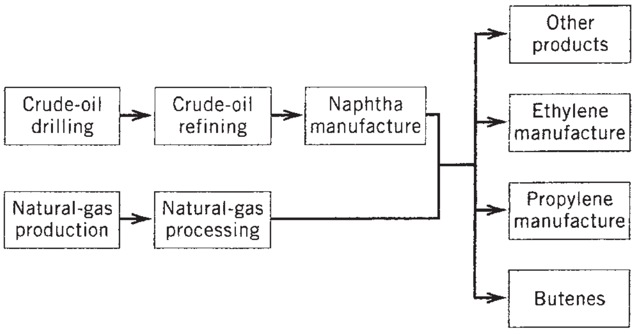

Figure 4. Steps in the production of ethylene.

Various LCI software packages are available to companies that do not wish to collect data or develop their own computer models. One such software package is REPAQ (trademark), which was developed specifically for screening packaging options. With the availability of LCI software such as REPAQ, the packaging engineer can now determine how modifications in packaging systems (shape, size, weight, and composition) can change the overall outcome of the LCI results (7). Figures 5–7 illustrate a partial output from REPAQ. The figures illustrate the comparative solid waste, atmospheric emissions, and energy usage of the jar and the bag from the example above. A typical computer output will consist of a comparative listing of 20–30 atmospheric emissions, 20–30 waterborne emissions, and a breakdown of solid waste and energy. The advantage of computer modeling that is the size, weight, and compositions of the two options can be modified, or secondary packaging can be added or removed, and the graphic summary will give immediate feedback on how the LCI results would change. With this type of information, a packaging system that helps meet environmental goals can be designed quickly.

IMPACT ASSESSMENT (INVENTORY ASSESSMENT)

The life-cycle inventory provides a great deal of information about the energy use and emissions associated with the life cycle of a given product. This information, however, cannot be generally applied to the product's effect on human health, ecological quality, and natural resource depletion. This is simply because one pound of a given emission may provide substantially different effects on human health or the environment than a pound of a different emission. Impact-assessment methodology helps to categorize the LCI information into sets of common impact measures, such as increased mortality, habitat destruction, or global warming, which allow the interpretation of the total environmental effects of the system being evaluated (8).

According to the definition of impact assessment put forth by SETAC and the U.S. EPA, the impact assessment can be broken down into three steps: classification, characterization, and valuation (2, 3, 9). *Classification* is the process of assigning the initial aggregation of LCI data

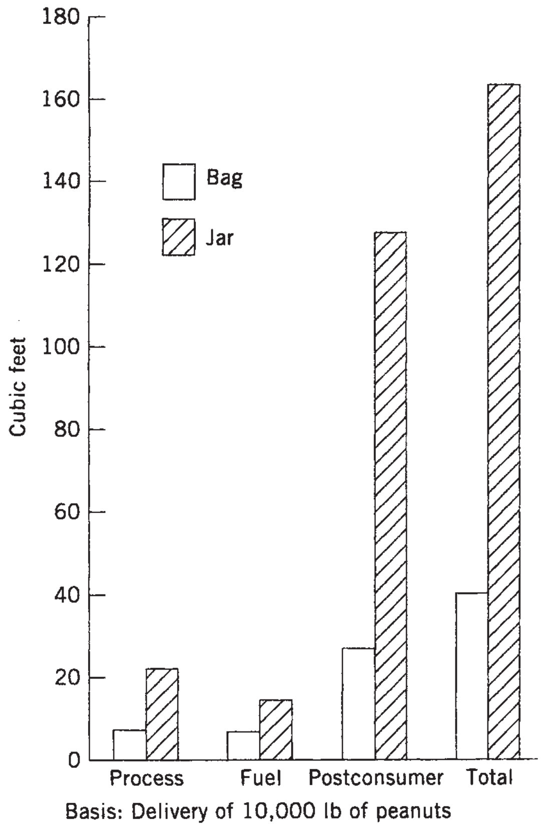

Figure 5. REPAQ comparison of solid waste.

into relatively homogenous impact groups. There are four general impact categories: environmental or ecosystem quality, quality of human life (including health), natural resource use, and social welfare. These categories are then broken down into even more specific impact groups. Two examples of these groups are global warming and ozone depletion. Each emission outlined in the inventory is placed into one or more of these impact groups. The selection of impact groups is somewhat related to what emissions are being released by the systems under consideration. The selection process is twofold, with the analyst first asking: “What environmental problems could these emissions potentially cause?” The second question the analyst asks is: “What environmental impacts are important or of interest to the audience of the study?” Answering both questions results in a comprehensive list of impact groups to evaluate.

Once the inventory emissions are classified into impact groups, the process of characterization begins. *Characterization* is the selection of the actual or surrogate characteristics to describe impacts. For example, acid equivalents could be used to characterize emissions classified as having acid-rain potential. This provides an assessment of the relative magnitude of the given impact on the more general categories such as human health. The difficulty in the characterization process comes with the fact that scientific factors have not been developed for all the impact categories, and thus coming up with a common descriptor for each group is subjective at best.

The third and final step of impact assessment is *valuation*, which is the assignment of relative values or weights to different impacts. This step essentially allows for the evaluation of the different emissions across all impact groups. With this composite information, decision makers can then decide the total impacts of a product system. Valuation is extremely subjective and is dependent on the value system of those assigning relative weights to the impact groups.

Beyond the classification step, impact assessment quickly becomes subjective and value laden. The lack of a well-accepted and nonsubjective model for impact assessment limits its applicability to industry. However, development of nonsubjective models, or models that limit subjectivity, is ongoing.

IMPROVEMENT ASSESSMENT

Similar to impact assessment, improvement assessment has not undergone the consensus examination of the methodology that life-cycle inventory has undergone. However, improvement assessment based on life-cycle inventories is common practice. The purpose of the improvement assessment is threefold: (a) it evaluates LCA results for their relevance to the predetermined LCA goals and objectives, and it identifies opportunities for reducing the environmental impacts of a product system; (b) it translates all results and their determined importance to the LCA audience in a clear and concise manner; and (c) it uses

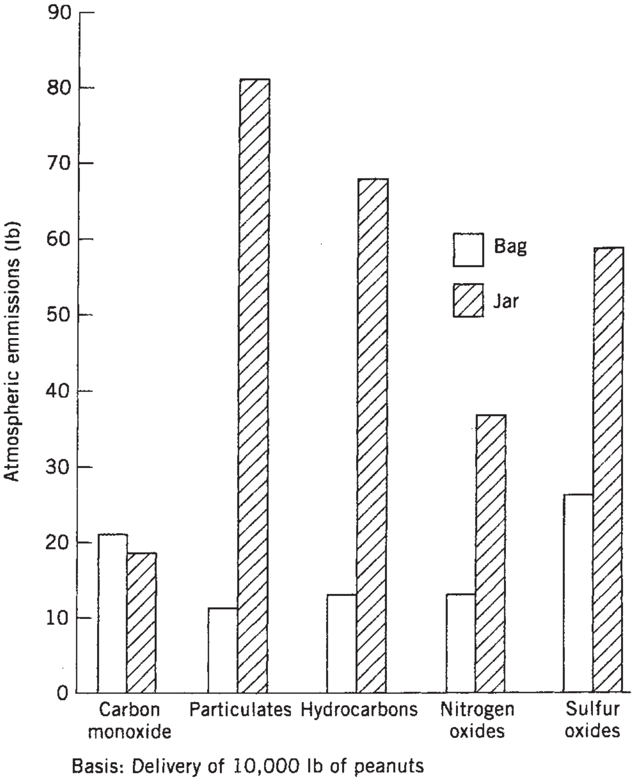

Figure 6. REPAQ comparison of atmospheric emissions.

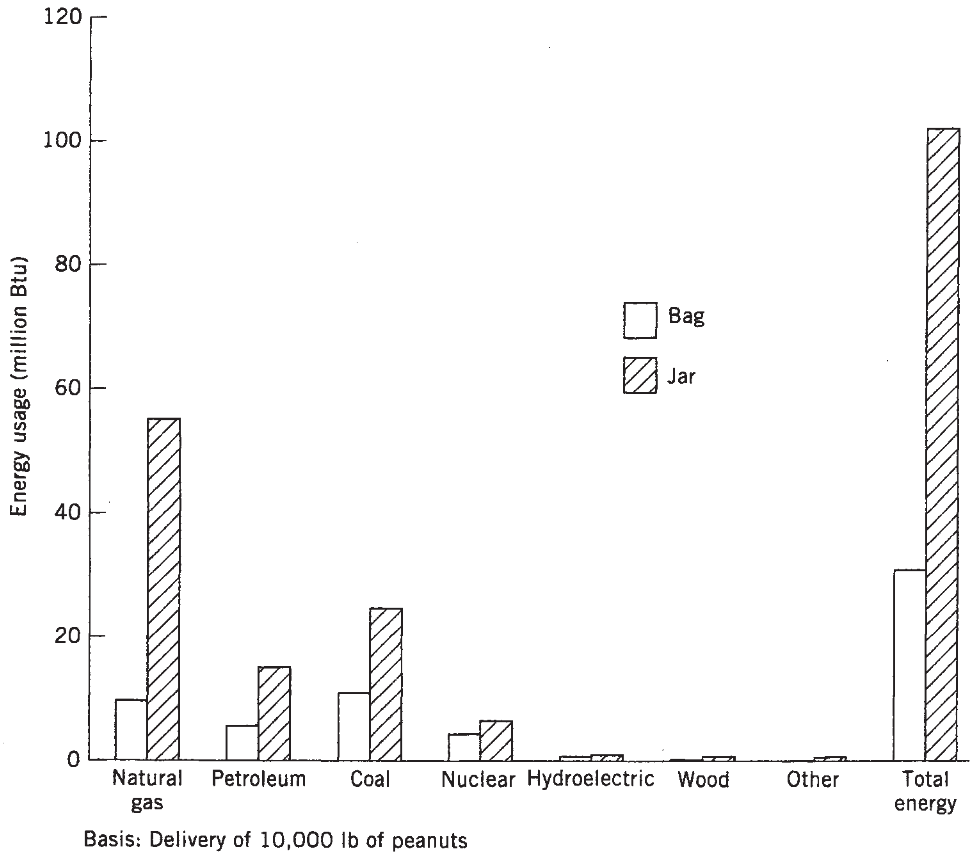

Figure 7. REPAQ comparison of energy usage.

the impact assessment or the LCI as a baseline to determine the effect, if any, of the instituted improvements.

Improvement assessment identifies and evaluates any opportunities for reducing environmental burdens. These opportunities may be uncovered by the inventory portion of the LCA by identifying areas of large energy usage or environmental emissions. The improvement assessment can then identify those areas where increased efficiency or modifications would be appropriate. Figure 8 is a table of some areas for improved efficiency that could be identified in an improvement assessment. The packaging of over-the-counter (OTC) medication is used for this example. The package components are listed in the first column, and possible modifications to the package system are listed in the top row. With this sort of grid, possible improvements can be assessed. For example, could some of the packaging, such as the paperboard box, be eliminated? Instead of packaging the bottle in a box, the bottle could be placed directly on the shelf. Could the packaging makeup be changed by using recycled content, making it lighter, or making it from a different resin? Could the package or the product be redesigned? For example, could the bottle be filled more, or could some filler be removed from the product? Each of these options can be reviewed to see how modification would affect the environmental burdens of the packaging as a whole.

Similarly, the improvement assessment can use information provided by the impact assessment. This information takes the inventory results one step further by identifying not only the quantities of energy used and environmental

emissions but also their potential impacts. The improvement assessment takes the inventory and impact information and condenses it to a few clear and concise conclusions. These conclusions drive the process or product change that will result in reducing the environmental impact of the system being studied. Once these changes are made, the impact and inventory portions of the LCA can be used as a baseline to determine the effects of any improvements made to the system.

LIMITATIONS OF LCA

Beyond the obvious limitations of the lack of consensus for impact and improvement assessments methodologies, LCAs do have limitations. Often LCA results—or, more specifically, LCI results—are extrapolated beyond what is supported by the study. Most studies have specific parameters that describe a given comparison. These parameters can include weight of the product, delivery of a quantity of useful product, time period, and specific location of the comparison. If any of these parameters are changed, then the relative comparison may or may not be accurate. Thus, the study results are limited to the specific study conditions. Second, there has been a desire to use LCAs as public policy instruments to determine whether a specific material or product is "good" or "bad" for the environment. Although LCAs and LCIs provide a foundation of useful information on resource usage, environmental emissions, and potential impacts, they do not quantify all environmental consequences of a product or process. Thus, LCA is an effective tool for evaluating environmental tradeoffs and consequences of specific actions. It is not a tool for measuring the magnitude of environmental "goodness" for specific materials or products. As processes and products change, their LCA profile also changes relative to other alternative processes and products.

Life-cycle assessments have been used by the packaging industry for 25 years to help meet both financial and environmental goals. They provide a strong basis for making design decisions as well as environmental planning. As the applications and knowledge of LCAs continue to grow, the value to the packaging industry will continue to grow as well.

WHAT IS LIGHT?

According to the electromagnetic wave theory, visible light is the small portion of electromagnetic energy with wavelengths between 380 and 770 nm that our eyes are sensitive to. The sensitivity of the human eyes depends very much on the wavelength of the light. Highest sensitivity is found in the green/yellow area peaking at 555 nm. At 400 and 750 nm the sensitivity is about 10,000 times lower than at 555 nm. Ultraviolet (UV) light is the portion of electromagnetic energy with wavelengths between 100 and 400 nm. This short-waved and energy-richer light can be divided into three bands according to their

---

biological effects: UV-C (100–280 nm), UV-B (280–315 nm), and UV-A (315–400 nm). Infrared light is the band between 770 and 1,000,000 nm. It contains the least amount of energy per photon of any other band (1).

Traditionally, light has been measured in lumen (lm) or lux (lm/m^2) by a lux meter. Lumen is the light flux through 1 m^2 of the surface of a globe with a 1-m radius with a light source of 1 candela in the center. One candela is roughly the light from one common candle and has been defined as 1/60 of the light from 1 cm^2 of the surface of a black object at 1773°C (temperature of freezing platinum). The wavelength chosen for definition of candela is 555 nm, the same wavelength to which the human eye is most sensitive (2). This means that the readings from a lux meter are strongly correlated to the sensitivity of the human eye, giving high response to green and yellow light and poor response to blue and red light. This may be very useful for measuring light related to human vision, but not useful for measuring light correlated to food photooxidation. In such cases a spectroradiometer is more relevant. This instrument measures the spectral power distribution of light in W/m^2 for each nanometer wavelength.

SUNLIGHT AND ARTIFICIAL LIGHT

Figure 1 shows the irradiation from the sun, measured on a clear winter day at 59°N, and from two common artificial light sources, a halogen lamp, and a warm-white fluorescent tube. While the sun and the halogen lamp emit energy in the whole visible region of the spectrum (although the energy emission is small in the blue part of the spectrum), the emission from the fluorescent tube is characterized by uncontiguous peaks of energy with a pattern typical for each type of tube. The visible light energy (380–770 nm) emitted from the sun is 16.6 times stronger than the visible light measures 30 cm from the fluorescent tube. The light energy from the halogen lamp is 2.3 times stronger than the fluorescent tube.

According to the Inverse Square Law defining the relationship between the irradiance from a point source and distance, the intensity varies in inverse proportion to the square of the distance (1). If the irradiance is 1.6 W/m^2 at 15 cm, the irradiance will be, for example, 0.4 W/m^2 at 30 cm and 0.04 W/m^2 at 100 cm.

THE EFFECT OF LIGHT ON FOOD

The effect of light on the sensory and nutritional stability of food can be explained by both photolytic oxidation (production of free radicals primarily from lipids during exposure to light) and photosensitized oxidation (3). Photosensitized oxidation begins with the absorption of light by special biomolecules, called photosensitizers, that are able to absorb light to elicit a specific response (4). Examples of photosensitizers in food are chlorophylls, pheophytins, porphyrines, riboflavin, myoglobin, and synthetic colorants (5). As light energy is absorbed, an electron is boosted to a higher energy level and the sensitizer becomes unstable. Only a few picoseconds are required for a chlorophyll molecule to absorb energy and be transformed into a singlet-excited state (3).

In the presence of oxygen, two competing reactions of the excited sensitizer can occur, called Type I and Type II reactions. In Type I reactions the excited sensitizer may react directly with a substrate forming radicals or radical ions, resulting in oxygenated products. In Type II reactions the excited photosensitizer may react with ground-state oxygen to form singlet oxygen that is very reactive, causing a variety of oxidation processes (6).

Important characteristics for photosensitizers are their molar extinction coefficient curves, indicating how much energy the molecule is able to absorb at each wavelength, and their absorption peaks. By comparing the molar extinction curves for riboflavin (vitamin B2), β-carotene, chlorophyll *b*, and octaethylporphyrin (7), it becomes evident that many of these photosensitizers absorb most of their energy up to ~500 nm (blue-blue/green area of the spectrum), indicating the potential harmfulness of this light. Chlorophyll b has, in addition, an absorption peak in the 630-nm region (red light) and the porphyrin has some

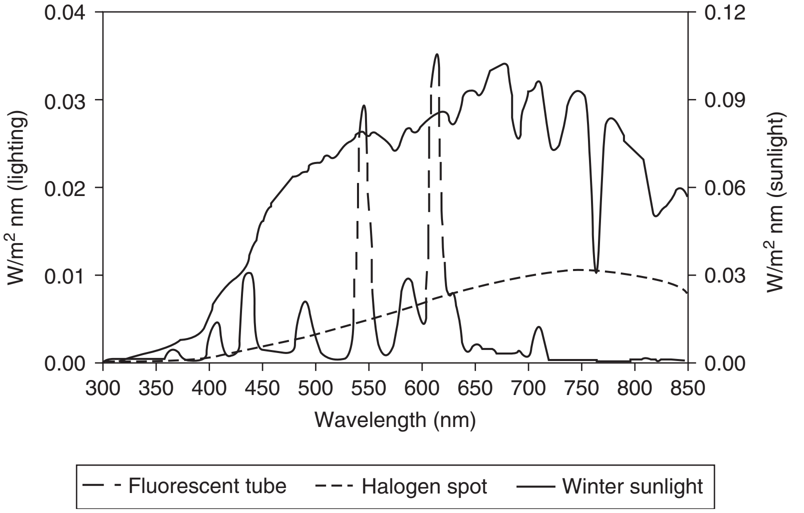

Figure 1. Energy distribution from the sun (measured 12 December 2007 11:55 at N59 39.945 E10 45.440), from a warm-white fluorescent tube (Osram L 58W/830 Lumilux Warm White) and a 12-V 20-W Ikea halogen lamp (both measured at a 15-cm distance). Measurements performed using an Apogee spectroradiometer (Apogee Instruments Inc., Logan, UT).

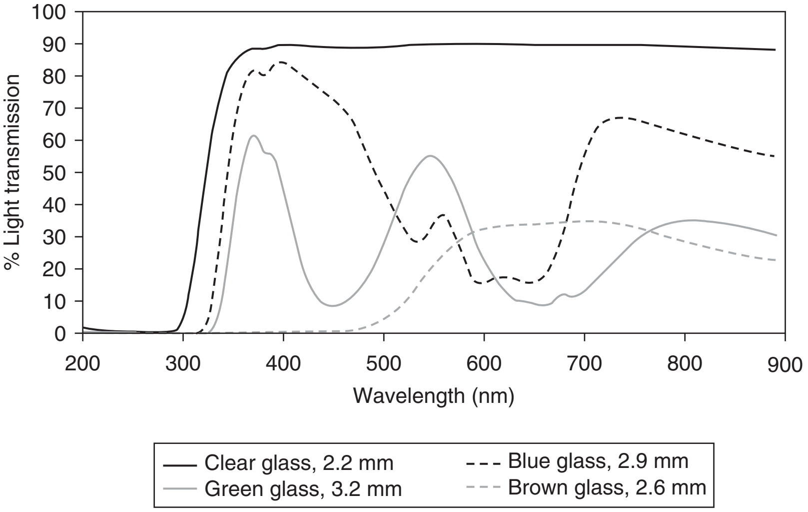

Figure 2. Light transmission in clear, blue, green, and brown glass as measured by a Perkin Elmer Lambda 800 UV–vis spectrometer with an integrating sphere (Perkin Elmer Ltd., Buckinghamshire, UK).

smaller absorption peaks in the 500- to 580-nm region (green and yellow light). While riboflavin is often identified as the major photosensitizer in food causing photooxidation (8), this compound has a 10- to 15-fold lower molar extinction peaks than the other three mentioned photosensitizers. Recent research (9, 10) has clearly demonstrated the importance of natural contents of porphyrins and chlorophyll-like compounds as powerful photosensitizers in dairy products.

Oxidative changes in food are important in terms of the nutritional quality, palatability, and even toxicity of our food supply (11). Riboflavin-photosensitized oxidation causes destruction of vitamin A, vitamin C, vitamin D, and vitamin E (12).

LIGHT PROTECTION BY PACKAGING MATERIALS

When sunlight, which represents a complete spectrum in the visible light region, reaches the surface of a piece of colored, transparent material, some light is reflected, some light is transmitted, and the rest is absorbed. The amount of energy transmitted in each part of the spectrum, the availability of oxygen (13) and the type and concentration of photosensitizers will determine the degree and character of the photooxidative degradation of the food product.

The importance of the optical properties of packaging materials is often underestimated, and little attention is generally given to the shelf life of light-sensitive food products (14). Today, consumers are demanding transparent packing, to better appraise the product prior to purchase. Furthermore, environmental concerns have caused a reduction in the use of aluminum and metallized foils. These factors have led to increased use of transparent packing materials within the entire food sector. However, packing of foods in transparent materials greatly increases the risk of light-induced oxidation (15).

Some packaging materials, such as tin-plated steel, aluminum (also foils), and thick fiber boards (e.g. corrugated boards and solid boards), are practically impermeable to light and thus offer very good protection against light. Materials that to varying degree offer light protection are discussed below.

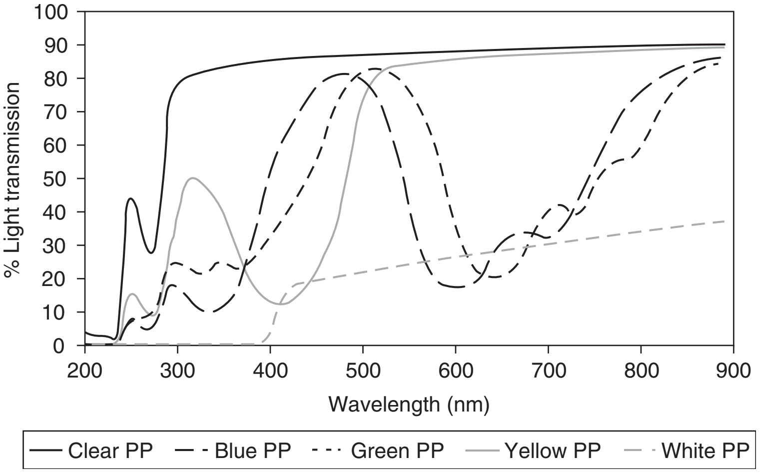

Figure 3. Light transmission in clear, blue, green, yellow, and white injection molded polypropylene lids as measured by a Perkin Elmer Lambda 800 UV–vis spectrometer with an integrating sphere (Perkin Elmer Ltd., Buckinghamshire, UK).

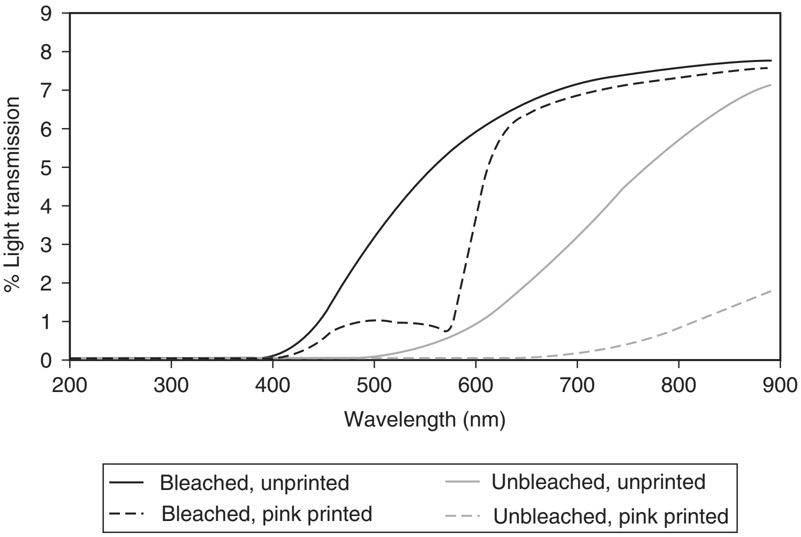

Figure 4. Light transmission in three different qualities of unprinted and pink printed liquid paperboard: bleached, unbleached, and bleached with oxygen and light barrier as measured by a Perkin Elmer Lambda 800 UV–vis spectrometer with an integrating sphere (Perkin Elmer Ltd., Buckinghamshire, UK).

Light Protection by Glass and Plastics

The light protection of glass and plastic depends on material thickness and type and concentration of pigment. Higher pigmentation will drastically reduce the light transmittance and increase the protection of the material. As shown by Figures 2 and 3, clear glass and plastic (injection molded polypropylene) transmit about 90% of the visible light and, respectively, 35% and 56% of the UV light, and they are therefore poor UV and visible light barriers. Blue glass and plastics transmit light in the UV, blue, and the red regions of the spectrum. As many photosensitizers absorb light in the UV and blue regions of the spectrum, this light is particularly harmful to many foods. Green glass and plastics transmit light in the UV, violet/blue, and green regions of the spectrum. In this area the porphyrins have some small absorption maxima, and prolonged exposure in this region may cause food deterioration.

Brown glass transmits light in the yellow, orange, and red region of the spectrum, an area where chlorophylls also have absorption maxima. However, brown glass is usually densely pigmented, offering good light protection for a variety of food products including milk and beer.

Figure 3 shows the light transmittance through an SiO_2-pigmented (white) injection-molded polypropylene plastic. Addition of this pigment results in a relative sharp cut off around 400 nm offering good protection against UV radiation. However, because normal artificial light sources used in retail normally emits only small amounts of light in the UV region (many have only a small emission peak in the 370-nm area), the transmittance of light by packaging materials in this region is not a serious threat during indoor distribution, storage and display. A limited effect is therefore achieved by adding a UV block to a transparent packaging material.

Light Protection by Liquid Paperboard

Different qualities of liquid paperboard coated with low-density polyethylene are used worldwide for packaging of fresh milk products. Figure 4 shows that despite their modest thickness (0.5–0.6 mm) commercial liquid

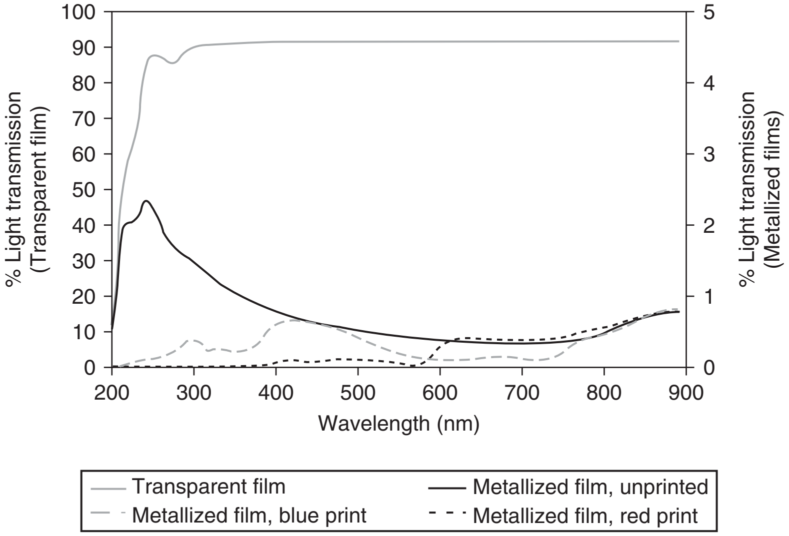

Figure 5. Light transmission in unmetallized, metallized, and printed, metallized polypropylene films as measured by a Perkin Elmer Lambda 800 UV–vis spectrometer with an integrating sphere (Perkin Elmer Ltd., Buckinghamshire, UK).

paperboard qualities offer a relatively good protection against light. Only 4.3% of the light in the visible (400–700 nm) region of the spectrum and 0.03% in the UV region are transmitted through the bleached paperboard. The unbleached board offers an even better light barrier. Only 0.8% of the visible light and 0% of the UV light is transmitted. Additional protection is achieved by printing. Only 2.6% of the light is transmitted through pink printed bleached paperboard, and most of the reduction appears in the region of the spectrum that is most detrimental to milk products—that is, up to 550 nm. Pink printed unbleached paperboard offers very good light protection. Less than 0.1% of the visible light is transmitted through this material.

If liquid paperboard is foiled with aluminum, it becomes virtually impermeable to light. Also the SiO_2/carbon black/EVOH-based light and oxygen barrier used by one supplier for certain products in some markets also offers very good light protection. Only 0.3% of the visible light is transmitted through this material (for unprinted, bleached board).

Light Protection by Metallization of Plastic Films

Metallization may be used to improve both light barrier and oxygen barrier of plastic films. As shown by Figure 5, the transmission in the visible region of the spectrum is significantly reduced from 92% for unmetallized film to 0.5% when the same film is metallized. The reduction in light transmission caused by the metallization is rather uniform in the visible area of the spectrum, similar to the effect of a heavily pigmented gray (neutral) filter. The effect of metallization is still very good in the UV region of the spectrum, but not as good as in the visible region. As for liquid paperboard, further reduction in light transmission is achieved by additional printing of the metallized film. The effect of blue print results in neglectable effect on light transmission in the blue region because blue print transmits light in the blue region of the spectrum. Similarly, the effect of red print is neglectable in the red region of the spectrum.

LIPID OXIDATION: CHEMICAL STABILIZATION

Karen M. Schaich
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

INTRODUCTION

Packaging must provide physical, microbiological, and chemical protection for foods. For the most part, providing physical protection is straightforward, as is preventing contamination of foods after processing and packaging. More challenging is meeting the requirement for inert storage environments that inhibit respiration in fresh fruits and vegetables, microbial growth in prepared foods and raw meats, and chemical degradation in stored foods. Lipid oxidation, or oxidative rancidity, is the chemical reaction that most limits long-term shelf life of foods, producing characteristic off-odors and flavors, browning, texture changes, co-oxidation of proteins and vitamins, and even toxic products in foods. Lipid oxidation is also a major cause of deterioration in cosmetics and many personal care products, changing surface tensions, breaking emulsions, oxidizing active components, and producing off-odors. Because of these extensive effects on product quality, lipid oxidation also forces the greatest demands on food packaging.

This chapter will describe the reactions of lipid oxidation in general terms and show how packaging can be used to inhibit and control lipid oxidation. Additional details of lipid oxidation reactions, factors affecting lipid oxidation, and strategies for prevention may be found in comprehensive reviews listed at the end of the chapter.

CHARACTERISTICS OF LIPID OXIDATION

Lipid oxidation is a chemical process in which unsaturated fatty acids in phospholipids and triacylglycerides react with oxygen and degrade to a variety of volatile and nonvolatile products. Lipids oxidize by a free radical chain reaction process involving three stages: initiation, propagation and branching, and termination. The classical sequence describing lipid oxidation is shown in Figure 1, along with catalysts and protectants at each stage.

The radical chain reaction has several critical consequences for lipid oxidation:

- Once started, the reaction is self-propagating and self-accelerating; that is, it keeps itself going.
- Many more than one LOOH is formed and more than one lipid molecule is oxidized per initiating event.
- Very small amounts of pro- or antioxidants cause large rate changes.
- Multiple intermediates and products are formed, and they change with reaction conditions and time.

Unlike most chemical reactions, lipid oxidation is a dynamic process with no fixed intermediates or endpoints. That the reactions of lipid oxidation change with time and conditions presents distinct challenges in measuring and controlling lipid oxidation, and it explains in part why lipid oxidation is a major problem in storage stability of foods and other lipid-containing products.

STAGES OF LIPID OXIDATION

Initiation

$$LH \rightarrow L^\bullet \tag{1}$$

Oxygen cannot add directly to the double bonds in unsaturated fatty acids, but it adds almost instantaneously to $L^\bullet$ free radicals to form peroxyl radicals that drive radical chain reactions. Thus, lipid oxidation requires special catalysts, or initiators, to form $L^\bullet$, on carbon atoms of lipid (L) molecules. Common initiators include ultraviolet light, photosensitizers and visible light, radicals from other sources, ionizing radiation, metals, heme compounds, and heat.

Propagation

$$L_1^\bullet + O_2 \rightarrow L_1OO^\bullet \tag{2a}$$

$$L_1OO^\bullet + L_2H \rightarrow L_1OOH + L_2^\bullet \rightarrow L_2OO^\bullet \tag{2b}$$

$$L_2OO^\bullet + L_3H \longrightarrow L_2OOH + L_3^\bullet \text{ etc. } \cdots\cdots\rightarrow L_nOOH \tag{2c}$$

Propagation reactions establish the free radical chain and keep it going. In this stage, lipid alkyl radicals, $L^\bullet$, react with oxygen almost instantaneously to form peroxyl radicals, $LOO^\bullet$, that are major players in lipid oxidation. Peroxyl radicals very selectively abstract hydrogens from adjacent lipid molecules, forming hydroperoxides and generating new $L^\bullet$ radicals in the process. Each new $L^\bullet$ radical in turn repeats the process to provide the driving force in the chain reaction. Chain propagation continues indefinitely until no hydrogen source is available or the chain is intercepted.

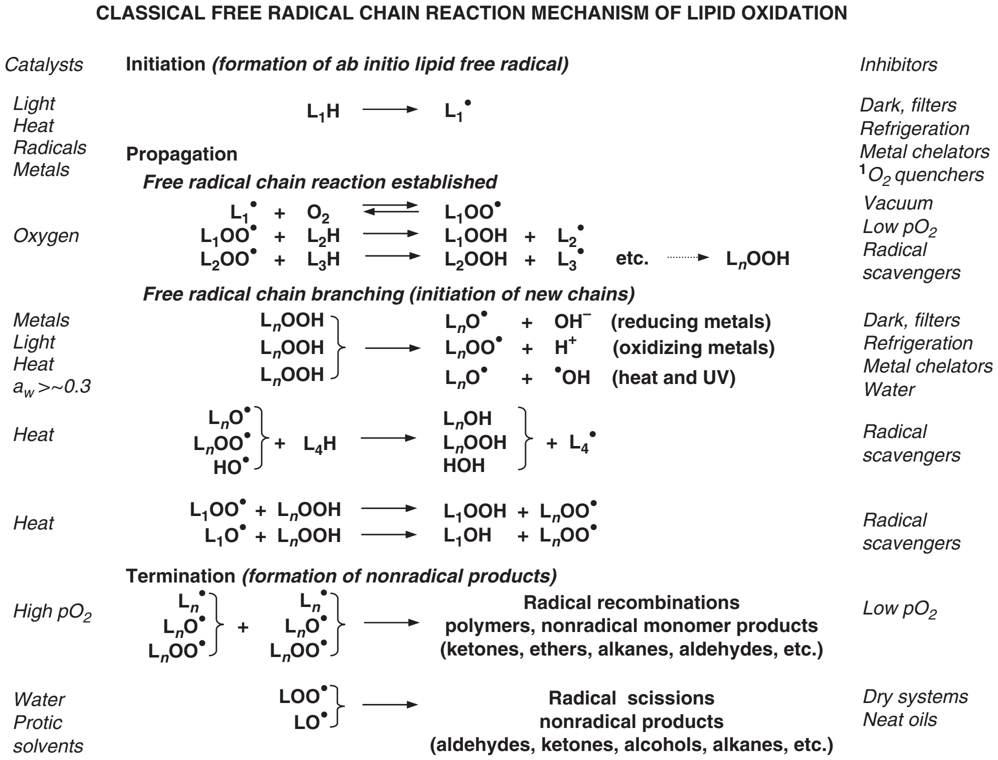

Figure 1. The stages and individual reactions involved in lipid oxidation as described by the classical free radical chain reaction, and the catalysts and inhibitors associated with each stage.

Chain branching

$$\left.\begin{array}{l} L_nOOH \\ L_nOOH \\ L_nOOH \end{array}\right\} \longrightarrow \left.\begin{array}{l} L_nO^\bullet + OH^- \\ L_nOO^\bullet + H^+ \\ L_nO^\bullet + {}^\bullet OH \end{array}\right\} \longrightarrow \text{more chain reactions} \qquad \begin{array}{r} (3a) \\ (3b) \\ (3c) \end{array}$$

Branching reactions are a second stage of propagation in which the radical chain reaction is expanded, establishing new chains at faster rates. In basic propagation (Reaction 2), peroxyl radicals are the only chain carriers; they react rather slowly ($k = 36–62\,\mathrm{L\,mol^{-1}\,s^{-1}}$) and quite specifically, and the chain continues one abstraction at a time from the initiation point. Without forces that decompose hydroperoxides, this process can continue indefinitely while hydroperoxides accumulate. However, UV light, moderate heat, metals, or heme compounds decompose hydroperoxides to give alkoxyl and peroxyl radicals plus ions (metals) or alkoxyl radicals and hydroxyl radicals (UV light and heat), all of which initiate new free radical chains that branch off of and expand the original chain. Hence, the net effect of LOOH breakdown is a transition in mechanism and kinetics. Lipid oxidation gathers steam, increasing in rate and extent as $LO^\bullet$ becomes the dominant, faster chain carrier ($k = 10^6–10^7\,\mathrm{L\,mol^{-1}\,s^{-1}}$) and secondary chains dramatically amplify and broadcast lipid oxidation. A single initiating event can thus lead to sequential oxidation of literally hundreds of molecules in the primary chain and in secondary branching chains.

In early stages of lipid oxidation while hydroperoxides are just beginning to accumulate, the hydroperoxide decompositions occur monomolecularly (Reaction 3). As oxidation progresses and hydroperoxides accumulate, decomposition shifts to bimolecular mechanisms that convert stable or slowly reacting species to multiple highly reactive radicals:

$$2\,LOOH \longrightarrow LO\underbrace{OH\ldots H}OOL \longrightarrow LO^\bullet + H_2O + {}^\bullet OOL \qquad (4)$$

$$LOO^\bullet + LOOH \rightarrow LO^\bullet + \text{epoxy} - LO^\bullet + {}^\bullet OH \qquad (5)$$

The initial effect of bimolecular decomposition is a dramatic acceleration of lipid oxidation, but eventually a point of net LOOH decomposition is reached. At that point, termination reactions such as radical recombination or alkoxyl radical scission take over, and oxidation slows, stable secondary products form, and off-flavors and odors become detectable.

Termination

Termination implies that a process is coming to a close. For lipid oxidation as a process, "termination" is a misnomer because lipid oxidation never fully stops. A *specific radical* may be terminated as it forms some product, but it leaves behind another radical *so the chain reaction continues*. Net oxidation slows down when radical quenching processes exceed the rate of new chain production, and the momentum of oxidation shifts from radical propagation and chain expansion to generation of stable products. To reflect this shift, "termination" in the discussion below refers to stopping an individual lipid radical, not the overall reaction. The cumulative effect on a reaction system such as food is determined by the number of radical chains being terminated.

Lipid free radicals terminate to form nonradical products primarily by three mechanisms:

(a) Radical recombinations
(b) Scission reactions when proton sources (e.g., water) are present to stabilize products
(c) Co-oxidation of nonlipid molecules such as proteins

The mechanisms dominating in a given system are influenced by the nature and concentration of the radicals, the temperature and oxygen pressure, and the solvent.

Radical Recombinations. The limitless number of variations possible for radical recombinations is one reason for the broad range of oxidation products detected in lipid oxidation. Despite the possibilities, recombinations are not random, and distinct patterns of favored recombinations have been identified. Some of the most important recombinations and their products are

$$\text{Alkyl radicals } (L_1^\bullet + L_2^\bullet) \rightarrow \text{alkane polymers} \qquad (6a)$$

$$\text{Peroxyl radicals } (L_1OO^\bullet + L_2OO^\bullet) \rightarrow \text{alcohols and ketones, alkyl peroxides} \qquad (6b)$$

$$\text{Alkoxyl radicals } (R_1O^\bullet + R_2^\bullet) \rightarrow \text{ethers, ketones, alkanes} \qquad (6c)$$

$$(R_1O^\bullet + R_2O^\bullet) \rightarrow \text{alkyl peroxides, ketones, alcohols} \qquad (6d)$$

Temperature and oxygen pressure are key determinants of radical recombination pathways (Figure 2). $L^\bullet$ reactions dominate under low-oxygen ($pO_2 = 1$ to about 80–100 mm Hg) and high-temperature (reduced O_2 solubility) conditions. High pO_2 and lower temperatures favor $LOO^\bullet$ reactions. $LO^\bullet$ contributions to the product mix dominate in secondary stages of oxidation and at moderate temperatures and oxygen pressures when LOOH or $LOO^\bullet$ decompositions are faster than their formation. Radical recombinations are diffusion- and concentration-controlled, so they are favored in neat oils; they decrease with lipid dilution.

Formation of dimers and polymers increases viscosity in oxidized oils. Perhaps just as importantly, alcohols, ketones, ethers, and so on, are volatile compounds and flavor components that augment those produced in scission reactions and provide the undertones and secondary notes that round out flavors. Ketones and dialkyl peroxides, in particular, are unique to recombination reactions.

Scission Reactions of $LO^\bullet$. Of all the pathways active in lipid oxidation, scission of alkoxyl radicals probably has the greatest practical consequences for any kind of consumer product because the products generated are

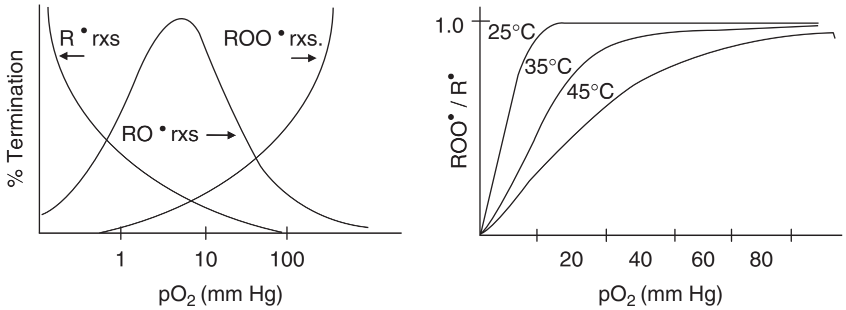

Figure 2. Effects of oxygen and temperature on termination processes in lipid oxidation. [Redrawn from Labuza (1) and Schaich (2). Used with permission.]

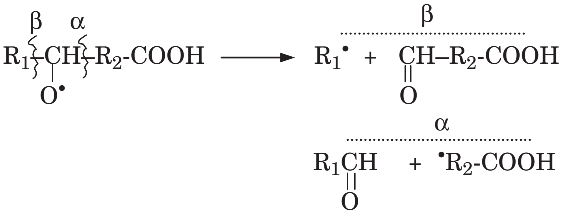
Table 1. Typical Scission Products Produced from Important Oxidized Polyunsaturated Fatty Acids Undergoing Oxidation and Associated Off Flavors

Product Classes	Carbon Chain Lengths	Major Products	Associated Flavors
		Oleic Acid	
Hydrocarbons	6–8	Nonanal	Fresh, citrus
Alkanals	2–4, 5, 6, 7, 8, 9, 10, 11	Octanal	Fresh, citrus
2-Alkenals	6–9, 10, 11	Undec-2-enal	Sweet, fatty
Acids	1, 6, 7, 8, 9	Undecanal	Fatty
Alkanols	5–8	2-decenal	Tallowy
Alkylformates	2–8		
		Linoleic Acid	
Hydrocarbons	3–5	Hexanal	Green-fruity, bitter almond
Alkanals	3, 4, 5, 6, 7, 8	2,4-Decadienal	Fried
Alkenals	7, 8, 9, 10	2-Octenal	Woodbugs-fatty, nutty
Dienals	9, 10	2-Heptenal	Fatty-putty, bitter almond
Oxo-alkanals	7–9	1-Octene-3-one	Metallic moldy, mushroom
Ketones	7, 8	Pentanal	Sharp, bitter almond
Alcohols	3, 4, 5, 6, 7, 8	Heptanal	Oily putty, soapy, fruity
Acids	1, 5, 6, 7, 9		
Esters	1, 6, 7, 8		
		Linolenic Acid	
Hydrocarbons	1–3	2,4-Heptadienal	Rotten apples, fried
Alkanals	1, 2, 3, 6	3-Hexenal	Green leaves, green tomatoes
Alkenals	4, 5, 6, 7	Propanal	Sharp, irritating
Dienals	7–9	2,4,7-Decatrienal	Fishy
Trienals	10	2-Pentenal	Sharp, painty, green
Ketones	5, 18	Octadienal	
Alcohols	3, 4, 5, 6, 7, 8	Pentene-3-one	Sharp, fishy
Acids	1, 5, 6, 7, 9	Octadiene-2-one	Fatty-fruity
Esters	1, 6, 7, 8		
Oxo-alkanals			
Arachidonic Acid			
Alkanal	2, 6, 7	Hexanal	Green-fruity, bitter almond
Alkenal	7, 8, 9, 11	2,4-Decadienal	Fried
Dienal	9, 10, 11, 12	2,4,7-Tridecatrienal	
Ketones		2-Heptenal	Fatty-putty, bitter almond
Alkanes	5, 6	2-Octenal	Woodbugs-fatty, nutty
Aldehyde esters	4, 5	Pentanal	Sharp, bitter almond
		1-Octen-3-one	Metallic, moldy, mushroom
		4-Decenal	Tallowy
		3,5-Undecadien-2-one	
		2,6-Dodecadienal	

responsible for the distinctive volatile off-odors and off-flavors associated with rancidity. Lipid alkoxyl radicals undergo scission of the C–C bond on either side of the $LO^{\bullet}$ group to yield a mixture of carbonyl products (typically aldehydes, alkanes, and oxo-esters from the initial alkoxyl radicals) and free radicals:



$$R_1\overset{\beta}{-}\underset{O^{\bullet}}{CH}\overset{\alpha}{-}R_2\text{-COOH} \longrightarrow R_1^{\bullet} + \underset{\|}{\overset{}{CH}}\text{–}R_2\text{-COOH} \quad \text{or} \quad R_1\underset{\|\\O}{CH} + {}^{\bullet}R_2\text{-COOH} \qquad (7)$$

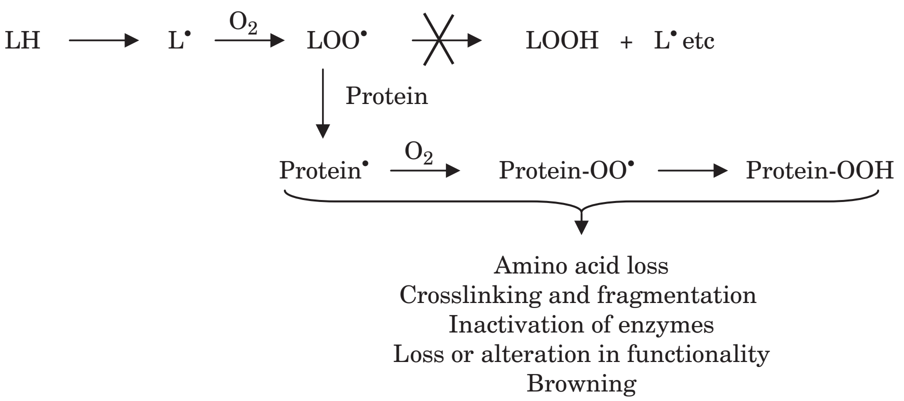
Unsaturated radical fragments oxidize still further and undergo secondary scissions in similar fashion to produce carbonyls and alkanes of still shorter chain length. Consequently, the mix of breakdown products that accumulate in oxidized lipids can become quite complex, as shown in Table 1 for the four major unsaturated fatty acids.

Scission requires a strong proton donor such as water to stabilize the products and drive the reaction forward. Scission is a minor process in neat lipids at room temperature. However, in the presence of water (e.g., in emulsions), acid, or other polar solvents, scission is rapid and competitive with hydrogen abstraction, accounting for about half of alkoxyl radical reactions, even in early oxidation. Scission is also favored in dilute solution of lipids where there is reduced competition from hydrogen abstraction. However, because $LO^{\bullet}$ scission has a large activation energy and Arrhenius factor, the greatest contribution of this termination (and propagation) reaction is at elevated temperatures. Heat accelerates alkoxyl radical scissions in all solvents, although the pattern of cleavage may change as temperature increases.

The most notorious scission product of lipid oxidation, malondialdehyde (MDA), arises from multiple scissions of cyclic internal hydroperoxides formed in fatty acids with three or more double bonds (linolenic and higher). MDA formation is facilitated in aprotic solvents and by low lipid concentrations, limited oxygen pressures, and photosensitized oxidation; and it requires conditions for endoperoxide cleavage, namely, mild heat and acid. In autoxidizing lipids, yields of authentic MDA are usually less than 0.1%; but in photosensitized fatty acids where internal hydroperoxides are formed in high concentrations, MDA concentrations can reach 5% or higher. Malonaldehyde is probably the most common measure of lipid oxidation in complex food systems, but its analysis is quite often misused and misinterpreted.

Co-oxidation of Nonlipid Molecules. Hydrogen abstractions by lipid alkoxyl and peroxyl radicals are not selective for fatty acids. Nonlipid molecules such as amino acids, proteins, nucleic acids, antioxidants, carotenoids and other pigments, carbohydrates, and even vitamins also have abstractable H's and thus can serve as substitutes for fatty acids, intercepting the lipid free radical chain. This process terminates lipid oxidation chains, but reroutes radicals and oxidation to proteins and other biomolecules. As in lipids, these radicals add oxygen to form peroxyl radicals that may also abstract H's from other molecules or lead to oxidative degradation of the molecular target, whatever class of compounds it may be. In this way, lipids serve to "broadcast" oxidation damage to other molecules which then provide footprints of lipid oxidation in foods and biological systems.

Radical transfer to nonlipid molecules has several critical consequences. Co-oxidation reactions alter lipid oxidation kinetics, mechanisms, and overall effects in foods and biological systems. Immediately, there is an apparent antioxidant effect in terminating individual lipid radical chains and slowing accumulation of measurable oxidation products. However, if initiation is not concurrently blocked, what appears to be inhibition of lipid oxidation is false: Detectable oxidation products are merely shifted from lipids to other molecules, but *ab initio* generation of new chains by initiators continues. If traditional lipid oxidation products such as peroxide values and aldehydes are analyzed, oxidation appears to be very low because radicals are transferred before lipid products are formed. However, production of off-flavors, browning, texture changes, nutritional losses, etc., continues, now mediated by other molecules, particularly proteins:



(8a)

(8b)

In some co-oxidations, lipids add to the target molecules, particularly proteins. This limits extractability of lipids for analysis and removes lipids from product streams normally analyzed, compounding problems in assessing the true extent of lipid oxidation. Consequently, in systems where co-oxidations are active, lipid oxidation must be followed by loss of fatty acids in addition to oxidation products such as peroxides, malonaldehyde, and anisidine values. Footprints of lipid oxidation in the form of specific co-oxidation products or molecular property changes (e.g., protein crosslinking, amino acid loss, degradation of functionality) must also be tracked to avoid severely underestimating both the extent and the effects of lipid oxidation in complex systems.

Time Course of Lipid Oxidation

Lipid oxidation is often divided into three rate periods described in terms of hydroperoxide reactions:

1. Induction period—very low level oxidation, formation of LOOH undetectable.
2. Monomolecular rate period—initial stages of oxidation up to $\sim 1\%$ oxidation, LOOH accumulate slowly and decompose as single, isolated molecules when exposed to UV light, metals, or heat (Reaction 3).
3. Bimolecular rate period—later stages of lipid oxidation up to $\sim 7–15\%$ oxidation, LOOH accumulate rapidly, begin to decompose in pairs via LOOH (Reaction 4) or $\mathrm{LOO}^{\bullet} + \mathrm{LOOH}$ (Reaction 5), and secondary products form.

The integration and progression of individual reactions of initiation, propagation, and termination into an overall oxidation process with these three rate periods is shown in Figure 3. During the induction and early monomolecular period, $\mathrm{LOO}^{\bullet}$ is the main chain carrier and propagation is relatively slow. As active oxidation develops and LOOH decompose, both $\mathrm{LOO}^{\bullet}$ and $\mathrm{LO}^{\bullet}$ contribute to propagation. However, $\mathrm{LO}^{\bullet}$ reactions are much faster and more specific, so $\mathrm{LO}^{\bullet}$ becomes the dominant chain carrier and controls directions of reactions in late monomolecular and throughout the bimolecular rate periods, partially accounting for increasing oxidation rates.

FACTORS AFFECTING LIPID OXIDATION: PRO-OXIDANTS

Many factors alter rates of lipid oxidation. Some of the most common catalysts and inhibitors are:

(a) Nature of lipids: number of double bonds
    i. Configuration of double bonds (*trans* versus *cis* and conjugation)
    ii. Level and type of phospholipids present
    iii. Free fatty acids versus esters versus triacylglycerols.
(b) Surfaces: Bulk oil – exposed surface versus emulsions versus dispersal on solid surface
(c) Presence of other components:
    i. Pro-oxidants
        - Preformed hydroperoxides
        - Metals
        - Porphyrins, chlorophylls, heme compounds
        - Lipoxygenase and cyclooxygenase
        - Amino acids
        - Ascorbic acid (low concentrations)
    ii. Antioxidants (endogenous and added)
        - Polyphenols
        - Amino acids
        - Metal chelators and complexers
        - Synergists
        - Glutathione peroxidase
    iii. Interceptors
        - Proteins
        - DNA
        - Vitamins
        - Pigments
(d) Environment and solvent system: temperature, light, oxygen pressures, water, pH, packaging.

Of these, light, oxygen pressure, metals, water, chelators, and antioxidants are amenable to control by packaging.

Light

Light is a key catalyst of lipid oxidation in foods and cosmetics, yet is often discounted during handling, processing, and even storage. At low wavelengths ($< \sim 254$ nm),

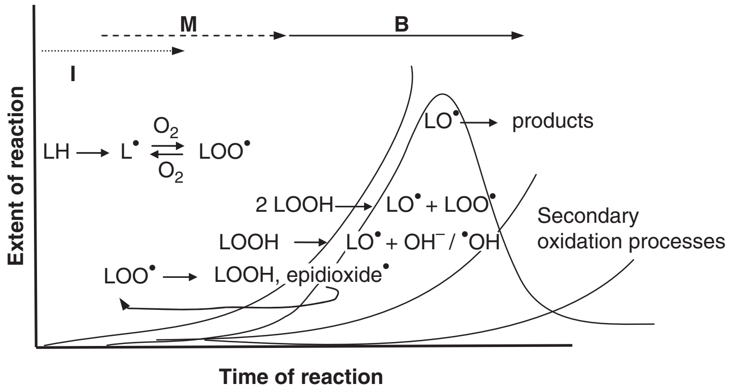


Figure 3. Changes in dominant lipid oxidation reactions and products over the course of lipid oxidation. Induction period (I), monomolecular rate period (M), and bimolecular rate period (B). [Modified from Schaich (2). Used with permission.]

ultraviolet light has enough energy to break bonds and form $L^\bullet$ radicals, although most uv damage to lipids occurs at wavelengths $<200\,\text{nm}$. Much more active is UV-induced decomposition of hydroperoxides to generate two reactive radicals that rapidly propagate the radical chain:

$$\begin{array}{lclcrl} \text{ROOH} & & \text{RO}^\bullet + {}^\bullet\text{OH} & & \text{ROH} & (9a)\\ \text{HOOH} & \xrightarrow{h\nu(uv)} & \text{HO}^\bullet + {}^\bullet\text{OH} & \xrightarrow{2L_2H} & 2\,L_2^\bullet + H_2O & (9b)\\ \text{LOOH} & & \text{LO}^\bullet + {}^\bullet\text{OH} & & \text{LOH} & (9c)\end{array}$$

(ROOH is any organic hydroperoxide, HOOH is hydrogen peroxide, LOOH is a lipid hydroperoxide).

Hydrogen peroxide is actively generated in foods by metal autoxidation, but can also be produced by UV degradation of aqueous solutions. Light decomposition of hydroperoxides is a major contributor to destabilization of stored foods, particularly under fluorescent lights in laboratories, storage facilities, and stores.

Visible light ($>400\,\text{nm}$) initiates lipid oxidation indirectly through photosensitizers, molecules that absorb light and transfer the excitation energy to molecular bonds in lipids to form free radicals directly (Type 1) or to oxygen to form singlet oxygen $^1O_2$, which then adds to double bonds and forms hydroperoxides in unsaturated fatty acids without intermediate radicals (Type 2). Photosensitizers in foods and biological materials are usually molecules with multiple carbonyls and/or an extended conjugated double bond system. Most pigments and other molecules listed below have this required structure. Chlorophyll, in particular, is a very potent photosensitizer that produces both free radicals and singlet oxygen, with the dominant reactions depending on substrate and reaction conditions. Food dyes are listed with a question mark because many food colors have requisite structures that make them good candidates for sensitization, but their action has not yet been documented.

	Type 1: Free Radical	**Type 2: Singlet Oxygen**
Sensitizers	Chlorophyll Pheophytin Hemes Protoporphyrin Myoglobin Hemoglobin Flavins (especially riboflavin) Xanthenes Anthracenes Anthroquinones Crystal violet Food dyes (?)	Chlorophyll Hemes Erythrosine Rose bengal Flavins Methylene blue Proflavine Eosin Food dyes (?)
Quenchers	Phenols, polyphenols Tocopherols (carotenes)	Carotenes Tocopherols

Quenchers are antoxidant compounds that can selectively react with light-induced radicals and singlet oxygen, thereby preventing their reaction with lipids and other biomolecules. Carotenes are important $^1O_2$ scavengers in foods. They are also radical scavengers, but listed in parentheses because in high concentrations they can become pro-oxidants.

Light catalysis is nearly always present, but can be verified by comparison of samples incubated open versus in the dark, by oxidation kinetics, and by presence of specific photolysis products. Type 1 photosensitization is qualitatively indistinguishable from autoxidation, but much faster. It characterized by the following patterns:

Mechanism:	Free radical
Kinetics:	Induction period present
	Dependent on pO_2
	Rate not $\propto$ number of double bonds
	Relative reactivity: 18:1 ~1 18:2 17 18:3 25
Products:	Conjugated dienes formed with LOOHs in external C-9, C-13, and C-16 positions
	Scission products all from external LOOHs

Type 2 singlet oxygen photosensitized oxidation has distinctively different oxidation patterns:

Mechanism:	“ene” rx, concerted addition of O_2 to double bonds to form LOOH without free radicals; radicals are generated subsequently by LOOH decomposition
Kinetics:	No induction period
	Independent of O_2 (when O_2 not limiting)
	Dependent on sensitizer concentration
	Rate directly $\propto$ number of double bonds
	Relative reactivity: 18:1 ~1 18:2 2 18:3 3
Products:	Both nonconjugated and conjugated LOOHs
	LOOHs at all positions, high proportion at internal positions (e.g., C-10 and C-12)
	High proportion of internal cyclics, endoperoxides, epoxides, di- and tri-hydroperoxides (all are precursors of light-induced off-flavors)
	Scission products from internal LOOHs, altered scission position preferences

When these kinetic characteristics and products are observed in products, light-mediated initiation can be presumed, and protection from light during processing and with packaging will be critical for stabilization. Indeed, blanking out light (e.g., by packaging) prevents both photosensitized generation of LOOH and UV decomposition of LOOH and thus has huge immediate effects on kinetics and consequences of lipid oxidation. However, caution is required when deducing causes of oxidation or mechanisms of a given agent from product mixes and kinetics because many photosensitizers change mechanisms with solvent and concentration. For example, riboflavin normally photosensitizes by free radicals but at low concentrations it converts to the $^{I}O_2$ mechanism. Thus, sensitivity to light often changes with product formulation and phase localization and distribution of photosensitizers and quenchers. For example, cheese will behave differently than milk under light, even though the fat and sensitizer composition is similar for each. This needs to be kept in mind when tracking and comparing causes of oxidation in different oils, foods, and cosmetic products and planning protection strategies.

Oxygen Pressure

Lipid oxidation requires oxygen, so removal or limitation of oxygen has been a traditional approach to inhibiting lipid oxidation in packaged processed foods. Nevertheless, effects of oxygen are evident mostly at low oxygen pressures and in early stages of lipid oxidation, so use of low oxygen to control lipid oxidation must focus on a rather narrow reaction window.

Since oxygen does not react with lipids directly, lipid oxidation depends critically on the concentration and reactivity of initiators that produce reaction sites for oxygen, either $L^\bullet$ by conventional initiators or $^1O_2$ by photosensitization, particularly in the low pO_2 range (1 to 80–100 mm Hg). Once reaction sites are available, oxidation rates increase dramatically as pO_2 increases (Figure 4), but the catalytic effect of oxygen levels off at $pO_2 \sim 100$ mm Hg or when $[O_2] > [LH]$ and $[L^\bullet]$ (exact level depends on reaction system). Similarly, once enough radicals are present to keep chain reactions going, formation of new $LOO^\bullet$ becomes much less important than hydrogen abstraction to propagate chains, and the effect of increased oxygen on rate reaches a steady-state equilibrium as oxidation progresses.

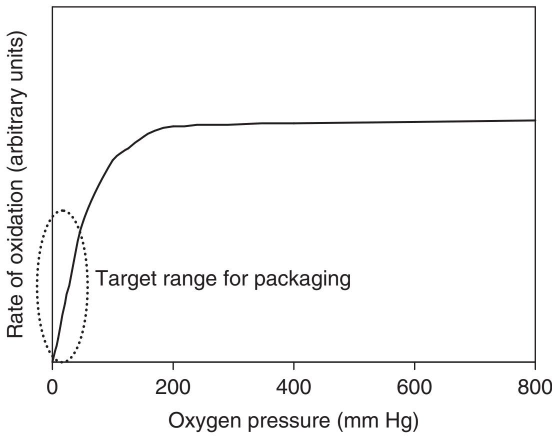

Figure 4. Effects of oxygen on the rate of lipid oxidation. Rate of oxidation increases rapidly with increasing pO_2 when oxygen is limiting but is not affected by additional oxygen when $[O_2] > [LH]$. [Figure generalized from data of Bolland, (3).]

Kinetic rate equations show the complex relationship of oxygen to lipid oxidation rate. At low pO_2, the rate of lipid oxidation may be expressed simplistically as

$$\text{Rate of oxidation (low pO}_2) = k_o(k_i/k_{t1})^{1/2}[\text{LOOH}]\,[\text{O}_2] \tag{10}$$

where rate constants refer to $L^\bullet$ oxygenation, initiation, and termination by $L^\bullet$ recombinations, respectively. During early oxidation (monomolecular LOOH decomposition), the rate-limiting step is formation of $L^\bullet$ and peroxyl radicals, which requires oxygen. As oxidation progresses and LOOH increases, propagation reactions (i.e., hydrogen abstractions by $LOO^\bullet$ and by $LO^\bullet$ from LOOH decomposition) become the dominant rate determinants and the relative effect of oxygen diminishes.

At high pO_2, more than enough oxygen is present to add to every $L^\bullet$ formed, so the rate dependence shifts from oxygen to the concentration of available oxidizable lipids and propagation processes:

$$\text{Rate of oxidation (nonlimiting pO}_2) = k_p(k_i/k_{t3})^{1/2}[\text{LOOH}]\,[\text{LH}] \tag{11}$$

The overall rate then is determined by the balance between initiation (k_i) and peroxyl radical recombinations (k_{t3}), and it is proportional to the total amount and degree of unsaturation of available lipid plus propagating LOOH concentrations. The rate-limiting step now is abstraction of hydrogens to form LOOHs (k_p).

Hence, low oxygen needs to be combined with minimization of initiators and catalysts to maximize inhibition of lipid oxidation.

Metals

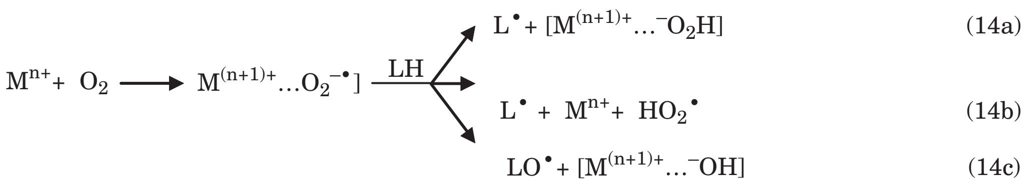
Redox-active metals are probably the most important initiators and catalysts of lipid oxidation in oils, foods, and biological systems because they are ubiquitous and active in many forms, they exert critical influence on both initiation and propagation, and trace quantities (nanomolar) are sufficient for effective catalysis. Only metals undergoing one-electron transfers (e.g., iron, copper, nickel, cobalt, vanadium, titanium, cerium) are active catalysts. Metals in their higher valence (M^{n+1}) states are primary initiators: They form $L^\bullet$ both directly by oxidizing double bonds in unsaturated fatty acids (Reaction 12, RCH=CHR is in a lipid chain) and indirectly by oxidizing other molecules to produce radicals that abstract hydrogens from unsaturated lipids LH (Reaction 13, R = lipid or any other oxidizable molecule).

$$\text{RCH=CHR} + \text{M}^{(n+1)+} \rightarrow \text{R}\overset{\bullet}{\text{C}}\text{H–}\overset{+}{\text{C}}\text{HR} + \text{M}^{n+} \xrightarrow{\text{LH}} \text{L}^\bullet + \text{RH} \tag{12}$$

$$\text{RH} + \text{M}^{(n+1)+} \rightarrow \text{R}^\bullet + \text{H}^+ + \text{M}^{n+} \xrightarrow{\text{LH}} \text{L}^\bullet + \text{RH} \tag{13}$$

Metals in their reduced forms (M^{n+}) —for example, Fe^{2+} and Cu^+—are not good initiators themselves, but they form reactive species by complexing with oxygen

(Reactions 14a–c) and by reducing oxygen to superoxide anion $O_2^{-\bullet}$, which dismutates to hydrogen peroxide and very reactive hydroxyl radicals (Reactions 14d–f).



$$M^{n+} + O_2 \longrightarrow M^{(n+1)+}\ldots O_2^{-\bullet}] \xrightarrow{LH} \begin{cases} L^\bullet + [M^{(n+1)+}\ldots {}^{-}O_2H] & (14a) \\ L^\bullet + M^{n+} + HO_2^\bullet & (14b) \\ LO^\bullet + [M^{(n+1)+}\ldots {}^{-}OH] & (14c) \end{cases}$$

$$M^{n+} + O_2 \rightarrow M^{n+1} + O_2^{-} \qquad (14d)$$

$$2O_2^{-\bullet} \quad \text{or} \quad O_2^{-\bullet}/HOO^\bullet \rightarrow H_2O_2 \xrightarrow{M^{n+}} HO^\bullet + OH^- \qquad (14e)$$

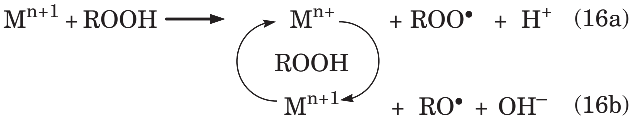
$$HO^\bullet + LH \rightarrow H_2O + L^\bullet \qquad (14f)$$

Metals also decompose any traces of preformed hydroperoxides ROOH present in foods (in lipids or any other molecule) to alkoxyl radicals ($RO^\bullet$) (Reaction 15a), and higher valence state metals oxidize hydroperoxides to peroxyl radicals ($ROO^\bullet$) (Reaction 15b); both of these radicals initiate lipid oxidation chains. Note that unlike UV reactions, metal decomposition of hydroperoxides releases only a single reactive radical that reacts with lipids to generate $L^\bullet$.

$$Fe^{2+} + ROOH \xrightarrow{\text{fast}} Fe^{3+} + RO^\bullet + OH^- \xrightarrow{LH} ROH + L^\bullet \qquad (15a)$$

$$Fe^{3+} + ROOH \xrightarrow{\text{extremely slow}} Fe^{2+} + ROO^\bullet + H^+ \xrightarrow{LH} ROOH + L^\bullet \qquad (15b)$$

When both reduced and oxidized metals are present, catalysis of lipid oxidation is amplified tremendously by redox cycling (Reaction 16). Redox cycles occur slowly with metals and hydroperoxides alone, but rates can be accelerated several orders of magnitude in the presence of appropriate reducing agents, particularly ascorbic acid, that maintain the faster reacting lower valence state in metals:



$$M^{n+1} + ROOH \longrightarrow M^{n+} + ROO^\bullet + H^+ \qquad (16a)$$

$$M^{n+} \xrightarrow{ROOH} M^{n+1} + RO^\bullet + OH^- \qquad (16b)$$

The mere presence of metals is not sufficient to guarantee catalysis of lipid oxidation. In foods and other products, metals are complexed to a wide variety of molecules, including organic acids, carboxylic acids, vicinal diphenols, amino acids, and proteins. How the metals are bound controls the rate of initiation by altering the availability of orbitals for electron transfer, the redox potential and oxidizing or reducing capacity, partitioning between aqueous and lipid phases, and associations with other molecules. In general, higher redox potentials make metal complexes better primary initiators, and low redox potential metal complexes markedly enhance propagation branching reactions. Selection of appropriate chelators can thus greatly modify metal reactivity in foods.

Heat

At frying temperatures, there is sufficient thermal energy to break covalent C–C or C–H bonds in the acyl backbone and form a variety of lipid alkyl radicals which then start the radical chains of oxidation. At moderate temperatures, heat exerts its main effects on processes that have high activation energies, so they can benefit most from a thermal boost. The rate constants in the list below refer to propagation, termination, and LOOH dissociation in sequence. As can be seen, most steps of lipid oxidation require little or no activation; only monomolecular and bimolecular decompositions of hydroperoxides have energy hurdles. Thus, in early stages of lipid oxidation, low to moderate heat breaks O–O bonds in traces of ROOH or LOOH preformed by other reactions, particularly metals, lipoxygenase, or photosensitizers. The $RO^\bullet$, $LO^\bullet$, and ${}^\bullet OH$ thus generated abstract hydrogens from neighboring lipids to form $L^\bullet$ and initiate radical chains. As oxidation progresses and LOOH accumulate, the major effect of heat shifts to acceleration of propagation rather than initiation.

Reaction	**Activation Energies (E_a)**
($L^\bullet + O_2$)	0 kcal/mol
k_p ($LOO^\bullet + LH$)	~5–15
k_t (2 $ROO^\bullet$)	~4
k_t (2 $R^\bullet$)	5
k_t ($R^\bullet + ROO^\bullet$)	1
*k_d (monomolecular)	31
*k_d (bimolecular)	50 uncatalyzed system

Accompanying faster oxidation kinetics is a heat-induced shift in dominant reaction pathways and resulting products that markedly affect food and cosmetic quality. The most important changes include:

- Abstraction of hydrogens from LOH and LOOH in preference to LH, shifting dominant products from volatile α and β scission products to >90% dimers and polymers.
- Shifts in types of dimers formed: β-scission of peroxyl oxygen increases → more C–O–C and C–C dimers and fewer C–O–O–C crosslinks.
- Altered scission patterns; for example, hexanal is major product of L under mild oxidation conditions, but 2,4-decadienal becomes dominant when systems were heated.

- Increased proportion of *trans* isomers, which certainly has implications under current labeling requirements for *trans* fats.

Although storage temperatures are always considered, the changes described above are much more pronounced at temperatures used in processing than at typical transportation and storage temperatures. Even relatively small increases in processing temperatures can dramatically shorten shelf life, as can be seen in the decreased induction period in oils [from Kaya et al. (4)]:

Induction Period of Fresh Oils (h)	**100°C**	**110°C**	**120°C**
Sunflower oil	9.0	4.4	2.2
Olive oil	12.4	6.2	2.8

Thus, control of temperature effects on lipid oxidation must be addressed at every stage of production as well as storage.

Water

No discussion of lipid oxidation is complete without discussion of moisture effects. As can be seen in the classical graph of moisture and water activity effects (Figure 5), lipid oxidation has very different reactivity patterns than other degradation reactions in foods. Unlike browning, enzyme reactions, nutrient decomposition, and microbial growth, which can all be stopped by sufficient removal or binding of water, there are no conditions under which lipid oxidation is not active. As would be expected, lipid oxidation is rapid at high moistures and water activity, as are all reactions (D), but surprisingly, lipid oxidation is just as rapid in very dry systems (A). The region of lowest lipid oxidation (B) corresponds to conditions in only a monolayer of water molecules is present on molecules in foods. Moving between regions, water appears to have both pro- and antioxidant effects on lipid oxidation. This biphasic action may be explained as follows:

A Dry systems—high oxidation:
Molecular sites of oxidation are bare, providing ready access of oxygen to lipids.
Metals are unhydrated and reactive.
Hydroperoxides are uncomplexed and decomposed readily.
The food matrix is open and porous, allowing free flow of oxygen

A→B Water binding to molecules provides surface protection—decreasing oxidation:
Water hydrogen bonds to LOOH, retards decomposition.
Water hydrates metals, inhibits electron transfers, and shifts redox potentials.
Water binding to surfaces of the macromolecular matrix retards oxygen diffusion.
Water attaches to potentially reactive sites, excluding oxygen.

B Monolayer value—lowest oxidation:
Conceptual single water molecules on molecular surface protects reactive sites from oxygen and catalysts but is insufficient for mobilization.

B→C Intermediate moisture region—increasing oxidation:
Hydration of molecules increases molecular mobility and reactivity.
Multilayers of water accumulate on molecular surfaces, dissolve catalysts, and increase their diffusion and interaction with lipids.
Metals mobilized and activated.

C→D Fluid water region—high but decreasing oxidation:
Water dilutes metals and other catalysts and reactants.
Emulsion formation separates lipid phases from most catalysts.
High moisture promotes nonenzymatic browning, products are antioxidants.

It is clear from the graph that the moisture content and water activity (a_w) of a product dictate an innate propensity for oxidation of products with unsaturated fatty acids, over and above effects of metals, heat, light,

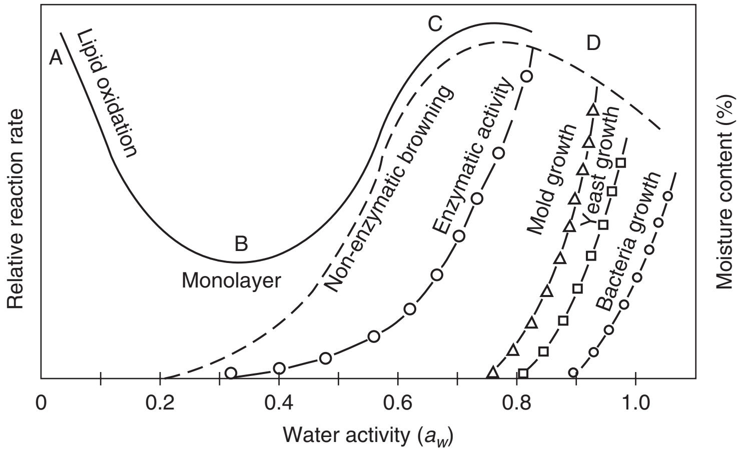


Figure 5. Effects of moisture content and water activity on rates of lipid oxidation in food products. [Modified from Labuza et al. (5). Used with permission.]

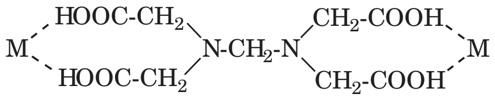
and other factors. While few foods or other products move from one extreme to the other during storage, drying out and moisture absorption to moderate extents are quite common and can occur within relatively short times, leading to rapid changing in lipid oxidation kinetics and products. A dry high-lipid product stabilized at the monolayer a_w can undergo explosive oxidation when it either loses or gains moisture and changes a_w. Similarly, intermediate moisture foods are moderately reactive, but they can be stabilized by losing moisture or have shelf-life severely shortened by gaining moisture and increasing a_w. Thus, moisture content and degree of water binding by system molecules (a_w) must be carefully controlled by formulation and packaging in order to stabilize foods and other materials against lipid oxidation.

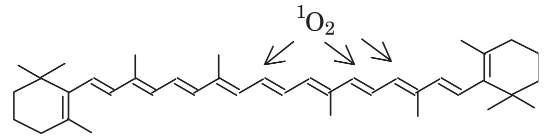
FACTORS AFFECTING LIPID OXIDATION—ANTIOXIDANTS

Type 1. Agents that Prevent Free Radical Production

These are metals chelators (the most important of which is EDTA, ethylenediamine tetraacetic acid, shown below), metal complexers (e.g., citric acid, polyphosphates, and to a lesser extent ascorbic acid), and singlet oxygen scavengers, particularly carotenoids. The conjugated double bonds of carotenoids provide many sites that preferentially react with $^1O_2$ and spare fatty acids.



EDTA



Carotenoids

Initiation inhibitors are commonly overlooked as antioxidants but serve perhaps the most critical role because they control the radical load that must be overcome by free radical scavengers. The radical load is the cumulative total of radicals from all sources that must be quenched to seriously limit progression of lipid oxidation. The radical load determines the type, amount, and reactivity of antioxidant necessary to stabilize a given system. If the radical load is too high, no amount of radical chain stopper—what is usually thought of as antioxidants—can prevent lipid oxidation. At the same time, initiation inhibitors cannot work alone. Some radicals from various sources are always produced, and these must be quenched to prevent establishment of cycling chain reactions. Thus, Type 1 antioxidants are usually combined with Type 2 antioxidants for improved all-round efficiency.

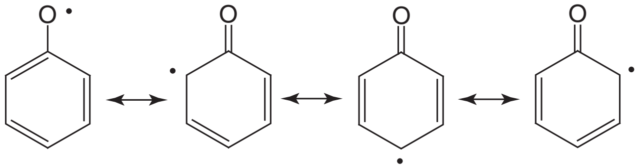
Type 2. Free Radical Chain Stoppers

These are radical quenchers that donate hydrogens to $LOO^\bullet$ or $LO^\bullet$ faster than lipid chains:

$$LOO^\bullet + AH \rightarrow LOOH + A^\bullet \qquad R^\bullet \tag{17a}$$

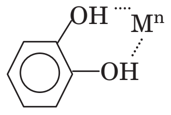
$$LOO^\bullet + AH_2 \rightarrow LOOH + AH^\bullet \rightarrow A + RH \tag{17b}$$

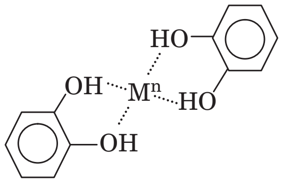
For a compound to be an antioxidant, its radical $A^\bullet$ must be stable and unreactive or yield nonradical products, so it does not propagate radical chains. The dominant antioxidant structures with H-transferring activity are phenolic compounds in which the $A^\bullet$ reactivity is reduced by resonance delocalization of the free electron over the aromatic ring.



The standard synthetic antioxidants BHA, BHT, and propyl gallate are all phenolic compounds, as are natural antioxidant tocopherols, flavonoids in fruits, and many herb and spice components, to mention just a few. Structures of some common phenolic antioxidants are shown in Figure 6.

Some antioxidants have more than one phenolic group per ring. In general, antioxidant activity increases with the number of phenolic groups on a single ring and per molecule in complex structures. Phenols with multiple –OH groups next to each other on the aromatic ring also complex metals, so they have multiple mechanisms for inhibiting lipid oxidation.

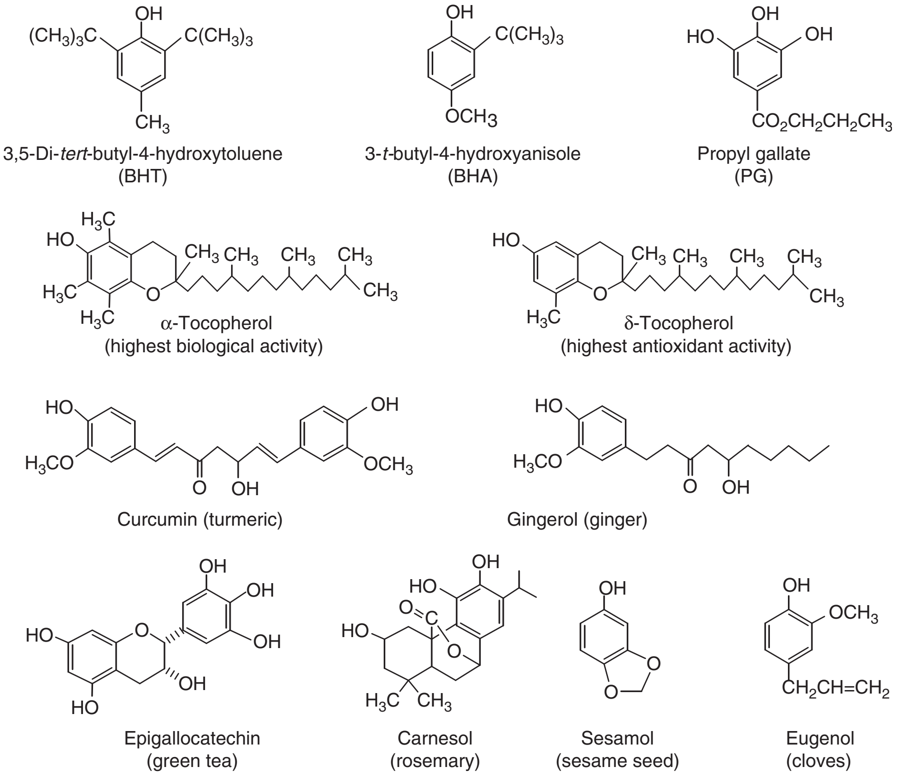




Type 3: Environmental Factors that Limit Oxidation

Environmental factors are not initiators or catalysts of lipid oxidation in themselves, but they provide conditions under which oxidation reactions occur, and thus they play critical roles in controlling the rate and direction of lipid oxidation as well as the resulting product mix during storage. Indeed, if environmental factors are ignored, no amount of primary antioxidant will be sufficient to stabilize a food or other material against lipid oxidation.

Environmental factors that can influence lipid oxidation encompass a wide variety of conditions to which a product is exposed in moving from formulation through processing to storage. Formulation factors include



3,5-Di-*tert*-butyl-4-hydroxytoluene (BHT)

3-*t*-butyl-4-hydroxyanisole (BHA)

Propyl gallate (PG)

α-Tocopherol (highest biological activity)

δ-Tocopherol (highest antioxidant activity)

Curcumin (turmeric)

Gingerol (ginger)

Epigallocatechin (green tea)

Carnesol (rosemary)

Sesamol (sesame seed)

Eugenol (cloves)

Figure 6. Structures of some common antioxidants. The top row shows synthetic antioxidants, whereas the other rows are antioxidants from natural materials.

moisture levels and pro-oxidant enzymes such as lipoxygenase and lipase that require blanching to inactivate. Processing environment factors that are important include everything from potential metal contamination from equipment and processing water to temperature, light, and oxygen exposure during processing. Packaging and storage environments include similar factors: pO_2 inside the package and surrounding it, vacuum versus inert atmosphere versus air headspace, moisture inside the package and migrating into or out of it, temperature and light exposures, and so on. Control of environmental factors to limit or prevent lipid oxidation during storage must be a major focus for packaging of foods.

WHAT ROLE DOES PACKAGING PLAY IN CONTROLLING LIPID OXIDATION?

Successful strategies for stabilizing any product against lipid oxidation start with product components and formulations that first minimize endogenous catalysts, then incorporate chelators, antioxidants, and $^1O_2$ quenchers to deactivate those that cannot be eliminated. Then add processing that protects at every step (e.g., by use of lowest feasible temperatures and light exposure), as well as limitation of oxygen via nitrogen blankets or vacuum. Packaging is the critical finishing step that maintains product quality during storage. Packaging cannot cure deficiencies of formulation and processing, but the storage environment it provides largely determines what reactions occur and how long products are stable during storage.

Packaging barrier properties and delivery modes contribute to control of lipid oxidation at all three stages: initiation, propagation and chain branching, and termination. Different reactions dominate and different factors affect each stage, so it is not likely that a single protective approach will meet the demands of all stages. Here, the concept of radical load must be highlighted. To be successful, any antioxidant or protective function must deal with the total lipid radical load generated from all sources in formulation, processing, and packaging. If the total radical load is extremely high, no single approach can eliminate the oxidation. Thus, two general guidelines should be followed to efficiently limit lipid oxidation:

1. When designing antioxidant strategies, emphasize limitation of initiation. Radicals not generated do not propagate chains or need to be quenched.
2. Use combinations of antioxidant approaches that address action at each stage of lipid oxidation and that act on multiple aspects of lipid oxidation simultaneously.

Table 2 shows the multiple functions that packaging provides to limit lipid oxidation during storage and the various approaches that can be used and combined to achieve them. Limitation of initiation is especially critical for products requiring significantly extended shelf lives, so most emphasis is placed on this stage. The light and oxygen barriers of traditional packaging materials such as glass, tin cans, and some polymers provide an essential primary line of defense against lipid oxidation, preventing or severely limiting levels of $L^\bullet$ and $LOO^\bullet$ produced during

Table 2. Packaging Actions and Approaches for Controlling Initiation, Propagation, and Termination of Lipid Oxidation

Oxidation Stage and Action	Necessary Packaging Action	Control Factor	Packaging Approach	Examples
Initiation				
Oxygen	Provide and maintain inert atmosphere	Oxygen	Remove or replace oxygen	Hermetic packaging with vacuum, deaeration, nitrogen headspace
	Oxygen barrier, prevent LOO$^\bullet$ formation		Impermeable materials	Glass, EVOH, polyamide, PVDC
			Laminants with barrier layers	Metal foils and oxides, hydrocarbon films, whey protein isolates, Starch films, hydroxy-functional hyperbranched polyester films
			Barrier coatings	Hydrocarbon films on PET
			Polymer multilayers w/wo additives	Montmorillonite clay nanoparticles in PET, PVDC/PE
	O_2 scavenger in package or film, remove residual oxygen		Oxygen sorbent sachets, labels, lid liners	Elemental or ferrous iron, cobalt-fatty acid salts in olefin plastics
			Oxygen sorbent packaging	Fe^{2+}, ascorbic acid, glucose-glucose oxidase, Co(II) acetate, PP in food contact layer
Light	Block light access	Light	Light-impermeable materials	Colored glass, cans
			Impermeable laminant layers	Metal laminant layers
	Light filter		Plastics or coatings with UV blockers	Hydroxyaromatic compounds, hindered amines, salicylates
Metals	Remove metals from package contents	Chelators	Controlled release packaging	EDTA, citric acid, amino acids
			Metal-bonding layers	Chitosan, N-carboxymethyl chitosan
Radicals	Deliver radical quenching antioxidants	Antioxidant levels	Controlled release packaging	Tocopherol, sesamol, BHT, BHA, TBHQ
Propagation				
H abstraction	Deliver radical quenching antioxidants over time	Antioxidants	Controlled release packaging	Tocopherol, sesamol, BHT, BHA, TBHQ
LOOH decomposition	Light barrier (UV and visible): prevent decomposition of LOOH → branching	Light	See light in Initiation	

(*Continued*)

Table 2. Continued

Oxidation Stage and Action	Necessary Packaging Action	Control Factor	Packaging Approach	Examples
	Moisture barrier:	Moisture	Impermeable materials	Glass, oriented PP, metallized polyester films
	Prevent dehydration and exposure of reactive sites Slow molecular migration Stabilize LOOH		Laminants with barrier layers	Polyamide layers, zein, starch, soy protein/wheat gluten, Propylene glycol midlayer between PVA sheets
	Limit scission reactions that release volatiles		Impregnated or coated papers	Polyolefins, waxes, starch acetates, acrylic-based latex, Polyvinyl alcohol
	Maintain low oxidation rates		Moisture sorbers	Silica gel, clays, encapsulated polyvinyl alcohol
	Temperature maintenance, prevent LOOH decomposition	Heat	Insulation	Biofoams
Regeneration of $LOO^{\bullet}$	Oxygen barrier, limit $L^{\bullet} \rightarrow LOO^{\bullet}$	Oxygen	See oxygen in Initiation	
Termination				
Radical recombination	Oxygen barrier, limit oxydimer and polymer formation	Oxygen	See oxygen in Initiation	
	Intercept radical reactions	Antioxidant levels	Controlled release packaging	Tocopherol, sesamol, BHT, BHA, TBHQ
$LO^{\bullet}$ scission	Moisture barrier: prevent moisture sorption Limit $LO^{\bullet}$ scission Inhibit generation of volatile off-flavors and odor compounds	Moisture	See moisture in Propagation	
Secondary oxidation reactions	Oxygen barrier, limit oxidation to a few major products	Oxygen	See oxygen in Initiation	

storage. This, in turn, allows fewer oxidation chains to be generated and fewer radicals to be propagated, greatly reducing the amount of antioxidant needed to quench the radicals present. Innovative packaging that can deliver active compounds such as UV absorbers, singlet oxygen scavengers, metal chelators, or phenolic antioxidants supplements traditional packaging and offers new opportunities for creative combinations of approaches that increase overall antioxidant effectiveness.

Barrier properties of packaging also limit progression of lipid oxidation, particularly by excluding light that decomposes hydroperoxides and by controlling moisture loss that destabilizes LOOH; also, moisture gain mobilizes catalysts. Radical propagations are particularly active during this period, so exclusion of oxygen remains very important, and here the advent of oxygen scavenging films and sachets have added exciting new opportunities to remove residual oxygen that remains in packages after processing and fuels oxidation during storage. Caution is warranted, however, when using iron-based oxygen scavengers: Any leaching of molecular or solid iron into the package can catalyze rapid lipid oxidation. New controlled-release packaging is being developed to deliver either volatile antioxidants such as BHT (synthetic) or sesamol (natural) or nonvolatile antioxidants such as mixed tocopherols slowly over time as endogenous antioxidants are consumed. Combining controlled release with high barrier packaging greatly increases the effectiveness of packaging, protecting food quality and significantly extending shelf life.

Although usually overlooked, barrier properties of packaging also play important roles in directing the types of products formed during lipid oxidation. Oxygen and moisture, in particular, favor formation of volatile breakdown products that are responsible for the off-odors and flavors associated with rancidity; these volatile products are immediately noticeable when the package is opened and can lead to consumer rejection. Packaging delivery of radical scavengers in this stage, where antioxidants naturally present in the food or added in the formulation have already been consumed, can have a major impact on limiting secondary oxidations and polymerizations that markedly degrade product flavor and aroma, color, and texture, and nutrition.

Unfortunately, some questionable practices are also developing. Because the off-odors of lipid oxidation are one of the first signs of trouble when a package is opened, and a bad whiff can lead a consumer to dump the product directly, there is currently intense interest in incorporating carbonyl scavengers in packaging to bind and remove volatile odor products of lipid oxidation. However, there are serious legal issues with this practice because FDA regulations prohibit any practices that cover up faulty practices or decomposing foods. Rancid off-odors definitely indicate product deterioration and the possible presence of toxic products. Removing them eliminates consumers' first indicator of trouble and is tantamount to covering up spoiled food. Both short-term and long-term toxicity issues with oxidized lipids remain to be clarified, but all evidence points to the need to avoid ingestion of oxidized lipids through foods, nutraceuticals, or cosmetic lotions.

SUMMARY

Lipid oxidation is indeed a complicated reaction that plays havoc with stability of any product or material containing lipids. The multiple pathways and products can sometimes seem overwhelming and impossible to control. Nevertheless, there is also logic and organization in lipid oxidation that, with careful consideration, make it possible to monitor, understand, and control in a wide range of products.

Packaging alone cannot prevent lipid oxidation, but no product can be stabilized against lipid oxidation without appropriate and effective packaging. By providing barriers against oxygen, light, and moisture, packaging works in concert with endogenous antioxidants to limit the total radical load in foods, cosmetics, and other products so that primary antioxidants can be more effective at lower concentrations; these barriers also provide an environment that greatly slows down radical reaction chains that do become established. New active packaging that delivers radical scavengers, metal chelators, and singlet oxygen quenchers offer unique opportunities for tailoring packaging to individual product compositions and increasing antioxidant effectiveness. Combining barrier and delivery properties of packaging provides flexible options for protecting product quality and significantly extending shelf life.

LIQUID-CRYSTALLINE POLYMERS, THERMOTROPIC

Robert R. Luise
Hytem Consultants, Inc.
Boothwyn, Pennsylvania

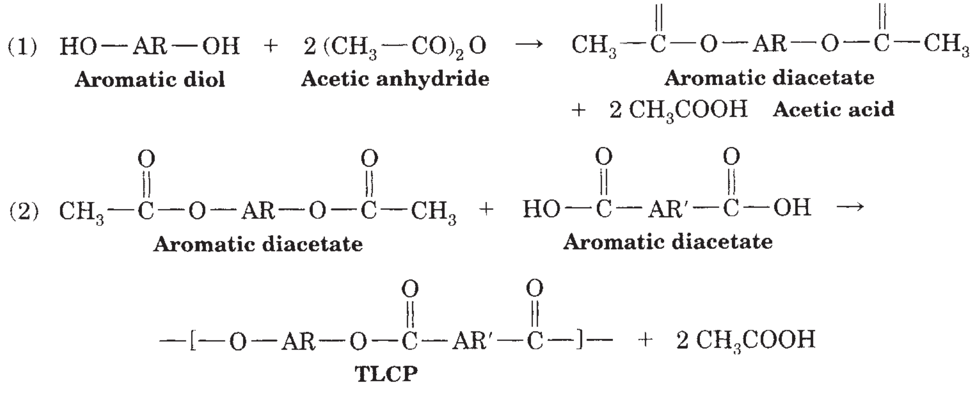
Main-chain thermotropic or melt-processible liquid-crystalline polymers (TLCPs) are a class of high-performance condensation polymers represented mainly by *para*-extended aromatic polyesters (1). Although these polymers were invented in U.S. industrial research laboratories in the 1970s, development was inhibited until the 1980s by high monomer costs and the lack of attractive markets. With the emergence of a market niche in molded electronics packaging and enhanced prospects for lower monomer costs, rapid 20–25% annual growth of the TLCP market currently estimated at 10–15 million lb is projected for the remaining 1990s (2).

TLCP property advantages include high thermal, electrical, and solvent resistance combined with exceptional flow (low-melt viscosity) in the 300°C (572°F) range, precision moldability, and dimensional stability; these features are ideal for injection-molded, close-tolerance applications such as thin-walled electrical connectors that constitute about 90% of the present market. In film form, the dense uniaxial LC morphology affords excellent barrier properties, but development in packaging applications has been inhibited by high resin costs and the need for special technology to prepare balanced film. With lower resin costs and recent progress in balanced and coextruded film technology, most notably using counter-rotating dies (3), medical and food-packaging applications are expected to emerge rapidly. In addition, the unique post-heat-strengthening capability of these materials by solid-phase polymerization of the final part results, for example, in high-strength fibers with the mechanical properties of Kevlar aramid fiber (4).

FUNDAMENTALS

TLCP chemistry is relatively simple and involves reaction of an acetylated aromatic diol with an aromatic dicarboxylic acid, as illustrated in Figure 1. The diol is usually acetylated *in situ* with acetic anhydride at 150–200°C (300–392°F) under nitrogen in the presence of the diacid, and the melt polymerization finished under vacuum at higher temperatures (300°C, or 572°F range) over a period of several hours. Acetic acid is the principal reaction byproduct. Principal monomers used in commerical materials shown in Figure 2 are *para*-oriented, phenyl or naphthyl rings preferred, but a certain amount (≤ 40 mol%) of non-*para* or “soft” comonomers (e.g., isophthalic acid, ethylene glycol) can be tolerated without destroying liquid crystallinity. Other linkages or colinkages are also feasible, e.g., ester–amide, ester–imide, carbonate, and azomethine, but the predominant linkage is ester.

The rodlike character of the extended chain molecules results in a preference for parallel packing in the melt,



$$(1)\quad \underset{\textbf{Aromatic diol}}{\mathrm{HO{-}AR{-}OH}} + \underset{\textbf{Acetic anhydride}}{2\,(\mathrm{CH_3{-}CO})_2\,\mathrm{O}} \rightarrow \underset{\textbf{Aromatic diacetate}}{\mathrm{CH_3{-}\overset{O}{\overset{\|}{C}}{-}O{-}AR{-}O{-}\overset{O}{\overset{\|}{C}}{-}CH_3}} + 2\,\mathrm{CH_3COOH}\ \textbf{Acetic acid}$$

$$(2)\quad \underset{\textbf{Aromatic diacetate}}{\mathrm{CH_3{-}\overset{O}{\overset{\|}{C}}{-}O{-}AR{-}O{-}\overset{O}{\overset{\|}{C}}{-}CH_3}} + \underset{\textbf{Aromatic diacetate}}{\mathrm{HO{-}\overset{O}{\overset{\|}{C}}{-}AR'{-}\overset{O}{\overset{\|}{C}}{-}OH}} \rightarrow$$

$$\underset{\textbf{TLCP}}{\mathrm{{-}[{-}O{-}AR{-}O{-}\overset{O}{\overset{\|}{C}}{-}AR'{-}\overset{O}{\overset{\|}{C}}{-}]{-}}} + 2\,\mathrm{CH_3COOH}$$

driven by entropy, much like "logs in a stream." Packing occurs in the form of optical-size birefringent domains that contain uniaxially oriented polymer chains, which are randomly oriented with respect to one another. At flow conditions, the domains easily orient with respect to each other, which frequently results in anisotropic properties in the final part. This result can be an advantage in some structural materials (e.g., fibers), but a disadvantage in others that require balanced properties (e.g., films). Differences in flow behavior of liquid crystalline and conventional or flexible chain polymers are illustrated in Figure 3. This type of simple uniaxial ordering is referred to as a "nematic" *meso*phase in LC terminology and is predominant for TLCPs. The use of optically active comonomers can also lead to chiral stacking of domains and the "cholesteric" mesophase in the melt (5).

COMMERCIAL SOURCES

Major commercial TLCPs include Vectra (Hoechst-Celanese), Xydar (Amoco), and Zenite (DuPont). All are high-temperature aromatic polyesters with heat-distortion temperatures in the 240–270°C (464–518°F) range and are glass-filled, geared mainly to injection-molded applications in electronics. Vectra is a 73/27 copolymer of *p*-hydroxybenzoic and hydroxynaphthoic acids, Xydar a 50/25/25 copolymer of *p*-hydroxybenzoic acid, 4,4′-biphenol and terephthalic acid (and optionally a small amount of isophthalic acid) developed initially by Carborundum in the 1970s and Zenite, an all-aromatic polyester. Vectran is a high-performance TLCP fiber based on the Vectra composition manufactured by Kuraray in Japan under license from Hoechst-Celanese. Worldwide capacity of these materials is estimated at 15–20 million lb; Hoechst-Celanese/Polyplastics and DuPont have recently announced new plants in Japan and Tennessee, respectively, onstream in 1995. Rodrun, a lower-temperature TLCP based on PET (20–40%) and *p*-hydroxybenzoic acid developed initially by Eastman in the 1970s, is also available in limited quantities from Unitika–Japan.

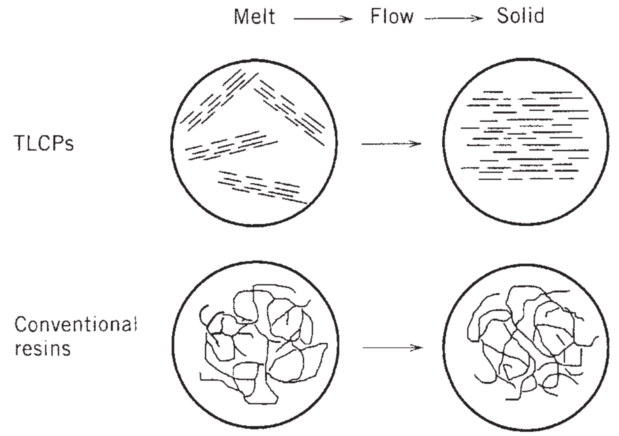

Figure 3. Flow behavior of TLCPs versus conventional resins.

TLCP cost is presently high: \$5–\$11/lb for glass- or mineral-filled molded grades and \$12–\$22/lb for extrusion grades; resin cost, however, is expected to approach the \$3–\$5/lb range over the next several years (2), which results lower prices projected for key monomers such as 2,6-naphthoic acid, also a monomer for PEN and now available from Amoco at \$1.50/lb, and economies-to-scale price reductions expected for *p*-hydroxybenzoic acid (to \$1.00/lb range from \$2.50/lb present) and 4,4′-biphenol (to \$2.00/lb from \$5–\$7/lb).

FILMS

Processing. TLCP ease-of-flow orientation results in unbalanced films with poor lateral properties by conventional film extrusion that are generally not poststretchable. Kuraray has reported reasonably balanced Vectra-type films by conventional film blowing at high shear rates (6), but the best results have been obtained by Superex, which uses a combination of film-blowing and counter-rotating extrusion dies (3). In the latter case the annular die consists of counter-rotating inner and outer mandrels that impart an opposing biaxial or "crisscross" orientation to the respective inner and outer film surfaces. Stretch is controlled by gas blown through the center and attenuation/takeup

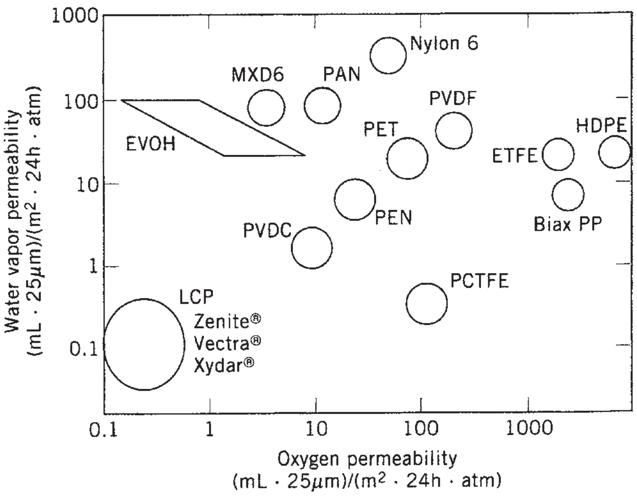

Figure 4. Permeability of selected polymer films. (Courtesy of Superex Polymer, Inc.)

speed. The latter technology, also applicable to tubing, is available from Superex by special licensing. Another approach reported in patents by Nippon Oil involves conventional extrusion of cholesteric TLCP film with improved property balance through the use of chiral (optically active) comonomers that results in a biaxial twist or chirality to the morphology in the film plane (7).

Properties. TLCP films generally possess exellent permeability resistance to gases (e.g., oxygen, water vapor, and carbon dioxide), which is attributed to the highly compact uniaxial morphology. A comparison of permeability of various polymer films in Figure 4 illustrates the unique barrier resistance of TLCPs to both oxygen and water vapor, which far exceeds other packaging resins. Film studies attribute low permeability to low solubility indicative of a highly ordered substrate (8); moderate reductions in oxygen permeability were observed (9) with orientation (45%) and solid-phase polymerization (10–20%). Larger reductions in oxygen permeability (200–300%) have been observed by Kuraray in studies of aliphatic—aromatic TLCPs based on PET and PEN copolymers with HBA and HNA (10), whereby permeability is found to decrease with increasing naphthyl (vs phenyl) content, probably due to decreased solubility. These partially aliphatic materials also were found to be poststretchable biaxially and, in some cases, transparent. Wholly aromatic TLCP films (e.g., Vectra), in contrast, are not poststretchable and are opaque, except in the case of ultra-high-oriented ("monodomain") film prepared from uniaxial layups of TLCP fiber (11).

Applications. A comparison of the general properties of balanced TLCP Vectra film with other high-performance polyester (PET, PEN) and polyimide (Kapton, Upilex) films is shown in Table 1. In contrast to polyimide, TLCP appears to offer similar high-temperature and electrical properties with lower moisture absorption and lower cost, for electrical applications in flexible-film substrates. Compared to polyester, TLCP offers higher thermal, mechanical, and barrier properties for medical and food-packaging applications that require sterilizing, retorting and long shelf life. In the latter case, even at a resin cost of $20/lb, TLCP offers about five times better cost-barrier performance (oxygen, water vapor) vs PET and PEN, assuming resin costs of $1 and $4/lb for the latter polymers (12).

Also noted is the high-use temperature capability of TLCP film [~200°C (~392°F)] despite relatively low glass temperature [110–125°C (230–255°F)], attributed to the crystalline uniaxial morphology. TLCPs with glass temperatures in the 200°C (392°F) range that may have future application in packaging have recently been disclosed (13).

A TLCP drawback has been the lack of availability of balanced film in the marketplace, but this may change very soon. Superex has recently announced a number of consortium activities targeted for the marketplace, which include development of a copper-clad balanced film for electronics multilayer circuit boards and multichip modules (14), and coextruded TLCP and PET film and tubing for electronics, medical, and food applications that require high temperature [205°C (400°F)] resistance (15). The latter features a tie layer, probably of a PET/TLCP blend, to improve heat-sealing and formability. A one million-pound production level is expected by 1997 and cost will be competitive with EVOH and PVDC. A possible application is a shelf-stable, retortable food tray. Superex also has

Table 1. Properties of Balanced Films

announced consortium development of a PET/TLCP alloy with twice the oxygen- and moisture-barrier resistance of PET at 10% TLCP loading (16). Flexible-to-rigid monolayer or coextruded packaging that is both recyclable and reusable should be feasible. Projected price is $3/lb with up to 50% package downgauging possible. A key to the PET alloy technology is the preservation of the TLCP barrier phase using special compatibilizers to control ester interchange. In addition to film packaging, Superex TLCP biaxial tubing is now being manufactured under license by ACT Medical for endoscopic surgical instruments (17). Advantages include five times higher stiffness vs conventional tubes and 50% cost savings over fiber-reinforced composite tubes. Superior electrical properties and broad sterilization capabilities are also exhibited. Superex' biaxial TLCP tubing was a 1995 Award Winner selected by *R&D Magazine* as one of the top 100 technologically significant products of the year.

Neste Oy (18) has also announced development of coextruded LDPE/TLCP barrier film based on a new low-melting TLCP [210–260°C (410–500°F)] with heat-distortion temperature of 148°C (300°F). The blend includes a compatibilizer to improve heat sealing and processibility. Multilayer coextruded and paper-coated constructions with LDPE have been prepared by conventional processing. Special biaxial processing is not required, apparently because films are less anisotropic because of the higher flexibility of the TLCP (perhaps due to aliphatic linkages). Three- and five-layer constructions with LDPE far exceed oxygen-barrier cost performance of similar PET constructions and are competitive with those of EVOH, with the added advantage of recyclability. The LDPE/TLCP materials are intended as EVOH and aluminum-foil replacement, particularly in aseptic packaging.

SUMMARY

TLCPs are a class of high-performance engineering polymers represented mainly by aromatic copolyesters with exceptional processibility and high thermal, electrical, and barrier properties. About 90% of the present TLCP market of 10–15 million lb consists of injection-molded electronics connectors, but rapid development of biaxial film and tubing technology (Superex) and coextruded films and blends with conventional packaging resins (e.g., PET, PEN and LDPE) should expand opportunities near-term to applications in electronics, medical, and food packaging. With resin costs expected to drop to the $3–$5/lb range over the next several years because of reduced monomer costs, rapid 20–25% annual growth is forecast for the remaining 1990s to a 40–50-million-lb market by the year 2000. It is expected that food and medical packaging will constitute a significant share of this market driven by improved thermal stability, longer shelf life, and ease of recycling afforded by TLCPs.

LOGISTICAL/DISTRIBUTION PACKAGING

DIANA TWEDE
School of Packaging, Michigan
State University, East Lansing,
Michigan

The two key drivers of logistics management are the goals of reducing the total cost of logistics activities and improving customer service. It aims to integrate the supply chain to eliminate waste and optimize service.

Logistics Management is defined as "that part of supply chain management that plans, implements, and controls the efficient, effective forward and reverse flow and storage of goods, services and related information between the point of origin and the point of consumption in order to meet customers' requirements…. Logistics management is an integrating function that coordinates and optimizes all logistics activities, as well as integrates logistics activities with other functions" (1).

Logistical packaging is more than just cartons, crates, and corrugated board (2). Also known as *distribution packaging* and *packaging logistics*, it focuses on the "interaction and relationship between the logistical system and the packaging system that add value to the combined, overall, system—the Enterprise" (3).

Packaging affects the cost of every logistical activity and has a significant impact on the productivity of supply chains. Transport and storage costs are directly related to the size and density of packages. Handling cost depends on unit-loading techniques. Inventory control depends on the accuracy of manual or automatic identification systems. Customer service depends on the protection afforded to products as well as the cost to unpack and discard packing materials. And the packaging postponement/speculation decision affects the cost of the entire logistical system. An integrated logistics approach to packaging can yield dramatic savings.

Logistical packaging facilitates product flow during manufacturing and distribution. Logistical packaging includes shipping containers for consumer goods (which are almost always also in consumer packages), industrial packaging for factors of production ranging from automobile parts to food ingredients, and institutional packages. There is also a packaging aspect to vehicle loading and unloading, as well as to intermodal containerization. Every factory and/or logistical operation receives and ships logistical packaging; most operations unpack, reconfigure, and repack products, as well as purchase and dispose of packaging materials.

This article deals with the role of packaging in the logistics systems of supply chains. Readers who seek more general information about logistics and supply chain management are referred to texts in the field (4–8).

LOGISTICAL PACKAGING FORMS

Since the early 1900s, common carriers in the United States have tried to "regulate" the packages they transport. The American Association of Railroads and the American Trucking Association publish packaging material "requirements" in their freight classification books. Most of the requirements were developed with the help of the Fibre Box Association (or its predecessors) and use more corrugated fiberboard material than may be required for adequate performance (2).

The justification for these requirements has been that carriers are responsible for paying in-transit damage claims. One of the carriers' common law liability defenses is "an act of the shipper," including insufficient packaging, and carriers have tried to maintain that only the packages in the "Classification" are "sufficient."

These requirements have traditionally been a barrier to packaging innovation. The existence of the "Cardboard Rules" has caused many firms to make logistical packaging simply a purchasing responsibility, rather than an area for proactive management (9).

The barrier has fallen; however; since transportation was deregulated in 1980, carriers have been able to exercise much less control over logistical packaging. After all, carriers are responsible only for in-transit damage, and there are nonapproved packages that are at least as protective as those in the Classification.

The logistical channel members who buy, own, and sell products have a much bigger stake in preventing damage and controlling other packaging-related costs. The underlying logic of integrated logistics management is the ability to control such systemwide costs.

Furthermore, transportation deregulation has caused less freight to be subject to common carriers' packaging rules since much less freight pricing is governed by the Classification and more contracts are negotiated. More freight today is shipped by full truckload, never handled by the carriers' workers, and is therefore less subject to abuse in transit. Today, the Classification "Cardboard Rules" apply only to less-than-truckload (LTL) common-carrier freight. And even LTL carriers will accept a packaging exception to the rules if it is certified as passing a series of performance tests (10).

This loosening of "rules" has triggered a renaissance in logistical packaging. Shippers are questioning traditional packaging materials and forms and are experimenting with new, less costly packaging systems. For example, some appliance shippers have reduced the cost of their packaging by 50%, by replacing corrugated fiberboard with film-based (shrink- or stretch-wrap) packaging systems. Some furniture manufacturers have reduced their package purchase and disposal costs to almost nothing by utilizing "blanket wrap" (moving van) trucking service. Assembly companies have switched from expendable to reusable packaging. These innovations have also been shown to dramatically reduce damage (11).

Most of the new packaging systems are simple variations of traditional packaging forms, using traditional materials in new and innovative ways. They all have two things in common: They are tailored to perform for specific products and logistical systems, and they minimize packaging purchase and solid-waste disposal costs.

The traditional logistical packaging materials and forms are

- Wood pallets, crates, blocking, and bracing
- Corrugated fiberboard boxes, dividers, inserts, and dunnage
- Solid fiberboard slipsheets and boxes
- Plastic and multiwall paper bags and drums
- Intermediate bulk containers, bulk bags
- Steel cans, pails, drums, and straps
- Steel racks and cages
- Fabric (burlap and woven plastic) bags and blankets
- Plastic film shrink wrap and stretch wrap
- High-density plastic boxes, slipsheets, and pallets
- Blanket-wrapping, decks, and restraints

- Plastic strapping
- Plastic foam cushioning and dunnage for fragile or irregular shapes

Descriptions, properties, and specifications of most of these materials can be found elsewhere in this Encyclopedia.

LOGISTICAL PACKAGING PERFORMANCE

Logistical packaging only adds value because it functions in a logistical system to provide protection, utility, and communication. Performance specification and value analysis, which can be used to guide packaging innovation, employ a functional approach.

The amount of protection that a package must provide depends on the characteristics of the product and conditions in the logistical system. The relationship can be conceptualized as

$$\text{Product characteristics} + \text{logistical hazards} = \text{package protection required}$$

Damage is a symptom of a system out of adjustment, resulting from product problems, handling problems, or packaging problems. Packaging is generally responsible for the product quality that is maintained after the name goes on.

The relevant *product characteristics* are those that can be damaged during distribution. Examples include the propensity of food to deteriorate as a result of temperature, oxygen, or moisture; the tendency for furniture to rub during transit vehicle vibration; and the fragility of products and packages that can break when dropped during material handling operations.

The *hazards of a logistical system* depend on the types of transportation, storage, and handling used. For example, full truckload (TL) transportation generally causes less damage than less-than-truckload (LTL) transportation where packages are handled repeatedly during transloading operations and have many more chances to be dropped or loaded beneath or beside damaging cargo. Railroad shipment often incurs damage as a result of railroad switching and coupling operations.

The hazards of international transportation range from flatbeds to bikecarts. Intermodal containerization for international shipment has reduced impact and moisture damage, compared to “breakbulk” shipping. But even when products are shipped containerized, they will probably be handled in a breakbulk operation inland overseas for which they require adequate packaging performance.

In general, moisture protection and protection from oxidation are obtained by using barrier materials—which keep water and water vapor, oxygen, and other destructive contaminants away from the product, and conserve flavor components in food—or by enclosing desiccant or oxygen-absorbing packets. Shelf life can be lengthened by the use of barrier materials and/or controlling the atmosphere inside food packages. Temperature protection requires insulated containers.

Protection against impacts can be obtained through the use of cushions for shock-sensitive products. Protection to prevent impacts from bursting a package wall requires improving the walls’ tensile strength and puncture resistance. To prevent products from shifting during railroad switching and coupling impacts or as an intermodal container is placed onto or removed from a flatbed railcar, trailer chassis, or ship, loads are blocked and braced to the boxcar or container floor (12–14).

A basic rule for improving protection against impacts, vibration, and compression is to always pack products tightly so there is no headspace, no room to rattle, and a shared reliance on box walls for stacking strength. Vibration or abrasion protection may also require changing package surface or spring–mass characteristics. To improve stacking, compression strength may need to be added to the package walls.

The relative protectiveness of alternative packaging systems can be evaluated and compared in laboratory and field tests. Standardized tests are available from the ASTM International and the International Safe Transit Association (ISTA), which can be used to develop more specialized tests to evaluate specific properties. The best tests target the package’s specific damage characteristics (e.g., bags’ ends burst in side drops) and provide a measure of the difference between alternative packages’ performance (how much energy is required to burst), rather than simple pass/fail tests.

The more liable the product is to damage and the more hazardous the logistical system’s operations, or the higher the cost of damage, the more packaging protection is required. It is important to note, however, that the amount of protection is not directly related to the cost of packaging. In most cases it is possible to improve protection and reduce packaging cost at the same time by simply choosing more appropriate materials and methods. For example, the U.S. Food for Peace program has been able to reduce the number of paper piles in multiwall bags and improve protection by simply changing the bag sealing method.

Accurate measurement of damage can provide the most valuable information for directing attention to problems. But packaging decisions regarding damage prevention are often made without sufficient information. Typical reports of damage problems are unspecific as to the amount, types, and causes. It is difficult to quantify costs for damage, because they are scattered among firms in a logistical system (15). Since carriers are (to the extent of their contract) responsible for the damage they cause, documented in-transit damage claims are the first place to look for damage trends (16). Damage that is caused by wholesalers and retailers is more elusive, and their cooperation is required to report and evaluate losses.

In order to reduce waste, improve customer service, and control packaging costs, some firms have developed systems to track and manage product quality during distribution (17). Such logistics quality-control systems resemble systems for managing product quality during manufacturing and include the following steps:

- Setting standards for critical defects
- Appraising conformance to standards, including

- Monitoring and collecting data (e.g., electronic data interchange)
- Reporting and evaluating data (Pareto analysis)
- Corrective action (modify the package, product, or handling

Once a firm knows about its logistical damage, it can target initiatives where they will do the most good. For example, some furniture companies target specific packages and products for improvement when damage quantity and/or costs are higher than normal (18). Initiatives may include changing the product, changing the logistical hazards, or changing the package. Specific information about damage is particularly useful when developing package tests and performance levels for alternative packages. For example, some food manufacturers have learned that a most common source of damage is box-cutter damage. In response, they have developed easy-open display-ready packages (19).

In many cases, it costs much less to reduce the hazards than to "improve" the packaging. Examples include

- The use of refrigerated transportation and storage to protect fresh produce
- The use of storage racks in warehouses to prevent compression damage
- Good sanitation practices during distribution to reduce the need for packaging to prevent vermin infestation.

In other cases, the lowest-cost solution is to design products to better survive shipment hazards. Product design changes range from reducing fruit bruising through genetic modification, to improving the impact resistance of an electronic product's circuit-board fasteners. An impact-resistant product requires little cushioning, which minimizes cube and trash, and is more reliable in use than a fragile product.

Packaging must also protect people in the logistical system from injury and accidents. Workers' ergonomics and safety problems can be solved through better packaging, especially since there are so many possibilities for injury while working with packages. Routine package handling can be linked to chronic stress injuries, and material-handling accidents can kill people.

Routine manual handling of packages has always been taken for granted, but it is traditionally the source of many back injuries. OSHA guidelines answer the question "How heavy should manually handled packages be?" with an answer that depends on how far and how often the lifting is done. For example, for "continuous high-frequency lifting, variable tasks," such as manual receiving operations, weights below 17 lb are acceptable and represent nominal risk, weights between 17 and 50 lb are acceptable only with administrative or engineering controls, and packages weighing over 50 lb are unacceptable (20).

Accidents happen. Personal-injury lawsuits involving packaging materials and methods are increasing. The liability judgment generally depends on whether the accident could have been foreseen and whether adequate packaging and training procedures were followed. For example, when a long-shoreperson is injured by a bag that slips from a stack, the fabric is accused of not complying to standards, the unit-loading technique is examined (maybe it should have been stretch-wrapped), and the port practices are questioned. It is especially important for firms to evaluate packages that are involved in previous accidents, in order to prevent future occurrences.

The packaging function of utility relates to how packaging affects the productivity and efficiency of logistical operations. All logistical operations are affected by packaging utility—from truckloading and warehouse-picking productivity, to transportation and storage cube utilization, to customer productivity and packaging waste reduction.

Productivity is the ratio of real output to real input:

$$\text{Productivity} = \frac{\text{number of packages output}}{\text{logistics input}}$$

Logistical productivity is the ratio of the output of a logistical activity (like loading a truck) to the input (like labor and forklift time required). Most logistical productivity studies center around making the input, particularly labor, work harder.

But packaging unitization and size reduction initiatives easily increase the output of logistical activities. Almost all logistical activity outputs are described in terms of number of packages. Some examples include number of cartons loaded per hour into a trailer, number of packages picked per hour at a distribution center, and number of packages that fit into a cubic foot (ft^3; "cube utilization") of vehicle or warehouse space (21). Testing alternative packages for their logistical efficiency is a simple matter of productivity measurement.

For example, palletization and/or unitization improves the productivity of most handling operations. Warehouse-order-picking productivity can be improved by making packages easy to find and recognize, by packing items in order picking quantities (e.g., dozens), and by making it easy to repack the heterogeneous order.

Cube utilization can be improved by reducing package size. Package size can be reduced by concentrating products (e.g., orange juice and fabric softener) or by eliminating space inside packages by shipping items unassembled, nested, and with minimal dunnage. In most cases, the amount of dunnage materials (e.g., expanded polystyrene loose-fill) can be minimized simply by reducing box size. Experts believe that improving cube utilization is packaging's greatest opportunity and predict that, in general, packaging cube can be reduced by 50%, doubling transportation efficiency.

Cube minimization is most important for lightweight products (like assembled furniture) that "cube out" a transport vehicle far below its weight limit. Trailer sizes vary; most in the United States are 53 ft long, with inside dimensions of 52.5 ft × 99 in. × 98 in. (high cube trailers are 108 in. tall); and cargo weight limits are generally about 40,000 to 44,000 lbs depending on the weight of the vehicle itself. On the other hand, heavy products (e.g., liquid in glass bottles) “weigh out” a transport vehicle before it is filled. Weight can be reduced by changing the product or the package. For example, substituting plastic bottles for glass significantly increases the number of bottles transported in a trailer.

Packaging utility also depends on the compatibility of packages with pallets and other material-handling equipment used in a logistical system. Pallet-load efficiency can be improved by designing shipping containers to better fit the footprint: Most grocery pallets in the United States are 48” × 40”; most in Europe are 1200 mm × 800 mm. There are efforts underway to implement a compromise standard of 1200 mm × 1000 mm. In some logistical systems, especially internationally, pallets are not used, and packages may need the ability to be efficiently manually handled (or by the longshoreperson’s hook) repeatedly.

Packaging can also add utility for logistical customers. The cost of unpacking is seldom considered by the firm that packs products. But easy-opening features improve retailer’s direct product profitability by reducing customers’ costs of opening and displaying or installing products.

Packaging disposal is also borne by logistical customers. Besides the environmental impact, logistical packaging trash disposal costs money and can severely reduce a customer’s productivity, particularly in nations such as Canada and Germany, which have enacted legislation to reduce packaging waste.

Packaging solutions to disposal problems include reducing, reusing, and recycling. Reduction of packaging also saves on packaging purchase costs. Packaging reuse generally adds some costs for sorting and return transportation. Recycling is growing in more widespread use and gaining popularity, thus reducing costs and increasing markets.

Recycling is a good disposal method for most logistical packaging waste, since logistical packaging waste naturally collects in large heterogeneous piles. Manufacturers, warehouses, and retailers discard large amounts of pallets, corrugated fiberboard, polyethylene film, plastic foam, and strapping. Recyclers appreciate such concentrated and relatively clean sources (compared to sorting and cleaning curb-side and food-service wastes). Likewise, purchasing packages made from recycled material encourages the growth of a recycled products market and infrastructure. Recycling is sometimes called “reverse logistics” (22).

One of the most popular trends is the use of more *reusable/returnable packaging* for products such as assembly parts, food ingredients, and snack chips, from retail warehouse to store totes and intraplant shipments. Most reusable packages are steel or plastic; some firms reuse corrugated fiberboard boxes and pallet boxes. There are also flexible reusable systems: blanket-wrapping and intermediate bulk containers such as bulk bags.

The growing reusable packaging applications all have one thing in common: a short vertical marketing system. A vertical marketing system (as contrasted to a “free-flow” marketing system) is one in which the primary participants are either corporate ownership, contracts, or administration under the control of one firm (23).

A vertical marketing system is important because of the need to control the movement of returnable containers and the need to share the investment benefits. All partners in a returnable system must cooperate to maximize container use, and an explicit relationship is required for coordination and control. Otherwise, containers are easily lost or misplaced. Alternatively, deposit systems may be necessary in free-flow marketing systems (like groceries), where the channel members are linked only by transactions. Deposit systems have been used for beverage bottles, pallets, and steel drums.

The shipment cycle should be short, in terms of time and space, in order to minimize the investment in the container “fleet” and to minimize return transportation costs. The size of the investment depends on the number of days in the cycle.

Deciding to invest in a returnable-packaging system is a very different task from purchasing “expendable” containers. The decision involves considering explicit relevant costs—purchase cost, including number of packages in the cycle, and transport cost—versus the purchase and disposal cost of expendables. Intangible benefits such as improved factory housekeeping, improved ergonomics, and decreased damage are often considered. Generally, there are a number of unexpected costs, including sorting, tracking, and cleaning. Most financial analysis of returnable systems has been limited to “payback period” justification rather than net present value calculations, which would demonstrate the strategic and profit potential of a returnable-packaging system investment.

The efficiency of the logistics system that returns containers or pallets to use determines the cost as well as the environmental sustainability (24). Most logistical systems for reusable packaging use a shared pool system, rather than a strict one-for-one return. These can be owned by the supply chain, rented from third parties or traded in a free market (such as the market for used wooden pallets) (25).

The function of communication is becoming more important for logistical packaging, as logistical management information systems become more comprehensive. For all practical purposes, the package symbolizes the product throughout logistical channels. Correct identification of stock-keeping units (including name, brand, size, color), counting, special shipping instructions (e.g., “Hazardous”), and address are critical to quality logistical information management. International shipments require the language of origin, destination, and intermediate stops, as well as international markings for handling instructions.

For example, automatic identification (e.g., bar coding or radio-frequency identification) highlights the communication function and can interface with information systems throughout a logistical system if the symbology is standardized (see Radio Frequency Identification (RFID)). But even manually readable packaging must be clearly legible to interface with logistical management information systems; workers must be able to quickly recognize a package from its label. Almost every logistical activity—entails reading the package and recording or changing its status in an information system—inventory control, shipping and receiving, order picking, sorting, and tracking. Automatic identification technologies such as bar coding and radio-frequency identification enable a systems approach to managing logistical information where every input is standardized and errors are reduced.

The functions of packaging—protection, utility, and communication—are the basis for packaging performance specifications. Performance specifications outline what the package must do (e.g., be able to survive an impact). The specification of performance guides packaging changes that add value and reduce costs.

Many firms and government agencies have adopted packaging performance specifications for logistical packaging. For example, the U.S. Department of Transportation (DOT) has replaced hazardous-material packaging specifications with "Performance Standards" that do not specify material, but do specify tests (e.g., impact, permeability, or compatibility tests) for specific product/package/hazard conditions.

Performance specifications encourage innovation, and innovation results in lower packaging costs. Material specifications are necessary, of course, for routine packaging purchases, but adding a performance specification offers two benefits: (1) a firm that examines its current and expected levels of packaging performance will always uncover opportunities to cut packaging-related costs; and (2) suppliers who are invited to compete on a performance basis will always suggest lower-cost packaging solutions.

TYPICAL LOGISTICAL PACKAGING PROBLEMS

There are three types of logistical packaging problem: engineering problems, cost problems, and logistical problems with packaging solutions. Generally, logistical packaging problems require on-site investigations—the best way to find out more is to go and look.

Packaging professionals use engineering principles of material science to develop new packages and solve protection and productivity problems. The most common material properties that can be scientifically determined are cushioning (for fragile products), impact and vibration resistance of filled packages (26), shelf life and permeability for oxygen- or moisture-sensitive food products (27), and compression strength for hard-to-stack products (28). Packaging professionals also use some industrial engineering principles to configure packing operations and choose packaging machinery.

Management of logistical packaging, however, involves more than "package engineering." Most packaging problem solving is not associated with developing new packages for new products. In fact, most "new" logistical packages are simply variations of packages used for similar products and require very little "engineering."

The second principal activity of a packaging professional is to reduce the cost of purchasing packaging materials and the cost of packing operations. The most common areas for cost reduction are reducing package weight or size, material substitution, size reduction, automation of manual tasks, and standardization. Innovative incremental packaging solutions, which reduce cost and improve performance, abound in the packaging supply industry. Manufacturers of packaging materials and equipment are sources of a great amount of free, if potentially biased, consulting advice, so it is wise to consult more than one. Other good references include trade journals such as *Packaging*, *Materials Handling Engineering*, *Modern Materials Handling*, and *Transportation and Distribution*.

The third type of packaging problem consists of logistical problems and opportunities with packaging solutions. Packaging can reduce the cost of every logistical activity: transport, storage, handling, and inventory control, and it can improve customer service. It can reduce the cost of damage, safety, and packaging disposal. Integrated management of packaging and logistics is required, if a firm is to realize such opportunities (29–32).

When packaging and logistics are integrated, it is reasonable to consider where and when packaging operations fit into a logistical channel. Packaging postponement can dramatically reduce the cost of an entire logistical system.

The logistical concepts of postponement and speculation can be profitably applied to packaging logistics. These question where and when to add value (time, place, and form utility) in distribution channels in order to reduce costs or improve customer service. The principle of speculation says that manufacturing and shipping should occur at the earliest possible time in the marketing flow in order to achieve economies of scale. The opposite principle of time and form postponement reduces risk by requiring that changes in form and identity and inventory location occur at the latest possible point in the marketing flow, since every differentiation that makes a product more suitable for a specified segment of the market makes it less suitable for other segments. The traditional inventory tradeoff is to reduce risk by postponement (just-in-time logistics) or to reduce cost with economies of scale (forward buying) (33).

Traditionally, the packaging point for bulk products has been postponed or speculated, on the basis of product and market conditions. For example, produce is canned in the fall and stored in "bright" cans; labeling is postponed until food-marketing companies buy and brand it throughout the year. Labeling postponement minimizes the risk of inventory misforecasts and economizes on canning production during a busy season. On the other hand, processing and packaging of frozen fruit concentrates, such as orange or grapefruit juice, is an example of speculation, resulting in low costs because weight is eliminated before shipping and homogenous waste at the orchard is processed for animal food.

Postponement and speculation also apply to assembly and packaging of more sophisticated products in a global market with global sources. When products are similar, but differentiated for local markets, assembly and packaging postponement offers opportunities for customizing packaging for the local markets while minimizing long-distance transport costs and the amount of differentiated inventory in the pipeline.

For example, one of the largest cost-savings initiatives in packaging history (tens of millions of dollars per year) is a case of international packaging postponement. To reduce high transport and inventory management costs, a major electronics manufacturer has postponed the packaging for products shipped overseas. The products are shipped in "bulk packs," palletized and stretch-wrapped, with minimal interleaving between layers. Once there, products are packaged to order. Transport costs have been cut in half, since differentiation and cushioning are postponed until they are required (34).

INNOVATIVE LOGISTICAL PACKAGING

This article has approached the field of logistical packaging from a nontraditional perspective. The reason for this approach is to encourage innovative packaging solutions to logistical problems. Most traditional packaging forms date from the early 1900s and are the most costly packaging systems available. Innovation represents a dramatic potential for savings.

Packaging innovation is a process of problem identification, finding and testing potential solutions, deciding which action to take, and following through to implementation. It requires proactive management by a project champion—usually a packaging professional. It also requires a systems and team approach, since packaging affects so many other functional areas such as marketing, operations, plant and product engineering, logistics, accounting, and finance.

Identification of packaging-related problems is the first step. Problems of cost, protection, utility, and communication may be identified by customers, salespeople, logistical managers, or packaging professionals. The search for packaging solutions may be formal or informal, but the innovation process requires a potential solution before it can proceed. Sometimes problems languish for years before someone thinks of a good solution. Ideas for potential solutions can come from suppliers or consultants or from the advice of colleagues. Alternative packages are judged, subjectively or in lab tests, for their protection, utility, and communication performance, as well as systemwide cost implications. Next, the "best" solution packages are tested in the field (test shipments) and for market acceptance. The early rollout is a period of fine-tuning. Problems with the new package are discovered and corrected. Sustained implementation returns to a new level of business as usual—generally with substantial cost savings.

CONCLUSION

This chapter has shown that, beyond its purchase cost, packaging affects the cost of every logistical activity. Package size affects transportation cost; unitization methods affect order picking and handling costs; identification techniques affect inventory control; and customer service depends on damage control and the cost to unpack and discard packaging. Firms that manage packaging from an integrated logistical perspective, rather than from a traditional purchasing perspective, will find many opportunities for improving their profitability.

MACHINE DIRECTION ORIENTATION

D. Ryan Breese
Eclipse Film Technologies,
Hamilton, Ohio
Eric Hatfield
Vice President, MDO
Engineering, Cincinnati, Ohio

INTRODUCTION

In the MDO process, a polymer film, tube, or sheet is uniaxially stretched in the machine direction. MDO is also commonly seen as the first of two steps associated with biaxially orienting films, with the second step being the tentering, which stretches the film in the transverse direction.

Machine direction orientation (MDO) of polymer films provides improvements in stiffness, strength, optics, and barrier and has been commercially practiced for decades. MDO is being utilized to produce films for a wide range of applications and marketplaces, including food, medical, and industrial packaging. Due to the strong economic drivers, companies are utilizing MDO films at an ever-increasing rate (1, 2). The improvement in mechanical properties allows for the downgauging of a current film, which is the most common use of MDO films. In addition, MDO films can be used to replace a less desirable substrate, such as one that is more costly, is more difficult to source, is less receptive to ink, has a lower yield (MSI/lb), and/or is less environmentally friendly. Also, through the use of various polymers and film extrusion technologies, MDO can be used to produce a single film that has a desired combination of properties that were otherwise only attainable through a more costly secondary process, such as laminations or coatings.

STEPS OF THE MACHINE DIRECTION ORIENTATION PROCESS

There are four main steps to the MDO process, as shown in Figure 1 (3).

Figure 2 is a photograph of a commercial scale MDO unit and its respective unwinder.

Preheat (PH). The function of the preheat section is to uniformly heat the film to the desired orientation temperature. This must be done without generating wrinkles or damaging the surface of the film.

Drawing (SD, Slow Draw; FD, Fast Draw). After preheating, the film is oriented between the slow and fast draw rolls. In this stage, the fast draw roll is rotating at a specified ratio faster than the slow draw roll. The gap between these rolls can be adjustable to process a wide variety of films. Typically, the film can be oriented to as high of a ratio as 10:1 in a single draw section. Higher ratios are possible, but depend on the equipment's design, polymer selection, and film structure.

Annealing (A). The third section of an MDO consists of the annealing rolls. This section thermally stabilizes the film's properties, such as the percentage of shrink. For example, annealing the film at an elevated temperature allows it to relax, minimizing the

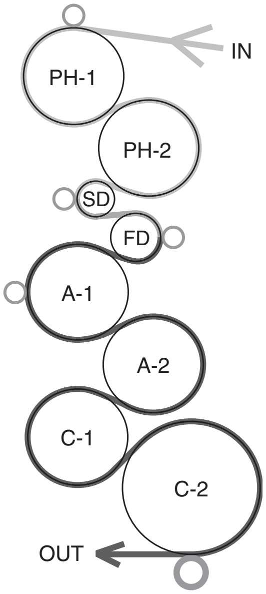

Figure 1. Schematic of an MDO. The equipment consists of preheat (PH), slow and fast draw (SD, FD), and annealing (A) and cooling (C) rolls. Nip rolls are shown on PH-1, SD, FD, A-1, and C-2.

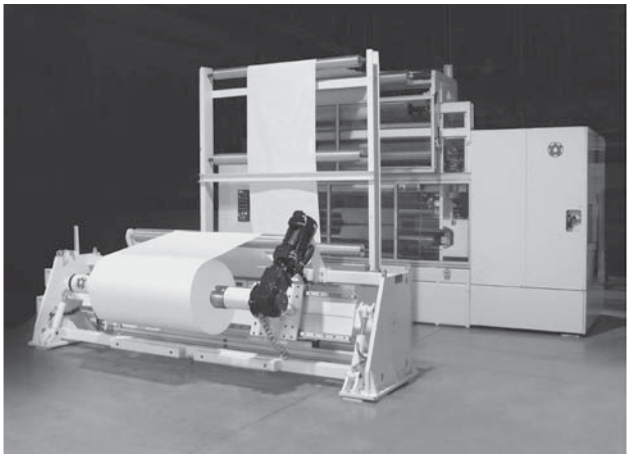

Figure 2. Photograph of a commercial scale MDO unit and its respective unwinder.

percent shrinkage when the film is exposed to elevated temperatures, as is the case with the pouch or bag forming process. Conversely, immediately cooling the film in the annealing section hinders the relaxation of the film. The residual stress in the film causes it to shrink when exposed to elevated temperatures. This characteristic is desirable in several applications, such as shrink wrap bundling and shrink bottle labels.

Cooling (C). The cooling section is the last stage in the MDO, where the film is cooled to near-ambient temperature for winding.

DESIGN OF THE COMPONENTS OF A MDO LINE

The MDO production line consists of the following components (3):

- Unwinder
- MDO unit
- Auxiliary equipment, such as treaters, profile gauges, and trim collection systems
- Rewinder

Unwinder

An unwinder is used if the MDO is not in-line with film extrusion, such as a blown or cast film unit. Often, the unwinder is very simple; however, more elaborate units can be utilized that make the process of changing rolls easier and improve the economics of the process by decreasing roll change over time. The following items must be considered when choosing an unwinder:

- Changing rolls needs to be done safely and efficiently.
- The unwinder should be able to handle rolls of the same dimensions as the rewinder.
- Tension control needs to be incorporated into the unwinder operations to minimize wrinkles as the film enters the MDO.

MDO Unit

While the basic sections of the MDO have already been discussed, some general comments about each section must be made.

Preheat Section of the MDO. In the preheat section, accommodations for the relaxation of the film must be included in the design of the MDO. If the film is heated too fast, wrinkles can form, causing inconsistent operating conditions from uneven heating of the film, resulting in unacceptable film quality and/or breaks. If the film is heated too slowly, the necessary orientation temperature will not be reached, resulting in uneven stretching and possible breaks.

Draw Section of the MDO. Orientation in the drawing section must be conducted in a controlled fashion, with uniform temperatures across the film. In addition, the rate at which the film is drawn is critical for establishing stable operating conditions. Process parameters, such as orientation temperature, draw ratio, incoming line speed, and draw gap distance are all critical for establishing a stable processing window. Often, it is desirable to orient the film to its maximum draw ratio prior to breaking. To do so, the preheating temperatures are typically set as high as possible without melting the film to the roll and the rate of draw optimized to reduce the risk of film breaking. Adverse effects of operating at such conditions include the risk of melting the film to the rolls, which can result in extensive cleaning, and increasing the amount of neck-in. Large neck-in, which is indicative of a slow rate of draw, results in heavier edge beads that must be trimmed. Operating in such fashion increases the amount of scrap and can result in downstream web handling issues, such as wrinkles and poor roll winding uniformity. In most cases, the draw rolls are smaller in diameter, relative to the other rolls in the MDO, to minimize the tangential distance between the release point off the slow draw roll and the inlet point on the fast draw roll. This design is critical for minimizing the amount of neck-in. In addition, with some polymers such as high-density polyethylene, draw resonance or “tiger striping” can be caused by too low of a rate of draw. This results in unacceptable film that has thick and thin strips in the transverse direction. Setting the draw gap too narrow can result in rates of draw that are above those the film can withstand, resulting in undesired web breaks.

Annealing Section of the MDO. The annealing section is one of the most important stages within the MDO for controlling film properties. In this section, the film is stabilized at a specific temperature to provide a film with a desired balance of properties. Inadequate annealing can result in films with higher shrink values at a given temperature, lower gloss, and higher haze values. Such issues can be detrimental to many secondary processes, such as pouch making, where the film will shrink once heated, resulting in an unacceptable seal. Annealing also reduces the amount of shrinkage on the roll after it has been wound. Insufficient annealing can result in excessive tensions within the roll, often causing poor roll profile and edges, blocking, and even crushed cores. Typically, if the film is not designed for a shrink application, it needs to be annealed to minimize the previously mentioned issues. Annealing is generally done near the orientation temperatures. The equipment must be properly designed to allow for adequate time to properly anneal the film prior to the cooling section, and it is typically done with several large-diameter rolls.

Cooling Section of the MDO. The function of the cooling section is to uniformly cool the oriented film to near-ambient temperature. It is important to note that the film is shrinking as it is cooled, so great care must be taken to ensure that wrinkles do not form in this section. This is done by setting the temperature profile and individual roll speeds in the cooling section to allow the film to relax in a controlled fashion. Typically, the cooling section consists of either a few large-diameter rolls or several smaller-diameter rolls closely placed together.

Auxiliary Equipment

Most MDO lines have a method of treating to increase the surface energy of the film. Such treatment is often necessary for secondary process, such as printing and laminations. Corona treatment is the most commonly used technique, but alternatives such as atmospheric plasma treatment can also be utilized.

A profile gauge at the outlet of the MDO is a useful tool for measuring the true draw ratio of the film, as well as determining the appropriate location on the width of the film to take edge trim.

Trim collection systems are also necessary in the MDO process. The simplest technique is to utilize a small trim winder. While these units can be economical and easy to use, they do require periodically changing rolls during production and may not be the most reliable solution. More elaborate blower systems can be utilized to collect the trim at the slitting station and pneumatically transfer it to gaylords, bailers, or compactors. While blowing the trim is a continuous process, it is more expensive to purchase, install, and operate, is not as portable, and may require more maintenance than winders. In addition, blowing trim into gaylords results in inefficient scrap management and higher transportation costs.

Rewinder

Selecting a high-quality, versatile rewinder is critical to the production of high-quality MDO films. With the wide range of physical properties attainable through MDO, a robust rewinder is absolutely necessary. Inherent issues with MDO film, including post-orientation shrinkage, heavy edges, and warmer film temperatures, may make it necessary to wind the film using low tensions as it comes off the MDO line. Doing so will allow it to shrink on the core after it has been oriented and minimize quality issues.

IMPROVEMENT IN FILM PROPERTIES

MDO greatly improves the mechanical properties of polymer films (4–8). Table 1 shows the typical relationships between the changes in film properties as they relate to increasing draw ratio.

The modulus of the polymer film can increase significantly with increasing draw ratio (4–6), and in some cases by 10 times in the machine direction and nearly twice in the transverse direction (4, 5). Similar magnitudes of change were seen in the machine direction break strength (4).

Table 1. Relationship Between Changes in MDO Polymer Films Relative to Increasing Draw Ratio

Property	Change
Modulus	Increases
Tensile strength	Increases
Barrier (water, oxygen, grease)	Increases
Gloss	Increases
Haze	Decreases
Machine direction tear strength	Decreases
Transverse direction tear strength	Increases
Dart drop	Decreases

Barrier properties also improve significantly: The water vapor transmission rates were reduced by nearly 70% for MDO HDPE (6), and oxygen transmission rates were decreased by over 40% in LLDPE/tie/EVOH/tie/LLDPE coextruded films (7). In addition, the MDO film had 70% better oxygen barrier at high relative humidity (90% RH) when compared to the undrawn film (7). For bimodal HMW-PE films, the oxygen and moisture transmission rates go through a maximum, relative to increasing draw ratio, prior to decreasing significantly at higher draw ratios (8). More complicated MDO films rival the oxygen and moisture barrier properties of less desirable coatings and laminations containing PVdC and metalized films (2). These examples demonstrate how MDO can be used not only to provide high barrier but also to tune the barrier properties of polymer films.

Optical properties improve significantly after orientation. For HDPE, the gloss increased by over 70% while the haze decreased by nearly 60% at a draw ratio of 6:1 (6). For LLDPE/tie/EVOH/tie/LLDPE film, the gloss increased by 60% and the haze decreased by over 70% at a draw ratio of 6.5:1 (7).

Typically, machine direction tear and dart drop strengths decrease with increasing draw ratio. Specially formulating film structures can have acceptable tear strengths for a given application, while obtaining several of the previously mentioned benefits from the MDO process (5). Additional work has also shown that through film design, the relationship between dart drop and draw ratio can be reversed, producing films that have increasing dart drop impact strength with increasing draw ratio (1).

ECONOMIC BENEFITS OF USING MDO FILMS

Packaging costs can be significantly reduced, often with an improvement in performance, by utilizing MDO films. Three ways that MDO films can reduce packaging costs are (2):

- Downgauging a current film
- Replacing less desirable films
- Reducing or eliminating additional steps necessary for the production of a flexible packaging

For the first scenario, the improvements in the modulus can allow a converter to downgauge a film used in a

Table 2. Typical Data for a Standard Sealant Film and a Downgauged MDO Sealant Film

Property	Units	Standard Sealant Film	MDO Sealant Film
Gauge	mil	2.0	1.5
Yield	MSI/lb	15.0	19.7
MD modulus	psi	35,000	310,000
MD break strength	psi	4,500	28,000
TD break strength	psi	4,000	2,400
Haze	%	10	9.0
45° Gloss		65	75
Heat seal temperature for 5 lb/in. seal strength	°F	200–250	250

structure, such as a sealant web for a stand-up pouch, without compromising the structural rigidity of the package. Typically, this structure consists of a sealant film laminated to a stiffer reverse-printed film. Pouch makers are limited on downgauging the sealant film by the rigidity requirements necessary for the stand-up feature of the package. Through MDO, the stiffness of the sealant film can be increased, while still maintaining sealing properties, allowing the converter to use a downgauged sealant film without compromising performance. Table 2 shows an example of an MDO sealant film, when compared to a standard sealant film, that, captures a significant yield increase with improvements in mechanical and optical properties.

When comparing the downgauged MDO and generic sealant films, the MDO film provides a 32% increase in yield, a nearly 800% increase in machine direction modulus, an over 500% increase in machine direction break strength, a 40% decrease in transverse direction strength, similar haze, and better gloss. This film forms a seal with strengths of approximately 5 lb at 250°F sealing temperature.

Table 3. Typical Data for Oriented Polyester Film and a MDO Polyolefin Film (2)

Property	Units	0.48 mil PET	MDO Polyolefin Film
Gauge	mil	0.48	0.6
Yield	MSI/lb	42.2	48.6
MD modulus	psi	400,000–600,000	500,500
MD break strength	psi	32,000	60,000
TD break strength	psi	39,000	5,600
MD break strain	%	110	48
TD break strain	%	70	6.7
MD Elmendorf tear	g/mil	30	11.1
TD Elmendorf tear	g/mil	30	54.0
Haze	%	3.6	12

An example for the second scenario would be replacing a polyester film with an MDO polyolefin film. A specific case involves replacing a 0.48-mil PET film with a 0.6-mil polyolefin film (2), as shown in Table 3.

While the gauge of the polyolefin film is 25% heavier, the yield (MSI/lb) is improved by 15%. This is due to the difference in the densities of the two polymers. Additional benefits include a 90% increase in machine direction break strength, an anisotropic tear resulting in better straight-line tear characteristics, the inherent hydrophobic nature of the polyolefin, and a heat-sealable film. Significant shortcomings of the MDO polyolefin film should be acknowledged, and they include the lack of thermal stability at elevated temperatures, higher haze, lower oxygen barrier, and lower transverse direction tensile properties. As a result, some applications can utilize the MDO polyolefin film and capture the yield benefit, while others may be limited by the shortcomings of the MDO polyolefin film.

High-barrier films for sealant webs or lamination replacements are a third application where MDO films can be utilized to significantly reduce packaging costs (2). These films would be utilized to reduce costs in pouch applications where the inherent properties of MDO films, such as increased modulus, barrier, strength and gloss, add value to the finished package and lower package costs by reducing the need for secondary processes. The following example of a sealable high-barrier MDO film combines excellent moisture and oxygen barrier, good heat sealability, high stiffness, high gloss, and low haze (Table 4).

The film's tensile properties are significantly higher than those of laminated polyester structures. In addition, the high-gloss surface is similar to, if not better than, other lamination-grade printed films and provides excellent aesthetics to the package.

This film has oxygen and moisture barrier properties similar to those of many coated and metalized films (9–11), as shown in Figure 3.

Table 4. Properties of a Sealable High-Barrier MDO Film for the Replacement of Laminated Barrier Structures in Flexible Packaging (2)

Property	Units	Sealable High-Barrier MDO Film
Gauge	mils	2.6
MD modulus	psi	230,000
TD modulus	psi	170,000
MD break strength	psi	13,400
TD break strength	psi	3,100
MD break strain	%	57
TD break strain	%	1,440
MD elmendorf tear	g	190
TD elmendorf tear	g	250
OTR	cc/100 in.^{2}/day	0.091
WVTR	g/100 in.^{2}/day	0.314
45° Gloss (print side)		90.1
Transparency	%	93.9
Haze	%	10.5
Heat seal temperature for 10-lb/in. seal strength	°F	250

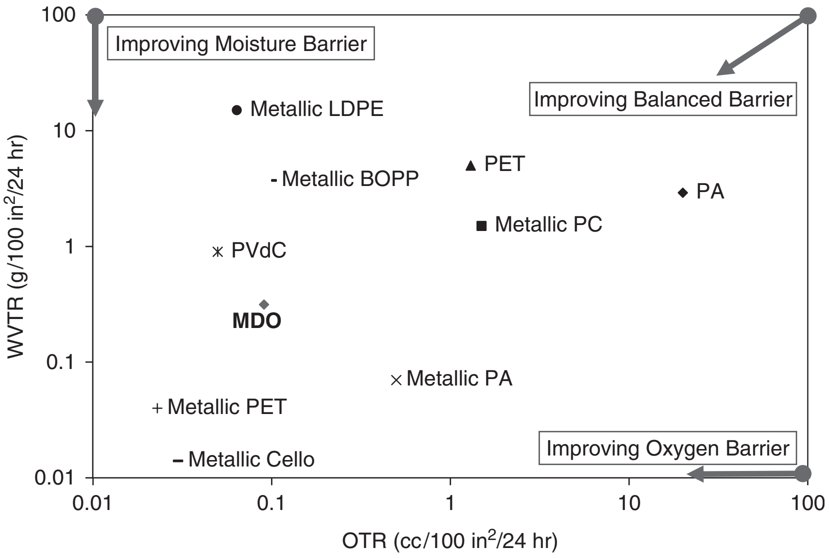

Figure 3. Water and oxygen transmission rates for various polymer films. Data for all films other than the MDO film from references (9–11). Data for the MDO film taken from reference (2).

CONCLUSION

Machine direction orientation (MDO) of polymer films provides significant improvements in both the cost and performance of flexible packaging. Significant increases in stiffness, strength, optics, and barrier are easily attained through MDO. Each section of the MDO unit is critical for the production of high-quality film, with each requiring careful consideration during the equipment design process. Utilizing MDO films can reduce packaging costs through downgauging, replacing less desirable films, and/or reducing the need for more costly secondary processes in the manufacturing of flexible packaging.

GLOSSARY OF TERMS

Blocking Blocking occurs when two layers of film adhere to each other. This is typically seen when a roll is wound with too high of tension and cannot be easily unwound. Winding with lower tensions and/or the addition of an anti-blocking agent to the polymer film can minimize the effects of blocking.

Crushed Core Crushing a core refers to the event where the paper cores that are used to wind the rolls are crushed by the film that is being wound around them. This can occur if the film is wound with too high of tension and/or the film shrinks after it has been wound on the core. Crushed cores make it difficult to unwind rolls in secondary processes.

Dart Drop The impact strength of the film, as measured by a moving weighted dart.

Draw Gap The draw gap is the distance between the slow draw and fast draw rolls. The draw gap can be given either in terms of a radial or tangential distance between the two rolls.

Draw Ratio (DR) The ratio at which the film is being oriented. Draw ratio is also the ratio of the film thickness before and after the orientation process.

Draw Resonance Draw resonance, also known as tiger striping, is the presence of thick and thin streaks in the transverse direction of the film. It is a property inherent to the type of polymer being oriented.

Edge Bead An edge bead is the thick portion of film located at the edges of the roll. Typically, the edge bead is removed by cutting a small piece of film off the edge, known as trim, prior to winding.

Gloss The amount of light reflected from the surface of the film at a specified angle. Gloss is the shininess of the film.

Haze The percentage of light that is not transmitted through the film. Haze is the lack of film transparency.

MDO Machine direction orientation.

Neck-in The amount the width of the film changes after orientation. The neck-in is calculated by subtracting the width of the film after orientation from the width of the film prior to orientation.

Nip Rolls The nip rolls are typically rubber covered rolls that are used to pin the film to the surface of the heated/cooled roll. Nip rolls are critical for proper tension control throughout the process.

Orientation Temperature The orientation temperature refers to the temperature to which the film has been heated by the preheating rolls prior to the orientation stage.

Profile The profile refers to the thickness of the film in the transverse direction.

Rate of Draw The rate of draw is the rate at which the film is being oriented. It is also referred to as the acceleration in the gap. The rate of draw is calculated by dividing the difference between the fast draw and slow draw speeds by the tangential distanced of the drawing gap.

$$\text{Rate of draw} = \frac{(\text{Fast draw speed} - \text{Slow draw speed})}{\text{Tangential gap distance}}$$

Roll Profile Roll profile refers to the uniformity of the roll in the transverse direction of the film.

Trim A small piece of film cut from the edge prior to the winding of the roll to remove the edge bead.

Yield Yield refers to the surface area, typically given in thousand square inches (MSI) of one pound of film (lb).

MANAGING THE PACKAGING FUNCTION

Al Corning
A Corning Consulting, Inc.,
Lombard, Illinois

Ongoing disagreements and/or confusion exists as to where in the organization packaging best "fits" and, even worse, a general lack of understanding on the part of senior management, and other corporate groups, as to what packaging can or should be doing to best serve that business.

LOCATION IN THE ORGANIZATION

Where is the packaging function best positioned to serve the company? Granted, there is no easy answer to this question. The close relationship with suppliers that are typically desired or required directs one to elect location within the purchasing department as optimum. Especially when one considers the increasing importance of cost control, cost reductions, specification negotiation, and supplier problem resolution—especially quality problems.

Cases exist in which the manufacturing function has a dominant need; and in all cases, packaging must assure good working relationships with production management *and* line personnel.

In essence, there is no one best answer for all, *but* the wrong or inappropriate corporate location of the packaging function ensures hampered performance and limited professional growth or recognition of value.

PACKAGING RESPONSIBILITIES: KNOWN AND UNDERSTOOD

Perhaps the prime responsibility of a packaging manager is to understand clearly all that is *currently* and appropriately expected of the function, and, likewise, to educate upper management, continually, as well as their peers or "customers" in other company functions' as to what the department's capabilities and expected productivity are. The latter is basis staffing, training thereof, budget, and assigned priorities.

The emphasis on *current* expectations is to ensure that the department manager keeps aware of ongoing changes in the company and/or industry that continually impact respective responsibilities and priorities. Those changes must also be quickly communicated to the packaging staff.

STAFFING

One must expect the typical, and likely ongoing, understaffing that exists today has existed for years, and it will likely continue in the future. This understaffing is due partially to failure to communicate to senior management the needs, benefits, and cost-effectiveness possible within the packaging function. "Cost-effectiveness" is a combination of cost reductions and avoiding major costly claims or mistakes that impact other corporate functions. This is concept covered in a later paragraph.

Appropriate staffing is usually a matter of budget restraints and the collective expectations of the packaging department. Clearly delineated project assignments and regular progress reports help emphasize possible understaffing. If certain engineers have more work assigned than they can reasonably handle, then the resultant tardy results and stress will quickly magnify the need for added staffing. One cannot emphasize enough the need for establishing a project priority system as the best measure of "appropriate" staffing. In essence, continuing failure to meet objectives and particularly timelines (schedules) will be a failure of *management*. That could include department managers and their superiors! If added staff is not made available, then a reduction in priority assignments is in order if timelines are to be met.

TRAINING

Because packaging as a whole is both complex and ever changing, ongoing training programs are of paramount importance, which include both technical and nontechnical. Good examples of the latter include total quality, teamwork, the development of leadership thereof, as well as interpersonal relations and communications.

A need always exists for prompt and optimum decisionmaking. Therefore, *everyone* in the department should attend a course in problem analysis and decisionmaking. They last throughout a career!

Finally, department managers are responsible for training their successors; the earlier, the better.

BUDGET

The woes of an inappropriate budget are a great teacher for future budgeting. Properly budgeted departmental costs, as well as cost reductions, are a key to avoiding monthly or quarterly stress through the year. Department managers must take the time to fully understand what is expected of them in the year ahead, both of themselves and all others. This understanding helps establish a budget, which at least *allows* for a good to excellent performance. A constant review is essential through the year as "surprises" come or situations change. The resultant changes in priorities or workload can be deafening (which refers to the screams from those individuals who expect a certain level of performance from the packaging functions).

EDUCATING ASSOCIATES AND SENIOR MANAGEMENT

It can be enlightening to find out how little your peers and/or senior management understand about packaging! The better packaging is understood, the more likely you can expect proper recognition and understanding of *your* problems in day-to-day affairs.

It is clearly worthwhile to prepare a brief, but thorough, description of what you do and for whom. Also, consider the benefits of a meeting in which you can explain in some detail, and others can ask questions to learn, the complexities and potential of the packaging functions *in your company.*

COST REDUCTIONS AND CRISIS AVOIDANCE ($ AND $)

These concepts are two critical aspects of a packaging department, which impact staffing, growth, and respect. Every packaging person in the department should have some cost reduction budget dollars assigned annually, with a total cost reduction budget of 1–3% annually on the basis of the total package material expenditures for that year. Cost reductions affect the corporate "bottom line" and should get attention at the highest levels, especially if a year-end summary is sent out with wide circulation!

Equally important is the avoidance of major packaging crises, especially claims due to unsalable merchandise. These claims can, and have, mushroomed into millions of dollars. Then packaging is in the spotlight negatively! Good packaging specifications and the enforcement thereof, along with participation in vendor screening or selection, are the responsibility of packaging. Many horror stories exist about packaging and product claims that serve to remind us how important the proper package and package quality are to the marketplace.

PROFESSIONAL GROWTH AND ASSOCIATIONS

Packaging managers should assume responsibility for their own and the department's growth professionally speaking. In addition to the training programs previously mentioned, opportunities are present to participate in the local chapter of the Institute of Packaging Professionals (IoPP). Furthermore, it allows you to become a Certified Packaging Professional (CPP) through the IoPP exam. The CPP program has been modified to allow more alternatives to qualify for the CPP certification. This certification is truly a matter of personal pride and industry recognition of your interest in being a professional member.

PROJECT CONTROL

The packaging manager should assume full responsibility for projects assigned to the department and their successful completion on a timely basis. The number of projects accepted and their comparative or assigned priority should be a direct responsibility of the department manager and should be clearly understood in total by the manager and the assigned engineer.

This control is a critical basis for good interrelationships between packaging and other departments, especially new-product development, marketing, and manufacturing. Such activity often calls on the manager's diplomatic skills in explaining current workloads and any new assignments' comparative priority.

SELF-DIRECTED PROJECTS

One major means of helping the staff engineer gain and retain pride in their work is to encourage their self-initiated projects. This encouragement could, if not should, involve up to 10% of their time. It certainly develops a sense of personal pride and professional growth.

This might be a good time to emphasize the benefit of motivation in the individual engineer. A lack of motivation to excel and/or improve is a sure sign that something is awry and needs attention from the department manager. Such lack of motivation can, and usually does, result in less than quality efforts, all the way to sloppy or careless work. The longer it continues unabated, the worse the results become.

GLOBAL OUTLOOK

Today's packaging manager must have a global interest and awareness. Matters such as new products, materials or equipment, and cost impact because of impending worldwide shortages or market glut allow for constructive planning and activity. Whether this knowledge is primarily from trade magazines, meetings or seminars, supplier presentation, or whatever, the point is that there must be sources of global packaging knowledge for packaging department managers. They, in turn, can sort out the likely impact on their company products or industry and keep the management appropriately informed.

PACKAGING SPECIFICATIONS

A first step in developing a worthwhile specification program might be "descriptive" specifications. By definition, these specifications describe the package structure and size. They lack any assurance of quality, or better-controlled quality, from the vendor. This benefit comes only from "performance" specifications that are complete and negotiated with the vendor to ensure that they are realistic. They should be signed off by the supplier and your purchasing department as recognized operating documents. Many historical examples exist in all industries of how performance packaging specifications prevented claims and/or market disasters. Today, with the constant emphasis on quality, it is the bestway to ensure that the package is what was planned, tested, and expected from the package development effort.

CONCLUSION

In summary, the packaging manager has the opportunity to hire motivated engineers and technicians, implement an ongoing training program for their growth on the job, and help ensure optimum department location in the corporate structure that improves effectiveness as well as the company profits. The latter is the result of well-executed cost reductions and claim avoidance, along with carefully prepared performance packaging specifications. Truly, it is a professional effort conducted by a Certified Packaging Professional (CPP).

MARINE ENVIRONMENT AND EXPORT PACKAGING

John P. Colletti
John P. Colletti and Associates,
Pittsburgh, Pennsylvania

PURPOSE AND SCOPE

Before any meaningful discussion can occur about the preparation of goods for export shipment, there must first be an understanding of the terms "preservation", "packaging", and "packing". These three terms constitute a total system that, when properly implemented, serves the following purposes:

- To protect cargo from the elements and the normal rigors encountered in export transportation
- To facilitate handling
- To provide a degree of rigidity to the cargo
- To provide continued protection to the cargo in short- and long-term storage

This article is intended to offer the shipper a ready reference on how to prepare a product for export shipment. The fundamentals of preservation, packaging, and packing, including the selection of materials, are discussed. Proven methods of construction of skids, crates, and boxes are presented. The problems associated with marine transportation and with the use of sea containers are given special attention.

DEFINITIONS

Preservation is the operation by which goods are protected from the elements, i.e., freshwater and salt water, heat, cold, corrosive atmospheres, and humidity. Preservation usually consists of the direct application of a coating specifically designed to protect against a known hazard such as rust. Other types of preservatives are vapor-corrosion inhibitors (VCI) and vapor-phase inhibitors (VPI), which are additives in the form of powder or chemically treated paper that serve to inhibit the formation of water vapor and the rust resulting therefrom. Desiccants are also used as preservatives because they absorb moisture.

Packaging is an operation that consists of wrapping or boxing an item as a preparatory step prior to placing the item into the final shipping container. The nature of an export shipment, i.e., by marine transportation, is such that the cargo is handled many more times than a domestic shipment, and for that reason, greater consideration must be given to known or assumed levels of shock and vibration. The type and extent of packaging depends on these considerations as well as on marketing requirements and segregation requirements. It is usually performed as an intermediate step in the protection of the item from the rigors of transportation.

Packing is the final step in the preparation of goods for shipment. Packing consists of the outer or external shipping container, whether it is a box, crate, or sea container. Cushioning, blocking, bracing, and anchoring are additional protective measures taken within this outer shipping container.

If shippers would view the preparation of their goods for shipment as a system consisting of preservation, packaging, and packing and would conscientiously evaluate their goods for susceptibility to the rigors encountered in marine transportation, their goods would stand a substantially better chance of arriving at the ultimate destination in sound condition.

VCIs and VPIs, when incorporated in waterproof packaging, can add a substantial measure of protection against moisture.

Desiccants are usually moisture-absorbing powders contained in packages such as boxes or cloth bags. When placed in relatively watertight or waterproof voids, these desiccants will absorb excess moisture. They cannot, however, be expected to continue to absorb water or moisture beyond their absorption capability; therefore, the amount of desiccant used must be carefully determined considering the expected temperature and humidity levels and the volume of the spaces that they are to protect.

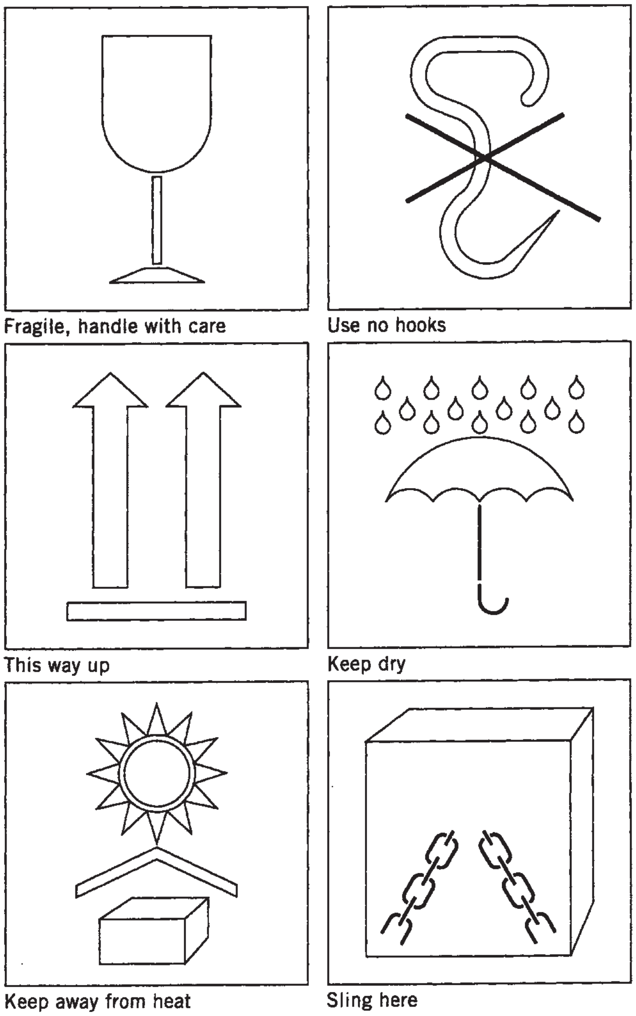
Marks and numbers are extremely important. The outer or external shipping container must clearly show certain critical information essential to the safe handling and expeditious delivery of cargoes to their final destination: The name and full address of the consignee; an identifying number or code relating to the particular item being shipped; full dimensions and gross and net weight in both metric and British systems; and the appropriate international shipping symbols such as "Keep dry," "Fragile," "This side up," and "Lift here" or "Sling here," are all part of the labeling requirements (see also Figure 1).

Unitization is the assembly of cargoes of similar size and configuration into a single bundle, group, platform, or pallet. The purpose of unitization is to reduce cubage, to facilitate handling, and usually to provide a greater degree of rigidity to the unitized cargoes. The bundling of pipe, coiled wire, lumber, and structural steel members are examples of unitization.

Palletization is a special case of unitization and consists of placing one or more similar units of cargo on wooden pallets and securing the cargoes to the pallets usually by means of steel or synthetic fabric tension bands. If required, overwraps may be applied to the palletized units to provide either watershed or waterproof protection. Other common methods of restraining and securing palletized cargoes are shrink wrap and tension wrap (polyethylene or polypropylene films).

The term *protective materials* generally refers to contact preservatives such as paint, grease, and oil or to the watershed or waterproof liners and wraps applied to protect the cargo from the elements. Protective materials can also include cushioning materials and blocking and bracing.

Skids are wooden timbers or alternative materials used either as a base to facilitate handling for heavy cargoes where cargoes possess inherent rigidity; or skids serve alone as a base for cargoes that lack inherent rigidity, protecting them and facilitating handling. Skids are also major structural members in crate construction. It is important to note that if skids are used alone as a base to carry a cargo with or without inherent rigidity, then attention must be given to the type of load (i.e., uniform or concentrated), and the skid must be designed accordingly. In addition, for economic reasons, skids used as structural members in true crates can be significantly smaller in cross section than the skids used as support bases because crate side and top and end panels contribute significantly to the overall strength of the crate.



Fragile, handle with care
Use no hooks
This way up
Keep dry
Keep away from heat
Sling here

Figure 1. International shipping symbols.

A *wood crate* (see Figures 2–7 for examples of open-crate design) is a structural framework of members fastened together to form a rigid enclosure that will protect the contents during shipping and storage. This enclosure is usually of rectangular outline and may or may not be sheathed. A crate differs from a nailed wooden box in that the framework of members in the sides and ends provides the basic strength, whereas a box must rely for its strength solely on the boards of the sides, ends, top, and bottom. The crate framework can be considered to be similar to a type of truss used in bridge construction. It is designed to absorb most of the stresses imposed by handling and stacking.

A *wooden box* is simply a rectangular enclosure that consists of wooden boards or planks nailed along their ends or sides to adjacent boards or planks. Boxes generally do not employ framework such as that used in crates. However, boxes can and should employ *cleats* and *battens*, which are wooden members that act as nailers and stiffeners.

The *wood species* most commonly used in crate construction are divided into four groups largely on the basis of density. In general, it is good practice to use species in the

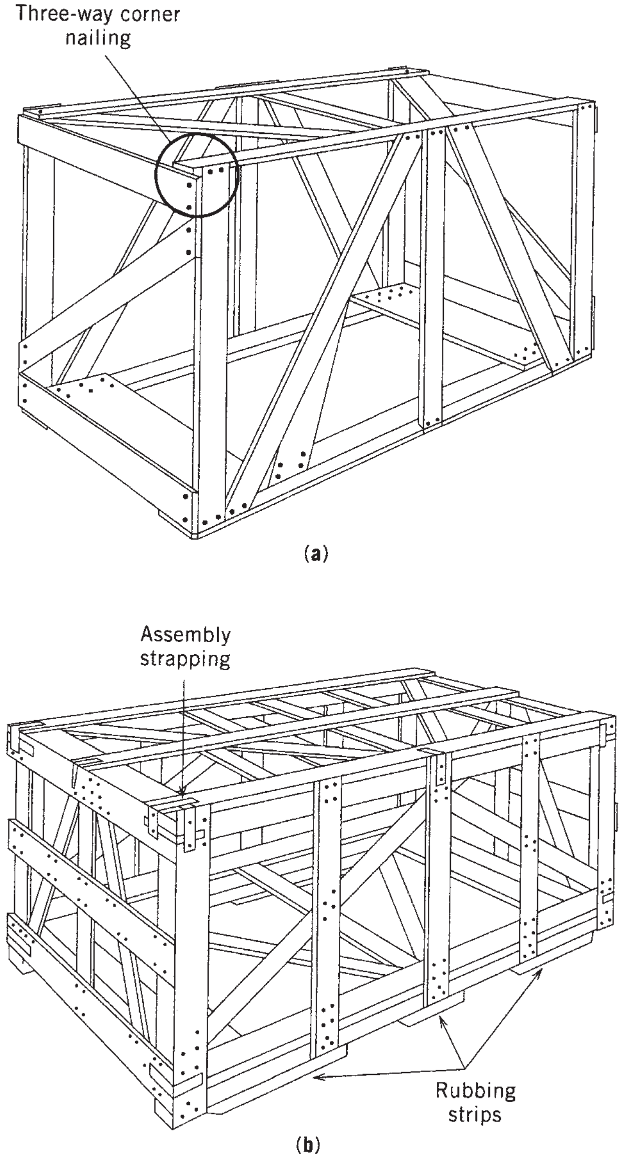


Figure 2. Open-crate designs: (**a**) light-duty open crate (for loads to ≤200 lb) with three-way corner nailing, the key to proper assembly nailing of crates of this type; (**b**) limited military-type open crate (for loads ≤2500 lb) designed for the shipment of light, bulky items that do not require a waterproof container (2).

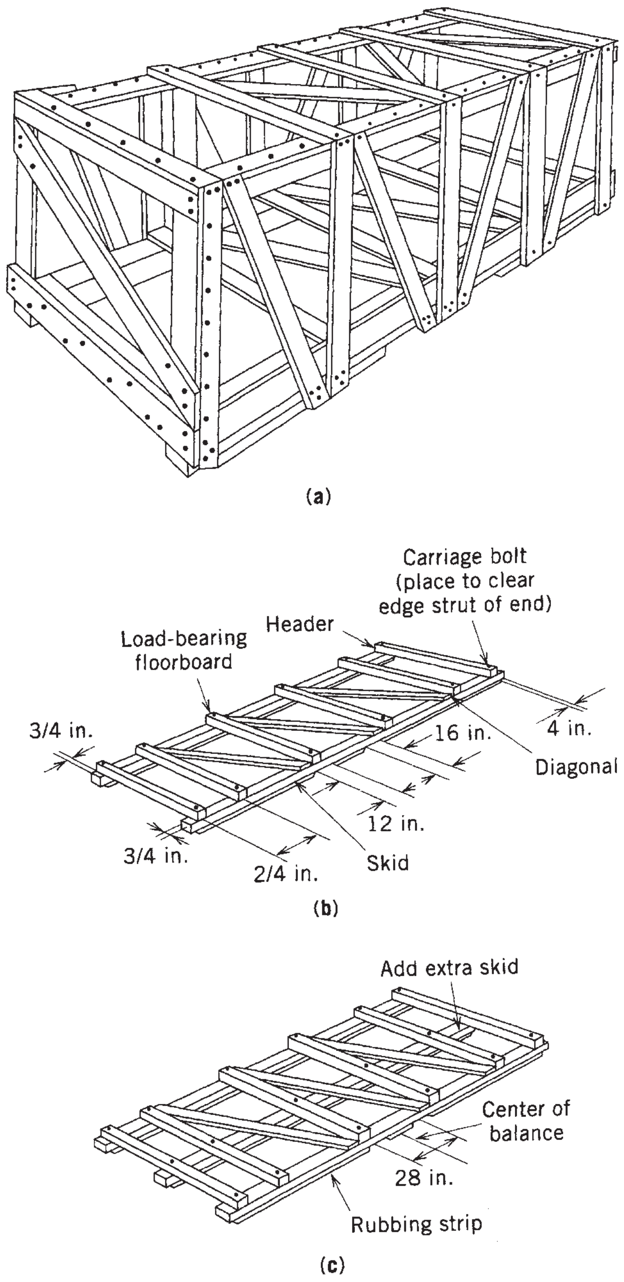

Figure 3. (**a**) Typical open crate; (**b,c**) bases for light-duty open crates [(**b**) ≤42 in. wide; (**c**) >42 in. wide] (2).

same group for similar parts. Group I consists of the softer woods such as pine, spruce, and chestnut. Group II consists of heavier woods such as Douglas fir and Southern yellow pine. Group III woods are generally hard woods of medium density and possess relatively good nail-holding capacity. Examples of these woods are ash, soft elm, and soft maple. Group IV woods are heavy hardwood species, the heaviest and hardest domestic woods. They have the greatest capacity to both resist shock and hold nails. They are difficult to nail and tend to split but are especially useful where high nail-holding capacity is required. Oaks, hickory, birch, and white ash are examples of Group IV wood.

Wood defects should be carefully considered when selecting wood for skid, crate, and box construction. Seasoned wood is preferable to green lumber. Knots and other various defects, such as slope of grain, decay, wane, shakes, checks, splits, and warping, are defects that affect the strength and long-term serviceability of wood. Guidelines for selecting wood with defects are contained in great detail in the USDA *Wood Handbook* (1) and *Wood Crate Design Manual*, Agricultural Handbook No. 252 (2).

Rub strips or runners are lumber strips secured to the underside of skids and skid-based crates to facilitate handling. Rub strips are an essential part of skid assemblies and crates and in box construction for loads in excess of 200 lb.

Tension bands are metal or fabric bands or straps used to secure or bind cargoes to pallets or skid bases or as an

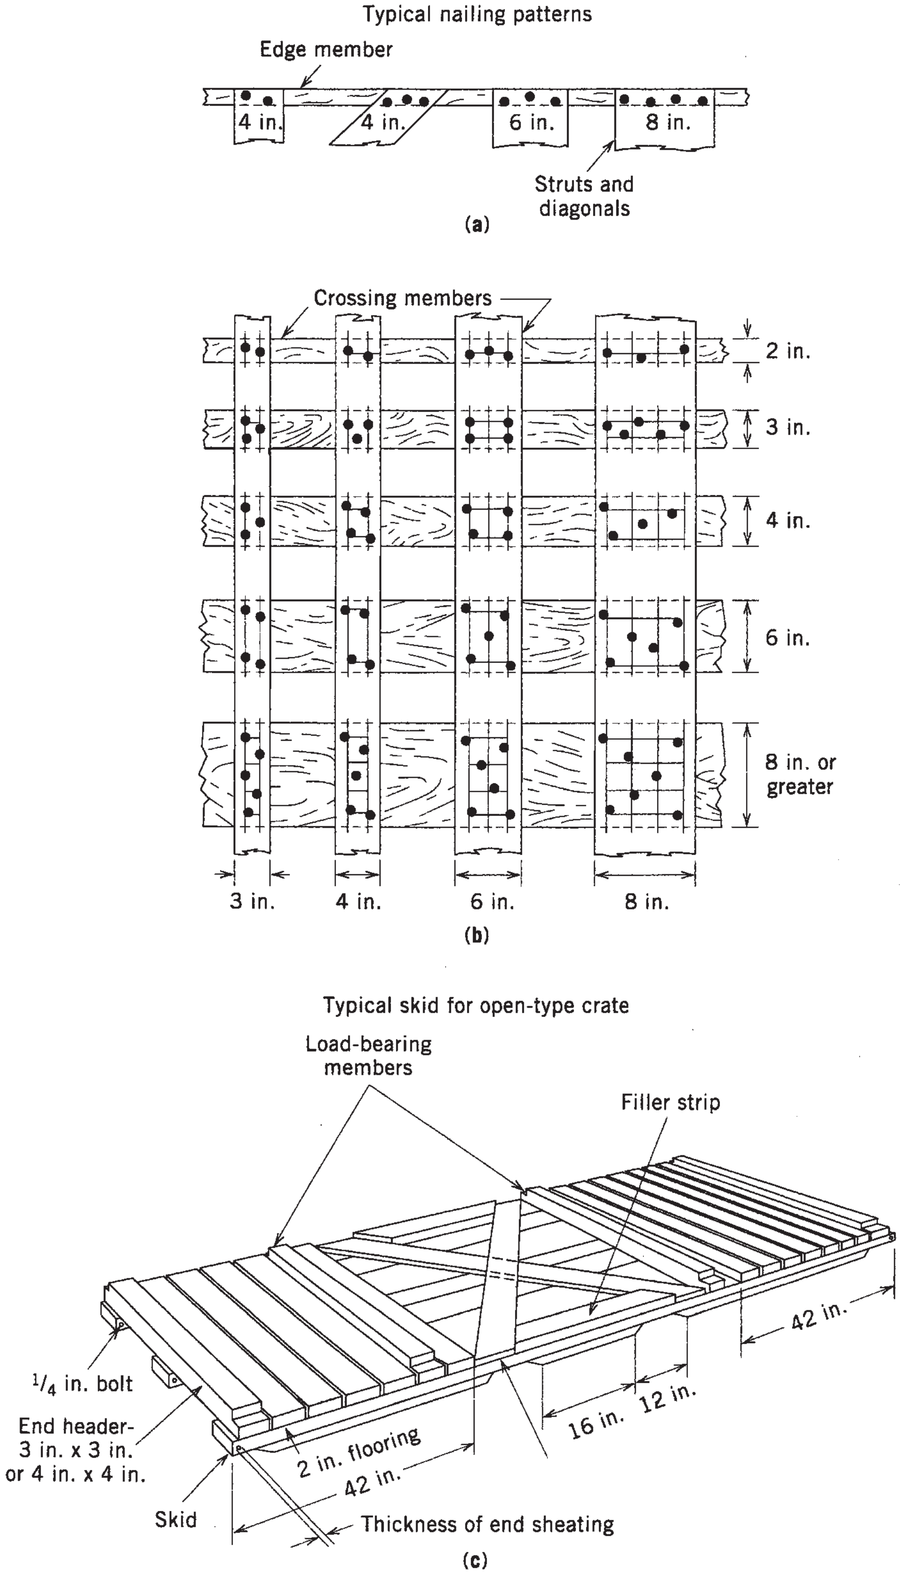

Figure 4. (**a,b**) Typical nailing patterns; (**c**) typical skid for open-type crate (2).

added measure of binding the external members of crates and boxes. Tension bands are manufactured in a variety of dimensions and are applied by means of mechanical or hydraulic tensioning equipment. Tension bands are also an essential part of good packing.

Reinforcing straps (see Figure 8) are mild steel metal bands fitted with nail holes and can be affixed at the corners of crates and at the junction of side-panel vertical members and top-panel horizontal members. Reinforcing straps should be applied in two directions where possible.

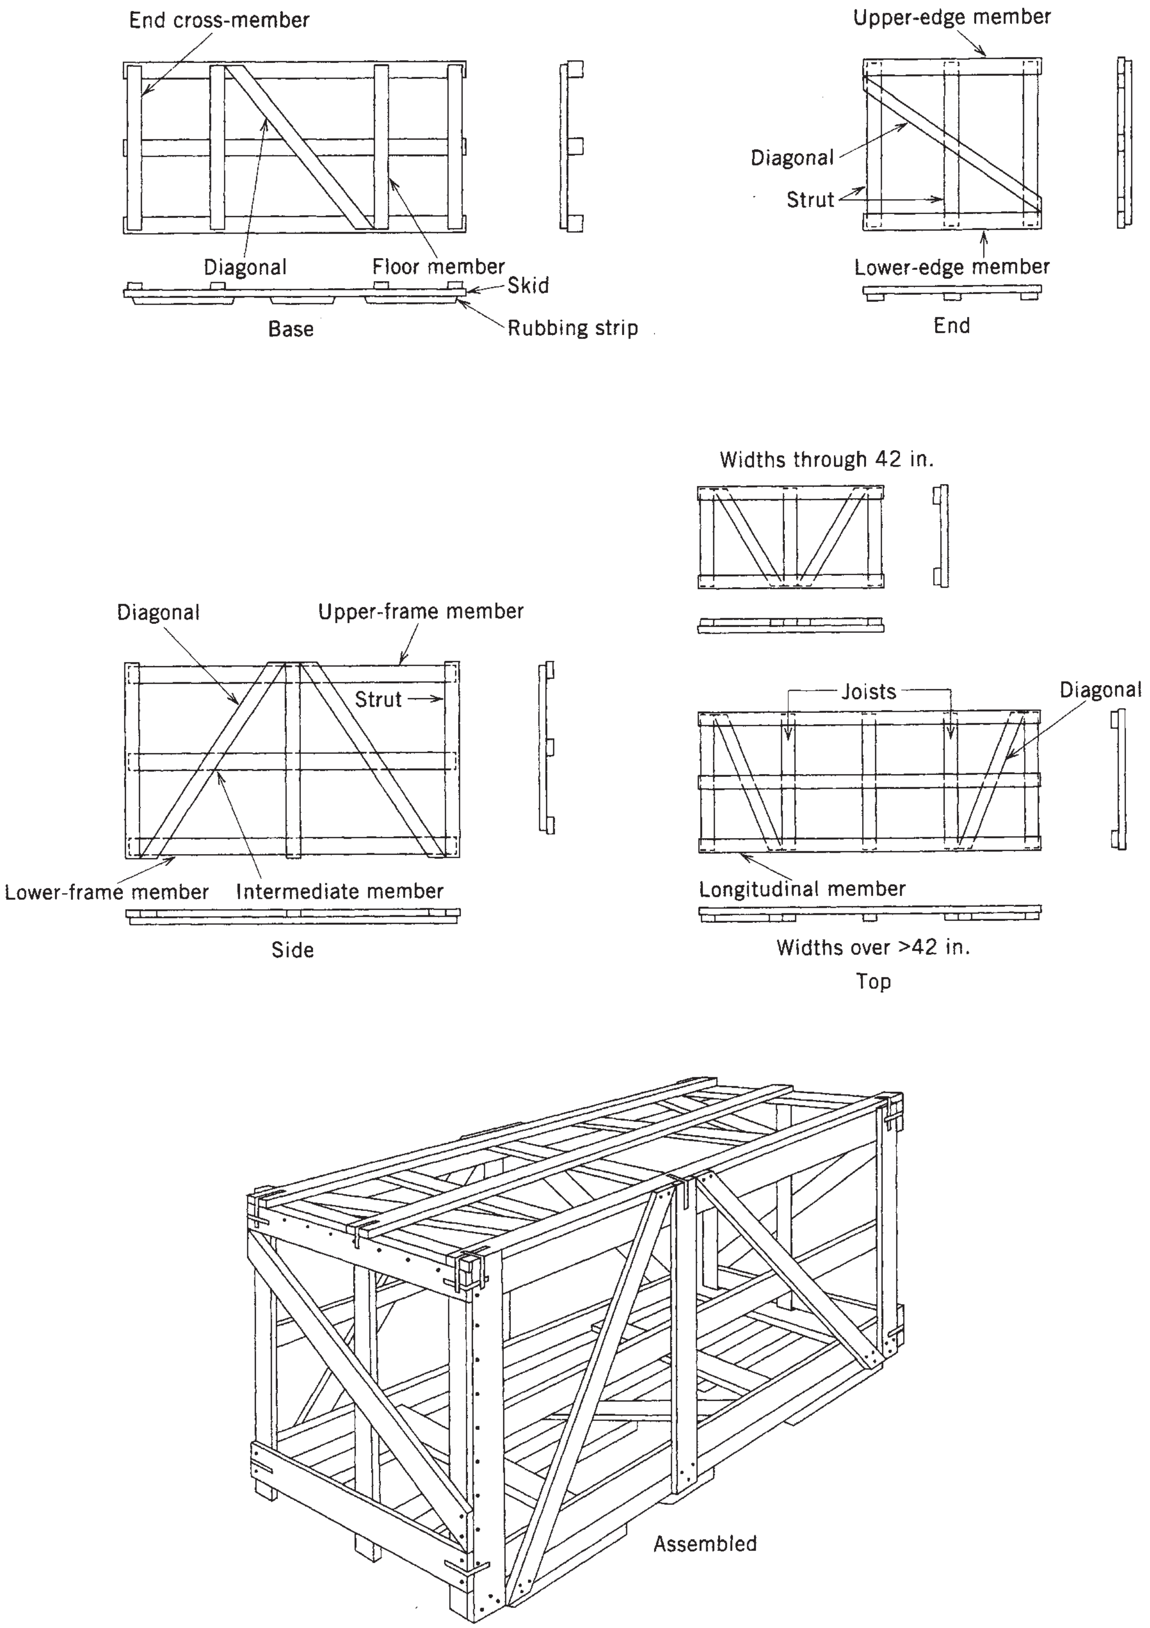

Figure 5. Crate components and final assembly (2).

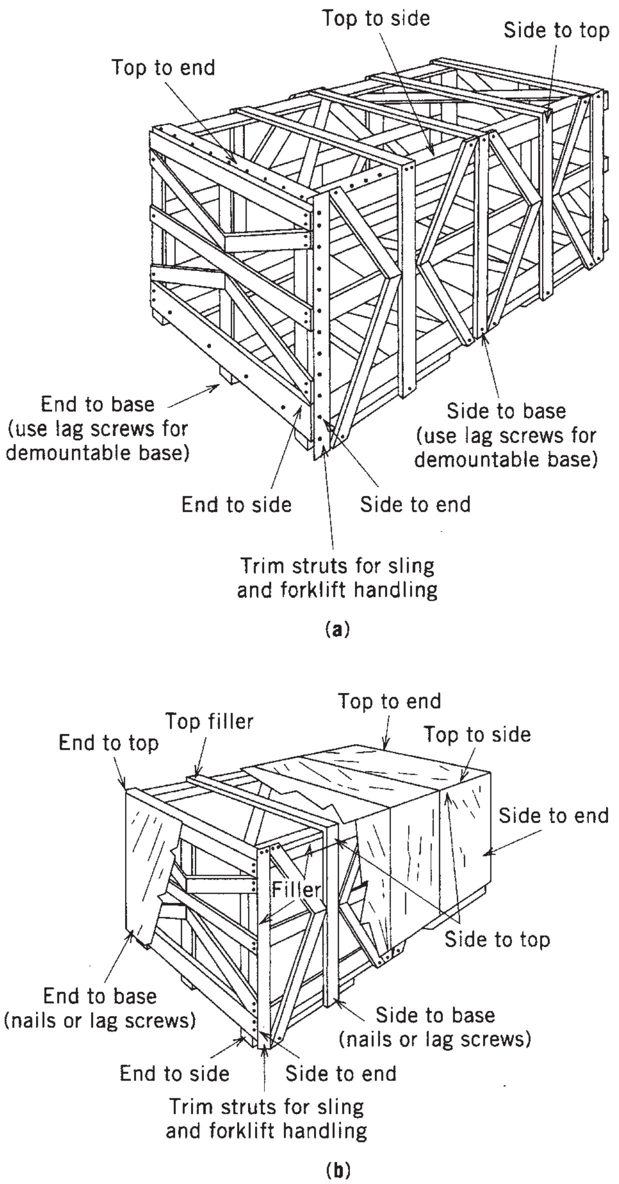

Figure 6. Assembly of (**a**) light-duty open crate; (**b**) covered-style light-duty open crate (2).

These straps serve as an added measure to prevent the separation of joints.

Headers are timbers or alternative materials that are bolted across the end of skid assemblies. Generally, they are to be of at least the same cross section as the skid members they join. Headers are an essential part of skid assemblies in skids acting alone as well as skids serving as part of a crate.

Load-bearing floorboards are wooden members or alternative materials that are fastened transversely across the tops of skid assemblies and carry the load of the item for which the skid assembly is intended.

Splicing refers to the joining, end to end, of two lengths of timbers of similar cross section to make one longer section with approximately the same longitudinal strength as a single continuous piece. The ends to be spliced are to be notched to half the timber thickness, and through-bolts are to be placed vertically through the joining notched sections. Lapped along each side of the splice is to be a $\frac{1}{4}$-in. steel plate of length no less than three times the thickness of the members joined and through-bolted, side to side, with at least two bolts in each half of the splice.

A *uniform load* refers to a load that is distributed more or less evenly over the entire unsupported length of the member on which it rests. As was pointed out above, consideration must be given to the type of load, i.e., uniform or concentrated, when determining the size of members to be used as skids and load-bearing floorboards.

A *concentrated load* is a load that is not distributed evenly over the unsupported length of the member on which it rests. Rather, it is centered over a shorter segment of the member on which its rests, which results in a bending moment higher than that produced by a uniform load of similar magnitude.

Rigidity refers to a strength property of materials that allows them to resist deformation such as longitudinal bending or racking. For example, a 20-in.-diameter pipe with $\frac{1}{2}$ -in. wall thickness and length of 20 ft may be able to be picked up by a sling at its midlength without any noticeable deformation, whereas a 2-in.-diameter pipe with wall thickness of $\frac{3}{16}$in. and length of 20 ft would droop noticeably if lifted with a sling at its midlength. Items with no inherent rigidity, which are intended for export shipment, should be skidded or crated to facilitate handling and prevent damage.

Fragility is a term used to describe the degree of susceptibility to damage from the normal rigors of transportation, i.e., shock and vibration.

The Bending moment, as used within the scope of this article, refers to the product of a load acting over a distance to produce deformation of a structural member that is subjected to the load at some point along its length. The load may be uniform or concentrated as described above. As an example, consider a beam supported only at its extreme ends and subjected to a load at its midlength such that the resultant of the load acting downward and the reaction forces at the extreme ends acting upward is a sagging of the beam. What actually happens here is that the fibers of the beam in contact with the load are in compression, whereas the fibers on the underside of the beam opposite the load are in tension. The bending moments described above can be written in the form of the mathematical expression

$$\mathrm{BM} = \frac{WL}{4}\,(\mathrm{ft} \cdot \mathrm{lb})$$

where BM is the bending moment, W is the applied load, L is the unsupported length of the beam, and the denominator 4 takes into account that W is a concentrated load. Similarly, the mathematical expression for the bending moment resulting from the application of a uniformly distributed load on the same beam

$$\mathrm{BM} = \frac{WL}{4}\,(\mathrm{ft} \cdot \mathrm{lb})$$

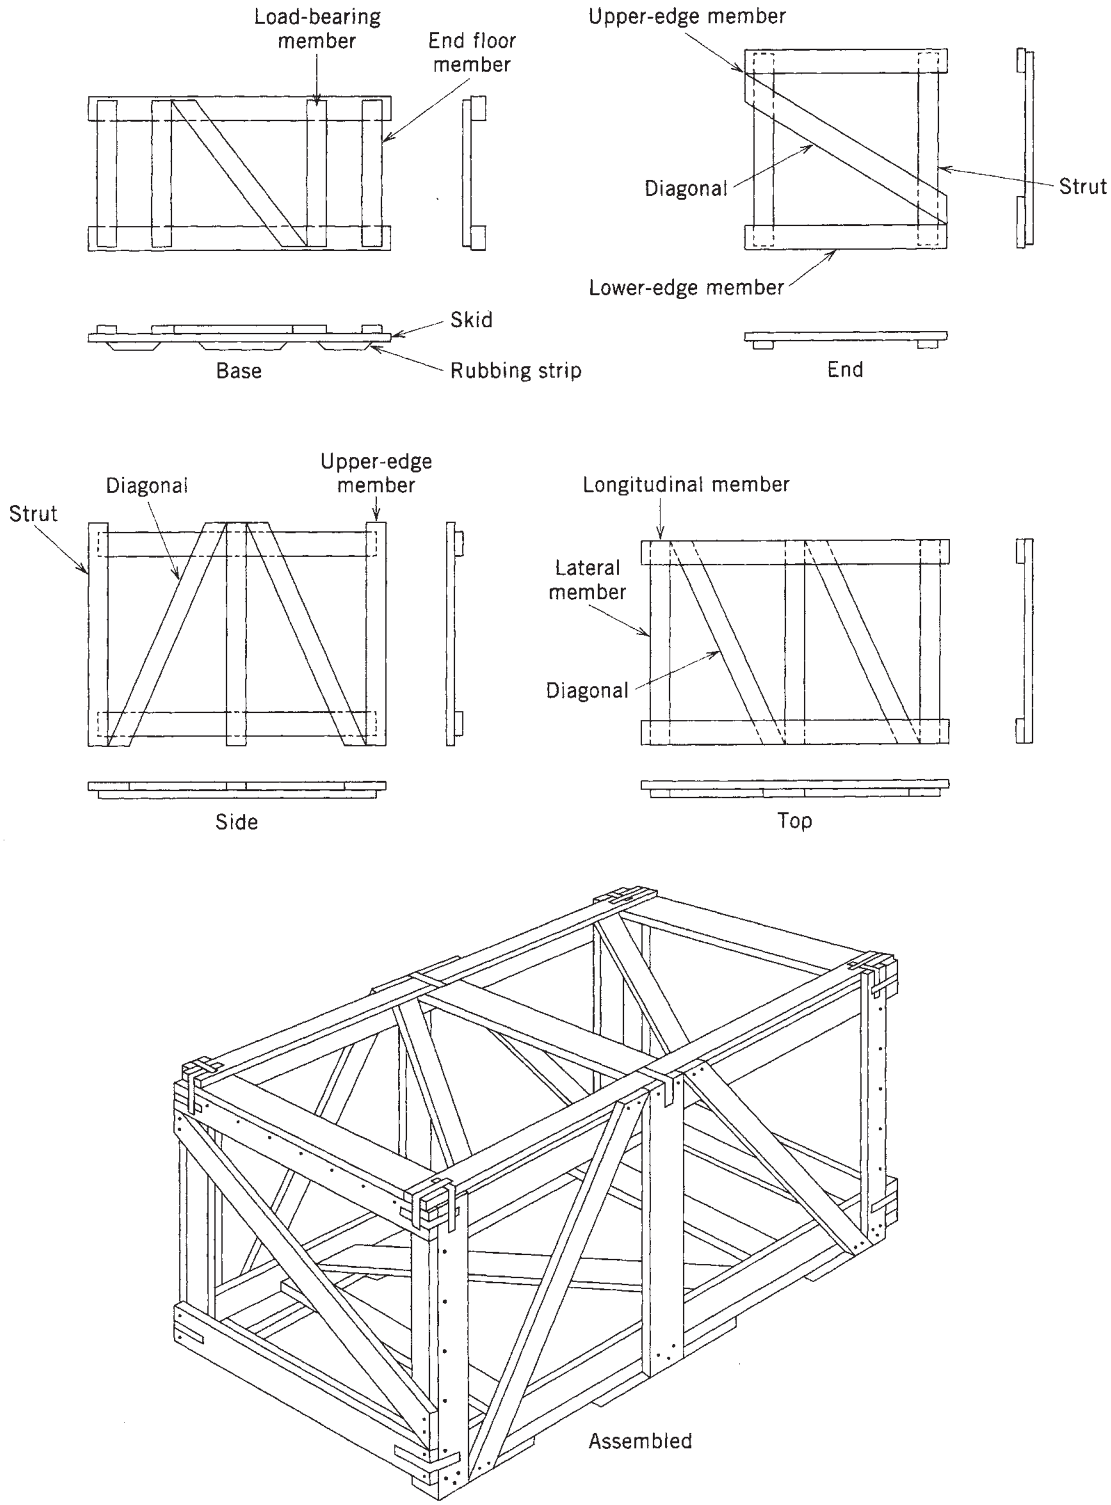

Figure 7. Style A, limited military-type open crate (2).

where the denominator 8 accounts for the fact that W is a uniform load. In some calculations for determining bending moments on beams where the applied loads are neither strictly uniform nor strictly concentrated, it is convenient to use the denominator 6.

Stress is directly related to the bending moment. Mathematically,

$$\text{Stress} = \frac{\text{BM}}{\text{SM}}\,[(\text{in.} \cdot \text{lb})/\text{in.}^3] = \text{lb/in.}^2$$

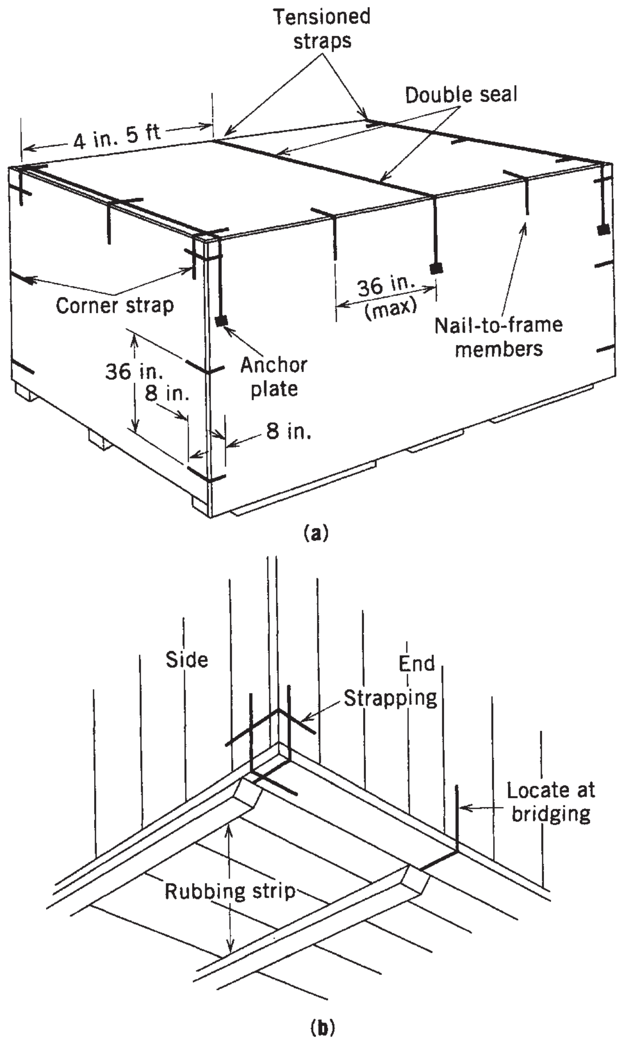

Figure 8. Strapping for crates: (**a**) sheathed crate with skid base; (**b**) additional strap for sill-type base (2).

where SM (section modulus) denotes a property of a particular beam cross section. It is defined as the moment of inertia I (in.^{4}) divided by the distance of the most remote fiber from the neutral axis, and it is denoted by the symbol Z or SM. A simple mathematical expression for section modulus is $(bd^2)/6$, where b is the width (inches) and d is the depth (inches) of the cross section. It is clearly observed that section modulus is extremely helpful in determining the actual stress to which a beam is subjected under a known bending moment.

In this section, the term "engineered" means that an analysis must be made of the types of loads and their magnitudes on the various structural members of crates so that their required dimensions may be correctly determined by calculation.

MARKS AND NUMBERS

The purpose of marks and numbers is to identify the shipper, consignee, and purchase order; aid in safe handling; provide general information; and identify hazardous materials. Never identify the contents unless it happens to be hazardous materials.

Marks and numbers should be made in large (2-in. minimum height) block letters and numbers. All numbers such as gross and net weight and dimensions should be in both British and metric units. Marks and numbers should be placed on three sides of boxes and crates to ensure that they can be seen, and these should be accompanied by the international symbols such as the umbrella denoting "Keep dry," the wind glass denoting "Fragile," and the link chain denoting "Sling here." Marks and numbers should be in permanent ink or paint that contrasts with the background.

PRESERVATION

Some items, by their method of manufacture, are already preserved. Others require protective coatings such as oils, grease, paint, or some other contact preservative that may be specified by manufacturing, engineering, quality control, or customer requirements. Some items, in addition to contact preservatives, require a wax-paper wrapping or some other protective film around the item.

Certain items may require, besides contact preservatives, additional protection from the elements, especially water, such as shrouds, liners and linings, wraps, VPI or VCI (moisture inhibitors), or desiccant materials. Wraps applied over a contact preservative must be greaseproof and require a means of assuring that they remain in place during handling and transportation. Liners and linings are waterproof-barrier materials applied between framing and sheathing to provide watershed and diversion protection for the items crated. When shrouds are applied, all projections in sharp corners must be cushioned to prevent penetration or abrasion of the shroud from either internal or external sources. The bottom edges of all shrouds should be fastened down with batten boards and additional restraints provided to prevent ballooning or flapping of the shrouds in transit. Adequate bottom ventilation must be provided either by spacing floorboards ($\frac{3}{8}$-in. minimum) or by drilling one 1-in.-diameter hole for each 5 ft^3 of shrouded volume. When VPI/VCI materials are used, a sufficient quantity of treated paper must be used to completely enclose the item.

For general watershed and diversion protection, polyethylene films (4 mils minimum thickness), asphalt-laminated kraft paper, or filament-reinforced polyethylene- or polyethylene-coated kraft paper may be used. When applying water-vapor-resistant liners or lining, such as asphalt-laminated kraft paper or polyethylene films (6 mils minimum thickness), it is essential that they be sealed tight. Whenever VPI/VCI-treated papers are used, they must be inserted within a tight enclosure, and the linear or lining must be sealed with water-proof tape. This is also true of desiccants.

Skids, Crates, and Boxes. The materials used for skids must be Group IV (hard) woods such as beech, birch, hard maple, hickory, oak, rock elm, and white ash. These woods have the greatest nail-holding power and the highest overall strength and resistance to shock. However, they are very susceptible to splitting. These woods should be used for skids, headers, load-bearing floorboards, and critical joists.

Group II and III are generally acceptable for exterior box and crate construction. Group II woods include Douglas fir, hemlock, Southern yellow pine, Tamarack, and Western larch. These woods are harder soft woods. They possess greater nail-holding power, greater strength, and greater shock-resisting capacity than do Group I woods. They are more inclined to split, and their grains often deflect nails. Examples of Group III woods are ash (except white), cherry, soft elm, soft maple, sweet gum, sycamore, and tupello. These woods are similar to Group II in nail-holding power and beam strength but have less tendency to split and shatter under impact.

When using plywood as sheathing or floorboard material, type C–D interior plywood with exterior glue is the best economical selection.

Lumber Selection and Defects. A great deal of consideration must be given to a standard of quality of the wood selected for skids, crates, and boxes. Often, the cheapest grade of lumber will contain a large number of defects that are undesirable. Therefore, it may be necessary to select a higher grade of lumber to eliminate most disqualifying defects. Generally, knots are not to exceed one fourth of the width of the member. No knot, regardless of size, will be permitted on the edge of any member. Obviously, this is because the member may be subjected to bending and a knot may fall in an area subjected to compression or tension. The cross grain or slope of grain, disregarding slight local deviations, along the general direction of the grain as related to the longitudinal axis of the wood member, should not be steeper than 1 in. in 15 in. of length. Wane is either bark or lack of wood on the edge or corner of a piece of lumber. Generally, wane is permitted on one edge only, but it should not exceed one sixth of the width or thickness, or one third of the length of the member. Checks and splits, which are lengthwise openings from separations during seasoning, may reduce wood's resistance to shear. Checks and splits that extend through the entire thickness of the piece are not permitted. Shake is a separation along the grain, largely between the growth rings, which occur while the wood is seasoning. Shakes in members subjected to bending reduce the resistance to shear and, therefore, should be closely limited in structural members. Decay, which is a disintegration of wood, results from the action of wood-destroying fungi. It seriously affects the strength properties of wood and its resistance to nail withdrawal. However, if it is determined that the total amount of decay beneath the surface does not extend beyond the surface outline, the dimensional limitations for knots apply. Warp along the longitudinal axis of the lumber should not be more than 1 in. in 8 in. of length. Lengthwise, warp should not exceed $\frac{1}{8}$ in. in 4 in. of width. The acceptable range of moisture content in lumber used for skids, crates, and boxes should lie between 12% and 19%.

No opportunity should be overlooked to use materials besides wood or plywood for crate, box, or skid construction where practically and economically feasible. Steel alternatives for wood skid members may be the simplest substitution. For example, a 4-in. × 4-in timber may be replaced by a 3-in. × 4.1-lb steel channel iron or by a 3 in × 5.7-lb I-beam or by a 3-in × 3-in. × $\frac{1}{2}$-in.-angle iron. Wherever material substitutions are contemplated for heavy loads, they should be engineered for the specific purpose intended.

DESIGN

A proper analysis of forces to which skids, crates, and boxes may be subjected must include consideration of compression, lateral thrust, impacts, repeated handlings, abuse, tension, and inertial forces on the structure and the cargo. In this regard, it must be remembered that inertial loadings encountered aboard ship often exceed those encountered in the other modes of transportation.

Basic Design Criteria. Skids must be of Group IV woods and engineered for uniform or concentrated loads. Headers are to be bolted using washers and double nuts or upset threads. Skids are to be spaced not more than 48 in. apart and are to be of single-piece construction or, if over 12 ft long, spliced according to an approved method. The ends of skids are to be chamfered and are to rest on chamfered rub strips. Cargo is to be bolted or tension banded to skids using engineering design methods for determining the sizes of bolts and tension bands. For heavy loads, consideration must be given to the crushing strength of the wood or alternative material. Load-bearing floorboards can be analyzed as beams using the formulas for bending moment to determine the required section modulus. The allowable stress used in the formula for section modulus can be taken as 1000 psi. For hard woods, this allowable stress provides an adequate factor of safety. Where the distance between skids might exceed 48 in., it will be necessary to add an additional skid. The bending moment on the load-bearing floorboards, then, should still be calculated on the basis of the length between outside skids.

For example, suppose that a 15,000-lb load is to be supported on skids whose length has been determined to be 15 ft. Calculate the required timber size. Using the formula $\mathrm{BM} = (WL/6$, the bending moment will be 37,500 ft · lb. Then calculate the required section modulus = BM allowable stress = 450 in.^{3} Remember to multiply the bending moment by 12 to convert foot-pounds to inch-pounds. Because section modulus = $(bd)/6$, you can solve by trial and error by substituting cross-sectional dimensions as follows. Try a 10-in × 10-in. timber. This yields a section modulus of 166.7 in.^{3} Two skids of these cross-sectional dimensions yield a total of 333.4 in.^{3} It is obvious, then, that two 10-in. × 10-in. timbers do *not* provide the required section modulus (450 in.^{3}) for a quasi-uniform load. The next logical choice would be two 12-in. × 12-in. timbers. Note, however, that if the load is truly uniform ($\mathrm{BM}=WL/8$), then the required section modulus is only 337.5 in.^{3} The two 10-in. × 10-in. timbers then come close to making the required section modulus, and with the factor of safety provided by using the allowable stress of 1000 psi, the two 10-in. × 10-in. timbers would serve satisfactorily for a strictly uniform load. For most hard woods, the allowable stress of 1000 psi provides a comfortable factor of safety of approximately 1.5. In calculating the basic stresses for structural lumber, impact loading is generally ignored, but long-time loading and a safety factor are considered. A piece of wood will carry less load for a long time than it will for a short time. Consideration should be given to the expected interval of storage, i.e., short time versus long time. In addition, if research or historical data indicate that a particular port of loading and/or a particular port of discharge have a higher frequency of cargo claims because of rough handling, then timber sizes may be increased by applying an appropriate factor of safety or by requiring that the actual timber size be one full unit larger than derived by calculation. Remember that rub strips must be applied to the skids. An added precaution against the accidental loss of a rub strip is the use of reinforcing straps from the rub strip to the underside of the skid members.

Crates. In general, Groups II and III woods are to be used in crate construction except for skids, headers, and occasionally load-bearing floorboards that should be Group IV woods. All nails used are to be cement coated. Barbed, screw, or serrated nails are occasionally used, but for practicality and economy, cement-coated nails make the best selection.

All skid members in crate construction generally follow the same construction requirements as skid members used as skids alone. However, skid members sizes in crates can be substantially smaller in cross-sectional area, because in crate design, it is assumed that a large part of the load imposed by the contents is carried by the side panels acting as trusses. Therefore, large skids are not necessary as load-carrying members because the sides act integrally with the skids in this function. Although this assumption results in smaller size skids, it does not permit handling and moving a loaded base alone without the sides and ends fastened in place.

Crates may be either open or closed (sheathed). It is not always necessary to sheathe a crate if the contents do not require a degree of protection from the elements. Opened crates require less lumber and, therefore, if properly designed, can be less expensive to fabricate. This may not always be true, and to achieve greater economy, it is necessary to make an engineering economy analysis to determine whether an open crate or a sheathed crate is more economical in terms of labor and cost of materials. This article discusses the design and construction of open crates because the contents impose loadings on structural members that must be determined by either graphic analysis or engineering methods of resolving forces. The sides and ends, as well as some members of the base, are considered as part of a bridge truss. The Howe truss, with its parallel upper and lower chords and its vertical and diagonal members, has the same general pattern as the frame members of the side of a wooden crate. Because the truss is a framed structure composed of straight members, the stresses in the members caused by loads must be either compression or tension. The magnitude and character of the stress in each member can be determined. The required size of all tension members in the truss is determined by the formula $A = P/f$, where A is the required cross-sectional area of the member in square inches, P is the total load in pounds (as determined from the resolution of forces or from graphic analysis), and f is the working stress in pounds per square inch (in tension parallel to the grain). With support at each end, the major stresses in strut and lower frame members are tension stresses, and those in the diagonals and upper-frame members are compression stresses.

Compression members must be designed as columns, and column formulas must be used to determine their sizes. In crate design, essentially three column formulas are used. The selection of the proper formula depends on the unsupported length of the column, and columns are therefore classified as short, intermediate, and long. It is beyond the scope of this article to discuss the various factors and the application of these in the appropriate column formulas. The *Wood Crate Design Manual* (2) is an excellent reference text for the more determined crate builder. It must be remembered that it is most probable that crates of similar dimensions will be stacked vertically (one on top of the other) aboard ship or in storage. If crates are of exactly the same overall dimensions, then the corner posts will carry the superimposed loads as columns. These anticipated superimposed loads must be included in the strength analyses. If superimposed loads consists of smaller crates or other types of loads that do not rest on the corner posts, then the structural members of the top panels will be subjected to bending as well as to compressive loadings that result from handling, especially with slings or chains. Therefore, these structural members must be analyzed as beams subjected to bending and axial compression. If highly concentrated loads (in the center third of the crate) are to be crated, the skid depth must be increased. This, however, will be apparent if the side panels are properly analyzed.

Crates should not be higher than they are wide (even well-constructed, durable shallow crates are acceptable; see examples in Figure 9). Side panels are to be divided by a suitable number of vertical members so that diagonals are as close to a 45° angle as possible. Top and bottom horizontal and vertical members are to be through members (extend to full extent of length and height dimensions). All end panels are to have one or more diagonals. Avoid splicing members less than 16 ft long. Splicing, where required, must be accomplished using an approved method. Intersections of diagonals are to be reinforced using plywood gussets or lumber bridge.

If the crate height exceeds 72 in., a through intermediate horizontal member is required at midheight of the crate. Side-panel width (ie, between vertical members) must not exceed 42 in. The geometry of the panels must be altered to add an additional panel so that panel widths do not exceed 42 in. Lower horizontal members are to rest on the ends of the floorboards with notches cut in headers and load-bearing floorboards to accept these lower horizontal members. Vertical and diagonal members must be in the same plane and to the outside of the horizontal

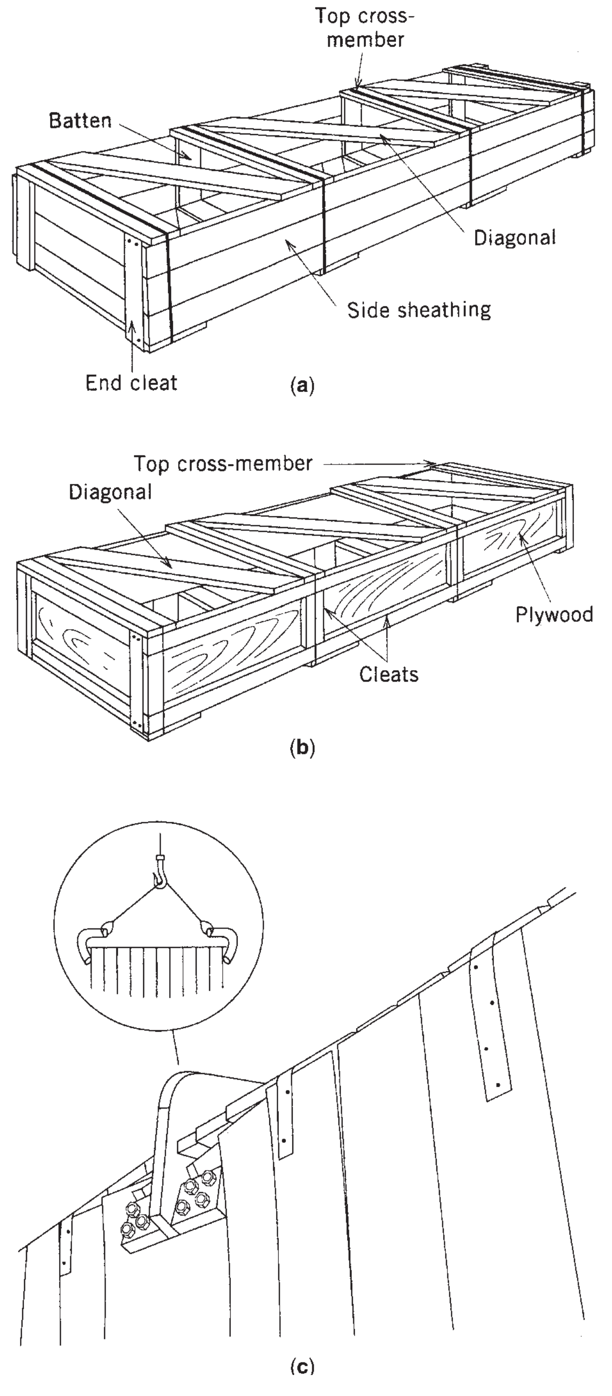

Figure 9. (**a,b**) Typical shallow crates [(**a**) lumber; (**b**) plywood]; (**c**) crate damage caused by a grabhook when insufficient joint support was available in the top of the crate (2).

members. Side-panel diagonals should slope from the top of a vertical member down to the skid base.

The end-panel design should not exceed 42 in. in width. End panels for crates with a skid width in excess of 42 in. will require intermediate vertical members. End panels for crates with more than two skids will require a vertical member above each skid. Filler strips will be required to allow end-panel vertical members to rest across the ends of skids. The filler strips will fill the void between the headers and the lower horizontal members.

Top panels are critical because most members will be in compression under the influence of various types of materials-handling equipment and superimposed loadings. Top-panel lateral and diagonal members will be in the same plane and rest on the longitudinals and extend to their edges.

Where protection from the elements is essential or to meet customer requirements, a sheathed-crate, either $\frac{3}{4}$-in. lumber or $\frac{1}{2}$-in. plywood (C–D, exterior glue) sheathing can be used. Reinforcement strapping is required on all corners and at all intermediate, horizontal, and vertical member junctures after the crate is assembled.

Where crate items require additional protection from the elements, as discussed earlier in this article, appropriate steps must be taken in the early stages of crate construction to apply the required crate liner between internal framing and external sheathing. If the crate is not to be watertight, then sufficient ventilation must be provided. If the contents are to be provided with waterproof protection, then the item must be properly and totally wrapped with either asphalt-laminated kraft paper or polyethylene film and sealed with waterproof tape in addition to the crate liner material.

The strength and rigidity of crates are highly dependent on the fastenings. Nails, lag screws, bolts, screws, and metal connectors are the most important fastenings in crate construction. This article briefly covers nails and nailing rules. Refer to Anderson's treatise on nailing better wood boxes and crates (3) for a more complete discussion of nails and nailing rules. Cement-coated nails are being more widely used today than ever before, primarily because many crate builders use automatic nailing equipment more readily amenable to the use of belted cement-coated nails. Nails should be driven through the thinner member into the thicker member where possible and should penetrate both members, leaving a minimum of $\frac{1}{4}$ in. for clinching. Clinching is one of the best methods of increasing effectiveness of nails. It is used almost entirely in the fabrication of crate panels, except when frame members or other crate parts are >2-in. thick. Clinched nails have 50 to 150% greater withdrawal resistance than unclinched nails when driven into dry wood. Predrilling the wood before the nails are driven may be necessary to prevent splitting in dense woods or with nails of large diameter. Nails should not be overdriven. They should be positioned no less than the thickness of the piece from the end or half the thickness of the piece from the side edge. When members (both of which have ≥ 3-in. thickness) are joined together, bolts are to be used. Nails should be staggered to prevent any two nails from entering the same grain line of any board. Follow approved nailing techniques as outlined in the handbook described above.

Where practical, the use of tension bands will provide an added degree of a reinforcement to the crate assembly. Tension bands should be tight enough to cause a light crushing of the ends of the main structure over which they pass. Tension bands should be stapled to prevent their movement during transportation and handling.

A crate can be assembled before or after loading the item on the skid base, whichever is appropriate, but internal blocking and bracing of the item in the crate must be done at the time the item is set on the skid base. The blocking and bracing must be of substantial design and construction to prevent the free movement of the item within the crate caused by the forces encountered in transportation and handling. Blocking and bracing are not to be taken lightly. The inertial loading on the crate and its contents aboard ship often exceeds twice that encountered in the other modes of transportation.

Boxes. Boxes are not to be used for loads in excess of 5000 lb or lengths in excess of 16 ft. Groups II and III woods are to be used. All nails are to be cement coated. Boxes that exceed 200 lb gross weight will require 2-in × 4-in. rub strips. When any unsupported span of top, end, or side lumber exceeds 36 in., additional interior battens or cleats will be required. Cleated plywood boxes for loads over 1000 lb must have load-bearing bases with properly sized skids, headers, and rub strips and are to be nailed in accordance with the preceding nailing rules. All boxes require tension bands sized according to the load and arranged in two directions passing over cleats or battens.

Bands should be stapled to prevent movement and should be tight enough to cause light crushing of the corners of the members over which they pass. If a boxed item is of large mass (weight), appropriate filler or cushioning materials filling the voids around the item may not be effective. Therefore, dunnage or blocking and bracing, where practical, should be used. Where the boxed item requires protection from the elements, the internal surfaces of the box may be lined as described under crates and the item itself should be properly preserved.

UNITIZATION AND PALLETIZATION

Unitization provides a more economic package than individually shipped pieces. It also provides ease of handling and storage and provides a greater degree of protection than individual units. Pipe and conduit are easily bundled. They may require special plastic end protectors to protect internal or external threads. The ends of bundled pipe can be boxed or completely covered with double- or triple-wall fiberboard secured with tension bands. In addition, long bundles may be bucked. *Bucks* are wooden frames that surround the girth of the bundle. They are to be nailed at the right angle junctures and be tension banded. Tension bands are to be stapled to prevent accidental loss of the bands. Bucks should be located at 5-ft maximum intervals.

Lumber and paneling are usually bundled. Care must be taken to avoid overtensioning bands that will mar their edges. Paneling should be covered with water-resistant paper or polyethylene film.

Coiled wire can be bundled. Because of the historically poor bundling methods used for wire, substantial losses have occurred. Consignees frequently use coiled wire to make nails, screws, and bolts. Kinked or crooked wire will interfere with the extrusion process, and substantial claims may arise.

Lumber and paneling can also be bundled. Care must be taken to ensure that tension bands do not damage the items bundled. Coiled wire can be bundled. The usual problem encountered here is when tension bands or wrapping wires comes off, allowing the coils to become disarranged or crushed. The consignee usually has a specific machine set up for manufacturing items such as bolts, screws, and rods. Hence, damage to the coils can result in a claim.

Palletization is best for similar-size fiberboard cartons, drums, and coiled sheet steel. Do not overload or stack the items too high. Overloaded pallets break. An excessively high stow can result in crushing of the cartons in the lower levels. Then, more damage occurs when the otherwise neat stacking falls apart. In-transit handling of broken-down pallets usually results in additional abuse. Fabric or steel banding is usually one of the best methods of securing an entire unit load. It may be advisable to employ vertical and horizontal corner protectors to eliminate banding damage. Shrink wrapping provides a high-strength securement to a palletized load. It can also be applied to protect against contact with water.

Palletized drums must be fitted with partially framed tops to allow for safe use of tension bands. Tensioning of the bands must not cause damage to the pallet load-bearing boards or to the cargo. Fiberboard sheets across the top and partially down the sides of drums will serve to keep the tension bands positioned and provide a level surface for stacking other pallets.

In general, old or badly worn pallets should not be used. Pallets can be repaired. Some companies use secondary reusable pallets with good success. Still, old wood and loose nails can result in broken pallets that invite further abuse in handling.

CONTAINER PROBLEMS

Containers are subject to the same shock and vibration forces as are over-the-road trailers and railroad cars. In addition, high inertial loadings are experienced by the contents as a result of swaying, pitching, rolling, heaving, yawing, and surging of a ship at sea.

The major causes of damage to containerized cargoes are improper stowage, inadequate dunnage, lack of security, overloading, and poor weight distribution. Any assumption that the container is a substitute for safe stowage and handling is an invitation to disaster. A good rule to adopt is to stow and secure for the worst conditions.

Containers may travel to seaport by railroad. Constant vibration and occasional sharp humping forces must be taken into consideration. When loading a container for sea transport, always consider the six basic ship motions: yaw, heave, sway, pitch, roll, and surge. Occasionally heavy seas will have a pronounced effect on cargoes in containers.

Blocking and bracing is essential to the safety of the cargo. Materials commonly used for securement are lumber, plywood, strapping, fiberboard, and inflatables. Lumber can be used as a filler for decking, blocking and bracing, and constructing partitions. Plywood can be used as a partition, divider, and auxiliary decking.

Heavy-duty strapping can be used to separate cargo and to tie down heavy and awkward items. The strapping must be firmly anchored and properly tensioned for the greatest effectiveness. Fiberboard is available in sheets, rolls, and structural shapes and can be used for light-duty bracing, as dividers, decks, and partitions. Inflatables are available in paper or rubber and may be reusable or disposable. They are expensive and not recommended for voids in excess of 18 in. Inflatables are used for light- and medium-duty bracing.

Condensation is another major cause of damage to cargo. It is not generally known that fiberboard boxes and crate or dunnage lumber contribute to the generation of water vapor in sea containers. Furthermore, in changing temperature and humidity conditions, condensation can form within containers and drip down from the overhead onto moisture-sensitive packaging and cargoes. These conditions can be remedied, in part, by using seasoned lumber for dunnage and crate construction. Adequate (prepackaging) preservation of moisture-sensitive items can be the best method of protecting against water damage. Overwraps such as canvas or polyethylene sheeting will serve to divert condensation that drips from the overhead. With some types of cargoes, it may be necessary to provide completely waterproof liners or wraps constructed VCI/VPI or desiccant materials. Cargoes are more likely to be subjected to condensation and water damage over a long time interval such as long transportation distances or long-duration storage. Therefore, it is incumbent on the shipper to consider all these factors when preparing cargo for export.

The annual report of the Cargo Loss Prevention Committee of American Institute of Marine Underwriters contained valuable advice on the use of containers in shipping. Extracts from the report follow:

> Normal reaction is for a shipper to use domestic packaging and consider the container as an additional protection. It is our experience that containers may leak and the cargo must be protected against moisture and water damage. Additional emphasis is needed on the use of dunnage and tight packing in containers.
>
> Several offices report that losses have been experienced due to defective containers. Many shippers do not employ adequate container inspection procedures. It appears that some insureds think that because their goods are containerized the packing can be of a minimal nature. Our experience continues to show that such minimally packed goods are likely to be damaged by rain and/or seawater when shipped in poorly maintained containers.
>
> Many shippers continue to use containers as a means of packaging and claims due to crushing, water damage and improper or inadequate stowage, especially of heavy machinery, continue to be a problem.
>
> Losses have also been experienced where shipments of high value electronic units have been made in containers. The units are secured on lumber bases which in turn are then secured to pallets with the units being entirely shrouded in polyethylene sheeting which also encompasses the wooden base to which the units are attached. It was found that these wooden bases were constructed of green or improperly dried lumber, which gave off moisture, which became trapped in the polyethylene shrouding. During the course of transportation, fluctuations in temperature caused this moisture to condense on the exposed metal areas of the electronic unit, causing serious damage.
>
> We have also observed that machinery which is top heavy has on occasion been stowed in containers without adequate bracing and precautions to prevent the machine from tipping. On one occasion, a container loaded with tractor engines arrived at destination with every engine damaged, as a result of their center of gravity being high. Although the engines were braced along the floor of the container, and would prevent lateral or fore and aft movement, there was no bracing up higher and with their relatively high center of gravity they tipped, coming in contact with one another, causing damage. Shippers should be cautioned to be aware of the center of gravity of machinery and other heavy or odd sized pieces being shipped in containers and adequate bracing to prevent tipping should be done.
>
> Although containerization of cargo continues to grow worldwide, the packing of goods into house to house containers by shippers, as well as securing of the goods in the containers, continues to be a cause for concern. We find in many instances cargo to be damaged by condensation within the container and/or by extreme heating or freezing. Once a container is loaded and the doors securely shut, the only way in which the outside weather can affect the cargo is through changes in the temperature.
>
> Unless the internal temperature of the container is controlled by mechanical or other means, the temperature of the air inside the container will follow the temperature of the air outside. Extreme fluctuations in the air temperature can cause condensation to settle on the cargo; if the container is exposed to very high temperatures, the cargo within the container may sustain damage or, if the container is exposed to extremely low temperatures, the cargo can be damaged, such as change in the chemical state of some goods (eg, drugs) making them useless and sometimes dangerous, or freezing of bottled liquids with subsequent bursting of bottles.
>
> Taking into account the anticipated voyage, its length, and temperatures normally expected to be encountered, consideration should be given to goods which are susceptible to damage by extreme heat or cold by shipping them in insulated or refrigerated containers where the temperature inside the container can be controlled to some degree.
>
> In other cases, certain precision machinery or electronic equipment may require the use of VCI, VPI or powder desiccants. It must be pointed out, however, that in order for these moisture control measures to take full effect, the packaging and packing must be *totally* sealed.

SHIPPING LOSSES AND INSURANCE

Under normal conditions of domestic rail shipments, material loaded in open cars is inspected by railroad representatives before the car is moved, and the railroad assumes responsibility. In closed cars, however, the Association of American Railroads rules are not mandatory and are used only for guidance. Closed cars are not ordinarily inspected, but if damage occurs to the contents, they are inspected at the destination to determine the cause before a settlement is made.

Export shipping companies are specifically exempt from most forms of liabilities under the laws of many countries. The exceptions to this usually include loss or damage due to negligence in proper loading, custody, or delivery of the goods.

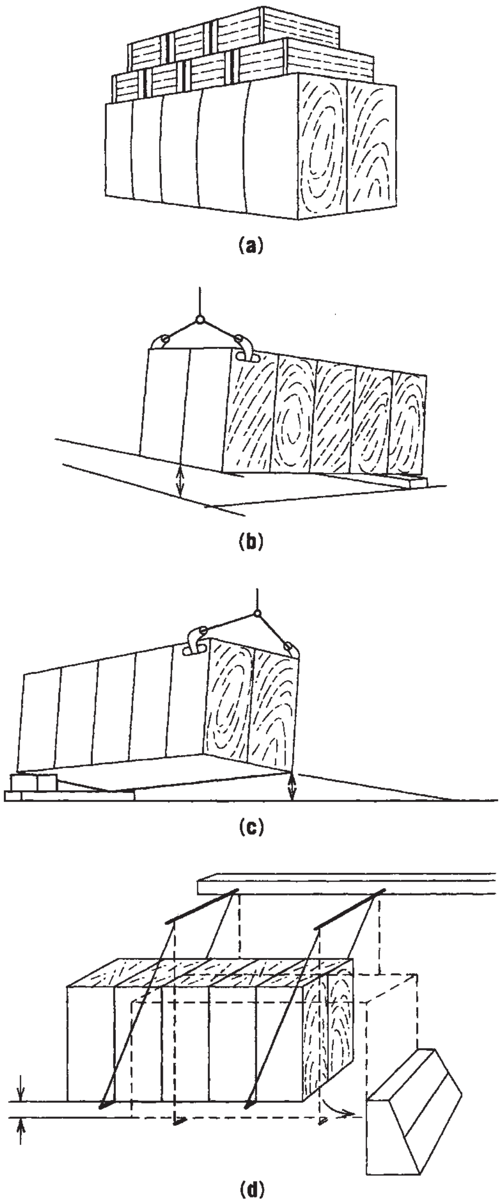

Figure 10. Rough-handling tests for crates; (**a**) superimposed load; (**b**) edgewise drop; (**c**) cornerwise drop; (**d**) pendulum impact (2).

The shipper or consignee must assume responsibility for all remaining risks during the shipment.

To prevent loss to the shipper, a form of marine insurance covers these losses. Marine insurance may be obtained to cover such perils as pilferage, theft, and leakage, as well as loss or damage if the ship should sink, burn, or be involved in a collision. However, the more hazards covered by the policy, the higher the rate, so it is not economical to pay for broader protection than is actually required.

Rates in marine insurance are rather complex and are not fixed. They depend on, among other things, the type of vessel, the route, the perils insured against, the type of packing used, and the loss record of the shipper. This latter factor reflects the type of container and the method of cushioning, blocking, and bracing used by the shipper, because well-constructed and well-packed crates will normally receive little damage during the voyage. A shipper who uses adequate containers pays lower rates. Underwriters keep statistical records of shippers with whom they deal and allow lower rates for those with good records.

DAMAGE AND CLAIMS

Too frequently one or more of the three steps in preparation for shipment are less than adequate, and this will inevitably result in damage of one type or another to the cargo. Precision machinery shipped long distances or subjected to long-term storage without adequate preservation will rust. Electronic equipment shipped without serious consideration being given to adequate protection from vibration and shock will sustain physical damage. Items requiring a degree of dimensional stability (rigidity) will be damaged if the packaging and packing is not properly engineered and constructed. One way to ensure greater construction durability is by preshipment damage testing of crates or other containers (see Figure 10).

With regard to containerization (sea containers), a tremendous number of cargo losses occur each year because of ignorance of the proper use of these containers, specifically the requirement for adequate blocking and bracing and protection of the cargo against condensation. It is imperative that the shipper understand that the use of sea containers does not guarantee that the cargo will be received by the consignee in sound condition.

A major marine insurance company has made an analysis of principal causes of losses and found that, in the “handling and stowage” category, 39% of all losses are caused by container damage including breakage, leakage, and crushing. In the “water damage” category, 10% of all losses are from fresh-water, sweat, and saltwater damage. Nevertheless, it concludes that 70% of all cargo losses are preventable.

CONCLUSION

In summary, shippers would do well to have as their first concern ensuring that the goods reach their customers in sound condition, and to that end, the author hopes that this article is a valuable aid.

INTRODUCTION

The Industrial Revolution of the late 18th–early 19th century saw the introduction of powered machines to replace manual labor in accomplishing the same or similar tasks. Consequently, gains in labor and productivity per worker-hour of individual workers were accomplished. Moreover, this time period observed the transition from a "domestic system" to a "factory system." Concurrently, the need for materials-handling systems (MHSs) increased to meet the needs of the more "productive" factory system. Initially, this need was for labor-saving devices to handle material in manufacturing and distribution (1, 2). However, in today's competitive and global marketplace, the rationale for materials-handling systems is multifaceted.

The "cost" estimates for materials handling vary in nature. Generally materials handling does not add value to the product, but it can and does add to the final product costs. Estimates of this cost range from as little as 20% up to 90% in some cases. Conversely, however, efficiently designed materials-handling systems have been known to reduce a plant's operating cost by 15–30% (3). This figure could vary depending on the industry and product categories. For example, the food-processing industry would have a fairly high per-unit cost, whereas an industry that uses tanks and pipes would have a significantly lower per-unit cost.

The potential costs and benefits associated with materials-handling systems are significant and thus impact our domestic and global competitiveness. This article provides an overview of materials-handling principles and guidelines, and it relates these to the field of packaging. Generalized definitions, objectives, principles, and examples of materials-handling checklists are included. Brief discussions on equipment are also presented, as well as approaches toward the design of materials-handling systems. Because of the strong relationship between facilities layout and materials handling, a brief section on techniques for facilities layout is also included. A final section showing the relationship between packaging and materials handling concludes the article.

DEFINITIONS

Simplistically and intuitively, *materials handling* is defined as handling material. However, various authors define this term in increasingly comprehensive manners. Meyers (4) indicates that materials handling is "the function of moving the right material to the right place, at the right time, in the right amount, in sequence, and in the right position or condition to minimize production costs." He also states that materials handling involves the handling equipment, the storage facilities, and the control apparatus. Tompkins and White (5) similarly state that materials handling uses the right method to provide the right amount of the right material at the right place, at the right time, in the right sequence, in the right position, in the right condition, and at the right cost. Again, the emphasis is more than just handling materials. Storage and control are also important. Time utility—the right material at the right time—and place utility—the right material at the proper place—are also emphasized. They also point out that materials handling can be described in terms of quantity, position or orientation, condition, space, profit, quality, safety, and productivity, which are also significant factors relative to packaging.

Gelders and Pintelon (2) offer the following definition from an engineering point of view: "the art and science involved in picking the right system, composed of a series of related equipment elements or devices designed to work in concert or sequence in the movement, packaging, storage and control of material in a process or logistics activity." Sims (6) states that materials handling includes the movement of liquids, bulk solids, pieces, packages, unit loads, bulk containers, vehicles, and vessels. He also defines a materials-handling system as a series of related equipment elements or devices designed to work in concert or sequence in the movement, storage, and control of material in a process or logistics activity, where each system must be custom designed for each unique application. Finally, Sims (6) states that materials handling is the portion of the business and economic system that affects the physical relationship of material, products, and packaging to the product, process, facility, geography, or customer without adding usable worth or changing the nature of the products.

Clearly, materials handling is more than "handling materials." It is a complex, multifaceted activity that extends beyond the physical confines of a manufacturing facility. Properly designed materials-handling systems, although not adding value to a product, have the potential to minimize overall costs, and even in the case of product/package-delivery systems, impact the end-use customer or consumer.

OBJECTIVES OF MATERIALS HANDLING

It is generally accepted that the primary goal of material handling is to have the least possible handling, i.e., less handling at less cost leading to reduced costs of production. However, a more specific and comprehensive set of objectives that more accurately reflects the diverse nature of materials handling, as stated by Gelders and Pintelon (2), are as follows:

- To increase the efficiency and effectiveness of materials flow
- To increase productivity in manufacturing (plant) or in distribution (warehouse)
- To increase space and equipment use
- To improve safety and working conditions
- To reduce materials-handling costs
- To avoid high capital requirements
- To ensure a high level of systems flexibility, reliability, availability, and maintainability
- To improve integration between materials and information flow
- To smooth the flow of materials through the logistics pipeline (from supplier to final customer)

How can these objectives be achieved via appropriate materials-handling system design? The following section provides guidance on basic principles, checklists, and critical questions that may be used to meet one or more of the above objectives.

BASIC PRINCIPLES OF MATERIALS HANDLING

To meet the primary goal of materials handling, as well as the expanded objectives listed above, a list of principles based on accumulated knowledge and practice of experts in the field has been developed. The list of 20 principles adopted by the Materials Handling Institute Inc. provides rule-of-thumb advice that facilitates optimized materials-handling system design and also serves to help develop checklists relevant to the system under focus. A slightly modified version (2) is shown in Table 1. These 20 principles provide an initial frame of reference to begin the design of a new materials-handling system, make modifications to an existing system, or analyze a system to determine whether it is meeting predetermined objectives.

METHODS OF ANALYSIS

Analysis of existing or proposed materials-handling systems can be approached in either a qualitative or quantitative manner. To facilitate the analysis of a materials-handling system in general, Tompkins and White (5)

Table 1. Basic Principles of Materials Handling

1. *Planning:* Study the problem thoroughly to identify potential solutions and constraints and to establish clear objectives.
2. *Flow:* Integrate data flow with physical materials flow in handling and storage.
3. *Simplification:* Try to simplify materials handling by eliminating, reducing, or combining unnecessary movements and equipment.
4. *Gravity:* Use gravity to move materials wherever possible, while respecting limitations concerning safety and damage.
5. *Standardization:* Standardize handling methods and equipment wherever possible.
6. *Flexibility:* Use methods and equipment that can perform a variety of tasks.
7. *Unit load:* Handle products in as large a unit load as possible.
8. *Maintenance:* Plan maintenance carefully to ensure high system reliability and availability.
9. *Obsolescence:* Make a long-range plan, taking into account equipment life-cycle costs and equipment replacement.
10. *Performance:* Determine the efficiency, effectiveness, and cost of the materials-handling alternatives.
11. *Safety:* Provide safe materials-handling equipment and methods.
12. *Ecology:* Use equipment and procedures that have no negative impact on the environment.
13. *Ergonomics:* Take human capabilities and limitations into account while designing a materials-handling system.
14. *Computerization:* Consider computerization wherever viable for improved materials and information control.
15. *Utilization:* Try to obtain a good use of the installed capacity.
16. *Automation:* Consider automation of the handling process to increase efficiency and economy.
17. *Operation:* Include operating costs (energy) in the comparison of materials-handling alternatives.
18. *Integration:* Integrate as much as handling and storage activities into one coordinated system, covering receiving, inspection, storage, transportation, production, packaging, warehousing, and shipping.
19. *Layout:* Keep in mind that layout and materials handling are closely linked and that an interactive procedure is often needed to obtain their best coordination.
20. *Space use:* Choose the material handling equipment so that effective use is made of all (cubic) space.

propose modifying the well-known engineering design process as follows:

1. Define the objectives and scope for the materials-handling system.
2. Analyze the requirements for handling, storing, and controlling material.
3. Generate alternative designs for meeting materials-handling system requirements.
4. Evaluate alternative materials-handling system designs.
5. Select the preferred design for handling, storing, and controlling material.
6. Implement the preferred design, including the selection of supplies, training of personnel, installation, debug and startup of equipment, and periodic audits of system performance.

Several other authorities in the field also suggest using this approach. Utilizing the expanded list of objectives and the principles of materials handling serves to address step 1 of this process. The next four steps can be approached qualitatively, or quantitatively. A qualitative analysis may take a questioning approach with yes/no or scaled/weighted answers. Basic questions to consider asking when addressing the system under study include “why,” “what,” “where,” “when,” “how,” and “who,” and “which.” More specifically, and at a *minimum*, Tompkins and White suggest asking and answering a set of questions as shown in Table 2 (see also Figure 1).

Table 2. Basic Materials-Handling System Design Questions

- Why
  - Is handling required?
  - Are the operations to be performed as they are?
  - Are the operations to be performed in the given sequence?
  - Is material received as it is?
- What
  - Is to be moved?
  - Data are available and required?
  - Alternatives are available?
  - Are the benefits and disbenefits (costs) for each alternative?
  - Is the planning horizon for the system?
  - Should be mechanized or automated?
  - Should be done manually?
  - Shouldn’t be done at all?
  - Other firms have related problems?
  - Criteria will be used to evaluate alternative designs?
  - Exceptions can be anticipated?
- Where
  - Is materials handling required?
  - Do materials-handling problems exist?
  - Should materials-handling equipment be used?
  - Should materials-handling responsibility exist in the organization?
  - Will future changes occur?
  - Can operations be eliminated, combined, or simplified?
  - Can assistance be obtained?
  - Should material be stored?
- When
  - Should material be moved?
  - Should I automate?
  - Should I consolidate?
  - Should I eliminate?
  - Should I expand?
  - Should I consult vendors?
  - Should a postaudit of the system be performed?
- How
  - Should materials be moved?
  - Do I analyze the materials-handling problem?
  - Do I sell everyone involved?
  - Do I learn more about materials handling?
  - Do I choose from among the alternatives available?
  - Do I measure materials-handling performance?
  - Should exceptions be accommodated?
- Who
  - Should be handling materials?
  - Should be involved in designing the system?
  - Should be involved in evaluating the system?
  - Should be involved in installing the system?
  - Should be involved in auditing the system?
  - Has faced a similar problem in the past?
- Which
  - Operations are necessary?
  - Problems should be studied first?
  - Type equipment (if any) should be considered?
  - Materials should have real-time control?
  - Alternative is preferred?

Source: Reprinted with permission from Tompkins and White (5).

This “questioning attitude” leads to the basic equation of developing the best materials, moves, and methods to arrive at the preferred system. Some issues to consider in this equation include the type of materials and their physical characteristics, the quantities of the materials to be moved, frequency of moves, sources of moves, and methods by which this may occur.

Numerous checklists are available in the literature that aid in qualitative analysis and help to answer the basic questions listed above (2, 4–6). It should be noted that any checklist may have to undergo a certain amount of modification to fit the system at hand. Certain aspects of the checklist may not be appropriate, or additional aspects may be required. However, the previous stated objectives as well as the principles of materials handling can facilitate selection or development of checklists for use as a qualitative analysis tool. One such example of a recent checklist as compiled by Gelders and Pintelon (2) is shown in Table 3.

Quantitative analysis can provide an objective basis to evaluate MHSs as compared with the more subjective qualitative techniques. This may include computing measures such as *efficiency*, which can be defined as the theoretical computed input divided by the actual consumed output; *effectiveness*, which is the actual achieved output divided by the theoretical expected output; and *productivity*, which is defined as output over inputs. Gelders and Pintelon (2), among others, refer to these as performance indicators (a related discussion of these issues can be found in the article by Zepf in this Encyclopedia). For instance, throughput time (cycle time) is one measure of effectiveness, use of warehouse space, or pallet space (unit load) is a measure of efficiency, and productivity may be measured in terms of labor

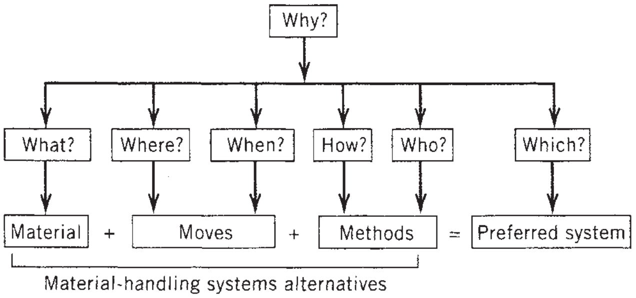

Figure 1. Basic equation for materials-handling system design. Reprinted with permission from Tompkins and White (5).

Table 3. Checklist for MHS

- General questions
  - *Topic:* Global aspects of the MHS
  - *Examples:* Is the MHS flexible enough to cope with changing product volumes and mixes, throughput and service needs, technology options, customer requirements, etc.?
    - Is the MHS integrated with the production system? Are interfaces with other business functions working okay?
    - Is standardization a main concern while investing in new equipment?
    - Has the company clear objectives concerning the degree of automation to apply to the MHS?
- Specific questions
  - *Topic:* Different areas of (and interfaces with) the MHS
  - *Examples:*
    - Receiving, including dock operations and inspection
      - Does the dock equipment match the types of warehouse help to reduce energy costs?
      - Could doors between dock and warehouse help to reduce energy costs?
      - Do quality control and inspection reports satisfy the needs of the customer, i.e., the manufacturing process?
    - Storage
      - Are there any unnecessary packing-unpacking operations needed because of a lack of standardization or choice of the wrong unit load?
      - Is the storage equipment sized correctly for the material stored?
      - Is the tradeoff between storage density and selectivity optimized?
    - Handling operations in the manufacturing process
      - Is there any backtracking in the flow path?
      - Are there any areas with traffic congestion?
      - Is production work delayed because of poorly scheduled delivery and removal of material?
    - Other picking
      - Are travel distances between picks minimized where possible?
      - Would a part-to-picker instead of a picker to part system improve the picking operations?
      - Are low-activity items out of the way but accessible to pickers when necessary?
    - Packaging
      - Are mispicked orders corrected in a timely manner?
      - Is volume sufficiently high to justify addition of automatic packing equipment to replace manual operations?
      - Did you make the right choice between strapping, wrapping, etc.?
    - Shipping
      - Are receiving and shipping operations separated so that they do not interfere?
      - Are the shipping operations well planned?
      - Would additional equipment speed up the loading operations?
  - Information flow and data collection
    - *Topic:* The amount and type of data collected, the data processing, and information flow accompanying the material flow
    - *Examples:*
      - Does a computerized database of inventory information exist?
      - Does each stockkeeping unit have a unique identification number?
      - Is there a satisfactory performance reporting?

Source: Reprinted with permission from Gelders and Pintelton (2).

components relative to the materials-handling function. Comparing these or other measures against predefined targets may help to direct modifications to the entire MHS, or only portions of the same.

Overall MHS analysis may be accomplished through the use of simulation software. The software can be used to compare various alternatives against specified criteria and to perform what-if analysis (7–9). Most current simulation software packages offer animation capabilities that allow the designer to see dynamic representations of the system under study. Specialized software such as CAPE (10) or TOPS (11) may be used to focus on palletization and the unit-load concept as well as optimized package design. Simple spreadsheet analysis that uses macro programming may also be used for this purpose. Beyond ones own operations, benchmarking, that is, comparing one's own strengths and weaknesses to a competitor, may also be applied relative to materials-handling analysis.

One of the earlier structured approaches to MHS analysis was developed by Muther and Haganas (12). Their method, systematic handling analysis (SHA), was developed from the premise that any analysis must depend on material, moves, and methods. They describe the approach as "an organized, universally applicable approach to any materials-handling project," consisting of a "framework of phases," "pattern of procedures," and "set of conventions." They further identify four phases as "external integration," "overall handling plan," "detailed handling plan," and "installation." The total methodology makes extensive use of charts, checksheets, flow charts, and detailed procedures. In short, the method provides a systematic approach to determine solutions to materials-handling problems. When used in conjunction with the basic principles of material handling, it can provide a powerful framework for identifying good solutions to material handling problems.

PLANT LAYOUT AND FACILITIES LAYOUT

Materials handling is an integral part of plant layout. Conversely stated, plant layout is an integral part of materials handling (the proverbial chicken and egg). In short, both MHS design and plant layout design must go hand-in-hand. A cursory review of the stated objectives of materials handling and the MHS principles reveals commonalties, for instance, increase space and equipment use and improve safety and working conditions (objectives), flow, utilization, and space use (principles). These objectives and principles, to name just a few, are also pertinent to effective facilities and plant layout.

Facilities layout, much like material handling, is a volumous subject in and of itself. However, for the purposes of this chapter, some methods of analysis are briefly discussed. The techniques used may be simple or complex, and either quantitative or nonquantitative. Tompkins and White (5) provide a comprehensive discussion of the subject matter. The most basic method to determine layout design is by way of scaled templates of the facility, machinery, material, and people. The templates can be arranged using heuristics to determine the most appropriate layout. This can be accomplished with the aid of computer-aided-design (CAD) packages. When areas of a facility can be departmentalized, matrix techniques such as from–to charts, or "closeness" charts may be used. If some objective such as minimizing materials-handling costs, or minimizing distances traveled can be identified, several optimization models may be used (13).

A complete methodology, *systematic layout planning* (SLP), developed by Richard Muther, and similar in nature to systematic handling analysis (SHA) also is effective for use in existing or new facilities. Similar to SHA, it consists of a framework of phases, a pattern of procedures, and a set of conventions. In general the process includes four overall phases of establishing a location, planning the general overall layout, preparing detailed layout plans, and finally installation at the facility. Also like SHA, the method is logical in nature, includes detailed graphic procedures, and leads to good solutions based on the initial inputs.

Numerous computer software programs have been developed which address facilities layout. Three such programs are ALDEP (automated layout design program), CORELAP (computerized relationship layout planning), and CRAFT (computerized relative allocation of facilities technique) (13). More recently, factory CAD, factory plan, and facility plan flow suite of facilities-planning software (14) has been introduced based largely on the procedures pioneered by Muther. Programs such as these are useful when problems are large and complex. However, they are not guaranteed to provide optimum solutions. Experience, judgment, and intuition are still necessary when using this or other kinds of software.

MATERIALS-HANDLING EQUIPMENT, MATERIAL, AND METHODS

An abundance of materials-handling equipment exists for various applications. Usually, there are multiple choices for each application. The literature for materials handling contains guidelines, tables, and classification schemes to help in selecting the right equipment for the right purpose (1, 3). Furthermore, the proper use of the principles of materials handling and appropriate checklists, in line with stated objectives, can also serve to identify the right equipment for the given application. In general, the three broad categories of materials-handling equipment are trucks, conveyors, and cranes and hoists. In the total systems concept, storage devices such as pallet racks and bins, automated storage, and retrieval systems are also included; pallets, slipsheets, and returnable containers are examples of material and methods.

MATERIALS HANDLING AND PACKAGING

The previous sections of this article discussed general principles, objectives, and techniques of materials handling in a broad sense without reference to a particular industry or manufacturing application. However, as the most comprehensive definition (6) stated earlier implies, the issue of material handling is usually not singular in nature but is indicative of a more complex and comprehensive system. Consequently, materials handling can be approached from a systems perspective. Figure 2 illustrates the extent to which a systems view can be taken. This view shows an inclusive life-cycle approach that includes the supplier of the basic raw material and extends to disposal of the product and package. Decision-making criteria related to material handling, therefore, should extend beyond the confines of the "manufacturing" facility, or process, to include issues related to packaging, distribution and warehousing, wholesale or retail, the consumer, and solid waste.

Packaging, like materials handling, can also be viewed from a systems approach as shown in Figures 3 and 4. Figure 3 shows the broad, interdisciplinary nature of packaging, and identifies the functions it must address, ie, containment, protection, communication, and performance. It also illustrates that a package can be primary, secondary, tertiary, or quaternary in form and function. This view also indicates packaging extends beyond the confines of the "manufacturing" facility, and that a life-cycle approach toward the development of packaging is appropriate. The complexity of the systems view is influenced by the product itself and the particular industry classification. For instance, a consumer foods or

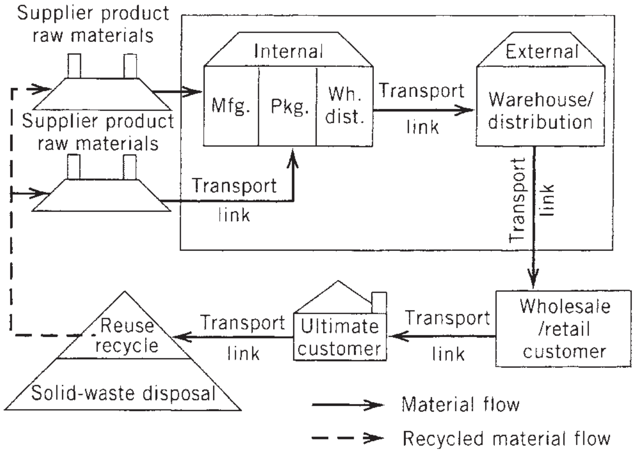

Figure 2. Materials handling in a system context.

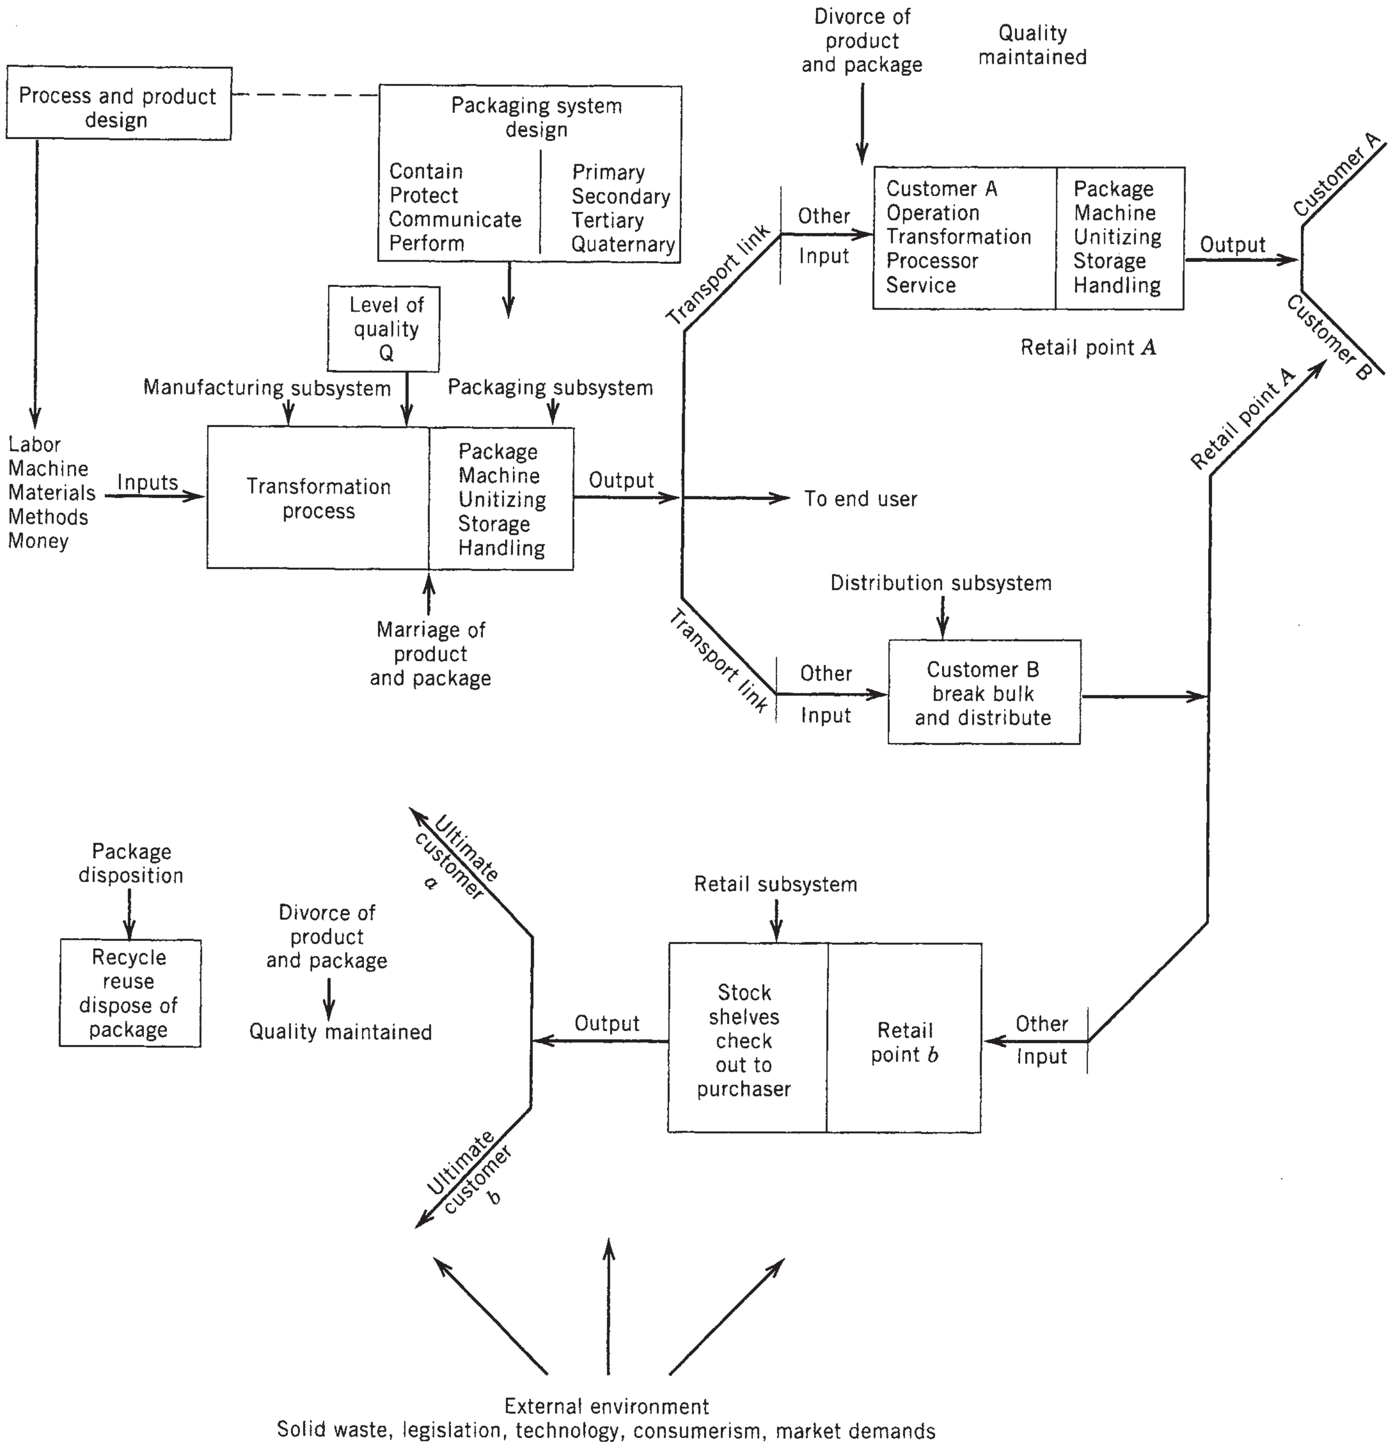

Figure 3. A systems representation of packaging.

pharmaceuticals company would have a complex system that may need to take into account product requirements, manufacturing requirements, distribution and warehousing requirements, marketing and consumer requirements, and solid-waste requirements relative to packaging development. The range of packaging material, processes, and equipment in this instance could be wide. However, the packaging for the manufacturer of a small electric motor for use in another product may be limited to corrugated boxes that are hand-packed and hand-palletized.

Figure 4 focuses more specifically on the point where the product, the package, and the package machinery meet and are united, influenced by human factors (labor and management policies). This view is relevant at the initial "marriage" between the product and the primary package as well as subsequent "marriages" when the

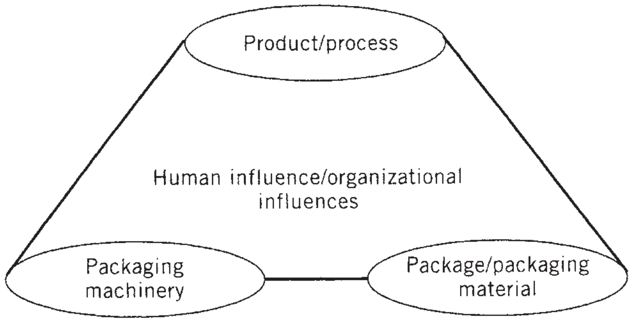

Figure 4. Marriage of product and package.

primary filled package (becomes product) is united to a secondary package, and so on. This view is typically confined to the "manufacturing packaging" facility, and it does not usually extend beyond those boundaries.

Although it is beyond the scope of this article to identify every packaging issue that influences materials-handling design, or vice versa, several examples may show that synergism does exist between material handling and packaging. In the systems view of both materials handling and packaging, the concept of the unit load—handle products in as large a unit load as possible (principle number 7)—is relevant to each. As previously mentioned, specialized software (10, 11) exists that can be used to optimize unit loading on a pallet, for single and mixed loads, or for optimized loading in the transport vehicle. Addressing this concept can help to meet objectives such as reducing materials-handling costs and packaging material costs, and also to increase productivity in manufacturing and distribution. In addressing the pallet, choices exist depending on many factors. Choices can be made between one-way pallets, or closed-loop pallets made from wood or plastic, one-way or closed-loop pallets made of recycled material, slipsheets, or no pallet at all. Those choices, in turn, impact the handling equipment such as forklift trucks, automated guided vehicles, and so on. Warehouse storage options such as rack storage or open-bay storage may also be of concern. Choices on how to maintain the optimized unit load may also exist. Current choices include stretch or shrink film, or spot gluing (15), strapping, and so on, which in turn influences equipment options. Using closed-loop pallet systems, pallets made from recycled material, or no pallet at all help to address material handling principle 12—ecology—which advocates using equipment and procedures that have no impact on the environment.

In the more restricted view of packaging shown in Figure 4, the packaging line is the primary issue of focus. Typically, the packaging line will consist of specific packaging machinery (filling, sealing, and labeling), handling equipment (conveying, accumulation, etc.), inspecting equipment, coding equipment, and so on, usually beginning at the depalletizer for empty containers and ending at the palletizer for filled and "packaged" products. The level of automation of the packaging line may be manual, semiautomatic, fully automatic, or a fully computer integrated operation.

The integration of the packaging line from a "macro" level through the proper use and selection of various materials-handling equipment can help to address objectives such as increasing productivity, increasing space and equipment use, and ensuring a high level of systems flexibility, reliability, availability, and maintainability, among others. For example, the choice of the appropriate conveying and accumulation equipment becomes extremely important depending on a range of factors specific to the package or packaging material, the speed of the packaging lines, how flexible the lines must be, and so on. For instance, handling requirements for empty lightweight plastic bottles are different from those for comparable heavier glass containers (16), thus potentially influencing productivity and other objectives (see the Conveyors, accumulation, palletizing, depalletizing article). Other examples may include the use of robotic palletizers (see the Palletizers article) increase the flexibility of the packaging line or the use of vertical versus horizontal accumulation to optimize space and overall facilities layout. Objectives can also be influenced at a "micro" level by proper design and selection of infeed mechanisms (star wheels and worm screw), transfer points (dead plate and power roll), right angle turns, and so on.

In short, there is much similarity between a systems view of materials handling and a systems view of packaging. In designing or evaluating packaging systems, issues relative to materials handling should be addressed. Correspondingly, when designing materials-handling systems, the requirements of the packaging system must be addressed as well. This is particularly true for industries such as consumer foods and products, pharmaceuticals, and beer and beverages. This is also true for the suppliers of packaging materials and equipment.

CONCLUSIONS

Materials handling is more than handling material. It is, in fact, a complex, multifaceted activity that extends beyond the boundaries of the "manufacturing" facility. This article has presented definitions, objectives, checklists, questions, and techniques that help to understand the complexities surrounding materials handling. Similarly, packaging is "more than just a box." This article briefly shows that packaging can also be viewed from a systems perspective and that synergies exist between material handling and packaging. This article mentioned only a few examples of the commonalties that exist between materials handling and packaging, but an entire article could be devoted to the topic. In conclusion, it is apparent that optimum design for both can depend in large part on understanding and analyzing each from a systems perspective.

MEDICAL DEVICE PACKAGING

Laura Bix
Javier de la Fuente
School of Packaging,
Michigan State University,
East Lansing, Michigan

INTRODUCTION

Medical devices achieve their therapeutic ends via physical means, as opposed to metabolic, immunological, or pharmacological processes. The Global Harmonization Task Force (GHTF) has proposed the following harmonized definition of a medical device:

Any instrument, apparatus, implement, machine, appliance, implant in vitro reagent or calibrator, software, material, or other similar or related article:

a. Intended by the manufacturer to be used, alone or in combination, for human beings for one or more of the specific purpose(s) of:
    - Diagnosis, prevention, monitoring, treatment, or alleviation of disease.
    - Diagnosis, monitoring, treatment, alleviation of, or compensation for an injury.
    - Investigation, replacement, modification, or support of the anatomy or of a physiological process.
    - Supporting or sustaining life.
    - Control of contraception.
    - Disinfection of medical devices.
    - Providing information for medical or diagnostic purposes by means of in vitro examination of specimens derived from the human body, and
b. Which does not achieve its primary intended action in or on the human body by pharmacological, immunological, or metabolic means, but which may be assisted in its intended function by such means (1).

By definition, devices are involved in many different aspects of healthcare. As such, devices, their manufacturing processes, and the packaging that contains and protects them are extremely disparate. Complicated capital equipment, such as MRI tunnels and X-ray machines, are medical devices, but so are simple, commodity-like items such as tongue depressors and syringes. Some are meant for mass markets, others are niche items. Some are packaged individually; others are packaged in boxes of 100 s or 1000 s. Some are reprocessed, others are disposable, and some are used for a lifetime. Risks associated with device misuse and failures are equally varied, ranging from inconvenience to patient death (2).

It is estimated that the medical device and equipment market will be worth $246 billion by 2011, with a 4.6% annual growth until that time (3). This is largely driven by aging populations who frequently engage in active lifestyles, a growing middle class in emerging markets, and the spread of “Western diets” (4).

A hallmark of the device industry is innovation, which results in short life cycles for many products. “Medical devices undergo constant development based on feedback from medical practitioners and advances in other sciences relevant to medical device technology” (5). “With this constant innovation, the medical device industry spends heavily on research and development” (2); a large portion of revenues go to R&D streams.

CLASSIFICATION OF MEDICAL DEVICES

The great variation present in the medical device industry means that devices can be classified in a number of ways. Devices can be categorized by:

- The risk associated with improper use or a failure (generally high, moderate, and low).

- Conditions of processing (reusable, disposable, capital equipment, etc.).
- Conditions of the therapy (invasive, noninvasive).
- Conditions of shipping and handling (capital equipment, commodity surgical, etc.).

Because the goal of these therapies is to maximize efficacy and protect patient safety, the most common way to classify devices is based on risk. Although the specific classifications and regulatory requirements vary from country to country, the intent is the same; risk-based classifications provide guidance regarding the appropriate level of manufacturing control and regulatory oversight required to ensure safe and effective products.

GHTF Classification

GHTF, a voluntary group of representatives made up of regulators and industry, works to encourage convergence in the evolution of regulatory systems through the use of guidance documents that can be adopted globally. Because regulatory scrutiny frequently employs risk-based classifications, and classifications vary throughout the world, GHTF has tasked a group to catalyze harmonization of the classification system.

On July 27, 2006 Study Group 1 (SG1) published its recommendations for device classification entitled "Principles of Medical Devices Classification" (6). This document is one of a series that, together, describe a global regulatory model for medical devices; although, at the time of writing, classification and other regulatory controls were yet to be harmonized.

The GHTF classification system applies to all medical devices that are not used for the in vitro examination of specimens derived from the body, and it is based on risk. Risk is "a combination of the probability of occurrence of harm and the severity of that harm" (7). Device risk is a function of (a) the intended purpose of the device, (b) the effectiveness of risk management techniques applied during design, manufacturing, packaging and use, (c) the intended user, (d) mode of operation, and (e) the technology being employed (6). GHTF recommends a classification system based on four levels of risk (see Table 1), with the expected level of control increasing with increasing risk (see Figure 1). For detailed rules regarding how best to classify the devices, see "Principles of Medical Devices Classification GHTF/SG1."

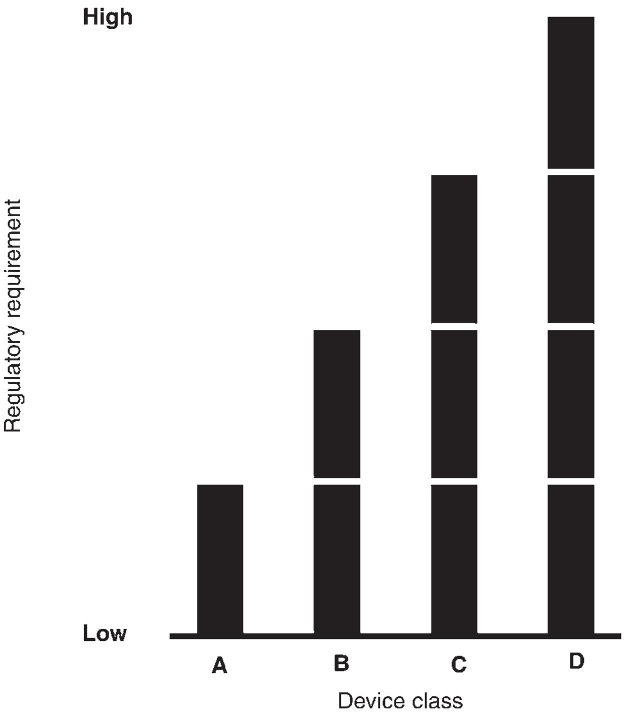

Figure 1. Relationship of regulatory control and GHTF classification. (*Source*: "Principles of Medical Devices Classification GHTF/SG1/N15".)

GENERAL CONSIDERATIONS FOR THE DEVELOPMENT OF MEDICAL DEVICE PACKAGING

Packaging Functions

As a general rule, packaging performs three broad functions—protection, utility, and communication—within three environments: the physical, ecospheric, and human (8). (See Packaging Design and Development for more detail.)

Protection. Protection refers to protection of the medical device from the environment and vice versa. For medical device packaging, product protection is necessary to maintain package integrity throughout its entire life, including: sterilization, shipping, storage, handling, and use. Typical issues include protection from shock and vibration, crushing, puncturing, tearing, bursting, splitting, pinholing, humidity, heat, and so on.

Table 1. General Classification System for Medical Devices Proposed by the Global Harmonization Task Group Study Group 1

Class	Risk Level	Device Examples
A	Low	Surgical retractors Tongue depressors
B	Low to moderate	Hypodermic needles Suction equipment
C	Moderate to high	Lung ventilators Bone fixation plates
D	High	Heart valves Implantable defibrillators

Source: Principles of Medical Devices Classification GHTF/SG1/N15.

The vital importance of maintenance of the sterile barrier system (SBS) is a distinctive characteristic of medical device packaging. Medical device packaging for disposables must not only maintain the SBS but, in many cases, also facilitate the sterilization of the device within. Such protective characteristics can be achieved through the package shape, particularly in thermoformed parts, in order to avoid product shifting or to keep kit components separated or nested.

For sealed packages, seal integrity is an important characteristic in product protection. Seals must be free of channels and must withstand the rigors of sterilization and transit.

Utility. Utility is related to the ease of use of the system. For many medical devices, quick and easy opening and removal of contents are crucial. While this consideration is also important for devices with relatively low risk, such as an adhesive bandage, it is extremely critical for sterile medical devices that are used in surgical arenas where the packaging must allow the device to be removed without contamination (aseptic presentation; see Figure 2). This particular need has led to the development of special materials and sealants that, when used in combination, can provide a package strengths that are adequate to endure the severity of processing and, at the same time, can be manually opened without imposing excessive stress on product or user.

Package design plays a key role in the opening function. For example, for tray lids, the seal area should transmit the peeling force smoothly around the package. The shape of the seal and design and location of the peel tabs affect the relative ease of opening. Preferably, peeling tabs are located on the corners of rectangular trays. Lids should extend slightly over seal areas to avoid edge tear when peeled. Most designs are based on the classic “Chevron seal” or “corner peel” designs. There are some cases where the package may serve other functions such as a measuring device, dispenser, stabilizing stand, disposal receptacle, and other suitable applications (9).

Communication. As with consumer goods packaging, secondary and primary medical device packages are a means to convey information through graphics, materials, and shape. Packaging communication operates at different levels, depending on the type of medical device. For over-the-counter (OTC) medical devices, such as condoms, glucose meters, adhesive bandages, thermometers, and so on, the communication role involves motivating a purchase, as well communicating important information for the safe and effective use of the medical device. Information may include directions, warnings, product benefits, brand differentiation, and so on. A very important aspect of package communication is product identification. This is especially true for devices that go into institutional settings, such as hospitals, where personnel may have to identify the correct device for a patient when seconds count.

Increasingly, the manufacturers of medical devices must provide crucial information in several languages. The crowded labels can make the legibility, visibility, and accuracy of the information, all of which are important, challenging to achieve. Package manufacturers not only face these challenges when it comes to labeling their products, but must also be sure that inks (as well as other components of the package like adhesives) do not interfere with the product’s efficacy or safety. In the event that components of the packaging migrate, it is important that these unintended additives are nontoxic and do not degrade or affect the intended performance of the device.

Package Forms, Materials, and Sealing

Selection of packaging style can impact package integrity. The type of package is largely driven by the characteristics of the device being packaged. These include size, shape, profile, irregularities, density, weight, and configuration (e.g., single unit or kit). For example, a high-profile, irregularly shaped device would be more securely packaged in a semirigid plastic tray than in a

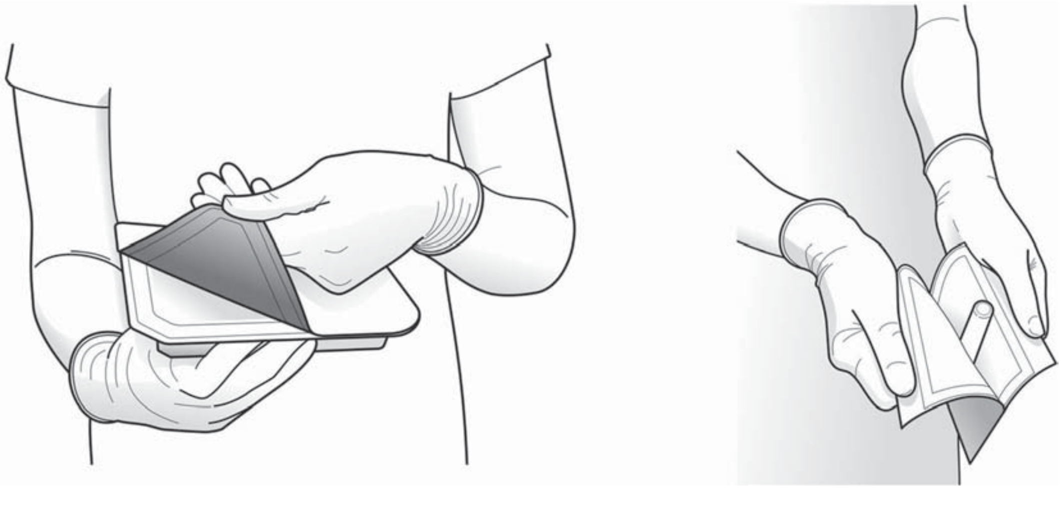

Figure 2. Aseptic presentation.

flexible pouch. As such, during the early design stages, it is critical to define the following parameters:

- Critical product characteristics.
- Type(s) of protection required (physical, ultraviolet light, O_2, water vapor transmission, etc).
- Type of sterilization process.
- Where and how the product is going to be dispensed (OTC, surgery, etc.).

Early packaging forms for medical devices included bags, cartons, and wraps; the primary material was paper. Glass and metal containers were used to a lesser extent. The coming of thermoformable materials in the 1950s and 1960s made tray and blister packaging possible, but the lack of good lidding materials limited their expansion. Boxes, cartons, and paper bags were not easy to use, inconvenient to dispense, and difficult to provide sterile delivery. The introduction of new thermoplastic polymers and peelable materials, along with improved film laminations, has led to the packaging forms most commonly used today (9). See Table 2 for a summary of materials and packages of the medical device industry.

Thermoformed Trays. Thermoformed trays are commonly used for surgical procedure kits and are ideal for high-profile, irregularly shaped devices. There are two types of thermoformed trays: semirigid and flexible. The most important difference is that semirigid trays are structurally self-supporting. They can provide good physical protection and are suitable for multicomponent applications. Formed flexible packaging is more suitable for low-cost devices and for simple tray configurations, but do not offer the same degree of structural protection as the semirigid trays.

The following characteristics are highly desirable for all formable materials:

- Ease of forming: The container should be free from mechanical stress to avoid sterilizer creep or seal fatigue.
- Heat resistance: The container should withstand heat sealing without deformation of seal flanges.
- Product compatibility: It is important that packaging components be nonreactive with the product.
- Sterilization compatibility: The packaging must withstand the rigors of sterilization and, in many

cases, must facilitate as well as maintain sterility throughout distribution and handling.

- Sealant compatibility: Compatibility of the materials and their thermal transitions must be considered so that they can be efficiently processed.
- Ability to age: Designers must consider the materials and issues of mass transfer that may impact the ability of the system to maintain the SBS throughout the product's stated life.
- Cost-effective.

Typical materials for thermoformed trays are high-impact polystyrene (HIPS), polyvinyl chloride (PVC), XT polymer, acrylonitrile, polycarbonate (PC), and polyethylene terephthalate glycol (PETG). Lids can be manufactured from paper, Tyvek®, or a film, depending on the function, sterilization, and sealer characteristics (10).

Flexible Nonformed Pouches. This type of pouch is commonly used for single-use disposable items such as gloves, catheters, tubing, adhesive bandages, dressings, syringes, and so on. Flexible packages tend to provide less physical protection than the rigid ones (10) and are a preferred choice for high-volume, low-cost devices. It is a packaging form that provides: a sterile barrier, the ability to withstand sterilization, and, if properly designed, easy-opening features for dispensing. Varying peel pouches can be run on form-fill-seal machines.

Examples of flexible, nonformed pouches are flat pouches and gusset pouches. Flat pouches are bags made from two webs and sealed along the perimeter. The end seal is usually V-shaped or "chevron" for ease of opening. Material combinations include: adhesive coated paper to paper, paper (coated or uncoated) to film, Tyvek® (coated or uncoated) to film, coated Tyvek® to Tyvek®, and film (coated or uncoated) to film. Foil laminations are used if additional barrier properties are needed. Pouches with the right material combination can be sterilized by all commercial sterilization processes. Pouches manufactured with nonpermeable materials are limited to radiation sterilization or, under controlled-conditions, steam (10). Gusset pouches are similar to flat pouches except that one web is gusseted on the sides or the bottom to accommodate higher-profile products.

Bags and Vented Flexible Packaging. Bags are extensively used in the industry—in particular when low cost and high profile are required. Early bags were made of paper; some types of which are still being used today. Paper bags have the porosity needed for gas and steam sterilization. On the other hand, paper bags do not offer a particulate-free opening and they provide poor puncture resistance. Traditional paper bags have been replaced by pouches and trays. Plain polyethylene (PE) bags are used when clean, but not sterile, delivery is necessary. PE bags have good mechanical properties, but they are not porous enough to allow simple sterilization. PE has been shown to be permeable to ethylene oxide (ETO) sterilization with slow and closely controlled cycles. Vented bags have been developed to provide a clean, low-cost, high-profile, strong package and sterilizable container. Vented bags with single and double vents allow for ETO sterilization of large-sized kits.

Examples of bags and vented flexible packaging include paper bags, vented bags, and header bags. Paper bags are fabricated from a single sheet of surgical paper with adhesive zone when sealing is needed. They usually have a back seam and can be gusseted on the sides or bottom. They can be manufactured on form-fill-seal (FFS) packaging equipment. Vented bags are made from film; they have small windows with breathable patches made of paper or Tyvek®. The patch is needed for gaseous sterilization. Header bags are also plastic bags but instead of having a breathable patch, the top of the bag is designed with a peelable paper or Tyvek® strip running across the top. Header bags allow for aseptic presentation while vented bags do not (10).

Package Sealing. The sealing of medical device packaging is critical. Inappropriate sealing can negatively affect the package integrity. There are two types of seals: weld and peelable. Weld seals are achieved by heat or ultrasonics and produce a joint that is not designed to open. Peeable seals are achieved with heat and without heat (cold seals) and are designed to open. Peelable cold seals are accomplished by applying a cohesive material to both webs and then a uniform pressure contact. This seal type cannot be resealed; as a result, it provides a tamper-evident feature. Peelable heat seals are more complicated to achieve since they involve exact control over temperature, time, and pressure.

Sterilization Processes

Medical devices that will be in contact with blood or internal tissues, other than the gastrointestinal tract or other mucosa, and devices that deliver parenteral fluids or drug substances to the same tissues are expected to be sterile. Sterility is defined as having not more than one viable microorganism in a million sterilized products ($\text{SAL} = 10^{-6}$). A sterile device must keep its sterility until it is removed from the primary packaging for use on the patient (11). In the past, manufacturers of sterile medical devices frequently guaranteed the sterility of the product until the package was intentionally opened or accidentally damaged. This approach has changed in recent years. To maintain package integrity for such unlimited time poses a real challenge for any combination of materials, packaging forms, and seals. Recently, the European Union began requiring manufacturers to provide a shelf-life date and data that support the maintenance of the SBS throughout the stated timeframe.

Ethylene oxide (EtO) and radiation (gamma and electron beams) are the two dominant sterilization methods. As a rule of thumb, if product and packaging can withstand radiation, medical device manufacturers tend to use gamma radiation. If not, then EtO is the choice. Alternate methods such as heat (steam and dry) sterilization and several chemical and gas plasma methods represent a very small share of the market. However, these other methods offer efficiency, safety, and cost benefits which may make them attractive for particular segments of device sterilization.

Ethylene Oxide (EtO) Sterilization. EtO gas is an effective sterilant that causes cell death by denaturating of the proteins within it. The process does not cause discoloration and embrittlement of the packaging. However, it represents a major source of package stress and loss of seal integrity (seal fatigue or sterilizer creep). The higher stresses are induced by higher temperatures, pressures, and humidity during sterilization. In addition, the EtO residual level must be carefully monitored in order to prevent patient harm. The key criteria for packaging materials used in EtO sterilization are: porosity, hot adhesive strength, moisture and EtO tolerance, and broad product and chemical compatibility (9).

Radiation (Gamma and Electron Beam) Sterilization. Radiation is used to break up a microorganism's DNA molecules so that it cannot multiply. It is a fast and effective method for killing bacteria which leaves no toxic residue after the process is complete, eliminating many of the problems of EtO (heat, moisture, pressure, and chemicals). Since radiation processes do not require gas porous materials, all-plastic film packaging is suitable for this process. However, Tyvek® may be used in radiation applications because of its other high-performance characteristics, radiation resistance, and historic use. Material compatibility is an issue since gamma radiation may discolor or embrittle some polymers and some papers may yellow. When using gamma radiation, packagers need to focus on the effect of radiation on the package's properties, such as tensile strength, elastic modulus, impact strength, elongation, and color.

Heat Sterilization. Heat sterilization is one of the oldest techniques for killing bacteria. There are three types of heat sterilization methods. One involves the use of moist heat (high-pressure, saturated steam) as the sterilant; the second employs an autoclave to heat liquid already inside the package; and the third uses dry heat in an oven. The energy from the heat causes the coagulation of proteins in the cells, which, in turn, causes the microorganism's death. Steam under pressure is an effective sterilization method; the equipment needed is available in a wide range of sizes and prices, and there are no harmful byproducts from the process, although the whole cycle takes little time.

The major disadvantage is that it needs high temperatures that will deform plastics such as poly(vinyl chloride), polystyrene, polyethylene, and some synthetic fabrics. Fortunately, there are plastic materials that can tolerate varying levels of heat, these include nylon, polypropylene, oriented polyester, polycarbonate, and some grades of high-density polyethylene. Special precautions must be taken with Tyvek® since it is composed of HDPE fibers that melt at approximately 265°F. If sterilizer conditions are closely controlled between 250°F and 255°F, packages containing Tyvek® may be safely steam-sterilized.

The key criteria for packaging materials used in steam sterilization are (a) porosity (to allow the steam to pass through the package and contact the device), (b) seals and materials that can withstand high humidity at elevated temperatures, (c) bacterial barrier, (d) reactivity (so that product and package don't interact), and (e) the cost-effectiveness of proposed designs.

Packages that will sterilize devices via autoclave sterilization must contain water inside the sterile barrier system, have the barrier properties necessary to contain that water and provide a bacterial barrier, be nonreactive with the product, be able to withstand high humidity at elevated temperatures, and be cost-effective.

In a dry heat sterilization process, a package is subjected to controlled elevated temperatures (typically in excees of 300°F) for several hours. Silicone implants are sterilized using this technique.

Gas Plasma Sterilization. Low-temperature gas plasma (LTGP) provides an excellent alternative to EtO for sterilizing devices that are heat-sensitive and not radiation-stable. This is due, in large part, to its short sterilization cycles, negligible environmental impacts, and lack of aeration cycle (12). During this process "an aqueous hydrogen peroxide solution boils in a heated vaporizer and then flows as a vapor into a sterilization chamber containing a load of instruments at low pressure and low temperature" (13).

LEGISLATION, REGULATION, AND TEST STANDARDS

The systems surrounding the production of medical devices aim to maximize therapy safety and efficacy while minimizing cost. As a result, in most countries throughout the world, professionals in the device industry must demonstrate, with a high degree of confidence, that the products that they are producing are safe and effective. However, this must be done in an economy where cost-competitiveness is increasingly important and ballooning healthcare costs are creating concerns.

The question becomes, How do you ensure safety and efficacy and remain affordable? The solution generally involves using a scientific approach to design, production, and testing by using data to draw conclusions about the possibility of harm from a given device and/or lot. To do this, a variety of test standards are employed as the device and its packaging are developed.

Test Standards

The International Organization for Standardization (ISO). The International Organization for Standardization (ISO) has two standards regarding what type of information should be gathered to ensure the packaging of terminally sterilized medical devices performs as expected. The first, entitled “Packaging for Terminally Sterilized Medical Devices—Part I: Requirements for Materials, Sterile Barrier Systems, and Packaging,” “specifies the basic attributes required of materials and pre-formed systems intended for use in packaging systems for terminally sterilized medical devices while considering the wide range of potential materials, medical devices, packaging system designs and sterilization methods.” The second document, “Packaging for Terminally Sterilized Medical Devices—Part 2: Validation Requirements for Forming, Sealing, and Assembly Processes,” describes the validation process for forming, sealing, and assembly of the SBS. Validation refers to the need to systematically gather data through scientifically reliable means and interpret the data to determine that a process is capable of yielding the expected outcome.

Many organizations throughout the world have adopted the ISO standards (ISO11607 parts I and II). Among them are the Association for the Advancement of Medical Instrumentation (AAMI) and the American National Standards Institute (ANSI). AAMI went so far as to produce a Technical Information Report (TIR 22:2007) that provides guidance on implementing the ISO 11607 documents. Included in the TIR are the test methods typically used to indicate compliance with the requirements in the ISO standards (14). In general, the ISO documents indicate that:

- Package materials should be qualified.
- Packages should be tested.
- Processes should be validated.

These three things must be accomplished in order to ensure that the product is protected, the system is sterilized, and the sterility is maintained throughout distribution. (15) The “ISO strategy was to develop a single standard that addressed the required performance attributes of medical packaging without establishing specific performance criteria” (14). The material qualification, package testing, and process validation dictated by the ISO standards are all accomplished using data that are collected using relevant standards from a variety of organizations. See Table 3 for the types of tests that are conducted under these broad categories (15).

The use of standardized tests to qualify materials, test packages, and show evidence of controlled processes has several benefits. “Standardization of test methods allows laboratories to reduce the number of specific methodologies while retaining the overall capability. In addition, standardized test methods allow individual laboratories to assess their own capabilities against the stated intra laboratory variability” (14). The results provided from standardized tests should be comparable to those submitted by others, or obtained at different points in time.

The United States. Devices manufactured or sold in the United States are regulated by the U.S. Food and Drug Administration (FDA). Within the FDA, the Center for Devices and Radiological Health (CDRH) is responsible for drafting the specific requirements for the design, manufacturing, and packaging of medical devices. Among the key documents containing legislation and regulation of medical devices are:

- The Federal, Food, Drug, and Cosmetic Act of 1938
- The Medical Device Amendments of 1976
- The Design Control Guidance for Medical Device Manufacturers

Table 3. ISO Mandates. Types of tests conducted for material qualification, package testing, and process validation

Categories	Tests	
Material qualification	Microbial barrier Toxicity/biocompatibility/particulates Physical and chemical properties, as dictated by product requirements (extractables, retained solvents, etc.) Barrier properties Compatibility with the sterilization process Compatibility with the forming and sealing process Visibility and appearance Requirements for shelf life	
Package testing	Package performance	Distribution, handling, and storage Integrity (microbial and physical) Strength (burst, tensile, etc.)
Validation	Installation	Installed correctly? Operating as expected after installation?
	Operational	What are the process control limits? What are the actionable levels necessary in order to produce product meeting predetermined requirements?
	Performance	Does the product, when produced under the expected conditions of production, consistently meet the predetermined requirements?

Source: Adapted from Miller (15).

- The Quality Systems Regulations (QSR), which are located in 21CFR Part 820

The QSR document dictates the documented use of a quality system and the verification and/or validation of the system's ability to produce expected results. Documentation to meet these objectives heavily relies on data collected through standardized test methods. Test standards commonly used in the United States come from a variety of organizations. These include: ASTM International, the United States Pharmacopeial Convention (USP), the Technical Association of the Paper and Pulp Industry (TAPPI), and the International Safe Transit Association (ISTA). Standards that are frequently used to develop, test, and monitor SBS are indicated in Table 4.

The European Union (EU). In the European Union (EU), devices are regulated through a series of measures that are part of the "New Approach Directives." Directives relating to medical devices include: the Medical Devices Directive (MDD), the Active Implantable Medical Devices Directive (AIMD), and the In vitro Diagnostics Directive (IVDD). Compliance with the European Directives is signified through the use of a CE marking and declaration of conformity.

The EU authorized the Committee for European Normalization (CEN) to establish standards for compliance with European Directives. Previously, this was EN 868-1, "Packaging Materials and Systems for Medical Devices which Are to Be Sterilized—Part 1: General Requirements and Test Methods," this has since been replaced by the two ISO standards previously discussed. A series of vertical standards provide specific performance requirements and test methods for materials typically used in the packaging of medical devices (see Table 5).

CHALLENGES FACING THE MEDICAL DEVICE INDUSTRY

As indicated previously, the device industry invests heavily in R&D and has historically been characterized by innovation. That said, "traditional innovation is no longer sufficient to win in this competitive game" (4). The aging of the population, escalating healthcare costs, rising expectations, problems within the supply chain, and fierce competition have created a climate where the designers of medical devices and their packaging face a host of pressures and considerations as they make design choices.

The Aging of the Population

It is estimated that by the year 2050, over 5% of the U.S. population will be over the age of 85. The aging trend is not limited to the United States, but is a global phenomenon that warrants the consideration of those that design packaging for all types of products (see Figure 3).

Not only do aging consumers use medical products at a higher per capita rate than the general population, they are at risk from inappropriate product use for a variety of reasons. They are likely to have various chronic disorders that create the need to engage in multiple, complex therapies on a daily basis. Further complicating things is the fact that older consumers are also more likely to be experiencing mental, physical, and perceptual declines (see Figure 4).

This has prompted people like Patricia P. Barry, MD, MPH, and Executive Director at the Merck Institute of Aging, to issue a call to industry to begin thinking differently. In *The State of Aging and Health in America* (16), Barry indicated:

> "The demographic tidal wave is coming. Aging in the 21st century, however, is more than just a matter of numbers. The average 75-year-old has three chronic conditions and uses five prescription drugs. Older consumers have different challenges and medical needs than younger adults. Consequently, it is not enough to be aware of the demographic imperative; we must also be prepared for it" (16).

These trends have obvious ramifications for the designers of devices that are sold over the counter; however, this changing demographic also has impact for those that are sold for institutional use; increasing life spans will tax healthcare as we know it. As such, designs that catalyze system-wide efficiencies will become paramount.

Medication Errors and Patient Noncompliance

It is well documented, both in human and financial terms, that medical errors are a major problem in healthcare facilities throughout the world (17–19). At the turn of the 20th century, the Institute of Medicine (IOM) published "To err is human," reporting that in between 44,000–98,000 people in America die each year as the result of medication errors. "Even when using the lower estimate, deaths due to medical errors exceed the number attributable to the 8th leading cause of death. More people die in a given year as a result of medical errors than from motor vehicle accidents (43,458), breast cancer (42,297), or AIDS (16,516)" (20).

This comes at a significant cost; estimates for U.S. figures include the expense of additional care that is necessitated by the errors, as well as lost income and household productivity from resultant disability. These have been estimated at US$ 17–29 billion annually. Estimates for the cost of an adverse drug event (ADE) for each patient range from US$ 2000–5000 (21).

These problems are certainly not limited to the United States. Estimates from the United Kingdom indicate that "about 10% of inpatient episodes result in errors of some kind, about half [of which] are preventable" (17). A study published by Vincent et al. suggested that of the approximately 8 million hospital admissions that occur in England each year, about 850,000 result in a patient safety incident, costing the National Health Service (NHS) approximately £2 billion in extra hospital days (17, 22).

Issues of package and label design have been implicated as a significant part of the problem. The 2000 IOM report, which made numerous recommendations for improving the American healthcare system, stated that "drugs may be prone to error in use due to sound-alike or look-alike names, unclear labeling or poorly designed

Table 4. Standards and tests used to develop, test, and monitor sterile barrier systems in the United States

Categories		Standards/Tests
General		ASTM International F2097: Standard guide for design and evaluation of primary flexible packaging for medical products
		ASTM F99: Standard guide for writing a specification for flexible barrier materials
		ASTM F2559: Standard guide for writing a specification for sterilizable peel pouches
Material qualification	Microbial barrier	ASTM F 1608: Standard test method for microbial ranking of porous packaging materials (exposure chamber method)
		ASTM F2638: Standard test method for using aerosol filtration for measuring the performance of porous packaging materials as a surrogate microbial barrier.
	Biocompatibility	ISO 10993, Part 1: Biological evaluation of medical devices: evaluation and testing
		ASTM F2475: Standard guide for biocompatibility evaluation of medical device packaging materials
		USP <87> Biological reactivity testing, in vitro
		USP <88> Biological reactivity testing, in vitro
		USP <1031> Biocompatibility of materials used in drug containers, medical device, and implants
	Particulates	ASTM D 2019: Standard test method for dirt in paper and paperboard
		TAPPI T-437: Dirt in paper and paperboard (TAPPI dirt chart)
		AAMI TIR DP 01 Ed. 1 Particulates associated with vascular medical devices (in progress)
		ASTM D726: Standard test method for resistance of nonporous paper to passage of air (Guriey test for low porosity)
	Barrier (porous)	TAPPI T 536: Resistance of paper to the passage of air (HP method) (Gurley test method for medium porous materials)
		TAPPI T460: Air resistance of paper (Gurley test method for highly porous materials)
	Barrier (Nonporous)	ASTM F 2097: Standard guide for design and evaluation of primary flexible packaging for medical products (complete listing of test methods at ASTM)
	Durability	ASTM F 2097: Standard guide for design and evaluation of primary for medical products contains numbers for tests that can be used to characterize puncture and tear resistance, thickness, tensile, flexural durability, basis weight, bond strength, and aging
	Processing	ASTM D1894: Standard test method for static and kinetic coefficients of friction of plastic film and sheeting
		ASTM F 2029: Standard practices for making heat seals for determination of heat sealability of flexible webs measured by seal strength
		ASTM F 2217: Standard practice for coating/adhesive weight determination
	Visibility and appearance	ASTM D1003: Haze ASTM D 2457: Gloss ASTM D 589: Opacity
		ASTM D 5264: Standard test method for abrasion resistance of printed materials by the Sutherland rub tester
		ASTM F 2250: Standard practice for the evaluation of chemical resistance of printed inks and coatings on flexible packaging materials
		ASTM F 2252: Standard practice for evaluating ink or coating adhesion to flexible packaging materials using tape
Package testing	Integrity	ASTM F1886: Standard Test Method for Determining Integrity of Seals for Medical Packaging by Visual Inspection
		ASTM F1929: Standard Test Method for Detecting Seal Leaks in Porous Medical Packaging by Dye Penetration
		ASTM F 2391-05: Standard test method of measuring package and seal integrity using helium as the tracer gas
		ASTM F2338: Standard test method for nondestructive detection of leaks in packages by vacuum decay method

packaging” (18). This was reiterated in the 2006 IOM report, which indicated “drug information is communicated through labeling and packaging, marketing practices and advertisements. Poorly designed materials and inadequate representation of risks and benefits to providers and consumers have led to many errors” (19). Other organizations have echoed these sentiments. A study conducted by the United States Pharmacopeia indicates, “USP investigators calculated that confusing labeling or packaging of drug products contributed to more than half of the incidents [of error]” (23).

Although there are systems in place for the voluntary and mandatory reporting of adverse incidents associated with medical devices, “they are limited by underreporting

Table 5. Vertical European Standards for Medical Packaging EN 868 Series

Standard	Title
EN 868-2: 1999 (Sterile wrap)	Packaging materials and systems for medical devices which are to be sterilized, Part 2: Sterilization wrap—Requirements and test methods
EN 868-3:1999 (Paper for bags and pouches)	Packaging materials and systems for medical devices which are to be sterilized, Part 3: Paper for use in the manufacture of paper bags (specified in EN 868-4) and in the manufacture of pouches and reels (specified in EN 868-5)—Requirements and test methods
EN 868-4:1999 (Paper bags)	Packaging materials and systems for medical devices which are to be sterilized, Part 4: Paper bags—Requirements and test methods
EN 868-5:1999 AC:2001 (Pouches)	Packaging materials and systems for medical devices which are to be sterilized, Part 5: Heat and self-sealable pouches and reels of paper and plastic film construction—Requirements and test methods
EN 868-6:1999 (Paper for packs)	Packaging materials and systems for medical devices which are to be sterilized, Part 6: Paper for the manufacture of packs for medical use for sterilization by ethylene oxide or irradiation—Requirements and test methods
EN 868-7:1999 (Adhesive coated paper)	Packaging materials and systems for medical devices which are to be sterilized, Part 7: Adhesive coated paper for the manufacture of heat sealable packs for medical use for sterilization by ethylene oxide or irradiation—Requirements and test methods
EN 868-8:1999 (Reusable sterilization containers for steam sterilizers)	Packaging materials and systems for medical devices which are to be sterilized, Part 8: Reusable sterilization containers for steam sterilizers conforming to EN 285—Requirements and test methods
EN 868-9:2000 (Uncoated non-woven polyolefin materials, e.g., Tyvek)	Packaging materials and systems for medical devices which are to be sterilized, Part 9: Uncoated nonwoven materials of poiyolefines for use in the manufacture of heat sealable pouches, reels and lids—equirements and test methods
EN 868-10:2000 (Adhesive coated non-woven polyolefin materials, e.g., Tyvek)	Packaging materials and systems for medical devices which are to be sterilized, Part 10: Adhesive coated nonwoven materials of polyolefines for use in the manufacture of heat sealable pouches, reels and lids—Requirements and test methods

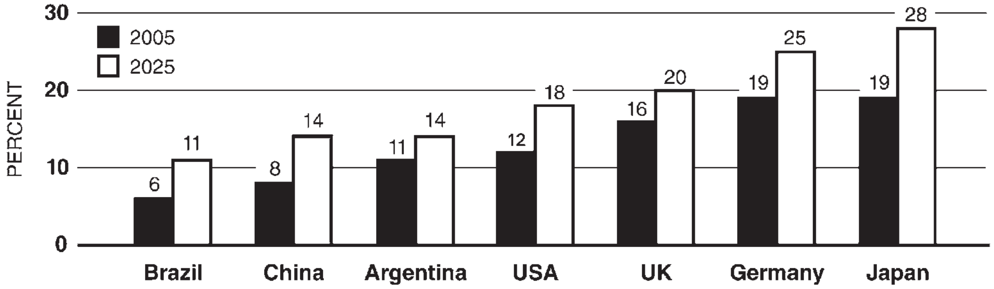

Figure 3. Global aging. Percentage of people age 65 and over in selected countries for 2005 and projected 2025. [*Source*: U.S. Census Bureau (37).]

and the absence of denominator data" (24). The diverse array of devices, environments of use, and risks associated with failures challenge the implementation of comprehensive surveillance plans. The information that is available suggests that adverse medical device events (AMDEs) are an important patient safety issue that are presently underreported; strategies for prevention and detection need to be implemented, and it is likely that packaging will play a role in these efforts.

Rising Nosocomial Infection Rates

The emergence of microbes that are resistant to cheap and effective, first-choice (or "first-line") drugs presents one of the most serious problems facing global healthcare. Bacterial infections that show the most evidence of resistant microbes include: diarrheal diseases, respiratory tract infections, meningitis, sexually transmitted infections, and hospital acquired infections. Implicated microbes include: penicillin-resistant *Streptococcus pneumonia*, vancomycin-resistant enterococci, methicillin-resistant *Staphylococcus aureus*, multi-resistant salmonellae, and multi-resistant *Mycobacterium tuberculosis* (25).

Treatment failures lead to the requirement for second-line therapies that can be more than 100 times expensive than first-line therapies. In countries where treatment becomes cost prohibitive, the consequence is not only the suffering and the potential death of the patient, but also possible spread of the drug-resistant disease. "Most alarming of all are diseases where resistance is developing for virtually all currently available drugs, thus raising the spectre of a post-antibiotic era…current trends suggest that some diseases will have no effective therapies within the next ten years" (25).

Additionally, several concurrent trends conspire to aid in the spread of infections. These include:

- The frequent need for hospital intervention of the aging population.
- Increases in urbanization and overcrowding.
- A resurgence in certain diseases (e.g., tuberculosis and malaria).
- Tremendous increases in global trade and travel.
- The AIDS epidemic, which gives rise to large numbers of immunocompromised patients that are susceptible to disease.
- Changes in the environment, which include pollution, environmental degradation, and changing wind patterns. These impact both the incidence and distribution of disease across the globe (25).

Although device packagers have long understood the need to maintain a sterile barrier throughout distribution, at no time in history has sterile presentation of packaged devices been more important. Designers must consider how the design will assist the sterilization process (e.g., pore size on sterilization efficacy), maintain the SBS throughout distribution and handling, and facilitate aseptic presentation of package contents to the sterile field.

As if the previously described challenges were not enough to consider, issues associated with the supply chain also create difficulties that should be considered by designers.

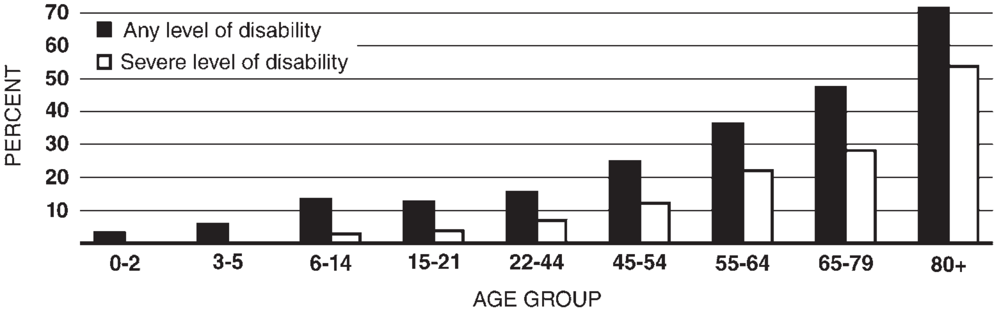

Figure 4. Disability prevalence by age. Percent with specified level of disability. [*Source*: U.S. Census Bureau (37).]

Illicit Activities within the Supply Chain

Devices can be grouped into two broad categories with regard to the supply chain: advanced devices and commodity-type medical surgical supplies. Advanced devices are higher-priced, lower-volume, technologically sophisticated diagnostic and therapeutic products. They are sold mostly to hospitals, but to different customers within the hospital supply chain: buying groups, distributors, and providers. The manufacturers of commodity-type medical surgical supplies have a more complicated supply chain; products are frequently sold through a series of distributors, a multi-echelon global supply chain that, at present, lacks transparency.

Even within the hospital, tracking therapies can be difficult. Complications of managing hospital inventories include the fact that items to be tracked are varied. As discussed previously, products are large and small, durable and expendable, disposable and reprocessed, numerous and few, and critical and noncritical to care. As such, the relevant information varies from item to item. Furthermore, a "hospital's size, geographic location, diversification, and various specializations all affect the nature of its business and, hence, the requirements of its supply chain. Likewise, each ward within a hospital is unique. The number of products and demand of those products, for example, varies greatly from an Emergency Room to a Cardiac Cath Lab to an Intensive Care Unit" (26).

As such, tracing devices back to their components can be difficult in the current system. Compounding this problem is the issue of arbitrage (both legal and illegal). The healthcare industry, by its very nature, must balance the tensions of innovation and access. The industry must provide access to therapies for all people, but if it is to continue to innovate, the costs associated with research and development must also be recouped so that they can be invested to develop future generations of lifesaving products. The way that the industry generally deals with the tension of access versus innovation is differential pricing, selling at what the market will bear. For example, OECD nations,* which can afford to pay more, generally bear the majority of the cost for future innovations; areas of the world that cannot afford this burden are sold therapies at much lower prices. Markets can be segmented along geographic borders, political borders, or buyer and payer classes within countries (such as U.S. Medicare, Medicaid, Veterans' Affairs, Federal employees, or private health plans).

However, one of the unfortunate side effects of differential pricing is that it makes the illegal arbitrage of healthcare products possible. Economic arbitrage is the opportunity to buy an asset at a low price and then immediately sell it in another market for a higher price (27). In instances where arbitrage involves intellectual property and the product crosses an international border, it is called parallel trade. Parallel trade involves "the act of taking goods placed into circulation in one market, where they are protected by a trademark, patent or copyright, and shipping them to a second market without the authorization of the local owner of the intellectual property right" (28). Parallel trade may or may not be legal, depending on the country's intellectual property laws. Additionally, the practice may be forbidden contractually, though this approach can run afoul of competition laws (27).

The problem of this global system of multiple hand-offs, arbitrage, and opacity is that it presents opportunity for those with illicit intentions. Criminals can participate in the supply chain of surgical supplies in a variety of ways. Tactics include:

- Buying medical supplies from "closed door" pharmacies and dispensaries of small institutions such as nursing homes, hospices, and AIDS clinics at discounted prices.
- Paying hospital or nursing home workers for devices from their supplies.
- Offering cash to Medicaid patients in exchange for their care items.
- Collaborating with corrupt company employees to break into warehouses, or steal shipments from loading docks.
- Stealing or purchasing devices that are intended for charitable or low-income markets in order to divert products to markets that will pay higher prices.

For those that are not willing to go to the effort that illegal arbitrage takes, there is counterfeiting. "Counterfeiting dispenses with the need to collect the product in far-flung locations, repackage it, and transporting [sic] it back to the OECD markets. Counterfeiting can be produced in market at very modest cost, more cheaply than obtaining diversions in low-income countries" (27). Counterfeiting of medical products (drug, device, and biologic) is attractive to those with illicit intentions for a variety of reasons, including:

- Lax penalties associated with the crime.
- The rise of technology which allows for easy production of many medical products.
- Cottage industries that use unemployed, skilled labor.
- The rise of internet sites where goods can be advertised and sold.
- An increase in the self-prescribing culture.
- Great potential for profit (in part due to differential pricing, in part due to the cost of genuine therapies).
- The nature of the industry; sick, and sometimes desperate, people are open to exploitation.
- The globalization of the healthcare industry and free trade, making the distribution of products easier.

Although the counterfeiting of drug products is more widely investigated and reported, the number of counterfeit medical devices is believed to have grown in recent years and the potential ramifications are serious (29). Both finished goods and device components have been successfully faked. Glucose meters and test strips,

---

* Countries that are members of the Organisation for Economic Co-operation and Development.

condoms, contact lenses, blood pressure meters, blood bags, surgical mesh, stethoscopes, sphygmomanometers, the components of X-ray machines, and even intra-aortic pumps, to name a few, have been counterfeit in recent years (30, 31).

As mentioned previously, manufacturers and even regulators are looking to packaging as a component of the solution to the problems associated with diversion and counterfeiting.

Escalating Healthcare Costs

The previously discussed issues (aging populations throughout the world, medication errors and patient noncompliance, rising rates of infection, and devices delivered by a supply chain that moves differentially priced therapies in a world of arbitrage and counterfeits) have obvious impacts. These issues, coupled with an ever-increasing reliance on technologies that provide human sustenance and comfort (i.e., complicated devices), are driving healthcare costs up the world over (32). "Health care costs are rising worldwide at rates that alarm governments, business and individuals"… and have grown as a percentage of GDP in most countries (33). This is happening in a world where cost-competitiveness is increasingly important and a reduction of ballooning healthcare costs is recognized as a priority.

In turn, governments, providers, purchasing organizations, insurers, and patients are demanding better outcomes for the dollars that they spend. Varying players within the medical products' supply chain are calling for evidence-based medicine and comparative evidence upon which decisions can be made. They desire the ability to link specific devices to patient outcomes in order to maximize the impact of the healthcare dollar. Packaging has the potential of playing a role in these efforts, because it contains identifying marking of contents that can be fed into patient records (and bills).

POTENTIAL SOLUTIONS

Automatic Identification

The use of automatic identification technologies (auto ID) to carry and communicate standardized information about medical devices is one approach that is being used to system efficiencies and reduce cost. "Auto ID is the broad term given to a host of technologies that are used to help machines identify objects or persons" (34) and includes bar codes, radio-frequency identification (RFID), and biometrics.

Proponents of implementing Auto ID in a standardized fashion for the medical device industry indicate the following benefits:

- Reductions in medication errors
- Facilitation of notification and recalls
- Identification of device incompatibilities
- Identification of potential adverse effects (such as allergic reactions)
- Deterrence of counterfeits
- Assistance in product authentication
- Data for evidence-based medicine
- Evidence for prosecution in the case of illicit activities (counterfeiting)
- Integration of product with electronic health records (EHR) and Computerized Physician Order Entry (CPOE) systems
- Improved inventory control
- Improved billing and reimbursement
- Improved post market surveillance (2).

The Rise of Combination Products

With increasing frequency, these challenges are being met using (a) designs that are a convergence of devices, (b) pharmaceutical and biologic products, or (c) customized kits, and combination products. Combination products are one way that device manufacturers can add value to medical products. The market size of all combination products in 2004 was estimated to be $6 billion and has been projected to grow to $10 billion by 2009 (35). This growth is largely due to the added convenience that these products provide.

Products like insulin injector pens, metered dose inhalers, transdermal patches, and prefilled syringes are combination products that add convenience, saving end-users time and effort. In these examples, two types of therapy (a drug and a device) are combined into a single product, and the device itself becomes a package for the drug product. Customized kits, in which multiple products are packaged into a single package, usually for a procedure, are another example of combination products. Regardless of whether the therapies are combined into a single product, or multiple products packaged together, things like shelf life, efficacy, package testing, product labeling, and regulation become more complicated. As such, people that design packaging for combination products must consider not only the physical environment (shocks, vibrations, and other aspects of dynamics), which can threaten the integrity of the sterile barrier, but also the ecospheric environment, which can render the drugs that have been added unefficaciously.

CONCLUSIONS

Because of the disparate array of medical devices, thoroughly covering the packaging of medical devices in a single book chapter is all but impossible. This article is meant to serve as a guide to other resources for the packagers of medical devices and also provide things to consider during the design process (present and future).

Acknowledgments: The authors gratefully acknowledge the advice, insights, and technical expertise of Dhuanne Dodrill. Dhuanne was immensely helpful in providing writing much of the technical information regarding materials, packages, and sterilization processes.

METAL CANS, FABRICATION

Jean Silbereis
SLCC Can Consultants
La Tour de Peilz, Switzerland

The metal can is one of the oldest forms of packaging preserved food for long periods. In the same way, it has proven to be an adequate container for food stuffs, beverages, and industrial products. Thousands of different products of all kinds have been packed in metal cans. The traditional method of manufacture is to start with a rectangular sheet of tinplate or canstock that has special surface treatments. Blanks, or bodies, are cut from the sheets, flexed and rolled into a cylinder, and then notched and hooked so as to form a locked side seam, which results in a longitudinal joint line bonding both the lateral cut edges of the blank.

Bodies are beaded for increased resistance against implosion of the can. More and more can bodies are necked to use ends of reduced diameters or/and thinner and more economical end stock, as well as to make cans stackable.

Ends, i.e., the closures at the bottom and the top of the cylindrical or any other geometrical section of the can body, are tightly secured to the body by a double seam (called so because they are made in two operations). Both extremities of the can bodies are flanged so as to create the body hook, which engages with the end hook so as to form a tight, compact, and interlocked closure. One end, which is called the maker's end, is fitted by the can manufacturer. The other, fitted by the filler or the packer upon filling the "open top" can, is known as the packer's end.

Because the container is made from three separate elements, it is known as a three-piece can. Its construction had remained basically unchanged for more than 150 years. Advances have been made in engineering, automation, and speeding up of the original manual canmaking processes. The metal input has been gradually and constantly reduced through more sophisticated design geometry and more recently by changing the methods of making the side seam from tin/lead alloy soldering to welding (see Figure 1).

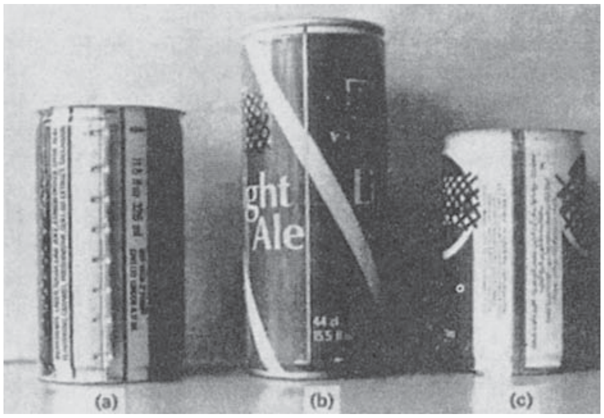

Figure 1. Three-piece can side seams (**a**) soldered; (**b**) cemented; (**c**) welded. Courtesy of *Proceedings, 3rd International Tinplate Conference*, 1984.

Since the early 1970s, a different concept of canmaking has gained acceptance in commercial production. In this, the body and one of the ends, are formed in one entity from a flat circular blank by press forming technique (1). The open top end is sealed with the usual packer's end. It is known as two-piece can. The methods of forming are identified: drawing and ironing (D&I in the United States, DWI in Europe) and draw and redraw (DRD) (2). D&I, for instance, was used in World War I for making shell cases. What distinguishes them in canmaking is the use of ultrathin metal in high-speed production to yield outputs counted in billions of cans per year.

CAN TYPES

All processes convert flat sheet material into finished cans, which are supplied with a loose end for the packer or filler, according to this basic scheme: prepare plate matching the products to be packed, their filling and processing conditions as well as market conditions (climates, shelf lifes, presentation of cans, sanitary regulations, etc.); make bodies and ends; apply finishes (decorative or/and protective barriers). The order may vary, depending on the process used. The manufacture of three-piece and two-piece DRD cans starts with the finishing step. Some cans are resprayed with a top coat for increased corrosion resistance in a final stage of fabrication.

Coils are usually cut into sheets or scrolled strips (technique Littell) if coil coated stock is used. Sheets are coated on one or both sides and are decorated if appropriate. The coatings are called enamels in the United States and lacquers in the United Kingdom. Decorations are always protected by over-or finishing varnishes to make them scratch proof and to add gloss. In case of processed cans, decorative or barrier coats have to resist the applied heat treatments in autoclaves.

If the starting point is a circular blank, as for DRD cans or ends, then the cut edges of the sheets are scrolled for economy of metal usage (Figure 2). Alternatively, precoated coil stock may be fed directly into the cupping press for blanking and drawing or into the multi-die end stamping press. In the manufacture of two-piece D&I cans, plain coil, as supplied from the mill, is the starting point.

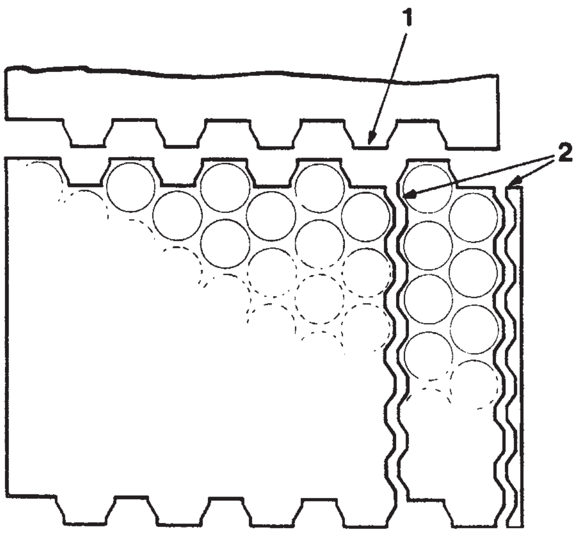

Figure 2. Scrolled sheet showing layout of blanks and scrolled edges for material utilization. 1, Primary scrolling used when cutting coil into sheets for coating. 2, Secondary scrolling used for cutting sheets into strips for feeding into the shell press.

Three-piece can manufacture is readily adaptable to making cans of any diameter and height. The production equipment is amendable to changes in size and is capable of production speeds of up 700+ cans per minute when cans are made as singles. In case of multi-high canmaking, the bodies are scored to final individual height prior to rolling and welding; subsequently separated outputs of 1200 to 1500 cans per minute are achieved on appropriately designed lines. Where the use of lead/tin solder is no longer acceptable, the change to welding can be made at minimal cost on existing lines, because only the equipment that makes the cylinder (the bodymaker) needs to be changed.

Three-piece manufacture is the choice of the small-to-medium-sized operation requiring flexibility for producing can sizes required in relatively modest quantities or to suit a variety of fill products that require changes in coating specifications. This is the salient asset of three-piece canmaking facilities. It allows the manufacture of various can types, i.e., food, flat and/or carbonated beverages, aerosols, and general line cans (industrial and dry products) by adding the adequate complementing equipment at limited cost to the existing line as long as the bodymaker can cope with the range of cans to be made.

Two-piece can manufacture is basically suited to a single can size, which requires outputs of at least 150 to 300 million cans per year. Yearly productions of modern lines are usually much higher, i.e., in the range of 400 to 500 million per annum. DRD, using precoated sheet or coil material, is used for food cans and predominently in the shallower sizes ($h/d < 1$). The process is being used, however, for food cans with an h/d ratio of 1.5 in the popular 3-in. (7.6 cm) diameter, e.g., 300 × 406 in the United States (for explanation of can dimensions: The first digit stands for inches and the two last ones, for sixteenths of inches; the measures are taken on the finished can overall in length and over the double seems in diameter).

The application of enamel to both sides permits the use of electrolytically chromium coated steel (ECCS), which has a surface that is too abrasive to be used uncoated (plain). It does also not offer any corrosion resistance. Because economics demand the use of the thinnest possible can stock, the high strength needed dictates the use of double-reduced (DR) grades. Additional strength is provided by beading or reforming the can bodies and adapting the profiles of the ends for increased flexibility in the autoclave, i.e., providing a maximum of expansion volume.

Generally, using two presses with a minimum of peripheral equipment, DRD provides a compact installation of relatively low capital cost for the achievable outputs. For that reason, it seems to be a preferred method for self-manufacture (captive canmaking) of relatively shallow containers by packers (e.g., tuna fish cans). However, the material property requirements and its constance of drawability are high, and the standard of enameling is critical to maintain integrity as the metal is formed.

D&I converts a plain coil into a fully finished can in a totally integrated, fully automatic process. The high capital cost of the full range of equipment needed implies a high volume in a nonfluctuating and constant ensured market. Together with the desirability of keeping the line running once harmonious operation has been achieved, this results in a 24-hour per day, 7-day per week operation with annual production up to planned business feasibility studies. Basically a single-can-size process, it is best suited for the production of beverage cans, which are made worldwide in a few standard sizes for use of high-speed filling-closing lines. D&I thin-walled cans are pressure packs (4 to 6 kg/cm^2 constant pressure in carbonated drinks cans and much higher in D&I aerosol cans). Their rigidity derives from the high inside pressure. Such pressures are currently generated in noncarbonated fills by inoculating a specific quantity of liquid nitrogen into the headspace of the filled cans just prior to closing the cans. This offers more and vast opportunities for lightweight two-piece D&I cans.

Either tinplate or aluminum is used, usually on a dedicated line. In recent years, because of the uncertain economics relating to metal costs, new lines are built as "swing lines," which basically can handle either metal. It does nevertheless require some downtime to make the change over, and lines normally operate continuously on the one metal.

THREE-PIECE CAN MANUFACTURE

The manufacturing process of three-piece cans is as follows: cut up coil stock into rectangular sheets; coat and/or decorate sheets; slit into rectangular blanks; form cylinders and side seam (soldered or nonsoldered, or welded side seams); inside and/or outside side seam striping (lacquer or powder application and curing); separate cylinders in case of multi-high cylinders; neck and or bead if appropriate; expand or reshape or reform cylinders if appropriate; form flanges at both extremities; fit maker's end; organized visual inspection or/and automatic leak testing; and casing or palletizing (see Figure 3).

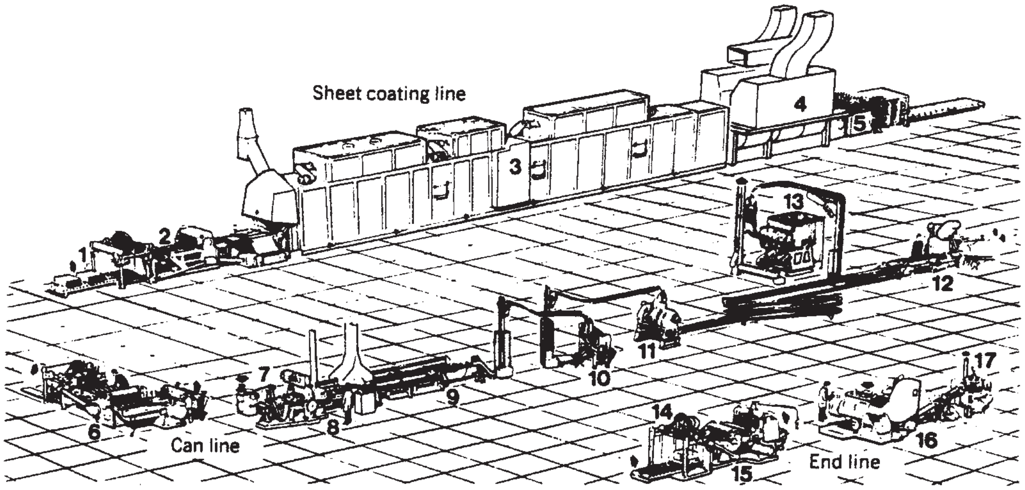

Figure 3. Three-piece can manufacture. Sheet-coating line: 1, sheet feeder; 2, roll coater; 3, oven; 4, cooler; and 5, unloader and sheet stacker. Can line: 6, slitter; 7, blank feed; 8, bodymaker; 9, side seamer; 10, flanger; 11 beader; 12, end seamer; and 13, tester. End line: 14, sheet feeder; 15, secondary scroll shears; 16, shell press; and 17, compound liner. Courtesy of Metal Box Ltd.

Cans for corrosive or delicate products (carbonated beverages or red fruit, etc.) are internally spray coated and cured prior to applying the maker's end. This coat is called "top coat," whereas the "bottom coat" is applied on the flat sheet in roller coaters and cured in wicket ovens. Both bottom and top coats can be spray coats with or without intermediate curing (spray–spray–cure or spray–cure–spray–cure).

Slitting. Large rectangular sheets of can body stock, precoated if required on one or both sides by roller coating techniques, are slit by pairs of circular knives (3) on tandem slitters, first logitudinally into strips in which the width corresponds with the development of the can bodies, and then transversely into rectangular blanks of the appropriate size corresponding with the can height, respectively, with the allowance to form the welding overlap (or the lock side seam in case lap-locked side seamed cans are made, soldered, or nonsoldered or cemented).

Because welded cans have considerably less overlap (0.4 to 0.8 mm) at the side seam than soldered cans (side seam allowance), slitting demands more rigorous precision (dimensions and right angles) than is needed for soldered can blanks. Circular slitting cutters can be positioned accurately by applying internal pressure at the bore of the cutter hubs to expand them so as to move freely on the slitter shaft (4). The said hubs can also be blocked on the shafts by screw jammed wedges or by application of hydraulic pressure (compressed grease) inside the hub. Any of these proven methods must apply the needed jamming pressure perfectly symetrically to avoid distorting the setting (narrow slitting gap, usually 5% of the body stock thickness) or/and cause wabbling of the slitter knives' cutting edges.

Bodymaking, Soldered Cans. The solder alloys commonly used consist of 98% lead and 2% tin. As more and more countries impose lower limits of lead content in food, the soldered can is being phased out in Western countries, if not being banned altogether as in the United States. Nevertheless, many soldering lines around the world will continue in operation for some time. The machine consists of a "bodymaker," which feeds single blanks from the feed hopper, and then scores (in case of multi-high can bodies), flexes, and forms the blanks into cylinders after slit and clip notching and hooking. The bodymaker is coupled to the side seamer, i.e., the soldering attachment where the joint is soldered and wiped off the excess of solder accumulated at the outside of the side seam.

Blanks are still commonly transferred manually from the slitter blank collector, although equipment exists for automatic transfer. In the first case, a visual check for quality and eventual rejects is possible, whereas sophisticated devices check automatically any miscut blanks and trigger the programmed intervention. The prepared hooks, or edges, as prepared and formed in the hooking station(s) of the bodymaker are interlocked on the forming horn and are compressed in the horn spline groove by the bumping steel. For high-speed operation, the body cylinder is usually formed by a pair of wings. (The term "wing form bodymaker" contrasts with "roll form bodymaker," which is a former American Can Co. technique.) In this technique, bodies are rolled and consecutively notched and hooked in the rolled shape.) Liquid flux is applied on one or both hooks prior to engage and bump the side-seam on the forming horn.

The lap-lock assembled bodies are fed out of the bodymaker and picked up synchroneously and individually by the clamping pawls of the soldering chain. The side seam area is preheated by ribbon gas burners before passing over a longitudinal solder roll where solder is applied. The presolder ribbon burners preheat the side seam, and by appropriate setting of the "bow and counter bow" burners the side seam is kept as straight as possible. When applying solder, post-solder ribbon burners ensure that the solder is "sweat" into the capillary gaps of the side seam, after which a rotating wiper mop removes excess solder, mainly in the form of blobs. Any solder splashes toward the inside of the can bodies have to be avoided. Rotary solder splash shields provide for this.

The can is then cooled by air jets before conveying to the downstream finishing operations. As lead contamination has become an increasing concern, the wiper mop unit has been the subject of considerable improvement to contain the lead dust generated by its operation, particularly at high-speed canmaking operation. By its nature, the process requires the use of tinplate, although blackplate had been soldered during World War II in the United States. To ensure sound soldering, a minimum "solderability" has to be ensured: rugosity of the steel base, a minimum of alloyed and free tin, oxidation, and so on. The line operator's skill and experience will overcome most of the material inherent drawbacks, the major one of which is the fluctuation of stiffness of the steel base of the blanks (open or thick laps).

Bodymaking, Welded Cans. The side seam is made by a resistance-welding process using the "lost-wire-electrode" principle (5) as well as *The Canmaker* June 1996 issue Evolution of a bodymaker by Sigfried Frei, Frei AG Switzerland. Body blanks are fed from the bottom of the feed hopper and then transferred through double blank detectors; then, the blanks are scored for eventual multi-high can bodies and flexed into the forming rolls (See Figure 4).

The two laps of the rounded cylinder are butted in the grooves of the Z-bar, and the cylinders are pushed along the Z-bar by one or more driven chains provided with pawls. Upon perfect radial centering in the Z-bar, the cylinders are introduced into the welding rolls at the same speed as the said rolls are driven at. The actuating mechanism of the reciprocating introduction pusher pawls are designed so as to guarantee that pushing speeds are accurately matching the peripheral roller electrodes speed. Only the outer electrode is driven.

Overlap accuracy over the full length of the side seam, which is also dependent on gauge and temper of the plate, has to be controlled as to avoid bodymaker jams and wrecks or mainly irregularly welded side seams. The two overlapping edges of the cylinders are bonded by a-c resistance continuous nugget welding using approximately 4000 to 7000 A at 8 to 5 V. Both overlapping edges must be free of contamination, each one on both sides (lacquer splashes or traces) to eliminate variations of resistance, which would lead to welding faults as well as eventual copper wire ruptures.

A significant amount of energy is lost in heating other parts of the welder, such as welding arms and electrodes, which need water cooling. In high humidity, this can lead to problems with condensation. Thermostatically controlled cooling media, even on upper acceptable limits of operation temperature, should avoid reaching dew points.

Each resistance welding spot, which is called a nugget, is achieved by one half of the a-c wave cycle. Welding current supply to the electrodes and welding speed are limited because the nuggets should overlap longitudinally to ensure a homogenous side seam over the full length of the side seam. To achieve higher welding speeds of up to 120th per minute, higher welding current frequencies have to be generated via an alternator or static transformers. Other sinuosoidal waveforms are applied and contribute to reaching high welding speeds coping with different canstock surface conditions.

Earlier systems used a large overlap (2 to 3 mm) and raised the steel temperature to the melting point by applying welding roller pressure to forge weld the metal. The latest welders use a small overlap as mentioned (0.4 to 0.8 mm) with metal temperatures just below the melting point and increased roll pressure to forge the two laps together. To ensure reproducible welding conditions over the full length of all double seams produced, the electrode contact is made by endless copper wire wrapping around both welding rolls and moving the cylinders at the preset welding speed. Any contamination of the welding electrodes by tin pick-up is thus continuously removed from the contact area. After use on both sides of the profiled wire, it is either chopped or rewound for recycling.

Having dealt effectively with the problem of tin contamination of the copper wire electrodes, the system paradoxically requires a minimum of tin coating on the can stock, around 0.09 lb/bb on both sides (1.2 g/m^2 on one side.) Table 1 shows the comparison of properties of various materials wherein nr 25 and nr 10 stocks have respectively tin coatings of 2.8 and 1 g/m^2 on one side. TFS or ECCS materials, as well as blackplates, are poorly weldable if at all under acceptable production conditions. They have to be "edge cleaned," i.e., the oxide films have to be abrased from the four sides of the overlapping edges of the side seam. Edge cleaning has, however, never found reliable solutions apart from edge cleaning by "edge milling" as practiced by the Continental Can Company in their Conoweld Technique. This system used welding rolls without an intermediate copper wire, but it is now of less importance in high-speed canmaking, mainly because of the frequent need for changing the electrode rolls.

The integrity and quality of the seam weld is usually tested by visual and mechanical means (e.g., Ball test). For a more detailed examination, weld cross and longitudinal metallographic inspection will reveal any sign of separation between laps, cavities and so on. Radiographical examinations are also used for quality inspections. Welders have been fitted with "weld monitors" to monitor welded seam quality continually. Usually, these monitors rely on measurements of voltage or current fluctuations between the welding electrodes. Welded seams, as well as single nuggets, made outside the preset limits are detected, and the faulty cans are ejected. Other monitoring systems have been explored for enhanced performance and were based on weld temperature or on the final thickness of the forge-welded overlapped side seam.

Renewed effort went into welding the side seam by means of a laser beam (6). The principle of can welding by a laser was demonstrated in the late 1970s, but welding speeds seemed to be too low to justify commercial exploitation. The technique was then discarded. Positive results of other ongoing research and development (R&D) work on the subject in the United States, Europe, and Japan are not known. Apart from the elimination of costly copper wire, the method offers pure butt welding with advantages to double seaming of the ends, necking, as well as

versatile decoration such as wrap-around printing. The copper-wire-welded seam and the plain welding margin in case of lacquered insides of the cylinder interrupt an otherwise smooth inside enameled (or plain) surface. The welded seam contains exposed iron and iron oxide as well as eventual traces of copper besides tin at either side of the weld. To protect the product from contamination and/or the weld from attack by the product that still results in contamination of the product, the side seam needs to be coated in most cases.

The formation of iron oxide can be avoided by neutral gas welding, in which case the weld area is isolated from the atmosphere by neutral gas jets such as nitrogen and a small percentage of hydrogen. This can be done at the inside and/or at the outside of the side seam.

Bodymaking, Cemented Cans. Cans used only for dry or otherwise neutral products, such as powders of specific natures, mineral or/and vegetable oils as well as many industrial products. Melted organic cements are injected into the inner hook of lap-locked side seams and, after engaging and flattening the side seam, they act as sealents. Before the almost universal use of two-piece cans for high-output beverage-can production, one method for making them was to cover the longitudinal edges of the blanks with a nylon strip, which was fused after forming the cylinder. The process has a many of proprietary names (eg, Miraseam and A-seam). An advantage was the complete protection of the raw-cut edges of the blank. It could only be used with precoated TFS, because the melting point of tin is close to the fusion temperature of the plastic. Even tapered corned beef cans were made in this way. When tin prices were a multiple of the current ones, using TFS was most cost-attractive solution. Cost cutting in metal packagings is therefore not an exclusive present-day problem. The bodymaker used to make the nylon-bonded cans was an adaptation of the soldering configuration.

Completing the Body. The plain cylinder must be furnished with a flange at each extremity of the cylinder or otherwise odd-shaped body for attachment of the closure. For food processed in and with the can, where the can may be subjected to external pressure especially at the cooling phase of the autoclaving cycle, or remain under internal vacuum during storage, the cylinder wall may be ribbed or beaded for radial strength. Beading profiles and distribution along the can body are to be designed so as to reach the desired proportion of radial against axial resistance of the cans.

Cylinders for shallow containers, especially those that cannot be made on bodymakers because of limited minimum cylinder height, may be made “multi high,” i.e., in a length suitable for two or three cans to obtain maximum efficiency from the forming machine. The welding speed remains unchanged thereby whereas the mechanical motions are divided by 2 or 3. Two techniques are used for parting the multi-high bodies into their double or triple components by breaking the score line or by cutting peripherally the unscored bodies.

TWO-PIECE CAN MANUFACTURE

Metal Forming Methods. Both methods of making two-piece cans use metal-forming principles that depend on

the properties of metal to “flow” by rearrangement of the crystal structure under the influence of compound stresses without rupturing the metal.

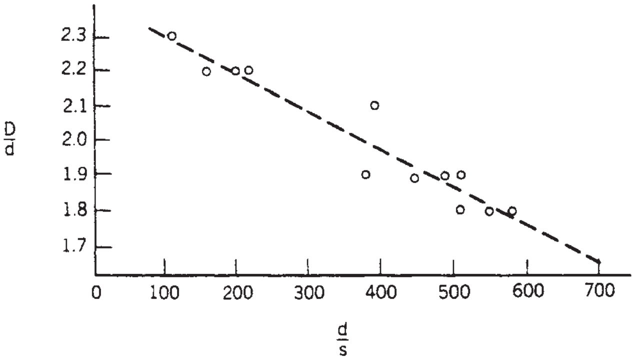

Figure 6. Limiting draw ratio. The maximum blank diameter which can be drawn into a cup without metal failure. The relationship illustrate the significance of sheet thickness (gauge). D = blank diameter; d = punch diameter; s = sheet gauge. Courtesy of International Tinplate Conference, 1976.

Drawing. In drawing, as applied to can manufacture, a flat sheet is formed into a cylinder or other section, such as oblong, e.g., fish cans, by the action of a punch drawing it through a circular or different shaped die. See Figure 5 showing the basic tool parts involved and the stresses and strains occuring in the material. Some thickening toward the upper part of the drawn element is inevitable, but the process is essentially one of diameter reduction at constant metal thickness and volume so that the surface area of the drawn part is practically equal to the surface area of the blank from which is has been formed. This factor forms the basis of design, in particular the calculation of metal use. The amount of diameter reduction achievable, i.e., from blank to cup diameter, is governed by the properties of the material, the surface friction interactions between the tooling and the material influenced by the tool, and material surface conditions and lubrication. The blankholder force is an additional factor that adds to the drawing force which the material has to stand between punch and draw radii. Drawing has been the subject of much research. One of the classic relationships is shown in Figure 6.

The diameter of the cup produced in the initial draw may be reduced even more by a similar redraw operation with a draw sleeve fitting between the punch and the

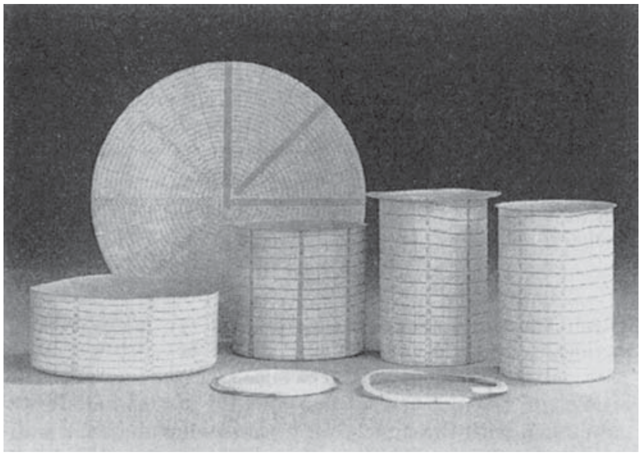

Figure 7. Reduction in diameter is accompanied by a corresponding increase in height. Courtesy of Styner O Bienz, Nieder Wangen/Bern Switzerland.

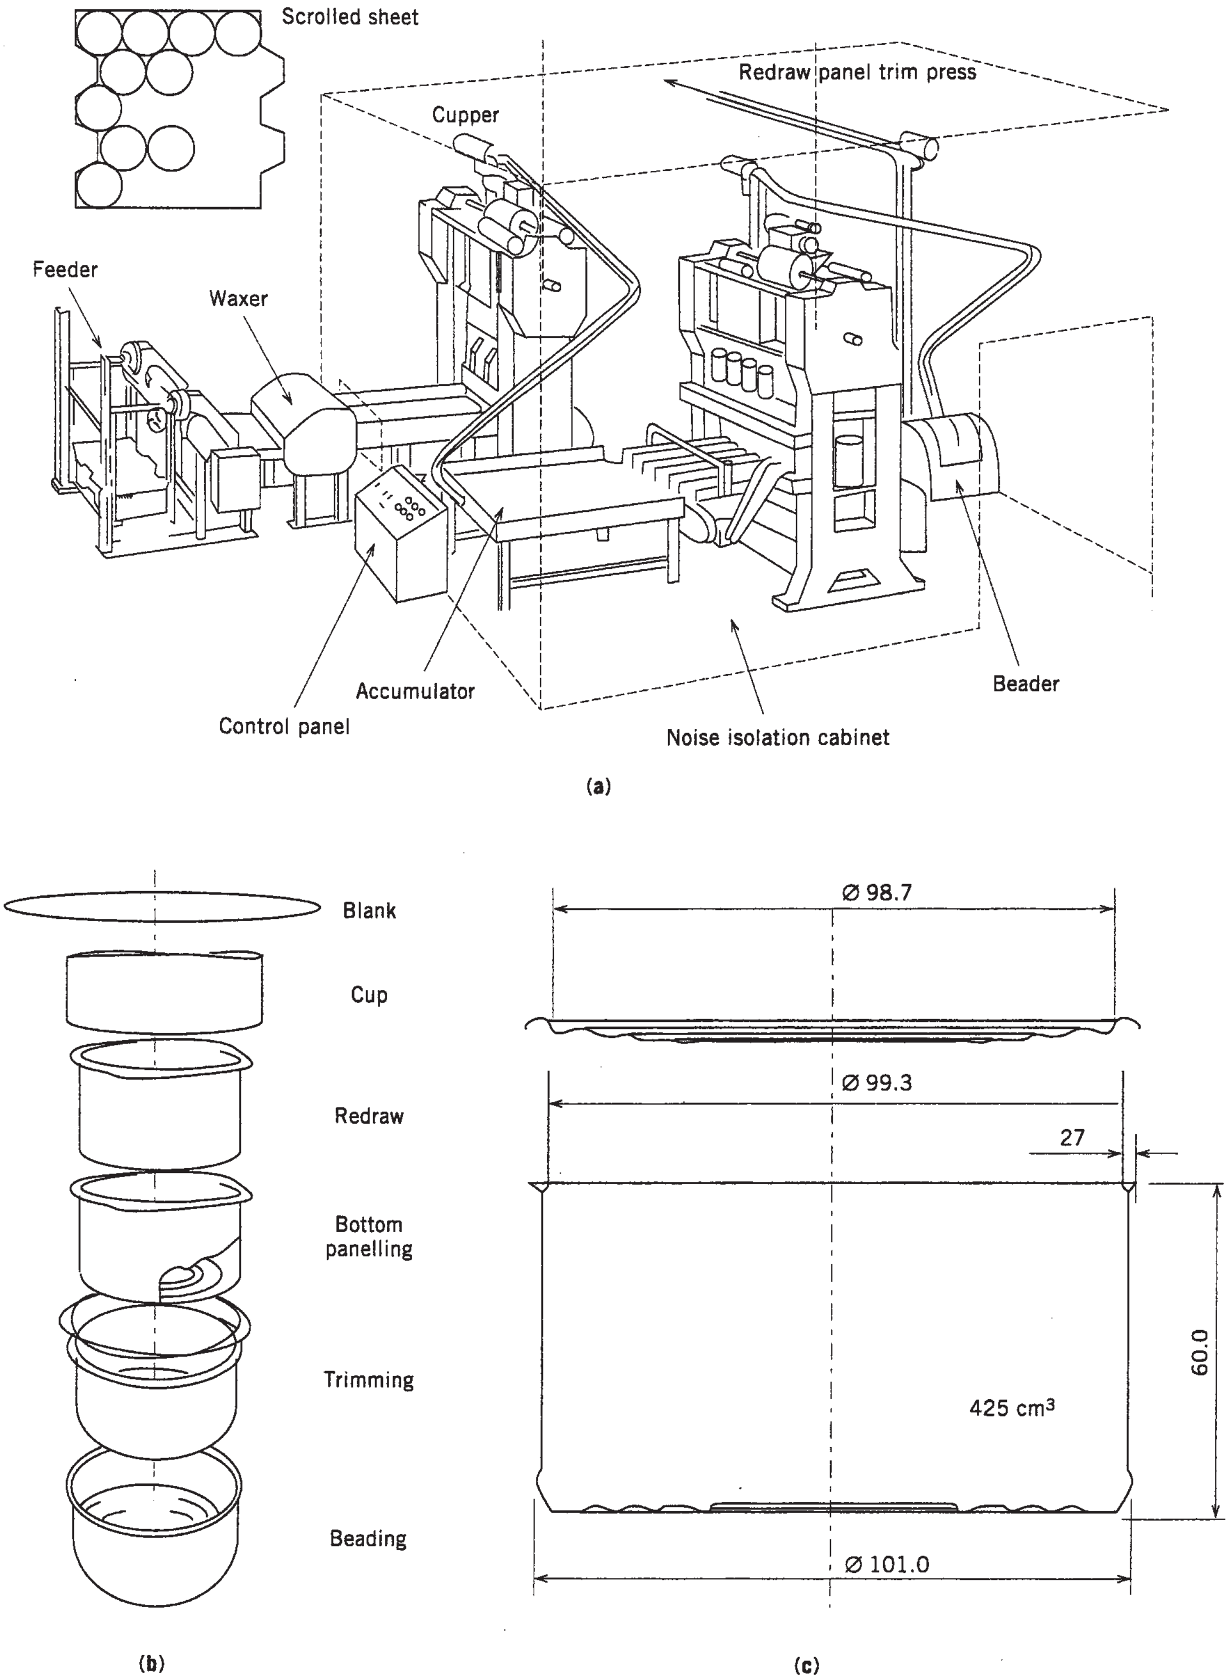

Figure 8. (**a**) Typical lay out of medium production of DRD cans. Courtesy of Ferembal Nancy/France. (**b**) Sequence of DRD fabrication steps (**c**) Typical 401 × 206 DRD can with end (for ref. only).

inside diameter of the cup. The said draw sleeve acts as a blankholder. The rule of constant area and volume determines that the reduction in diameter is accompanied by a corresponding increase in height (see Figure 7). The redraw operation can be repeated in several drawing stages, provided the progressive reductions fall between definite limits to avoid metal failure. Draws can be made “through the die,” and the drawn part be stripped from the punch at the end of the press stroke below the die or the press stroke can be limited so as to leave the drawn part with a flange. In this case, the drawn part is extracted from the die and is retained by the punch (friction and vacuum), and ultimately it is stripped from the punch for transfer or evacuating from the press. The stroke of the press has to be adapted accordingly. In the latter case, it is usually equal to 2.5 times the cylinder height as drawn. Figure 8(c) shows a typical drawn can provided with a stacking or/and label retaining bead if canstock is not decorated. Figure 8(b) is the sequence of operations from the blank to the finished can, and Figure 8(a) is a typical schematic layout of a DRD can production line of medium production capacity.

Wall Ironing. In pure ironing, as used in the D&I process, a cylindrically drawn cup is redrawn by the ironing punch and therefore precisely fits the said punch diameter. The redrawn cup is then forced axially through a set of ironing die rings, whose diameters, which are progressively decreasing, create a gap with the punch that is smaller than the wall thicknesses of the redrawn cup and the consecutive wall thicknesses from t1 to t4; see Figure 9(a) whereon the stated wall thicknesses are related with the punch and rings radii differences.

The process, which is similar to impact extrusion, thus results in a reduction in wall thicknesses at a constant diameter excepted for t3 where the punch diameter is recessed so as to form the “thick wall.” t4 is the “thin wall” that is reduced from 0.22 mm for t0 down to 0.07 mm. Here too, the governing principle is the constant metal volume. In other words, the volume of the metal in the ironed can body (prior to trimming) is equal to the ingoing cup and consequently to the original blanked disk. Note the sequence of operations in Figure 10. The amount of reduction at each stage is determined by the material properties, governed by the needs to avoid metal failure. The high friction, under extreme surface pressure mainly at the outer surface of the ironed can body, makes special demands during lubrication, which is combined with copious flood cooling to maintain the critical punch-to-die gap.

A similar effect can be obtained in drawing if the gap between the draw die and the punch is less than that of the metal being drawn. It is common practice to keep this gap equal to the nominal thickness of the canstock to control thickening caused by diameter reduction. This process is called sizing. The drawing gap can be reduced even more to produce a definite thinning of the wall, relative to the base material as a combination of drawing and ironing, or thinning. Special lacquering is primordial in this case.

D&I Can Manufacturing. The procedure of producing D&I cans is schematically as follows: unwind the plain coil; lubricate; conduct blanking and cup drawing; redraw; execute wall ironing; perform dome forming; trim body to correct height; wash and surface treat (if appropriate as for aluminum); implement dry or wash coat; and cure. Then for *beverage cans*, the process is as follows: base coat outside and cure (if appropriate; decorate and cure); coat inside and cure (eventually a double coat); and neck and flange open end (in the case of a tinplate, the order of the last two operations may be reversed). For *food cans*, the process is as follows: wash coat outside; neck and/or flange as appropriate and if body is not beaded; body beading; and coat inside (in some lines the order of the two last

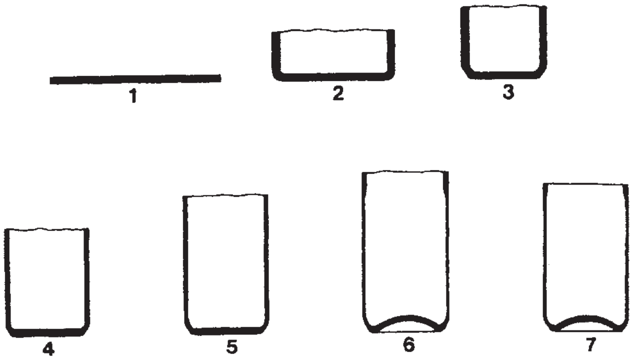

Figure 10. Stages in forming a D&I body. 1, Circular blank; 2, cup; 3, redraw; 4, first ironing stage; 5, second ironing stage; 6, third ironing and dome forming (note thickening at top where flange is to be formed); and 7, trimmed body.

operations is reversed). The *closures*, or *ends*, are made from precoated sheets or coil on multi-die presses, which are profiled in such a way that internal pressure will not cause any permanent deformation (peaking) in the chuck wall radius area. Their turned down edge of the flange (crown shaped or plain) is curled so as to allow stacking and automatic handling and assist the formation of the double seam. A sealing compound is nozzle injected onto the spinning ends and then placed and centrifuged so as to form a gasket in the finished double seam (see Figure 11).

Compounds are either solvent based (hexane) or water based, which are, respectively, drying by evaporation of the solvent or by heat drying (hot air or various radiations).

The components of a D&I line are shown in Figure 12. The coils are shipped with the axis vertical, for safety and to avoid damage to the laps. A down ender is used to bring the axis horizontal and to transfer the coil to a coil car for distribution to one of several dereelers (unwind stands), each feeding one cupping press or cupper. Dereelers may be dual and engineered in such a way that coil changes are rapid either when coils are finished or if one has to be removed for being defective. The coil is passed through a lubricator where lubricant is applied by dipping in a tank; the excess is removed in a couple of rubber-covered rolls. The lubricant is constantly recirculated for filtering, temperature control, and bacteriological control. It is essential that lubricants, coolant-lubricants and washing chemicals be compatible and form a system possibly supplied by the same manufacturer. The steel coils are additionally and continuously inspected to detect pinholes and surface defects (visual inspection), and to monitor the gauge thickness, which is interlocked to stop the cupper when out-of-specification material is detected. The cupper (7) is a double-action press used to blank and draw the cups under a perfectly controlled blankholder force. Blanking the disk and drawing the cup are two consecutive phases in one stamping cycle or press stroke.

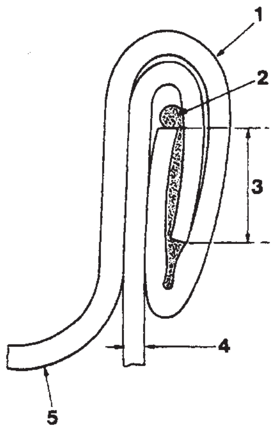

Figure 11. Double-seam closure. Showing fixing of end to cylinder, and function of lining compound: 1, end curl, folding round flange on cylinder, 2, lining compound; 3, seam overlap; 4, cylinder; and 5, end.

Depending on coil width, as many as 12 cups may be produced in one working stroke. The cuppers can be designed with top drives (Minster) or underdrive (Standun). Cups are produced at speeds of up to 200 strokes per minute.

The cupping process demands great precision because of (a) extremely narrow drawing gaps of 10% in excess of the material thickness, the between punch and die. Materials currently used have a thickness of 0.009” (0.24 mm) and canstock will undoubtedly become thinner still in the future. (b) Shreds (intervals) between two adjacent cuts of blanks is about 0.04 in. (1 mm). (c) All press and tool parts must be perfectly aligned, flat, parallel, and/or concentric. The cups should show no wrinkling or measurable or visual differences all around the walls. This is fundamental for successful ironing. The wall ironer (bodymaker in the United States) (8, 9) converts the cups into a cylinder with the correct preestablished and correct thickness distribution along the wall and dome shapes (the base) to resist elevated internal pressure. Figure 9(a) shows the arrangement of the ironing tool set as it is basically used in all ironers. At the end of the stroke, at the moment the punch reciprocates after the front dead point of the ram, spring-loaded stripper fingers, assisted by compressed air fed through the ram to the punch nose, strip the can body from the punch into a discharge conveyor, which transfers the cans sideways to the trimmer. For the alledged base of constance of metal volume, the length of the cans will vary with the tolerances of the material and toolings. The top end of the cylinder will be more or less wavy, earing, which is caused by specific characteristics of the canstock as long as toolings and alignments, as well as ironer stability, cannot be incriminated.

Ironers run at about the same speed as the cuppers, so that one wall ironer is needed for every tool or “out” in the cupper. In practice, one ironer was added as a stand by to bridge short interventions on the machine or/and clear jams, and so on. Newer generations of ironers run faster than the cupper and twin-ram machines allow to half the number of ironers in the canmaking line. Stand by must still be available as the loss of output is doubled during down time in case of twin-ram machines. The tooling uses inserts of carbides or/and ceramics in the ironing dies together with carbide or ceramic punches when steel cans

are fabricated. Good quality tool steels are adequate for aluminum cans. Associated with every ironer is a trimmer to which the eared bodies are transferred positively held by the base either magnetically or by vacuum. Rail (sickel knife) or roller trimmers are used.

In rail trimmers, the end of the canbodies is trimmed between a mandrel mounted on a rotating turret and a stationary rail. A certain number of mandrels are fitted and the turret is in continuous motion.

In the roll trimmer, cans are indexed to a position where the end is inserted between two rolls and rotated about their axis while the rolls are closed, one being pivotly mounted, to perform a peripheral trimming, or cutting, action. In one widely used machine, the cutting rolls are mounted in an easily removable cartridge for refurbishing and precision-setting in a toolroom environment.

After trimming the canbodies to their specified height, they are mass conveyed in bulk, in upright position, to a washer. The cans are conveyed on a flatbed open-mesh belt, open-end down, through a series of compartments fitted with spray nozzles above and below. The top conveyors are used in each spray compartment to restrain the cans from falling over. After prewashing with detergents for removing drawing and ironing lubricants, the cans are washed, prerinsed, and rinsed with demineralized/deionized water. Aluminum cans commonly receive an etching treatment to make the surface receptive to organic coatings applied in the finishing operations. Deionized water rinse ensures stain-free drying.

Alternatively, the final rinse may contain an organic coating to protect the outside surface of tinplate food cans underneath the paper label applied by the filler. The washed and dried cans are now ready for receiving internal and external finishes, both structural (necking/flanging and eventual reforming) and protective (coatings and decoration). The food cans are usually beaded for the thin wall to stand buckling and/or implosion in the same way as with three-piece cans. The machinery, however, is differing in detail because of the presence of the integral bottom and the absence of side-seam extra thickness as on three-piece cans. Spin flanging is invariably used to avoid split flanges in the axial metal grain structure caused by ironing, although excessive work hardening does not occur. The top of the beverage cans is necked-in to yield metal cost savings through the use of smaller diameter and therefore thinner ends material. The first necking steps may be die-necking operations followed by spin necking/flanging. This method is finding increasing application (10). When the first cans were die necked and spin flanged from 211 to 209 diameter, they are now necked down to 202. It creates an aesthetically pleasing neck profile and contour when cans are spin necked, and this technique provides with minimal strain on the split-prone flange and low axial force on the can. For the smaller necks, such as 211/202, several die prenecks are necessary when die necking is applied (11). Single-stage prenecks are currently practiced by spinning. The final spin-neck/flanging operation is done either before or after internal protection depending on local circumstances. In general, aluminum requires an enameled surface to prevent pick-up (galling) on the tooling. In some way, the enamel acts as a lubricant.

DRD Can Manufacturing. The manufacturing steps are as follows: cut up the coil into scrolled sheets (eventually coil coated stock); coat and/or decorate sheets; blank disk and form cups; redraw once or twice depending on the h/d ratio of the can; form base (or panel can bottom); trim flange to applying width; bead (if appropriate); spray coat (either single or top coat on roller coated material according to pack) and cure; and test and palletize. See typical production setup in Figure 8. As in D&I, a multitool cupper (7) (Figure 8) is used to cut blanks from wide coils or scrolled sheets and form them into shallow cups. Their D/d ratio (blank to cup diameter ratio) as chosen will influence the performance of the subsequent draws if cups are reformed by one or two more draws, which progressively reduce the diameter and increase the height. By stopping the final draw at an appropriate point, a flange is left on the can, but as with all metal-forming operations, the eared and irregular collar has to be subsequently trimmed. Prior to this, the can bottom, or base, has to be profiled, or paneled (see Figure 8) so as to withstand processing requirements. All these operations are usually carried out on multilane, multistage transfer press. Setups have to be coherent with regard to their production capacity. Each follow-up machine should have a capacity of 0.5% to 1% in excess of the foregoing one, and controlled infeed should ensure that no jams occur at stops and starts of the infeed whereas the machines should not be stopped. However, because of the critical nature of the die-trimming operation, separate machines that employ different principles can be used, such as rotary trimmers. When simultaneously drawing and ironing, it is convenient to draw the body right through the die to achieve thickness control in the flange area. In this case, the body is trimmed and flanged in conventional D&I equipment. For taller cans, the walls may then be beaded in the usual machine.

Variants in metal forming equipment are the Metal Box rotary press line (12) (Figure 13) and the Standun opposed-action press. The latter features a split blankholder with separate pressure controls, which is claimed to permit greater draw reductions and provide control of wall thickness through stretching rather than ironing, which is said to be less severe on the coating. Equipment of various origins are on the market for small to high production. More intelligently designed lines are engineered together by canmaking experts on proven presses, machines, and reliable toolings. Figure 8 represents such a setup.

COATING

With the exception of three-piece cans for certain products, organic protective coatings are applied to both in- and/or outside surfaces of the cans. Internally, they provide a protective barrier between the product and the metal, whereas externally they may protect from atmospheric corrosion. Outside decoration provides product identity as well as protection especially if inks are protected by an overvarnish. Coatings are applied “wet,” i.e., the resins are suspended in a carrier for ease of application and allowed to coalesce, flow out, or extend for proper film forming. The coating is then baked, stoved, or cured, according to countries of origin, first to remove the carrier, which may be an organic solvent or a mixture, predominantly water (waterbased lacquers) and then to polymerize (cure) the resins. The methods of application are in general commercial use: roller coating in case of sheet stock or on the outside of two-piece cans and spraying on the inside of formed bodies. Spraying is predominantly used for the inside of two-piece D&I cans, but DRD cans are sometimes sprayed as well. Certain categories of three-piece cans are sprayed for carbonated beverages or

Courtesy of Metal Box Ltd.

red fruit cans; the spray is a top coat applied on bodymaking and side seam striping, and the material has been roller coated. Alternative methods of application and curing are available, such as electrophoretic deposition. This method is also used widely for repair-coating Easy-Opening-Ends after conversion, i.e., scoring, riveting, and securing the pull tab. Drying and/or curing (polymerizing) are normally carried out by forced convection using hot air. To a lesser extent, inks and some lacquers are cured by ultraviolet (UV) radiation, electron-beam curing, infrared, or high-frequency energy. The most diffused nonconventional inks and lacquers are ultraviolet curing products, and they permit applications of virtually solvent-free "wet" coatings by conventional means. It requires the use of specially selected materials amenable to this form of polymerization, which demand care in storage and handling and complete polymerization, in the interest of health and safety. Its attraction lies in the absence of solvents in difficult environmental situations and extremely short curing times coupled with relatively low energy demand. It is thus used for high-speed operations or where space is limited, as for instance between two or more print color applications ("Interdeck Drying").

Powder Coating. When resins are applied "dry" in the form of fine powder, powder coating is directed in many cases by creating an electrostatic field, which charges the powder particles on the negative pole for being deposited by the positive pole; the latter is the element of the can, or the entire can body, which has to be powder coated. In three-piece canmaking, it is specifically the weld and the weld margin (lacquer-free) area that are coated. The absence of solvents avoids the otherwise excessive cost of drying and eliminates the eventual blistering caused by trapped solvents, which cause porosity or boiling off, because solvent-based lacquers are applied on too-hot welds. Curing, which is a simple fusion of the applied powder layer, is usually done by infrared radiation or high-frequency induction heating, as hot convected air could disturb the uncured coating. In many cases, the same curing ovens are used for powders as well as for lacquers. Only their length is different, as curing of the different, products used for side-seam striping need m ore or less curing time: polyester powder, 8 s; epoxy powders, 10 s; airspray lacquers, 12 s; airless sprayed lacquers, 14 s; and roller coated lacquers, 17 s. In case both powder or lacquer have to be applied, the oven length should fit the longer curing time. *Electrophoretic deposition* provides a means for electrically depositing a resin film on a metallic substrate from an acqueous suspension (13). Originally used at low speed for protecting automobile bodies, it has now been developed to be applied at can production speeds with practicable voltage and current demands. Two-piece and three-piece cans are currently coated on high production lines on both inside- and/or outside of the bodies. Decorated cans of either type can be washed, without affecting the prints, and inside coated in the most positive way. A system of process cells is described in Refs. (14) and (15).

It must be stressed that for food and drink cans, only the anodic system is applicable. Compared with spray application, it gives a more even distribution of coating over the full can wall and base, providing a saving of the quantity used without sacrificing the required minimum coating thickness. Its throwing power enables it to coat regions inaccessible to spray, which is useful for the severe profiles that have to be used to obtain adequate container strength with a thin plate. The system provides practically pore-free films, and practically near-to-zero milliampere current permeability tests are obtained, even when particularly severe tests are applied. Electrodeposition was initially used (American Can Co.) to repair-coat converted Easy Open ends, thus protecting scores, rivets, and cut edges of the tabs, as well as other possible damages to the roller-coated lacquer film applied prior to stamping shells and converting. This equipment is available on the market as an improved version, which is offered by CORIMA in Tresigallo/Italy.The *thermal transfer* of the complete design from printed paper to a plain coating on the can provides a method of obtaining a high-quality decoration in two-piece cans if the extra cost is justified (16). It is used in the Uunited Kingdom under the trade name Reprotherm (Metal Box Ltd.) for promotional designs or single-service beer cans.

COATING EQUIPMENT

Offset Coating. Offset coating is based on the offset printing principle, whereby a metered quantity of coating is applied to a rubber or polyurethane covered roller, to be transferred therefrom to the metal substrate (see Figure 14). In roll coating, metering is accomplished by a series of steel or rubber rollers that pick up the coating from a trough and ensure even distribution and weight control through a combination of relative surface speed and the pressure or gaps between them. Another method called gravure coating employs a pattern of cavities etched into a steel roll, which are filled as the roll dips into a trough. The excess is removed, and the precise amount filling the cavities is then given up to the transfer roll for offset application onto the metal substrate.

Rotary Screen Lacquering. A third method is a development that uses the old established principles of silk-screen printing. The screen is in the form of a cylindrical thin, narrow meshed sieve like metallic screen that is fed internally with the coating material, which is forced through the screen by an internal doctor blade onto the transfer roll. Several patterns govern the shape (cutting diagrams for blanks and/or ends) and weight of the applied coating by photomechanic methods.

Roll Coating. This method is the most common for coating in the flat, which is used for both coil and sheets. In sheet coating, it is possible to cut a pattern (stencil) into the transfer roll (which would be the blanket cylinder on an offset press) and coat only the areas to be used for blanks. In a large-scale operation, this could yield significant savings in material, but it requires the sheet to be accurately registered with the transfer roll. Most of the present-day coaters are provided with front lays that

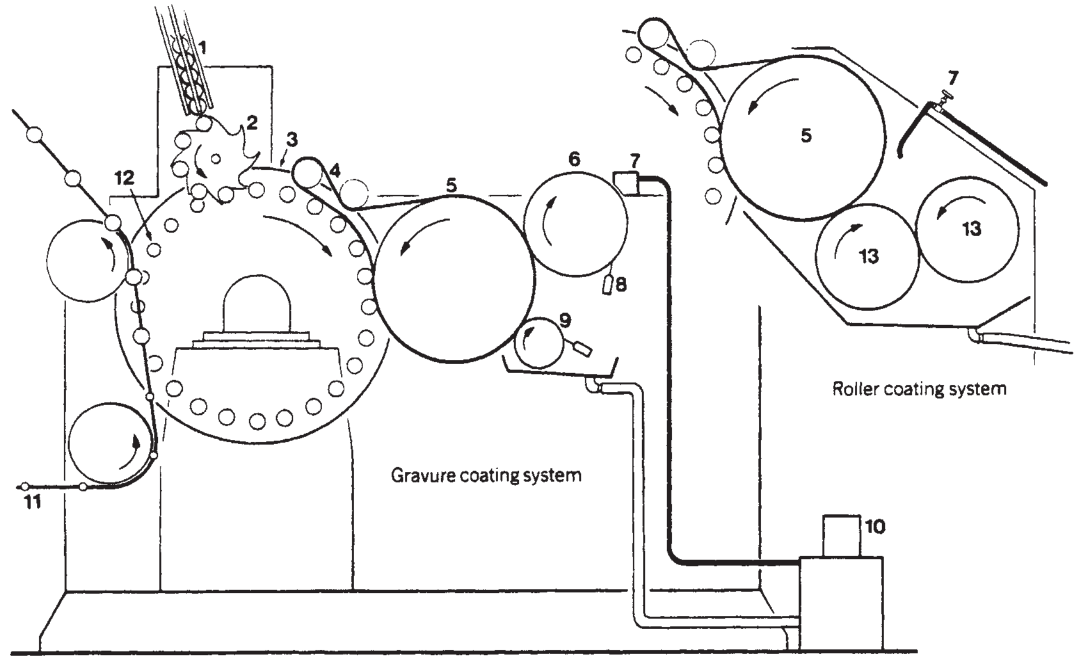

Figure 14. Offset coating, showing application to two-piece can bodies. 1, Body infeed; 2, star wheel; 3, mandrel wheel; 4, prespin; 5, offset cylinder; 6, gravure roll; 7, coating material feed; 8, doctor blade; 9, stabilizer roll; 10, coating material tank, with pump; 11, oven pin chain; 12, mandrel; and 13, metering rolls.

ensure precise registering, and magnetic or vacuum cylinders avoid irregular travel of the sheets while being transferred by the pressure contact between the transfer roll and the compression cylinder.

Rotary-screen coating permits a better definition of the pattern in the applicator itself without cutting (or stenciling) the transfer roll, which leaves a sharper, cleaner edge between coated and uncoated areas. Other advantages claimed are the ability to apply double the coating, which could possibly save one pass, i.e., the coating operation and curing, as well as applying differential coating weights on adjacent areas of the sheet or on individually coated spots. Thus, the coating pattern can be identical to an end-cutting diagram whereon all geometrical losses (shreds and skeleton) remain uncoated. In this way, the flange area of any end that receives the sealing compound can receive a low-weight lacquer film, whereas the curl portion can remain totally unlacquered. There is a twofold advantage: water-based compound adheres better on uncoated endstock, and the blank cut in the end-stamping press is made on a lacquer-free area. Cured resins, especially when they “feather,” act as emery in end tools, adhere to the tool parts, and scratch other ends, which causes downtime for cleaning. The uncoated curl area is covered by compound, at least to 1/64 in. from the cut edge of the end and does therefore disappear in the double-seam end hook.

Roller coating is similarly used, although in reduced dimensions as compared with sheet coaters, for the outside of two-piece cans. For this application, however, the more precise method of gravure coating is gaining favor. Decorators operate in a similar fashion (17) but are considerably more complicated, because they apply four, and sometimes up to six colors with extreme accuracy of registration to build up the total picture. Thus, a can decorator uses the same can-handling system as the coater, replacing the coating head by a reduced size offset press printing equipment for each color, all of them four to six colors, transferred onto one and the same blanket cylinder, which transfers the total label onto the can envelope in one rotation of the can. Cans (in the same way as collapsible tubes) are stripped from the printing mandrels and are transferred onto the pins of the pin oven chain for curing.

Spraying. The method normally employed is the airless spray system, where atomization of the enamel into fine droplets of appropriate size is achieved by the use of high pressure on the enamel, about 650–850 psi (45–60 kg/cm^2). A spray gun consists of a spray nozzle designed to give the desired spray pattern, a needle valve to cut off the flow without dripping, and the means to activate the valve at high speeds, usually a solenoid.

Because the viscosity of the enamel has a decisive influence on the spray pattern, discharged quantity and dripping, it is heated and continuously circulated through the gun. The quantity of lacquer deposited in the can is determined by precise timing of the valve. A typical spray time is approximately 100 ms. In modern practice, the gun is at a fixed position at the mouth of the can, although machinery exists for moving it axially inside the can during spraying. This is called a lancing gun. The can is indexed to a position in front of the gun and rotated at about 2000 rpm to ensure an adequate number of rotations while spraying is in progress. It is practically compulsory to keep rotating the can on its way from the spray coater to the oven to assist flow out (extension and full wetting for poreless film formation and avoid rundown) and even distribution. The pattern of coverage and number of coats depend on the type of product to be packed (beer or carbonated soft drinks), the can material (steel or aluminum), and the can size (h/d ratio). Coverage can be total, where one spray covers the total area, or zonal, where one spray is directed towards the base and lower side wall of the can, and a second one covering the upper side wall of the can up to its open end. Two coats may be applied in consecutive indexing stations on the same machine (wet on wet) or in separate machines with intermediate drying (wet on dry).

Internal Side-Seam Protection for Welded Cans. The bare metal that exists in the weld area must be protected in many cases. Roller coating, spray, and electrostatic powder coating are used. The applicator is mounted on an extension of the welding arm through which the coating material is supplied from a connection fitted before the can cylinder is formed around it. Roller coating permits a low-pressure fluid supply, but the lack of space makes the applicator components extremely small as they must be contained inside the sometimes small internal can diameter, i.e., 202 cans. Spray application requires a high-pressure fluid supply. Although good initial coverage can be achieved, liquid enamel tends to retract from sharp edges and cause eventual "splashes," so that high application weights are needed for adequate coverage of the cut edge of the blank. The overspray, which escapes from the gaps between the cans, poses exhaust problems, especially in avoiding external contamination through drips. Powder is fluidized with air for conveyance through the welding arm and electrostatically charged to achieve deposition on the welded area. This method undoubtedly provides the best protection, but it is expensive in material and must be run carefully in production. Wherever epoxy powders can be applied instead of polyester ones, the material cost is substantially reduced.

METALLIZING, VACUUM

Robert Bakish
Bakish Materials Corporation,
Englewood, New Jersey

INTRODUCTION

Vacuum metallizing, which is a physical vapor-deposition (PVD) process, produces coatings by thermal evaporation of metals under conditions that permit and enhance this deposition on a wide range of substrates. It is a process for the manufacture of a great variety of products, which include a diversity of polymeric webs of interest to the packaging industry.

The key here is the thermal evaporation of metals. Changes in needs and demand for new products have also led to the application of this process for coating of these webs with a variety of ceramics.

The control of the evaporation process and the evaporant depends on the thermal source, the properties of the evaporant, the vessel from which one evaporates, the manner of holding and supplying of the evaporant, and last but not least, the prevailing process pressure and/or environment.

In the equipment where this coating is performed, i.e., the vacuum metallizers, variables such as geometry, distance between the evaporant source and web, and presence or absence of chill rolls, which is a system component that determines the substrate temperature and coating velocity, all affect the properties of the coating.

Although sputter technology, which is another PVD process, could also be considered and in fact is a vacuum metallizing process, it is not referred to here. The process is considerably slower, and its high costs truly eliminate it from consideration in production of coatings for the packaging industry that this encyclopedia serves.

THERMAL SOURCES

Today, three basic heat sources are used in vacuum metallizing: resistance heating, induction heating, and electron-beam heating.

Resistance Heating. Source development began with resistance heating using refractory metals. The successful resistance source is an electrical conductor with resistivity that allows it to reach the evaporation temperature with reasonable current flow. This material must have a higher melting point and lower vapor pressure than the evaporant. It also must be chemically inert to the evaporant, and it certainly should not form by-products that could degrade the properties of the films produced. The source should be so designed to be able to contain the evaporant. The ease of handling and advantageous cost should also be integral characteristics of this source. The refractory metals—tungsten, molybdenum, and tantalum—have these characteristics, although tungsten is by far the preferred source. A range of configurations for braided wires to refractory metal boat sources is to be found in service. Usually when complexly shaped containers are needed, one will use tantalum. Resistance-heated wire sources and refractory metal boats sources are shown in Figure 1 (1). The refractory metal resistance source remains in use in small installations, but when we speak of industrial applications, the intermetallic boat is now the mainstay. Initial success with resistance-heated ceramic boats were recorded in the 1960s (2).

Let us now look at these. Boron nitride (3) with a filler of aluminum nitride, which permits the materials to be shaped in virtually any desired shape, seems to have wide acceptance for boats. This material has zero resistance when cold and an increasing resistance as the temperature increases.

As a result, sophisticated controls of the heat input are needed for these boats. Three-phase boats that consist of boron nitride, aluminum nitride, and titanium diborate are also used. Here, the A1N is added for its thermal conductivity and electrical resistivity properties. These boats operate at voltages of the order of 20 V with programmable current input that limits the power to the boat when it is cold to avoid cracking. There is a variety of ideas for the most efficient way to power the boats; two of these are shown in Figure 2 (4). Figure 2(a), which shows a

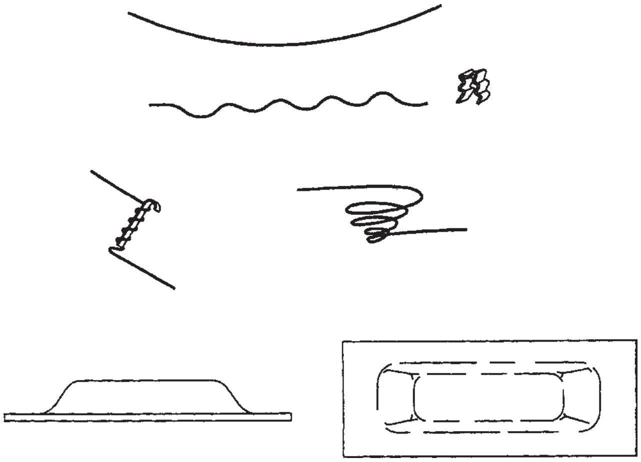

Figure 1. Resistance-heated wire sources (*top*); refractory metal boat source (*bottom*).

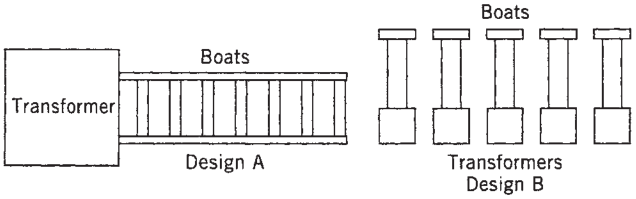

Figure 2. Two modes of powering resistance boats.

system where a single transformer is used to power all boats, has two main disadvantages. The first is that there is a voltage drop from the first to the last boat, which makes it virtually impossible to control the individual boats. The alternative approach, which is shown in Figure 2(b), is the more common and preferred method used. It permits individual boat control, which makes possible setting of uniform heating despite resistivity changes caused by aging of the boats.

In addition, the design of boats clamping must be properly engineered to permit good electrical contact and avoid mechanical stresses caused by thermal expansion. Various designs are possible. The size of the evaporation boats is dependent on the individual machine, and a wide range of opinions are related to boat size. Boats are habitually wire fed with a wide variety of feed drives to be found in the field. Overall resistance heating is rapid and provides efficient deposition rates. This source also has lower outgassing rate. The choice of boat material is determined for each installation based on machine parameters, operation experiences, and end-product requirements. Boat life varies extensively. Table 1 (5) shows some of the factors that influence it.

Induction Heating. Induction heating is the second heat source used here. Although in the past it used to be a very popular source, it seems that U.S. and European producers of metallizers have abandoned it in favor of resistance heating. Their reason for the move in this direction was their feeling, based on experience, that this source was difficult to operate, that it could not be feed continuously, and that it had unfavorable economics.

By contrast, it seems that ULVAC, the premiere Japanese metallizing equipment producer, has remained loyal to induction heating (6) for its metallizers. ULVAC feels strongly about it, listing the advantages in Table 2 (7).

Table 1. Some Factors Influencing Boat Life

Electrical contact[a]
Initial heating[a]
Initial wetting of the cavity[a]
Operating temperature[a]
Utilization of cavity area[a]
Vacuum level
Number of cycles (length of rolls)
Purity of aluminum wire
Correct resistivity
Age of unused boats
Cooling of boats[a]
Boat defects

[a] Operator controllable.

Table 2. Advantages of Induction Heating

Constant evaporation rate
Stable control on thickness uniformity using multiple evaporation source
No splaches; pinhole-free film can be coated
Automatic control of evaporation rate is easy and simple to operate
Aluminum purity can be 3N, instead of 4N or 5N
Aluminum blocks used can be easily available (10–300 g/piece)
Cheap running cost of evaporation source
Crucible life is long, and can be used for more than 40 batches
Simple evaporation source mechanism
Dense evaporated film structure
Higher yield of evaporation source: 95–98% for crucible and 90–93% for boat

Electron-Beam Heating. In electron-beam heating, the heat generated is a result of an energy conversion process. Here, the kinetic energy of the highly accelerated electrons is converted to heat on impact with the workplace. The *electron gun* is a device that generates electrons and, after columniating them, directs them to the workplace. Electron-beam heating has no upper limit, which makes it possible to evaporate virtually any material. Today, transverse and axial electron guns are to be found in metallizing systems. The transverse guns generate the electron beam, and after a 270° bending direct it to the workpiece. The reason for this path is mandated by the need to maintain the area where the electrons are generated free of the high-density material vapors that habitually are found on top of the evaporant and that can and will defocus the beam reducing its efficiency. The axial guns generate the beam and axially directs them to the workpiece.

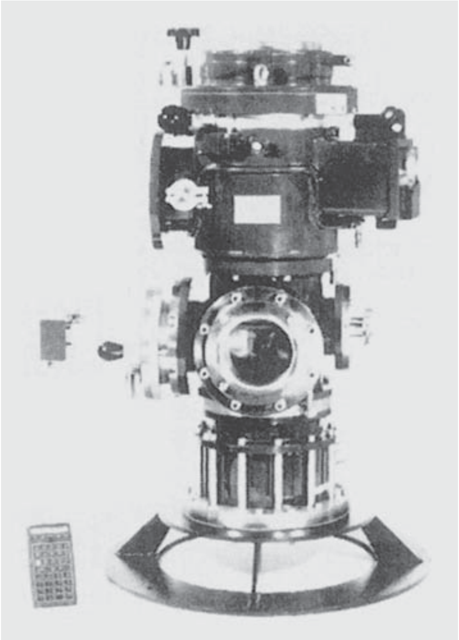

Figure 3. A 100-kW von Ardenne Anlagentechnik gun and parameters.

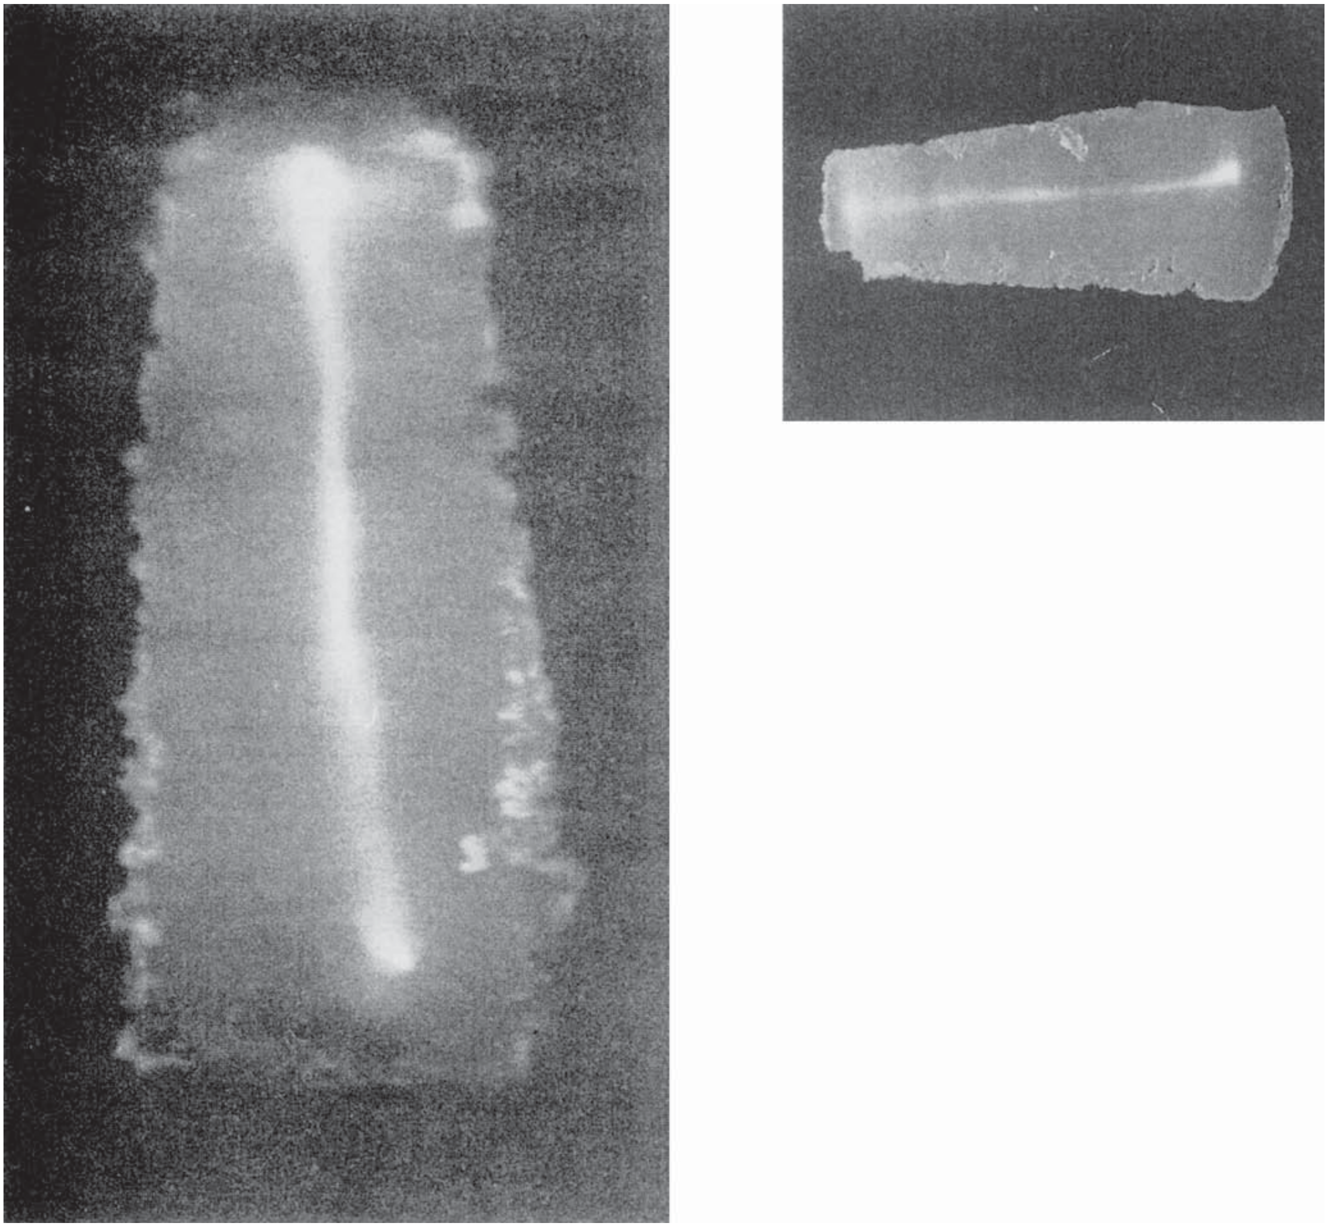

Figure 4. Evaporation line of an electron-beam line evaporator for 1000-mm web width.

With these guns, the beam is magnetically deflected to effect desired coverage of the evaporant filled crucible. A typical axial gun is given in Figure 3. It can produce a beam that, by suitable deflection, can cover the crucible containing the evaporant with virtually any desired configuration. This includes the beam in a line configuration that was first introduced in 1984 (8), which makes possible the generation of a uniform vapor curtain (see Figure 4).

When using electron-beam heating, one must ensure that virtually no secondary electrons impinge on the polymeric web; unless this is accomplished, their thermal load will lead to severe damage and even complete destruction of the web. Figure 5 shows 1000-mm crucible and magnetic trap for an electron-beam line evaporator in a roll-coating plant. Note, in electron-beam heating, that the evaporant, depending on its nature, is evaporated either from a cold crucible (i.e., water-cooled copper) or from a hot crucible vessel that can be made of a variety of ceramic materials. The specific selection is based on compatibility with evaporant. Table 3 shows a theoretical comparison between resistance and electron-beam heating for aluminum coating (9). As you can observe from this table, the electron-beam heating, although more expensive, is notably simpler.

From the heat sources, only electron-beam heating can be used for direct evaporation of ceramics. The electron beam can also be used for a deposition process referred to as plasma-activated reactive evaporation of aluminum (10). The geometry of the process is shown in Figure 6 (10). This process can be carried out equally well with a resistance-heated boat evaporator. Table 4 (10) shows maximum rates obtained by reactive evaporation. We

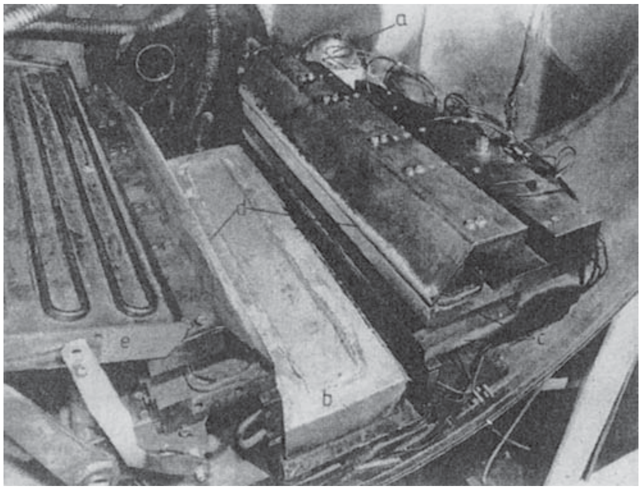

Figure 5. 1000-mm crucible and magnetic traps in a roll-coating plant.

are likely to observe considerably more reactive evaporation applications in the future. Reference should also be made to Table 5 for the advantages and limitations of the electron-beam evaporation (11).

METALLIZING EQUIPMENT

As with equipment to carry out any other process, so with metallizing equipment the details of the system are governed by the process to be used, and the product that it must produce. Once details are fixed, the ability to carry out the process in the system depends on the competence and the skill of the equipment producer. By saying this, one could say that the estimated 500 metallizers operating in the world today are, in fact, 500 different pieces of equipment. The estimate of their production is given in Figure 7 (12). Although in the true sense of the word this might be correct, I will only refer to a few typical systems. The metallizers, or roll coaters, if you will, accomplish a wide range of tasks far and beyond the needs of the packaging industry, which is the largest consumer of

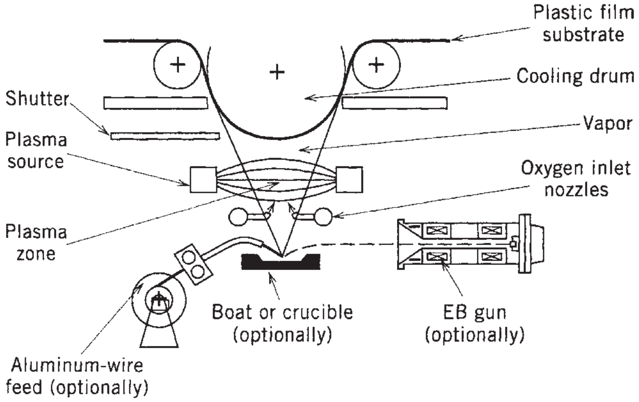

Figure 6. Schematic of the aluminum oxide deposition process by plasma-activated reactive evaporation of aluminum.

Table 3. Comparative Theoretical Evaluations between EB and Resistance Heating

General assumptions			
1000-mm coating width			
400-A Al layer			
10-ms^{-1} coating speed			
12-μm PET			
645/1000-mm roll diameter			
3-shift operation			
85% machine availability			
		Resistance-heated boats	EB
Cost calculation basis			
Number of boats/crucible		11	1
Price per boat ($)		35	400
Boat/crucible lifetime (h)		17	100
Pumpdown time/conditioning (min)		5	20 (15)[a]
Vent time (min)		5	20 (5)[a]
Investment costs (percent)		100	112 (120)[a]
	Resistance-heated boats	EB	EB with crucible lock chamber
Coating profitability		645-mm roll diameter	
Annual productivity (tons/yr)	1502	1141	1402
Coating costs ($/kg)	0.47	0.62[2]	0.53[b]
		0.57[3]	0.50[c]
		1000-mm roll diameter	
Annual productivity (tons/yr)	2093	1799	2036
Coating costs ($/kg)	0.37	0.45[b]	0.43[b]
		0.40[c]	0.38[c]

[a] With crucible lock chamber.

[b] EB evaporator with 50% higher Al consumption.

[c] EB evaporator with same Al efficiency as intermetallic boats. The calculation shows that in case of aluminum coating of PET, the EB-coating costs are definitely higher mainly because the inherently higher possible evaporation speed of the EB evaporator cannot be used.

Table 4. Maximum Evaporation Rates and Theoretically Derived Deposition Rates for Reactive Aluminum Evaporation[a]

		Boat Evaporator		
		per 100 mm (1 boat)	per 1000 mm (10 boats)	EB Line Evaporator per 1000 mm
Maximum evaporation rate (Al)	$\frac{g}{min}$	12 (cavity 30 cm^2)	120	≈200
Derived deposition rate (Al)	$\frac{nm}{s}$	2400 (200 nm/s per 1 g/min)	2400	≈4000
Derived deposition rate (Al_2O_3)	$\frac{nm}{s}$	75%–150% of Al deposition rate depending on the location of O_2 inlet		
Limitation for Al evaporation rate		Size of boats (max. 0.4 g/min per cm^2 cavity)	Number of boats per 1000 mm (10 boats per row)	Splashing (max. 2 g/min per cm^2)

[a] *Precondition:* No other limitation for deposition rate.

Table 5. Advantages and Limitations of EB Evaporation

Advantages	Limitations
High deposition rates for metals and dielectrics	Low source efficiency Multisource control
Direct deposition of oxides, fluorides, sulfides, and magnetic materials	Source inventory Thermal load to substrate
Coating material change over flexibility	Source orientation

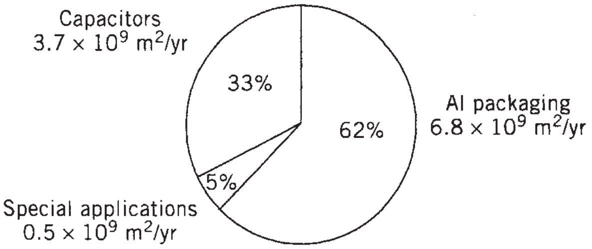

Figure 7. Estimates of worldwide 1993 metallizing production capacity.

polymer films coated with aluminum. It is thus appropriate to refer to Table 6 (13), which refers to most, if not all, products that can be made in metallizers. However, many of these are actually products of sputter technology.

Increased productivity and lower costs have been the engine driving this technology since its introduction. They have been responsible for (a) the widening of the metallizers, with ability to coat today's widths, exceeding 125 in.; (b) the increases in coating speed, today getting ready to exceed 3000 ft/min; and (c) numerous quantum leaps from the manual controls of yesterday, to fully computer-controlled systems of today (14), including the use of artificial intelligence (AI) techniques to provide real-time process control and troubleshooting advice (15).

Let us now look at schematics of few of the large variety of web coaters built over the years for the purpose of illustrating the equipment that operates in industry. Figure 8 (16) shows a cross section of a coater representing smaller type machines. In this schematic, electron-beam heating is indicated, although resistance heating for such systems is much more common. Figure 9 (17) shows a schematic of a coater, and Figure 10 (17) show its internal rolls assembly; note both electron-beam- and induction-heated sources. Figures 11 (18) and 12 (19) show cross sections typical of a high-speed, large machine. All these

Table 6. Present and Future Applications of Roll Coaters

Application	Products
Gold and silver yarns	Obi(sash), sash clip, bag, tie, sandals, curtain, towel, shawl, socks, slippers, embroidery, table cloth, lace, stage costome, tatami brim, etc.
Ornaments	Interior decorations, Christmas-tree decorations, nameplate, case, ballom, cosmetic package, etc.
Stamp foils	Pencil, book cover, postcard, label, Christmas card, poster, cigarette package, picture frame, lighter, cassete case, kimono, kimono sash, etc.
Packages	Medicines, confectionary, rice, cigarette, food, etc.
Building materials	Parasol, sunshade, greenhouse shade, interior wall, heat-insulation wall, solar film, firefighter's suite, curtain, space suit, etc.
Farming materials	Reflective sheet, beach mat, cooler bag, scarecrow, etc.
Reflection sheet	Traffic sign, number plate, mirror, guidance sign (airplane), etc.
Food package	Lunchbox, tableware, etc.
High added value products	Magnetic tape, copying film (substitute of copy drum), aerial photograph film, optical filter, multilayer flexible circuit board with polyimide, etc.
Precision capacitor	Logic circuit (communication device, personal computers, etc); bypass capacitor (TV, radio, VCR, etc).
Phase advance capacitors	High industrial power unit, etc; low power—washing machine, motor, Pachinko machine, home bakery, fluorescent lamp.

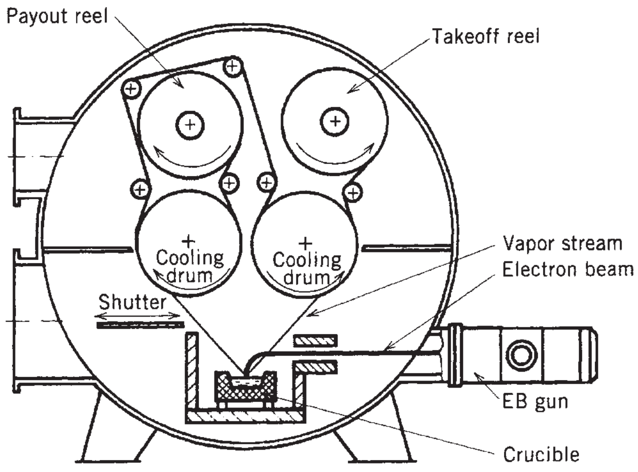

Figure 8. Outline of a vacuum roll coater typical of smaller machines.

are referred to as *batch* or *semicontinuous coaters*. The production cycle of these machines habitually consists of four steps as follows: (a) precoating, (pumpdown), (b) coating, (c) venting, and (d) recharging. These steps vary from machine to machine. Figure 13 (20) shows an example of such a cycle. One could look at it as somewhat representative of batch systems. However, one should note that there is considerable variation in the production cycle from machine to machine.

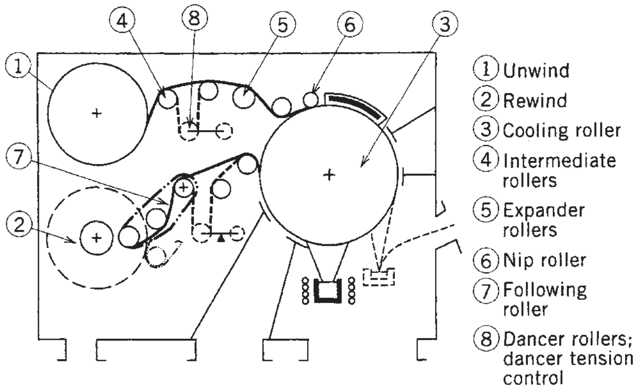

Figure 10. Internal roll assembly of water shown in Figure 9.

To increase productivity, air-to-air machines have been built. The producer of one of these (21) claims that output here can be increased up to 50% in relation to a batch-type machine. Figures 14 (20) and 15 (21) show schematics of air-to-air metallizers. The costs of the equipment, however, are notably increased. Although a limited number of air-to-air machines serve the packaging field, this type of installation remains primarily the province of metal strip coaters. To round up the discussion on metallizers, one should examine a couple of 1995 vintage systems serving the packaging and related industries. Figure 16 (*left*—machine; *right*—schematic) shows the Leybold

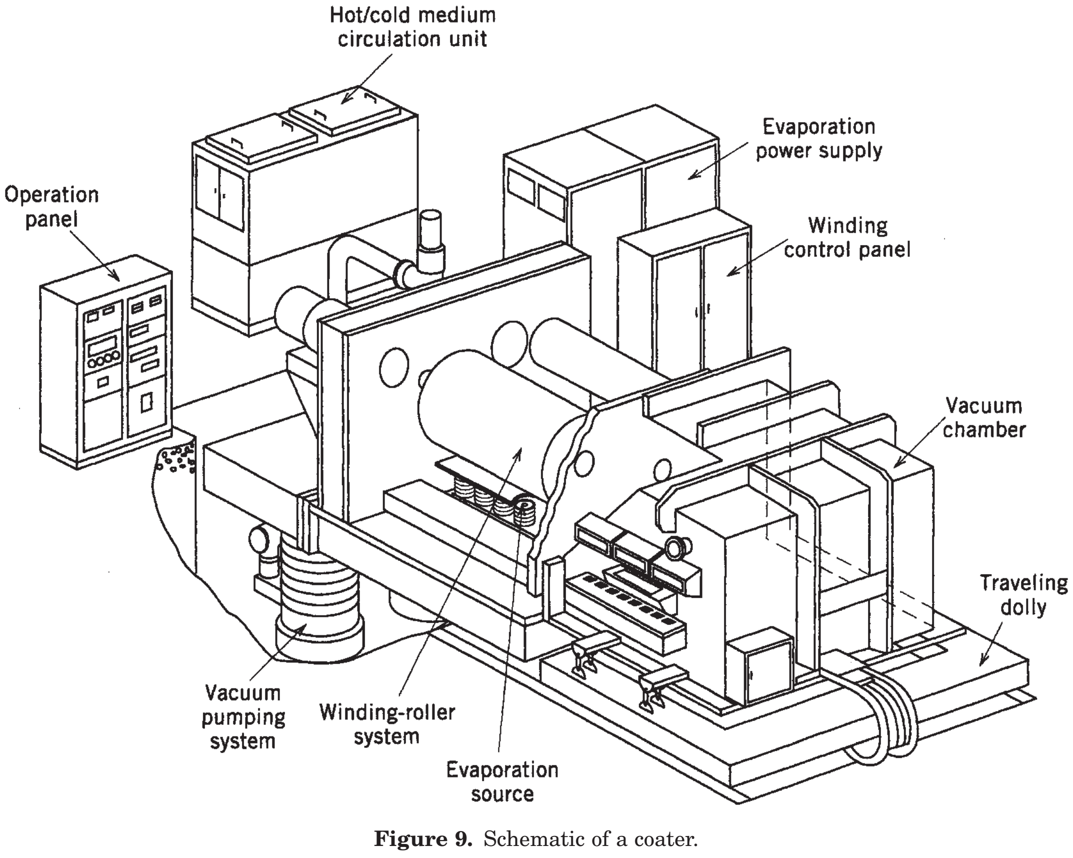

Figure 9. Schematic of a coater.

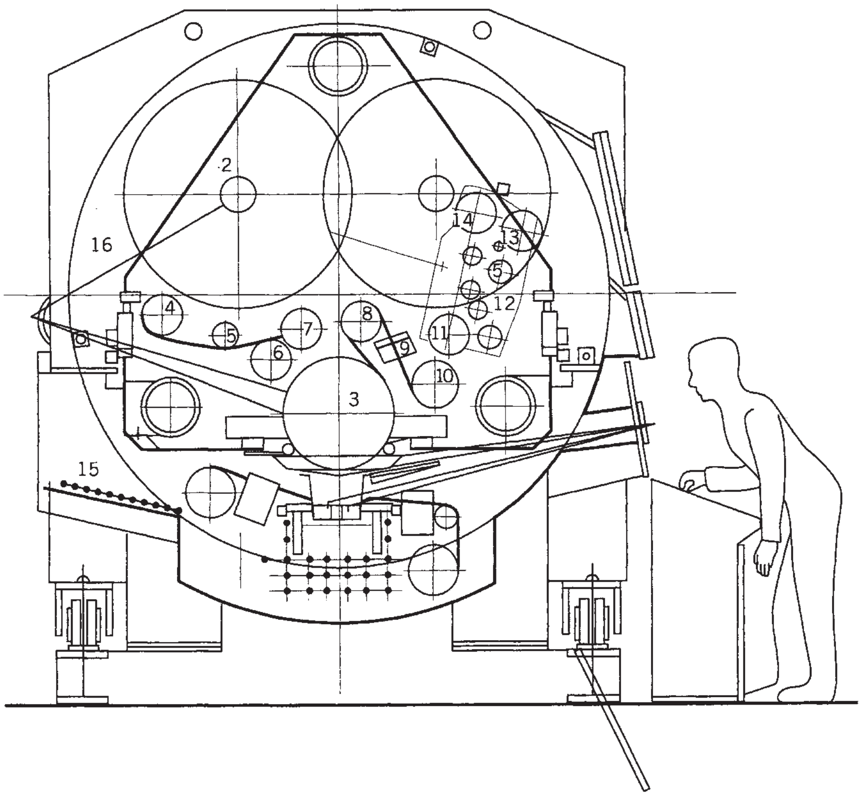

Figure 11. Cross section of a typical high-speed large machine.

electron-beam-powered "top beam" 2-m-wide coater for the packaging industry, whereas Figure 17 shows the resistance-powered "mega" 3-m-wide Galileo metallizer.

One can examine the equipment discussed above as the classic metallizing equipment. Efforts to develop competitively priced transparent barrier coatings, in progress for some time, are continuing. With minor exceptions, the products developed from these activities to date have yet to make a major impact on the coated products for the packaging market. Numerous reports on this research and development and on specific systems for production of such coatings can be located in the proceedings of the International Vacuum Web Coating Conference beginning in 1987 and those of the Society of Vacuum Coaters beginning in 1986. Many technologies for applying transparent barrier coatings are referred to in these publications. Specifically for coatings of SiOx, one can electron-beam evaporate silica. An alternate way to produce coatings of the same compound is through the reactive evaporation of silicon monoxide. SiO_2 coatings can be

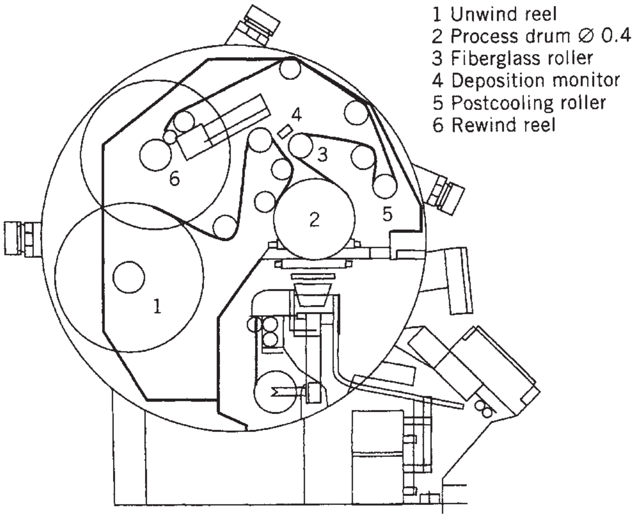

Figure 12. Cross section of a typical high-speed large machine.

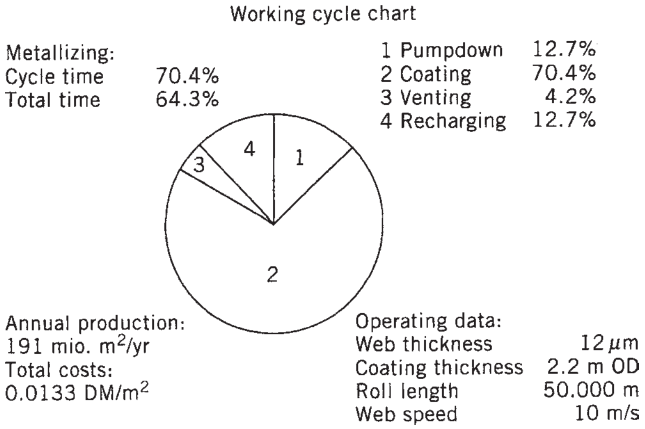

Figure 13. Representative working cycle.

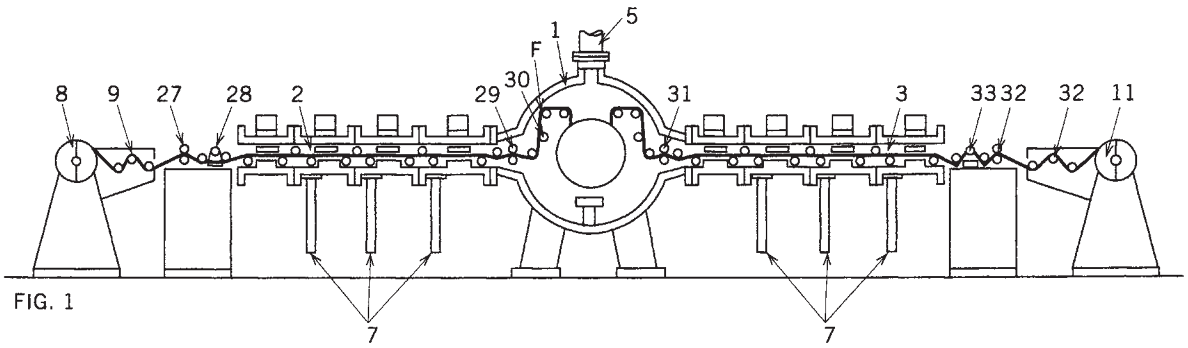

Figure 14. Schematic of a Hitachi air-to-air metallizer.

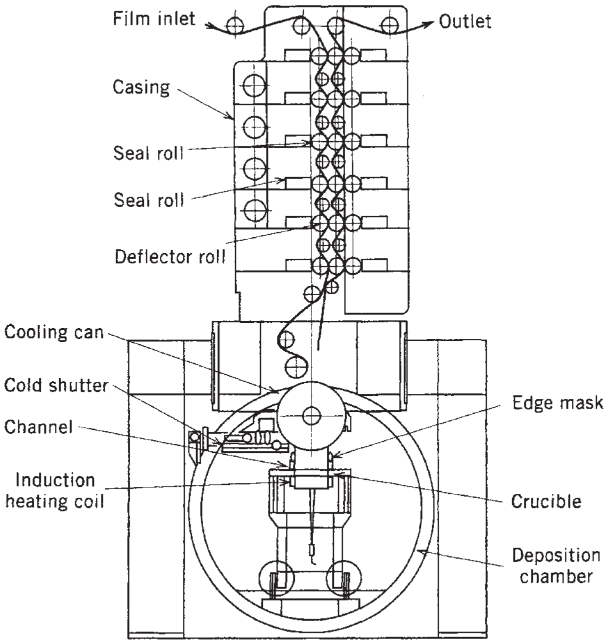

Figure 15. Schematic of an Mitsubishi air-to-air machine.

produced by plasma-enhanced chemical vapor deposition (PECVD) of organosilenes. Al_2O_3 coatings can be produced by anodization of aluminum coatings, which is entirely impractical, and by electron-beam evaporation of Al_2O_3. AlOx coatings can be produced by reactive evaporation of aluminum.

CONCLUSION AND A LOOK AT THE FUTURE

The field of vacuum metallizing serving the packaging industry has been one of steady-state growth. Advances in equipment have lead to price reductions of vacuum-metallized products and an ever-increasing market for these. The last decade has observed tremendous interest and activities in development of transparent barrier coatings. The technology to bring prices of these coated materials to levels acceptable to the packaging industry has prevented real acceptance of these products except in special situations. This effort undoubtly will lead to a breakthrough in the technology that will enable the suppliers to meet the pricing targets of this industry. Only then would transparent-barrier-coated materials begin a real penetration

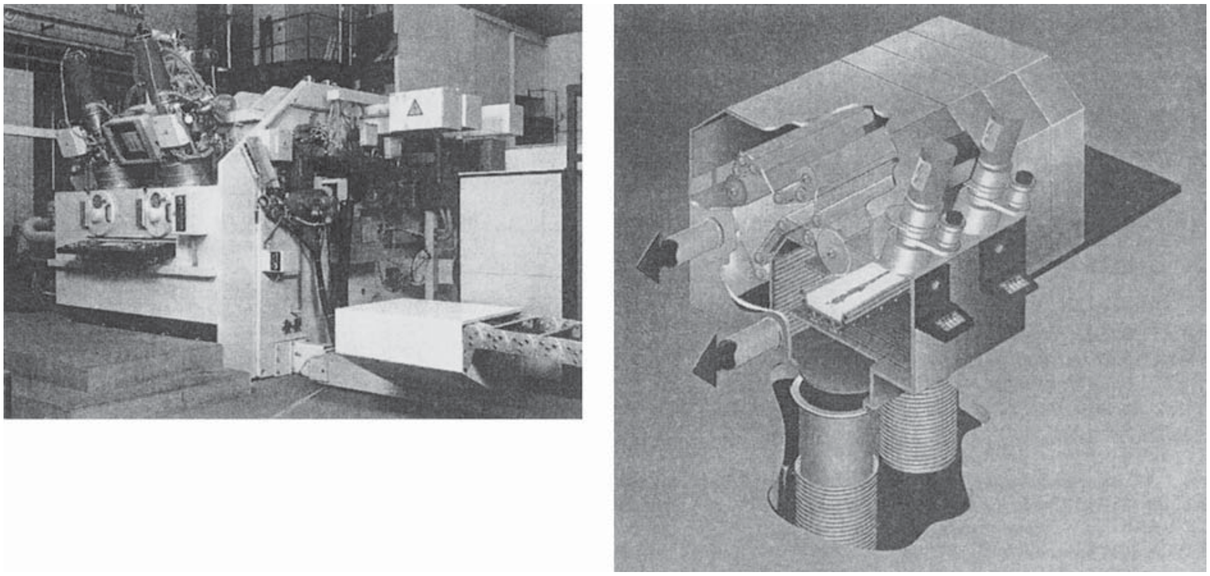

Figure 16. "Top-beam" coater.

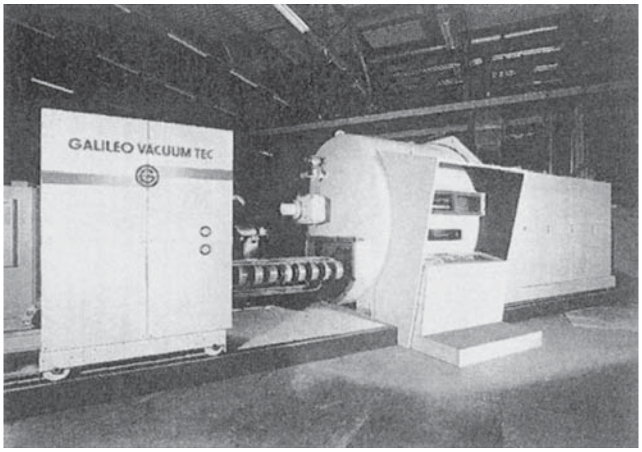

Figure 17. "Mega" line.

in the market dominated by vacuum-metallized aluminum in the packaging industry.

METRICATION IN PACKAGING

Ruben J. Hernandez
School of Packaging, Michigan
State University, East Lansing,
Michigan

The complete expression of any quantity requires both a *number* and a *unit*. Whereas the unit tells us what the quantity is about (and the standard by which is measured), the number indicates how many of those units are considered. Units are part of the daily framework of reference used by a society; when quantities are expressed in familiar units, they are easily understood. In the worlds of commerce, science, industry, and everyday life, we need to express quantities within one group of widely recognized coherent units, which is called a *system* of units. Nevertheless, because of the relative predominance of customary units in the United States, many people still feel uncomfortable when operating with quantities expressed in metric units. In an effort to glean the benefits of using the metric system, the United States has been making slow but steady progress in replacing the customary system of units with the metric one.

Table 1. SI Dimensions, Units, and Symbols

Dimension	Unit	Symbol
Basic units		
Length	meter	m
Mass	kilogram	kg
Time	second	s
Temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd
Electric current	ampere	A
Supplementary units		
Plane angle	radian	rad
Solid angle	steradian	sr

Because the metric system is simpler and easier to use than the customary system, it has become the internationally accepted system of units. The international metric system is a rational and coherent group of measurement units based on a decimal scale. Like the decimal money system (cent, dime, dollar, etc.), the metric system is organized in factors of tens: 1, 10, 100, and so on. The metric system is based on seven basic units: kilogram (mass), meter (length), degree Celsius (temperature), liter (volume), second (time), candela (luminous intensity), and ampere (electric current). In this article, a brief historical note of the metric system, its characteristics, and common conversion units used in packaging are presented.

HISTORICAL BACKGROUND

Whereas all industrialized countries have only one system of units, in the United States there are two major systems of units in use: the U.S. Customary System (USCS) and the International System (SI), which is also denoted as the *metric system*. The USCS is derived from the British Imperial System and has been customarily used since colonial time, although the current USCS is now somewhat different from the old British Imperial System. By action of state and federal legislation, the USCS has become the fundamental system of units in the United States (1). The metric system, however, is the only system of units that has ever been explicitly approved by the U.S. Congress. In 1866, Congress voted a law making it "lawful through the United States of America to employ the weights and measures of the metric system." In 1875, the United States was an original signatory part to the Treaty of the Meter, which established the General Conference of Weights and Measures, the International Committee of Weights and Measurements, and the International Bureau of Weights and Measures.

Table 2. Prefixes

Multiples	Prefix	Symbol
10^{18}	exa	E
10^{15}	peta	P
10^{12}	tera	T
10^{9}	giga	G
10^{6}	mega	M
10^{3}	kilo	k
10^{2}	hecto	h
10^{1}	deka	da
10^{-1}	deci	d
10^{-2}	centi	c
10^{-3}	mili	m
10^{-6}	micro	μ
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	femto	f
10^{-18}	atto	a

Table 3. Selected Units with Special Names in SI

Quantity	Unit Name	Dimensions	Symbol
Absorbed dose	gray	Gy	J/kg
Activity (radioactivity)	becquerel	Bq	s^{-1}
Capacitance	farad	C/V	F
Electricity (amount of)	coulomb	A · s	C
Electrical resistance	ohm	V/A	Ω
Energy	joule	N · m	J
Enthalpy	joule		J
Force	newton	kg · m/s^2	N
Frequency	hertz	S^{-1}	Hz
Heat (amount of)	joule		J
Illuminance	lux	lm/m^2	lx
Luminous flux	lumen	cd/sr	lm
Mass	metric ton	1000 kg	t
Potential difference	volt	W/A	V
Power	watt	J/s	W
Pressure	pascal	N/m^2	Pa
Stress	pascal		
Volume	liter	dm^3	L
Work	joule		

In 1964 the National Bureau of Standard made its policy to use the International System, "except when the use of these units would obviously impair communication or reduce the usefulness of a report." In 1975, Congress approved the Metric Conversion Act; Congress amended it in 1988 and declared the metric system to be the preferred system of measurement for U.S. trade and commerce. Furthermore, the Executive Order 12770, "Metric Usage in Federal Government Programs," was signed in 1991. Despite all the legislation, the United States has not yet embraced use the metric system for the bulk of its

Table 4. Selected Derived Units in Terms of SI Units

Quantity	Name	SI units
Acceleration	meter per square second	m/s^2
Area	square meter	m^2
Concentration	mole per cubic meter	mol/m^3
Density	kilogram per cubic meter	kg/m^3
Luminance	candela per square meter	cd/m^2
Specific volume	cubic meter per kilogram	m^3/kg
Velocity	meter per second	m/s
Volume	cubic meter	m^3
Wave number	reciprocal meter	m^{-1}

Table 5. Units Accepted in the Metric System

Names	Symbol	Value in SI
liter	1 or L	$1\,\mathrm{L} = 10^{-3}\,\mathrm{m}^3$
day	d	1 day = 86,400 s
hour	h	1 h = 3600 s
minute (time)	min	1 min = 60 s
degree (angle)	°	$1^\circ = (\pi/180)$ rad
minute (angle)	′	1′ = 1/60°
second (angle)	”	1” = 1/60′
electronvolt	eV	$1\,\mathrm{eV} \approx 1.602\,18 \times 10^{-19}\,\mathrm{J}$
hectare	ha	$1\,\mathrm{ha} = 1\,\mathrm{hm}^2 = 10{,}000\,\mathrm{m}^2$
metric ton	t	1 t = 1000 kg
unified atomic mass	u	$1\,\mathrm{u} \approx 1.602\,18 \times 10^{-27}\,\mathrm{kg}$

commercial and standard activities. Although the use of the metric system is mandatory in federal agencies, its use by the industry is voluntary. In an effort to promote metrication (the transitional process for converting to the use of the metric system), the Metric Program at the National Institute of Standard and Technology (NIST) has been established (2).

BENEFITS OF THE METRIC SYSTEM

There are many commercial, educational, and technical benefits in using the metric system. The metric system is the measurement system for products, processes, and information in international commerce (3). The European Union regulations will require by the year 2000 that all products sold in their boundaries be labeled in metric units and all the corresponding documentation be expressed in metric system. Japan opposes the import of products with nonmetric units. Other countries and regions, like England, Canada, Australia, China, Mexico, and South and Central America, have already converted their system of measurements to metric units.

With the steady increase in world trade and international interdependence, it is expected that the use of the metric system in the United States will necessarily increase. The use of the metric system by industry is also expected to benefit the consumer because it will promote standardized and simplified product packaging. This will reduce the vast amount of packaging, facilitate price–quantity of product comparison, and standardize shipping

and distribution conditions, including items such as boxes, containers, and pallets. Parallel to this, students learning mathematics will benefit because less time will be spent on cumbersome and distractive conversions.

INTERNATIONAL SYSTEM AND THE METRIC SYSTEM

In 1960, the General Conference of Weights and Measures which was made up of the signatory nations to the Treaty of the Meter, approved the modern version of the metric system, called the International System of Units. The International Systems is officially known by the French title *Systeme International d'Unites*, and it is referred as SI. In this respect, the SI and the metric system are equivalent. Nevertheless, it is accepted that products standards and preferred sizes (like liter) used by industries and governments through the world are considered part of the metric system. For instance, the Metric Conversion Act of 1975 indicates that "the system of measurement means the International System of Units … and as interpreted or modified for the United States by the Secretary of Commerce." Thus, although the metric system and SI are equivalent, the metric system also refers to other units related to SI.

The basic units of the SI are the seven units listed in Table 1 (4). Because the numbers in the quantities expressed in these units can be very large or very small,

[a] as = 1 atto second = 1×10^{-18} s.

[b] MW = molecular weight.

prefixes have been included as part of SI. A list of common prefixes is presented in Table 2. Additionally, derived units with special names are officially recognized in the SI and are presented in Table 3. Selected derived units in terms of SI units are shown in Table 4. Table 5 lists selected units accepted in the metric system. A list of conversion factors to convert units of the USCS into the SI, which as often used in packaging, was compiled in Table 6. Because the permeability units are more complex, they are presented separately in Table 7.

CONVERTING AND ROUNDING

Conversions should follow the simple rule of error propagation for multiplication (or division) of two numbers; figures that imply more accuracy than justified by the original data should not be included. For instance, 24 in. converted to cm (24 × 2.54) should be written as 61 cm, not 60.91 cm. Only two significative figures are given in 24 in. Similarly, 2.7 $\mathrm{lb/ft^3}$ converts to 43 $\mathrm{kg/m^3}$, and from Table 7, 0.3 mL (STP) · mil/(100 $\mathrm{in.^2}$ · day · atm) converts to 1×10^{-20} $\mathrm{m^3(STP) \cdot m/(m^2 \cdot s \cdot Pa)}$.

NAMING THE METRIC SYSTEM

All the metric system units have a name and a symbol; for instance, the symbol for the unit named liter is L. Important rules referring to the use of name, symbols, and prefixes in the metric system are as follows (1, 5):

1. The names of all units begin with a lowercase letter (unless at the beginning of the sentence). There is one exception to this rule: degrees Celsius, °C. The unit "degrees" in lower case but the modifier "Celsius" is capitalized. For instance, the glass-transition temperature of PET is 78°C. For other units, see Tables 1, 3 and 5.
2. Unit symbols are written in lowercase (e.g., m and kg). However, the following exceptions apply: liter is written in capital L (to avoid confusion between "l" with the numeral "1"), as well as units honoring a person, like W for watt, K for kelvin, Pa for pascal, and so on.
3. Symbols of prefixes indicating a million or more are capitalized (see Table 2); for example, M for mega (10^6). Symbols indicating less than a million are in lowercase: for kilo (10^3) is k, and milli (10^{-3}) is m. This may create some confusion, and attention should be given to distinguish for example, mN (millinewton) from N · m (Newton-meter)
4. When the preceding numerical value is more than 1, the name of the unit is made plural, and singular is used in the case of 1 or less (e.g., 50 μm, 105 kP, 0.25 g, and 0.5 L). Still, "degrees" is always plural when not referring to one; we say 1 degree Celsius, but 0.5 degrees Celsius. The symbols are never written in plural: 13.5 liters is 13.5 L, 67.3 megapascals is 67.3 MPa.
5. A prefix, however common, must not be used to replace a unit. For example, "kilo" (which is a prefix for 1000) should not be used for "kilogram." "Micron" is no longer accepted to indicate 1×10^{-6} m; the correct term is micrometer (μm). The unit of

temperature is degree Celsius, not degree centigrade (the latter term is no longer accepted).

6. Numeric values with five or more digits are sometimes separated by spaces, not commas (e.g., 7 689 734 Pa or 0.047 65 cm). For values of up to four digits, spacing is optional.

MICROWAVABLE PACKAGING AND DUAL-OVENABLE MATERIALS

George J. Huss
Rubbright Brody, Inc.
Eagen, Minnesota

INTRODUCTION

The 1980s saw the prolific growth of the consumer microwave oven resulting in a new category of food products. Development of the new products spawned a new market for packaging materials, some of which were capable of being rethermalized in a conventional oven as well as the microwave oven (known as *dual-ovenable* products and materials), while still other new products and their packages evolved that were developed strictly for heating in the microwave oven. The penetration of microwave ovens into U.S. homes and lifestyles grew rapidly from a mere 15% of households owning a microwave oven in 1980 to an impressive 78% by 1989 (1). Consumers were hungry for food products designed for cooking and rethermalization in the microwave oven, and a new category known as "microwave foods" developed seemingly overnight.

The new category was bolstered by microwave popcorn, a product that was developed specifically for preparation in the microwave oven. The standard was now set for other new food products that attempted to cater to consumers' desires for foods offering quickness and convenience in their preparation. In the mid-1980s, we saw a wave of premium-priced frozen dinners, positioned as a higher quality "TV dinner," that were now available on thermoset polyester plates, capable of being heated in the conventional-oven environment (up to 400°F) or the microwave. The new category of frozen dinners saw active growth and entry by several companies who were keen on capitalizing on the consumers' desire for foods that could be conveniently heated in the microwave oven. In many cases, the feature of a product that could be prepared as packaged in either a conventional oven or a microwave oven was important to food marketers, even when their research showed that 85% of their consumers were using the microwave oven.

The new microwave-foods category was growing at such a rate that it was difficult to ignore. New departments and teams were assembled in food companies to develop new products for the burgeoning new category. *Gorman's New Product News* tracked the number of product introductions, which increased from 278 in 1986 to nearly 1000 in 1988. Often, these new foods were merely traditional food products that were packaged for microwave-oven preparation or traditional foods that now included preparation directions for the microwave oven. As a greater understanding of the effect of microwave energy on different foods and packaging materials grew, so, too, did a desire to improve the quality of the food as eaten to the same level observed with conventional-oven preparation. Greater focus on foods engineered specifically for the microwave oven led to packaging materials that performed strictly in the microwave oven. The following is a list of materials that are currently available, or were used at some time, for use as packaging components for foods to be heated in the conventional oven, the microwave oven, or in some cases, both oven environments.

DUAL-OVENABLE MATERIALS

Coated Paperboard. Paperboard is available as a dual-ovenable material in the form of trays, plates, and cartons. Generally, the paperboard used is solid bleached sulfate (SBS), but solid unbleached sulfate (SUS), also referred to as *natural* or *kraft paperboard*, can be used; however, market applications are strongly skewed to SBS use. To make an ovenable material, the paperboard is coated, generally with a fine clay on one side to impart higher surface gloss and a proper surface for printing, along with an extrusion coating of a film made of polyester (PET) or, in some cases, 4-methyl-pentane-1 copolymer (TPX). The thin layer of a high-temperature plastic provides a relatively inexpensive method to produce containers that capitalize on the structural strength and economics of the paperboard component while adding the barrier required to keep fats and moisture in the food from entering the paperboard. Other plastics are also extrusion-coated onto paperboard, notably low-density polyethylene (LDPE) and polypropylene (PP); however, the maximum temperature resistance of LDPE is 215°F and 260°F for PP. The upper temperature limit for LDPE- and PP-coated paperboard will dictate the packaging application. With a maximum temperature limit of 215°F, LDPE-coated paperboard provides excellent properties for milk cartons and cold and hot-drink cups; however, its use in the microwave oven will be limited to products that will not get hot, such as a frozen dessert that may be microwaved to only soften the contents. Similarly, PP-coated paperboard is available for microwave-only packages in which there is no risk that the hot spots within a package can reach a temperature where the PP softens, causing structural changes in the package or the PP to break down, allowing some of its constituents to enter the food.

The dominant ovenable paperboard is PET-extrusion-coated. With a maximum temperature use of 400°F, PET-coated paperboard is well suited for forming containers to be used in dual-ovenable containers for a variety of food products. TPX-coated paperboard is preferred in baking applications because of its higher temperature resistance and its release characteristics for sugars that may become caramelized during the cooking cycle. TPX-coated paperboard is more expensive than PET-coated paperboard.

The clay coating is put on the paperboard either in-line on the paperboard-making machine or at a remote station. The clay coating in both cases is done on mill-size rolls of paperboard that are about 200 in. wide. The coated mill roll can then be slit to widths more appropriate for laminating equipment and forming and carton-making machines.

To form a tray from a roll of PET-coated paperboard, the paperboard is first moistened with water to a level of 8–11%. This softens the paperboard to allow pressure forming. The roll of paperboard is first cut into blanks that have the flange dimension of the finished container. The blank is then indexed into a heated matched metal mold that, when closed, forms the blank into the mold shape, i.e., the shape of the container. The heat in the mold dries the paperboard. Since the paperboard does not stretch, this type of forming will produce a square container with small creases in the corners or creases around the base of a round or oval container.

Molded Pulp, PET-Film-Laminated. PET-film-laminated molded pulp trays are cellulose-based containers most commonly seen as plates and trays. The PET film is required to provide the barrier resistance to fats and oils to go along with the structural characteristics of the lower cost pulp. The cellulose fibers are suspended in a slurry (which may contain other components such as sizing and treatments to provide better barrier properties) and pumped to the compression molds, which form the pulp into the desired container shape. The slurry is held into the mold by vacuum, which also draws most of the water out through a screen. Pressure and heat are applied as the mold closes to form the pulp into the container shape and draw out the remaining water. An advantage to this type of molding is the flexibility in the shape of the finished container, which may include divided compartments and areas with varying dimensional thickness for strength. After the molding cycle, the containers are laminated with a cast PET film, which is then trimmed of any excess and packaged.

PET-laminated molded pulp trays will withstand oven temperatures of 400°F with good stiffness and structural characteristics.

CPET. Crystallized polyester (polyethylene terephthalate) is a rigid plastic material that can be thermoformed into containers, generally shallow plates and trays. To become dual-ovenable, the PET must be crystallized during the thermoforming process. The PET contains nucleating agents that assist in the molecular crystallization. A key factor to consider when thermoforming CPET is the intrinsic viscosity (IV) of the material. The amount of crystallization and the IV will determine the balance between the container's stiffness at low (–40°F) and high (400°F) temperatures. Generally the crystallinity of the finished container will be 28–32% and the IV will range from 0.85 to 0.95.

Prior to extruding, the PET must be thoroughly dried to a level of 0.003% to remove inherent water. For thermoforming, great care must be given to temperature control to ensure consistency. The ovens used to heat the sheet on the thermoformer prior to forming must heat the sheet evenly across its dimensions. CPET is considered to be a difficult material to work with because of its toughness and narrow window of operating temperatures, so proper mold design is a consideration. Aluminum molds are used to promote even thermal conductivity during forming. Female molds are used, and the design should allow for generous radii and minimize undercuts. Often a second stage used in the molding process is a cooling mold that assists in shortening the cycle time, helps to stabilize the material after it is formed in the heated mold, and makes trimming easier. Because of its toughness, CPET is difficult to trim. Matched metal dies are used and should be sharpened periodically. Additionally, heavy-duty trim presses with quick cycle times should be used.

CPET has a temperature resistance of 400°F, has a high gloss, has a hard surface, and can be colored with pigment effectively, although the preferred colors in the market are black, white, and ivory.

PCTA. Another material in the polyester family that has higher temperature-resistance properties than CPET is a copolyester resin composed of a polymer of cyclohexanedimethanol and terephthalic acid (PCTA), often referred to by Eastman Chemical Company's trade name, Thermx. PCTA is a thermoformable material capable of withstanding temperatures in the range of 425–450°F. Processing is generally considered to be more difficult than CPET because of the higher temperatures required for extrusion and thermoforming and greater cooling requirements. A special nucleating agent is required; however, equipment specified for running CPET will generally be able to run PCTA with the proper adjustments. PCTA, like CPET, is able to be marked with the Society of the Plastics Industry (SPI) code as number 1—PETE for recycling purposes.

Foamed CPET. Shell Chemical Company has developed a method of making foamed CPET that it markets under the trade name PETLITE. The objective of this material is to produce containers with 35–40% less material than conventional CPET. Extrusion equipment used for CPET must be modified for running foamed CPET; however, a single-screw extruder can be used. The blowing agent used for the expansion is an inert gas. Generally, processing temperatures for extrusion and thermoforming are comparable with CPET as are pigmenting and trimming requirements.

PETLITE containers have a temperature resistance of 400°F. Currently, commercial applications include containers for baked goods such as muffins and cakes.

Borden Global Packaging, UK, has recently announced the availability of their version of foamed CPET under the trade name Ovenex Lite. Trays made of Ovenex Lite contain 25–33% less material than their solid counterparts. Commercial availability in stock sizes are available from Borden in mid-1996. Borden uses their own process for foaming CPET for which a patent is pending.

Thermoset Polyester. Thermoset polyester plates were the first commercial application of dual-ovenable materials when used for frozen meals in the mid-1980s. The compound used is an unsaturated polyester that is highly filled with minerals such as talc and calcium carbonate, along with glass fibers and catalyst materials to produce the chemical reaction to convert the compound into material that is irreversibly set. The polyester compound is mixed and extruded to form logs that are cut to the proper size and weight for the finished container. The material is placed into a heated mold in a hydraulic press that closes the mold. The pressure causes the material to flow into the shape of the mold, and the heat cures the compound while under pressure into the finished and irreversible material. Typically, the container must be sanded to remove any flashing around the edges and often is run through a conveyor oven for a postbake cycle to drive off any residual uncured compound, and washed to remove any dust from sanding. This process produces containers that are very strong and stiff, even at high temperatures (425°F), and are heavy with a china-like feel and appearance. Unlike thermoforming from a sheet of material with consistent thickness, thus producing containers having essentially the same material thickness throughout, compression molding permits the finished containers to have varying degrees of thickness throughout the dimension to add strength or design features where desired. Because of the amount of material used, the multiple steps in the manufacturing process, and the relatively low output per machine cycle for compression molding presses, the price for a thermoset polyester plate is proportionally higher than competitive thermoformed plastic materials that can be produced at much higher rates with less material and cellulose-based containers that have a lower material cost.

Nylon 6/6. Mineral-filled nylon (or polyamides) is a dual-ovenable material that today is no longer commercially available. Developed by DuPont Canada during the mid-1980s, mineral-filled nylon was also converted by DuPont Canada by injection molding into containers. Mineral-filled nylon plates have a higher temperature resistance and stiffness (500°F) than does CPET and were priced between CPET and thermoset polyester containers. Although the material was successfully introduced commercially, the use was limited because of the higher cost than CPET; also, the hydroscopic nature of filled nylon plates sometimes caused performance problems in the microwave oven. Nylon has good resistance to oils and fats; however, within the moist operating environment of the microwave oven, some of the water present in the food would be absorbed into the nylon plate, resulting in a loss of dimensional stability. Nylon plates' strength was in the conventional oven, where unlike some competitive thermoplastic materials, it retained its rigidity.

Nylon plates were injection-molded, a process that generally has higher tooling costs and higher operating costs when compared with thermoforming comparable unit volumes.

Polyetherimide. Polyetherimide (PEI) is a high-temperature thermoplastic resin available from General Electric Plastics under the trade name Ultem.

PEI provides a dual-ovenable material for applications of about 350°F. PEI is available only in injection-molding grades, and with its high price per pound, it is generally better suited for multiple-use versus single-use applications. PEI also has good chemical and stain resistance, allowing for it to effectively be cycled through commercial dishwashing systems.

PEI has been used for plates and containers in institutional feeding programs and airline meals.

Polysulfone. Polysulfone (PSO) is an amorphous thermoplastic with good rigidity and toughness. PSO is capable of withstanding oven temperatures below 325°F, making it well suited to low-temperature and microwave applications. PSO is available in transparent form, lending its use in appliances as a replacement for glass and other multiple-use applications.

Because of its high price, PSO has not been used in single-use applications.

Liquid-Crystal Polymer. Liquid-crystal polymers (LCPs) offer very good high-temperature resistance up to about 500°F in some grades. LCP can be injection-molded and is generally pigmented from its natural beige color (see also Liquid crystalline polymers).

LCP is transparent to microwave energy; however, the high price of this resin limits its use to specialized applications. At one time, LCP was in commercial use as dual-ovenable cookware marketed by Tupperware.

Aluminum. Prior to the explosion of microwavable foods during the mid-1980s, aluminum trays dominated the prepared- and frozen-meals market as well as food-service applications such as school-lunch programs. As a package material for use only in conventional ovens, aluminum was ideal. It was capable of withstanding very high temperatures for long times—certainly exceeding the temperature limitations of the food, was usually available at attractive prices, and could be run at a high speed on packaging equipment.

During the early stages of the microwave oven, arcing occurred when metal objects were placed in the oven cavity during operation, sometimes disabling the unit. This was largely corrected when the electronics were improved so that energy could not be reflected back into the magnetron. Even though it was safe for metal objects to be used in the microwave oven, consumers did not want to take the risk.

In the mid-1980s, Alcoa developed a plastic-coated aluminum tray that was formed without the typical wrinkled corners. The vinyl/epoxy coating was often pigmented to appear more like plastic and allowed the tray to work in both conventional and microwave ovens. Performance in the microwave oven is different from that of plastic- or cellulose-based materials since the aluminum shields microwave energy, often leading to longer heating times than for similar trays of competitive materials. This lends the design of the tray shape to be shallow to lessen the amount of microwave energy shielded. Coated aluminum foil trays were used commercially for pot pies where they were able to maintain high filling line speeds.

Polycarbonate. Polycarbonate (PC) is an amorphous thermoplastic resin that is capable of withstanding temperatures above 400°F. PC can be injection-molded, blow-molded, and thermoformed.

PC has been used in applications for multiple-use products such as microwavable cookware. PC is virtually unbreakable, making it a good replacement for glass. PC was used in a commercial package during the late 1980s for Stouffer's dual-ovenable meals. The structure used was thermoformed from a three-layer coextruded sheet; however, because of its high price per pound, it was replaced by competitive materials that offered acceptable performance for a much lower cost.

MICROWAVE-ONLY MATERIALS

Polypropylene. During the late 1980s, polypropylene grew as a microwave material because of its flexibility and relatively low cost. Polypropylene (PP) use in packaging was bolstered by the rapid growth of shelf-stable meals such as Lunch Buckets (registered trademark) and the like, in which ethyl vinyl alcohol (EVOH) is used to improve the oxygen-barrier properties required to safely preserve the cooked food at ambient temperatures.

Microwavable containers of PP can be thermoformed or injection-molded, generally in two different types: homopolymer PP and random copolymer PP. Homopolymer PP is produced using propylene monomer without the addition of other monomers. Random copolymer PP is similar in polymeric structure to homopolymer PP but also includes the random addition of ethylene to a polypropylene chain as it grows. Random copolymer PP gains some molecular orientation, providing certain advantages over homopolymer PP such as improved impact strength and much better clarity.

Homopolymer PP can also be filled with minerals such as talc or calcium carbonate at levels of 20–40%. Filled homopolymer PP will have a slightly higher end-use temperature and greater stiffness than its unfilled form.

Polyphenylene Oxide/Polystyrene. Polystyrene (PS) by itself does not have a sufficiently high-temperature resistance (about 180°F), but when blended with polyphenylene oxide (PPO), the temperature-resistance properties are increased depending on the ratio of PS to PPO. For temperature resistance in the range of 212–230°F, a blend of 25% PPO and 75% PS is recommended.

PPO has a low resin flow and is therefore difficult to form; however, when it is blended with PS, the flow characteristics and processing requirements are improved. PPO/PS can be thermoformed on equipment used for PS forming with only minor modifications. It is important to have accurate blending during the extrusion process; therefore, a high-intensity mixing screw is required. Additionally, PPO/PS is able to be foamed (much like expanded polystyrene) by extruding with tandem extruder systems and blowing agents used for polystyrene such as pentane.

PPO is available from General Electric Plastics under the trade name Noryl.

Polyethylene. High-density polyethylene (HDPE) is an acceptable thermoplastic resin for some microwave applications. HDPE starts to lose its rigidity at temperatures above 200°F, resulting in distortion of the tray or container, so care must be given in selecting this material for food products that will not exceed this temperature. This means that foods that have a high fat or oil content or those that generate steam will not be good candidates for HDPE. Generally, applications for HDPE are for foods that do not have a long heating cycle and have a homogenous texture to balance heating throughout the food, thereby eliminating hot spots.

The advantages of HDPE are its relatively low cost in comparison with other resins, its processing ease, and its good impact properties at frozen temperatures. HDPE for food trays is most commonly thermoformed but also can be injection-molded (see also Polyethylene, high density).

Glass. Although glass usage as a packaging material has declined steadily, it is a material that is able to withstand the rigors of microwave heating. Because of the advantages plastic has over glass in consumer safety, transportation costs, and design flexibility, there are very few applications where glass is selected as a packaging material because of its ability to be used in the microwave.

MICROWAVEABLE FOODS PACKAGING

Kit L. Yam
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

INTRODUCTION

While microwaveable food products have been quite popular in the past two decades, there still remain many challenges for the developer and manufacturer. Besides convenience, other factors such as taste and texture are also important to the consumer. Quite often, the consumer perceives food heated by the microwave oven as not tasting as good as that heated by the conventional oven. This is because the heating mechanisms of food in the microwave oven and conventional oven are indeed quite different. To develop successful microwaveable food products, the developer must have a good understanding of the microwave heating of food, as well as careful considerations of the package design and consumer expectation.

BASICS OF MICROWAVE HEATING OF FOOD

Microwave heating of food is a complex process that requires a good understanding of several relevant disciplines: electromagnetism, food engineering, food chemistry, food packaging, and food microbiology. It is beyond the scope of this article to provide detailed descriptions of the many aspects of this complex process. Instead, this article is aimed at acquainting the reader with the basic working knowledge most relevant to the microwave heating of foods. More general information can be found from references in the literature (1–3).

Microwaves

Microwaves are short electromagnetic waves located in the portion of electromagnetic wave spectrum between radio waves and visible light. The energy is delivered in the form of propagating sine waves with an electric field and a magnetic field orthogonal to each other. Microwaves are relatively harmless to humans because they are a form of non-ionizing radiation, unlike the much more powerful ionizing radiation (such as X ray or gamma ray) that can damage the cells of living tissue. Microwaves are used in daily applications such as cooking, radar detection, telecommunications, and so on.

Most microwave ovens for food applications operate at two frequencies. The household microwave oven operates at 2450 MHz (2.45×10^9 cycles per second), and the industrial microwave oven operates at 915 MHz (9.15×10^8 cycles per second). The wavelengths associated with those frequencies are 0.122 and 0.382 m, respectively, when the microwaves are assumed to travel at the speed of light (3×10^8 m/s). Microwaves travel at approximately the speed of light in air, but they travel at a lower speed inside a food material. The relationship between frequency and wavelength is expressed by the equation $v = f\lambda$, where v is velocity (m/s), f is frequency (Hz), and λ is wavelength (m) of an electromagnetic wave.

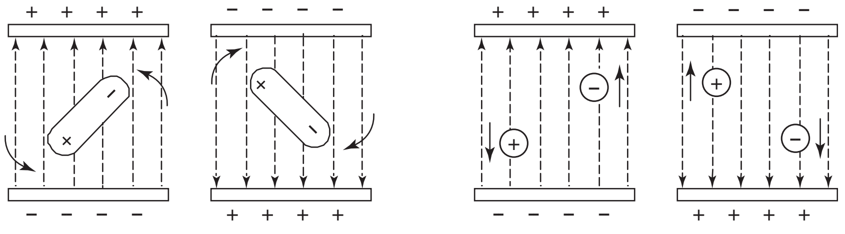
There are three possible modes of interaction when microwaves impinge upon a material: absorption of microwaves by the material, reflection of microwaves by the material, and transmission of microwaves through the material. The material may be a food or a packaging material. The food must absorb a portion of the microwave energy in order for heating to occur. Most foods do not reflect microwaves, and thus all the remaining unabsorbed microwave energy is transmitted. Some packaging materials, such as susceptors, absorb microwave energy and become hot. Metals, such as aluminum foils, reflect microwaves. Paper, plastics, and glass are transparent to microwaves. To optimize the microwave heating of food, it is necessary to consider the reflection, absorption, and transmission of microwaves by the food and the package.

In the microwave oven, microwaves are generated by an electronic vacuum tube known as a magnetron. The microwaves then travel through a hollow metal tube (called a “waveguide”) to the oven cavity. To improve the heating uniformity, the microwave oven is often equipped with a stirrer or a turntable. The stirrer is a fanlike set of spinning metal blades used to scatter the microwaves and disperses them evenly within the oven. The turntable rotates the food during the microwave process. The history, features, standardization, and safety matters relating to the microwave oven are discussed by Decareau (1).

Microwave/Heat Conversion

Microwave energy is not heat energy. In order for microwaves to heat food, they must first be converted to heat. There are two mechanisms by which this energy conversion can occur: dipole rotation and ionic polarization. The two mechanisms are quite similar, except the first involves mobile dipoles while the second involves mobile ions. Both dipoles and ions interact only with the electric field, not the magnetic field.

Figure 1a illustrates the dipole rotation mechanism of a polar molecule. In the presence of an electrical field, the polar molecule behaves like a microscopic magnet, which attempts to align with the field by rotating around its axis. As the polarity of the electric field changes, the direction of rotation also changes. The molecule thus absorbs microwave energy by rotating back and forth billions of times at the frequency of microwaves. Since the molecule is often bound to other molecules, the rotating action also causes it to rub against those other molecules. The rubbing action disrupts the bonds between the molecules, which in turn causes friction and heat dissipation.



(a) Dipole rotation (b) Ionic polarization

Figure 1. Microwave/heat conversion mechanisms. The dashed lines denote the alternating electric field at the frequency of microwaves. (a) A dipole rotates back and forth. At high frequencies (such as 2450 MHz), there is not sufficient time for the dipole to rotate 180°, and thus the actual rotation angle is much smaller. (b) A positive ion and a negative ion oscillate in an alternating electric field.

The water molecule is the most abundant polar molecule in food. The water molecules in liquid water are quite mobile, and they readily absorb microwave energy and dissipate it as heat through dipolar rotation. In contrast, the water molecules in ice are much less mobile due to the confined crystal structure, and they do not absorb microwave well. The distribution of moisture and the state of water (liquid water or ice) are often two critical factors that determine the behavior of microwave heating of foods.

Figure 1b illustrates the ionic polarization of a positive ion and a negative ion in solution. In the presence of an electric field, the ions move in the direction of the field. As the polarity of the electric field changes, the ions move in the opposition direction. The ions absorb microwave energy by oscillating themselves at the frequency of microwaves. The oscillating action in turn causes heat dissipation through friction. The common ions in food are those from salts such as sodium chloride. Since ions are less abundant than water molecules in most foods, ionic polarization often plays a less important role than dipole rotation.

Dielectric Properties

While dipole rotation and ionic polarization provide a qualitative understanding of the microwave/heat conversion mechanisms, the dielectric properties provide a quantitative characterization of the interactions between microwave electromagnetic energy and food. The dielectric properties, along with thermal and other physical properties, determine the heating behavior of the food in the microwave oven.

An important dielectric property is dielectric loss factor (ε''), which indicates the ability of the food to dissipate electrical energy. The term “loss” refers to the loss of energy in the form of heat by the food. It is useful to remember that a material with a high ε'' value (also known as a lossy material) heats well, while a material with a low ε'' value heats poorly in the microwave oven. The dielectric loss factor is related to two other dielectric properties by the equation

$$\tan\delta = \varepsilon''/\varepsilon' \qquad (1)$$

where $\tan\delta$ is loss tangent and ε' is dielectric constant.

The dielectric properties (ε' and ε'') are functions of frequency, temperature, moisture content, and salt content. Values of dielectric properties for foods and other materials can be found in the literature (4–6). Examples of ε'' and ε' values at 2450 MHz are shown in Table 1. Although the literature values can be used as guidelines, actual measurements are often required because of the variability of composition of the materials.

The dielectric properties provide a quick indication of how well a material heats in the microwave oven. For example, the ε'' value of water (12.48) at 25 °C is several orders of magnitude higher than that of ice (0.0029) at −12 °C. This means that water heats far better than ice in the microwave oven. Ice is almost transparent to microwaves because its molecules are tightly bound and do not rotate easily through the mechanism of dipolar rotation.

Table 1. Dielectric Constant (ε'), Dielectric Loss Factor (ε''), and Penetration Depth (D_p) of Various Foods at 2450 MHz

Food or Other Material	ε'	ε''	D_p (cm)
Ice (−12 °C)	3.2	0.0029	1203
Water (1.5 °C)	80.5	25.0	0.71
Water (25 °C)	78	12.48	1.38
Water (75 °C)	60.5	39.93	0.40
0.1 M NaCl (25 °C)	75.5	18.1	0.94
Fat and oil (average)	2.5	0.15	20.6
Raw beef (−15 °C)	5.0	0.75	5.83
Raw beef (25 °C)	40	12	1.04
Roast beef (23 °C)	28	5.6	1.85
Boiled potatoes (−15 °C)	4.5	0.9	4.6
Boiled potatoes (23 °C)	38	11.4	1.07
Boiled spinach (−15 °C)	13	6.5	1.11
Boiled spinach (23 °C)	34	27.2	0.45
Polyethylene	2.3	0.003	986
Paper	2.7	0.15	21.4
Metal	∞	0	0
Free space	1	0	∞

The dramatic increase in ε'' value is also observed when ice changes to water—that is, during the thawing of frozen foods including beef, potato, and spinach (Table 1). Plastics and paper have low ε'' values because they are almost transparent to microwaves.

Penetration Depth

The speed of microwave heating is due to the deep penetration of microwaves into the food, and the dielectric properties can be used to determine the extent of penetration. When microwaves strike a food surface, they arrive with some initial power level. As microwaves penetrate the food, their power is attenuated since some of their energy is absorbed by the food. The term penetration depth (D_p) is defined as the depth at which the microwave power level is reduced to 36.8% (or 1/*e*) of its initial value.

The meaning of penetration depth is further illustrated in Figure 2. At the first D_p, 36.8% of the initial power remains, while 63.2% of the power is absorbed. At the second D_p, $(0.368)^2 = 13.5\%$ remains and 86.5% is absorbed. At the third D_p, $(0.368)^3 = 5.0\%$ remains and 95% is absorbed. The penetration depth depends on the composition of material, the frequency of microwaves, and temperature.

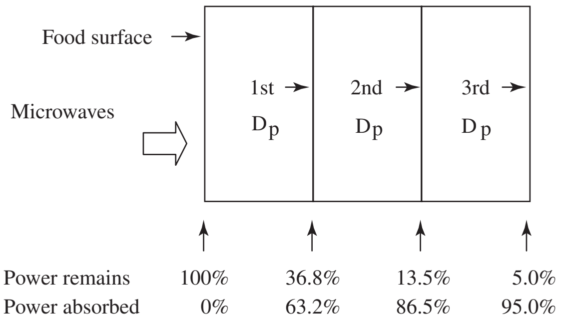


Figure 2. Power levels at various penetration depths.

Typical values of D_p for various materials at 2450 MHz are also shown in Table 1. As mentioned earlier, liquid water absorbs microwaves far better than ice. The D_p of water at 25 °C is 1.38 cm, but D_p of ice at −12 °C is 1203 cm! Frozen foods have longer penetration depths than unfrozen foods. For example, the D_p values for frozen beef and unfrozen beef are 5.83 cm and 1.04 cm, respectively.

CHALLENGES IN MICROWAVE HEATING OF FROZEN FOOD

While microwave heating offers the benefits of speed cooking and convenience, it also presents many technical challenges to the food scientist or technologist. Those challenges arise from the need to deal with the many variables relating to the food, package, and microwave oven. For the food, there are variables of food composition, shape, size, specific heat, density, dielectric properties, and thermal conductivity. For the package, there are variables of shape, size, and properties of packaging material. For the microwave oven, there are variables relating to the design of the oven. A related and more important challenge is to solve the problems of the consumer. From the consumer's point of view, the most noticeable problems are those associated with nonuniform heating, lack of browning and crisping, and variation in microwave ovens.

Nonuniform Heating

Nonuniform heating is a major problem associated with microwave heating. The problem is especially noticeable for frozen food. It is not uncommon for a frozen food heated in a microwave oven to boil around the edges while the center remains frozen. The problem is caused by the differences in microwave energy absorption of liquid water and ice.

In frozen foods, the water molecules on the surface are relatively free to move compared to the water molecules inside the food. When a frozen food is microwaved, heating begins at the surface where the water molecules are more ready to absorb microwave energy. This causes the adjacent ice crystals to melt and the surface temperature to rise, while the inside temperature is still little unaffected. As more liquid water is available, the heating of the surface becomes more rapidly. This can lead to "runaway heating," in which heating is excessive at the surface while the inside is still frozen. To minimize runaway heating during thawing, microwave energy should be delivered at a slow rate, which allows more time for heat to conduct from the surface to the inside.

Irregular shape of the food can also cause nonuniform heating. The thin parts tend to overcook, while the thick parts tend to undercook. This situation also occurs in conventional cooking but is less pronounced because the cooking is slower. Another cause of nonuniform heating is that different foods have different dielectric and thermal properties. When a microwave meal consists of two or more items, it is possible that the items heat at different rates. For example, when microwave heating a frozen meal consisting of meat and vegetable, the vegetable often becomes overheated and dried out before the meat reaches the serving temperature.

Lack of Browning and Crisping

Another problem is that, unlike the conventional oven, the microwave oven is not able to produce foods that are brown and crisp. This is because the heating mechanisms of the conventional oven and the microwave oven are quite different.

In the conventional oven, the food is heated by hot air in the oven; and if the heating element is not shielded, the food is also heated by radiated heat. Heating is concentrated on the food surface by means of heat convection and radiation. The inside of the food is also heated, at a slowly rate, by means of heat conduction. The heating causes the moisture on the food surface to evaporate rapidly, and later it causes browning and crisping to occur. Although the moisture inside the food tends to migrate to the surface, the rate is not sufficiently fast to prevent browning and crisping. As a result, the food surface becomes brown and crispy while its inside remains moist and soft.

In the microwave oven, there is no hot air, and heating is mostly due to the interaction between microwaves and water. Microwave heating is not concentrated on the food surface, but it is distributed within the food depending on the penetration depth. The heating on the food surface is no longer sufficiently intense to cause browning and crisping. Unless the food is microwaved for a long time to remove all or most of the water in the food (which is not desirable because the food quality may no longer be acceptable), browning and crisping either do not occur at all or are inadequate.

Browning formulations have been developed for various meat and dough products (1). Commercial steak sauces, barbecue sauces, soy sauces, and so on, are brushed on meat before microwave heating. Reusable browning dishes are also available for browning food surfaces in the microwave oven. Most of the commercial browning dishes are made of glass–ceramic substrate with tin oxide coating on the underside. The packaging industry has also developed a disposable browning and crisping material, known as susceptor, discussed later in this article.

Variation in Microwave Ovens

Yet another problem is the large variation of performance in different microwave ovens. Microwave ovens are available in different powers, oven cavity sizes, with or without a turntable, with or without a stirrer (to distribute microwaves more evenly in the oven). Consequently, different microwave ovens may produce greatly different results, even if the same cooking instructions are used. To accommodate the differences, the food manufacturer can only place vague microwave heating instructions on their packages. For example, a package may contain vague instructions such as "heat between 4 and 8 minutes, depending on the microwave oven."

Meeting the Challenges

There is no easy solution to deal with the complex process of microwave heating. In developing a microwavable food product, the scientist or technologist has to rely on the somewhat useful but incomplete scientific knowledge described in the previous sections, as well as trial-and-error or empirical methods.

From the discipline point of view, there are three approaches to deal with the challenges. The first is the food chemist's approach, in which food ingredients are modified and browning formulations are added to make the food more microwaveable. The second is the packaging engineer's approach, in which the package is modified to enhance the performance of microwave heating. The third is the microwave engineer's approach, in which new and useful features are added to the microwave oven. Ideally, these approaches should be integrated into a system to deliver the highest quality of microwaveable foods to the consumer.

Many microwaveable food products have failed in the past because of lack of performance or high cost. Good technical and marketing tools are essential for developing better-tasting microwaveable products, without increasing the cost or decreasing the effectiveness of cooking. Although the food manufacturer and the packaging supplier have been working together to develop microwaveable products, there has been relatively little collaboration between them and the oven manufacturer. There is a need to have all parties (including also the academia) work more closely together to bring about innovations that can deliver better microwaveable products to the consumer.

MICROWAVEABLE PACKAGING

The primary functions of the package are to contain, protect, and sell the product. A general discussion on the packaging of frozen foods is presented in Chapter 6. If the package is used to hold the food during microwave heating (as is the case for many microwaveable frozen meals), the interactions between microwave and the package must also be considered. Since the package can transmit, reflect, or absorb microwaves, it can also greatly influence the microwave heating behavior. The package may act "passively" by simply transmitting microwaves. The package may also act "actively" by reflecting and absorbing microwaves in a manner that the power distribution of microwaves and the surface temperature of package are modified. To optimize microwave heating, it is necessary to properly balance these three microwave/package interactions (transmission, reflection, and absorption) to optimize the heating of the food. Microwaveable packaging materials may be classified into microwave transparent materials, microwave reflective materials, and microwave absorbent materials.

Microwave Transparent Materials

A microwaveable package must be wholly or partly transparent to microwaves. The most common microwave transparent materials are paper and plastics. Although glass is also transparent to microwaves, it is seldom used to package frozen food.

Plastic-coated paperboard trays are popular for microwavable frozen meals, mainly because of their low cost. The trays combine the rigidity of the paperboard and the chemical resistance of the plastic. The inside of the trays is either extrusion-coated with a resin or adhesive-laminated with a plastic film. For microwave-only applications, plastics such as low-density polyethylene (LDPE), high-density polyethylene (HDPE), and polypropylene (PP) are used. For dual oven applications (i.e., usable in both microwave and conventional ovens), polyethylene terephthalate (PET) is used because of its high temperature stability (up to about 200 °C).

Molded pulp trays are another common paper product. The containers are dual ovenable and can be molded into several compartments. They are stronger and can carry more load than the paperboard containers.

Thermoformed plastic trays are also common heating containers for microwaveable frozen foods. LDPE trays are suitable for light microwave heating because the trays tend to distort at temperatures as low as 75 °C. PP trays have a distortion temperature of about 110 °C. Homopolymer PP trays are brittle at low temperatures and can crack during distribution and handling at freezer temperatures. Copolymer PP trays have somewhat improved low-temperature durability. Crystallized PET (CPET) trays are the most widely used plastic trays for microwaveable frozen meals. The CPET trays are functional in the temperature range from −40 to 220 °C. Thus the trays can withstand not only the low temperatures encountered in distribution and handling, but also the temperatures in conventional oven (i.e., the trays are dual ovenable).

Microwave Reflective Materials

Aluminum foil, aluminum/plastic laminate, and aluminum/plastic/paperboard laminate are the most common microwave reflective materials. Since these materials do not allow the transmission of microwave, they are also known as microwave shielding materials.

Aluminum is often used to selectively shield microwaves from certain areas of a food (Figure 3). For example, a multicomponent meal may consist of food items that heat at different rates in the microwave oven. The more microwave-sensitive food item(s) can be shielded so that the entire meal can be heated more even.

Aluminum is also used as an electromagnetic field modifier to redirect microwave energy in a manner to optimize the heating performance (10). Aluminum can intensify the microwave energy locally or redirect it to places in the package that otherwise would receive relatively little direct microwave exposure. This approach has been used to redirect microwave energy from the edges to the center for frozen food products such as lasagna.

When aluminum foils are used in the microwave oven, precautions are necessary to prevent arcing, which can occur between foil packages and the oven walls, between two packages, across tears, wrinkles, and so on. Arcing can be prevented by following several simple design rules (11). For example, any foil components should be receded from

Figure 3. Trays with selectively shielded areas. (Courtesy of Graphic Packaging Inc.)

the edge of the package to avoid arcing with the oven walls. In additional to following those rules, it is also necessary to thoroughly test the package/product to ensure that the package is safe to use.

Microwave Absorbent Materials

Microwave absorbent materials used for food packaging are commonly known as susceptors. The major purpose of susceptors is to generate surface heating to mimic the browning and crisping ability of the conventional oven. Although many types of susceptors have been invented (12), the only commercially available type is the metallized film susceptor (Figure 4). This type of susceptor consists of a metallized polyethylene terephthalate film laminated to a thin paperboard. The metal layer is a very thin (less than 100 angstroms), discontinuous layer of aluminum, which is responsible for generating localized resistance heating when exposed to microwaves. The heating can cause the susceptor to reach surface temperatures over 200 °C within seconds.

Figure 4. Metallized film susceptors. (Courtesy of Graphic Packaging Inc.)

Susceptors have been used for products such as pizza, French fries, waffles, frozen hot pies, and popcorn. Susceptors are available in the forms of flat pads, sleeves, and pouches. The flat pads are suitable for products (such as pizza) that require heating only on one surface. The sleeves and pouches are suitable for heating on multiple surfaces (9). Susceptors are also available in various patterns, in which portions of the metallized layer are deactivated (10). The patterns are designed to provide more control of heating. A company uses a printed checkerboard pattern to generate various levels of heating based on the size of the check.

There is a public concern of migration of mobile compounds from the susceptor to the food, because the susceptor can reach high temperature. The FDA has issued voluntary guidelines regarding the safe use of the susceptor for the packaging to follow.

CONCLUDING REMARKS

While microwaveable foods and meals have become an integral part of our lifestyle, improvements are still needed to continue to justify their place in the freezer case. Although microwaveable products can provide the consumer with convenience, they often fail to impress the consumer with taste and texture. There are many technical and economical challenges for developing new and improved microwaveable frozen products. To meet those challenges, the industry (food manufacturer, packaging supplier, and oven manufacturer) and the academia should work more closely together—to innovate and develop better microwaveable food products that are more tasty, healthy, and convenient to use.

MIGRATION FROM FOOD CONTACT MATERIALS

Manfred Ossberger
FABES Forschungs-GmbH

INTRODUCTION

Food and packaging are closely tied together. Food packaging material requires optimization of its properties to control physical and chemical interaction between food and packaging. In general, food consists of numerous ingredients with in many cases low chemical stability. Therefore, food has to be packed to protect it against spoilage, insects, micro-organisms, light, and other environmental impacts like humidity or oxygen, which could all lead to a decrease of the food quality. Protection against unauthorized access and information about the packaged foodstuff are some other important functions of packaging. There are a variety of plastics with different properties composed of several polymers and containing additives that are likely to migrate used to fulfill the specific packaging requirements. It is important to realize that not only the food quality is time dependent, but also the food packaging is not at "steady state." After production the packaging mass transfer processes starts immediately. Two diffusion-controlled processes have to be considered:

- Permeation (lat. *permeare*) refers to the process, where chemical substances diffuse from the environment into the food or vice versa.
- Migration (lat. *migrare*) means the diffusion of substances from the packaging into the food or from the food into the packaging.

In addition, chemical reactions in the packaging or food or between them are also possible and have to be taken into account.

PLASTIC MONOLAYER MATERIALS IN CONTACT WITH FOODSTUFF

Diffusion (kinetics) and partitioning (thermodynamics) constitute the most important interactions:

The driving force of diffusion comprises different chemical potentials between two adjacent media, which was first mentioned and investigated by Adolf Fick (1829–1901), who postulated the following laws:

$$\text{Fick's 1st law: } J = -D\frac{\partial c}{\partial x} \tag{1}$$

where J expresses the flux (or "current density" of particles), c the concentration of particles, and x the distance for particles travel. The flux J expresses the amount of matter passing through a unit area of a film in unit time. Fick's 1st law is the solution of Fick's 2nd law under steady state conditions $\partial c/\partial t = 0$ as in the case of permeation, e.g., of gases like oxygen or water vapor through packaging materials (1, 2).

$$\text{Fick's 2nd law: } \frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} \tag{2}$$

where t expresses the time and D the diffusion coefficient. Fick's 2nd law describes the diffusion of migrants, e.g., in the two-phase system of packaging and food in the direction of the concentration gradient.

Most solutions of the second diffusion equation for systems in contact with liquid are derived from analogous mathematical solutions of the heat conductance equation (standard works by Carslaw and Jaeger, Crank) (3, 4). These analytical solutions are obtained by using simplifying assumptions. For example, one get the expression

$$\frac{m_{F,t}}{A} = \frac{2}{\sqrt{\pi}} c_{P,0} \rho_P \sqrt{D_P t} \tag{3}$$

where $m_{F,t}$ is the amount of the migrated compound at time t, A the contact area, $c_{P,0}$ (wt/wt) the initial concentration of the migrant in the polymer, ρ_P the density of the polymer, D_P the diffusion coefficient of the migrant in the polymer, and t the contact time. There it is assumed that the solubility of the migrant in the liquid is very high, the thickness of the packaging infinite, and the migration far from equilibrium.

This expression overestimates migration as the system approaches equilibrium (mass transfer greater than approximately 60%). Therefore, more general solutions have to be defined to characterize the migration process (see next equation):

$$\frac{m_{F,t}}{A} = c_{P,0} \rho_P d_P \left(\frac{\alpha}{1+\alpha}\right) \times \left[1 - \sum_{n=1}^{\infty} \frac{2\alpha(1+\alpha)}{1+\alpha+\alpha^2 q_n^2} \exp\left(-D_P t \frac{q_n^2}{d_P^2}\right)\right] \tag{4}$$

$$\text{with } \alpha = \frac{V_F/V_P}{K_{P,F}}, K_{P,F} = c_{P,\infty}\rho_P / c_{F,\infty}\rho_F \text{ and } \tan q_n = -a q_n$$

where in addition to constants defined for Equation (3), ρ_F is the density of the liquid food, d_P is the thickness of the polymer, V_P and V_F the volume of the polymer and the liquid food, $K_{P,F}$ the partition coefficient, and q_n the positive roots of the trigonometric identity. $K_{P,F}$ is defined as the ratio of the migrant concentration in the polymer and the liquid food at equilibrium. Using this expression, overestimation is limited and the migration can be estimated at equilibrium; there a finite volume of the polymer is assumed.

Regarding Equation (4), the total amount of material is transported away from the contact layer into the foodstuff at the beginning of migration. Thus, the concentration in the contact layer goes to zero. Whereas the diffusion rate of the migrants in the packaging material is the rate-determining step, the partition coefficient $K_{P,F}$ (and α, respectively) plays an increasing role with longer migration times. Especially for $K_{P,F} \gg 1$ ($\alpha \ll 1$), there is only very low migration into the food.

If the foodstuff is viscous or solid, one gets a different solution of Fick's 2nd law since the diffusion coefficient of the migrant in the solid food has to be taken into account:

$$\frac{m_{F,t}}{A} = \frac{2}{\sqrt{\pi}} c_{P,0} \rho_P \frac{\beta}{1+\beta} \sqrt{D_P t} \tag{5}$$

$$\text{with } \beta = \frac{1}{K_{P,F}} \sqrt{\frac{D_F}{D_P}}$$

where D_F is the diffusion coefficient of the migrant in the food. For $D_F \gg D_P$ and $K_{P,F} \leq 1$, equation (3) results.

In order to use equation (4), the two coefficients D_P and $K_{P,F}$ are needed. As the values of both coefficients can vary over orders of magnitudes and may not be readily available, one has to assume "worst-case" scenarios like good solubility of the migrant in the liquid food or simulant (i.e., $K_{P,F} = 1$). In order to estimate upper limits of D_P, the following semi-empirical formula was developed (5–7):

$$D_P = D_0 \exp\left(A_P - 0.1351 M_r^{2/3} + 0.003 M_r - \frac{10454}{T}\right) \tag{6}$$

$$\text{with } A_P = A'_P - \frac{\tau}{T}$$

where D_0 is 10^4 cm^2/s, A_P the material specific constant, M_r the relative molar mass of the migrant (Dalton), and T the temperature (Kelvin). Values of the constant τ and A'_P for certain polymers are given in Table 1. The equation can be used for $M_r \leq 4000$ Dalton. As regulation asks for safety margins and thus "worst-case" A'_P values for modeling migration to avoid underestimation, it is possible to match the parameter A_P to yield a "worst-case" value, A'^{*}_P (see Table 1). This leads to corresponding D^{*}_P instead of the real D_P. In equation (6), $A_P \leq A^{*}_P = A'^{*}_P - \tau/T$, the parameter A^{*}_P should now be regarded as an "upper-bound" conductance of the polymer.

Table 1. Values for worst case A_P (A'^{*}_P), mean A_P ($\bar{A}'_P$) and the parameter τ for estimating diffusion coefficients D_P in polymers (eq. 6)

Polymer	A'^{*}_P	$\bar{A}'_P$	A'_P (max)	A'_P (min)	τ
LDPE	11.7	10.0	11	7.0	0
HDPE	13.2	10.0	12.6	5.0	1577
PP	12.4	9.4	12.9	6.2	1577
PET	6.35	2.2	7.2	−4.3	1577
PEN	3.7	−0.34	3.8	−5.5	1577
PS	−0.7	−2.8	0	−6.5	0
HIPS	0.1	−2.7	0	−6.2	0
PA(6,6)	1.9	−1.54	2.3	−7.7	0

Values for A_P are obtained by performing kinetic studies, measuring migration after, e.g., 1, 2, 4, 8, and 10 days (see example; Figure 1). By comparison of the experimental data with calculated data (software programes, please see last section), one can calculate D_P and $K_{P,F}$.

For the polyolefines, another semi-empirical diffusion model has been developed by Limm and Hollifield (8):

$$D_P = D_0 \exp\left(\alpha M_r^{1/2} - K M_r^{1/3}/T\right) \tag{7}$$

with values for D_0, α, and K given in Table 2.

A basic conclusion of both Fick's laws is that if a concentration gradient is present, diffusion takes place immediately. The velocity of mass transport is subject to the diffusion coefficient D, the kinetic dimension of the diffusion process, which is a function of temperature. D for a migrant with medium molecular weight varies from ca.

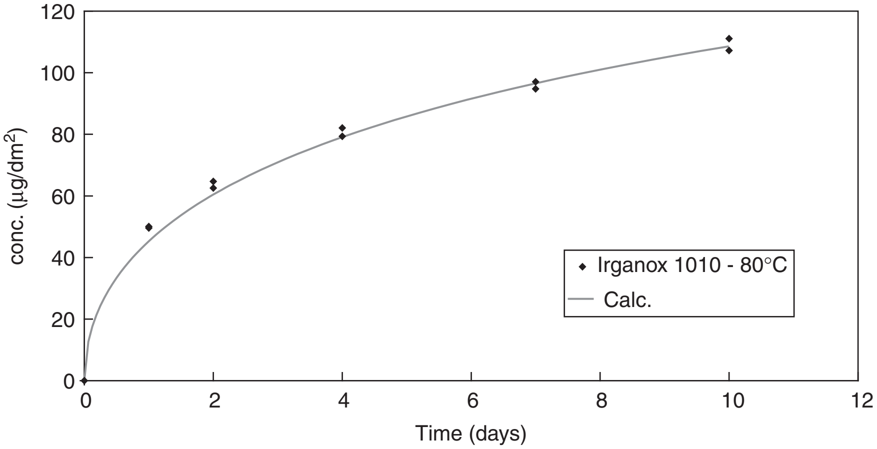

Figure 1.

Table 2. Values for D_0, α and K in eq. (7).

Polymer	$\ln(D_0)$	α	K
LDPE	−4.16	0.555	1140.5
HDPE	0.90	0.819	1760.7
PP	−2.10	0.597	1335.7

$10^{-5}\,\mathrm{cm}^2/\mathrm{s}$ in solutions to $10^{-18}\,\mathrm{cm}^2/\mathrm{s}$ in PET-materials. The quantity of migrants in the other layer(s) can be further dictated by thermodynamics, which is expressed by the partition coefficient K. Consequently, if the diffusion rate is high, but the migrant is not soluble in the other media, there will be only low mass transport from the origin to the adjacent layer(s). This coefficient is strongly influenced by the solubility of the migrant in the contacting media and varies roughly from $K_{P,F} = 1$ for well solubility to $K_{P,F} = 1000$ for bad solubility. In addition to estimations for diffusion coefficients, procedures exist to estimate the partition coefficients (9).

In summary, the quantity of migration is strongly controlled by the diffusion coefficient (D) and partition coefficient K, which are affected by the *identity* of the packaging material and its chemical structure (→ D, K), *chemical structure* and *polarity* of the migrant (→ K), *molecular weight* of the migrant (→ D), *concentration* of the migrant in the packaging (→ D), *kind of packed food* (water, acid, alcoholic, fatty, dry) (→ D, K) and if there is an *interaction* between food and packaging (→ D), *volume* of the packed food (→ K), and *time and temperature conditions* (→ D, K) at which the packed food is stored.

The preceding discussion holds true only if the diffusion and partition coefficients are constant while diffusion takes place and if the packaging is inert against the packed foodstuff. Otherwise if D and K vary with time or swelling is observed, diffusion can no longer be described by Fick's 2nd law ("non-Fickian processes"). In addition, at very low migrant concentrations, the migration rate may no longer be proportional to its concentration in the polymer. Considering paper and board, physical interactions and mass transportation are controlled by sorption processes, what makes estimation more intricate.

MULTILAYER PLASTIC MATERIALS IN CONTACT WITH FOODSTUFF

In the past, packaging was generally made of monolayer materials like polyethylenes (PE), polypropylenes (PP), polyamides (PA), polystyrenes (PS), polyethylene terephthalates (PET), paper and board, aluminium, ceramics, and glass. As each material has unique useful properties, several materials are now combined into multilayer materials. In addition, such multilayer systems consist of lacquers, coatings, printing, and/or adhesive layers. Migration processes may originate from all different layers, each with different physical properties (like D and K, vapor impermeability). As a consequence, migration processes are more complicated and the use of numerical models and algorithms is sometimes necessary (see the section "Measurement Procedures for Quantification of Migrants"), especially if there are analytical problems.

MIGRANTS

The use of glass as a food contact material is advantageous as there is no migration possible. In contrast, as mentioned, migration in plastics has to be considered. A common feature of all polymer materials is their backbone of natural or synthetic macromolecules composed of hundreds of repetitions of small chemical units (monomers) that are connected via covalent bonds. Compared with pure natural polymers, e.g., proteins, synthetic polymers are polydisperse; i.e., the polymer is a mixture of molecules with various chain lengths and molar masses. Up to ca. 2% of low-molecular-weight molecules with $M_W < 10^3\,\mathrm{g/mol}$ account for the polymer, which are of possible toxicological interest. All other polymer compounds are immobile due to their high molecular weight.

Hence, there is a trend to switch from monomeric additives to polymeric additives. The disadvantage of this is the lower reactivity, and thus, higher concentrations of polymeric additives are needed.

Actually many more substances are incorporated into plastics that the producer and end user has to pay attention to. In addition to the residual amounts of initiators (e.g., peroxide compounds) and metal oxide catalysts, there are a huge amount of additives, such as antioxidants, plasticisers, antistatics, lubricants, and pigments, added to the polymer for better processing, protection, or appearance of the polymer, which are all possible migrants. Some common examples for each additive group are given in Table 3.

Beside that *not-intended-additives* (NIAS) such as transformation products and contamination from plastic and additive production are additional sources of migrants.

As stated in the Introduction, migration is possible in two directions, from the packaging into the food and from the food into the packaging. Therefore, many substances (and flavors) in food are also likely to migrate (e.g., Limonene, which is contained in soft drinks, migrates into plastic packaging). This is also true considering permeation. "Flavors" or gases can permeate from the environment into the food and thus have to be taken into account. It should also be stressed that sometimes migration of, e.g., antistatics and lubricants is intended and crucial for certain applications.

MEASUREMENT PROCEDURES FOR QUANTIFICATION OF MIGRANTS

The purpose of migration testing is to ensure the compliance of food packaging by detection and quantification of migrants. Since migration and not extraction is to be measured, interactions changing the mechanical and diffusion properties of the package should be minimized between food contact material and foodstuff.

Table 3. List of several common plastic additives

Antioxidants	Octaethyl-3-(3,5-di-tert-butyl-4-hydroxyphenyl)propionate		Phosphorous acid, tris(2,4-di-tert-butylphenyl)ester	Plasticiser	Di-n-octylphthalate	UV absorbers	2-(2′-Hydroxy-5′-methylphenyl)benzotriazole		2-Hydroxy-4-n-octyloxybenzophenone	Acidity regulator	Stearoyl-2-lactylic acid, calcium salt	Lubricants/ Antistatics	Glycerol 1-monostearate		N,N-Bis(2-hydroxyethyl)lauramide		Behenamide	Antifogging agent	Sorbitan, esters with acids, aliph., monocarbonic acids (more than C5) (R)	Slip agent	(Z)-13-Docosenamide (Erucamide)	
Usually the following procedures are used for detection and quantification of migrants: Foils and boards are fixed into a migration cell (see Figure 2(a)), covered with the food or adequate food simulant and stored at specific time and temperature conditions, which are laid down in specific directives (see the section on "Regulation"). As food itself is too intricate to analyze, certain food simulants are allowed to be used instead: simulant A (distilled water) for aqueous foods, simulant B (acetic acid 3%) for acidic foods (pH$\leq$4.5), simulant C (ethanol 10%) for alcoholic foods, 50% ethanol for milky products, simulant D (olive oil) for fatty foods, and the synthetic polymer Tenax for dry foods. As olive oil presents analytical problems, there are two alternative food simulants for fatty foodstuffs, ethanol 95% and isooctane.

The migration solution is analyzed by means of gas or liquid chromatograph coupled with certain spectrometers and/or detectors. Another option is the complete immersion of the package into the liquid (see Figure 2(b)). Quantification is derived from using internal standards (semiquantitative procedure) or by using calibration solutions (quantitative procedure), and evaluation is done depending on existing legislation requirements.

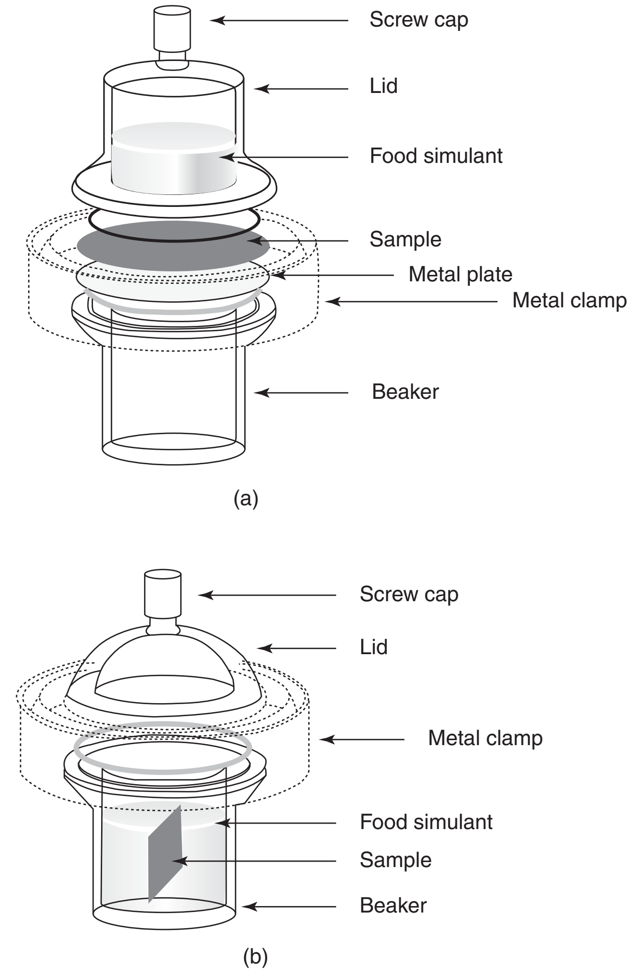

Figure 2.

Sometimes it is more convenient to start not with analytical determination of migration but with calculation. When the initial concentration of the migrant in the polymer ($c_{P,0}$) is known, it is common and legal practice in verification of compliance with migration limits to assume complete mass transfer of the migrant from the packaging material into the food or food simulant. If the result is below the specific migration limit, no more analytical measurements are necessary regarding this specific migrant.

As shown in the second section, mass transfer from *monolayer* materials into food is a predictable physical process, which can be quantified with appropriate mathematical algorithms. After European authorities completed the project "Evaluation of Migration Models to be used under Directive 90/128/EEC" (10) in 2002, migration modeling could now be used as an alternative method for evaluation purposes and the use of migration modeling was legalized in the "plastic directive" 2002/72/EC (Article 8, Section 4) (11). Details on which types of plastic materials and foods are covered by this paragraph as well as the basic mathematical algorithms that can be used for the migration estimation are summarized in the "Practical Guide" and "Note for Guidance" (12, 13) for "Estimation of migration by generally recognized diffusion models." This document states a series of conditions that should be considered when someone intends to use modeling to determine compliance of a certain packaging material. Several software programmes have been developed (e.g., (14) to aid in migration estimations.

It is stated above that many different types of materials are used in multilayer packages and it is assumed that there is no interaction between packaging and food simulants.

However, migration processes are more complicated and sometimes it is difficult to choose the correct simulant that does not swell the material. For this reason, the use of *numerical* models and algorithms are necessary to get reliable migration results and/or a consistent interpretation of experimental data, and to get a deeper insight and understanding on migration processes. Software programes like MIGRATEST©EXP (15–17) have been developed and adapted to deal with the increasing complexity of multilayer food contact materials. Because of the huge amount of different (food) contact materials and because multilayer systems pose analytical problems, the use of existing sophisticated migration modeling software programs and their continued development will be indispensable.

REGULATION IN THE EU AND USA

Conservation of the high quality of foodstuff is the most important function of food packaging materials. As outlined in the previous sections, potentially harmful migrants may diffuse out of the packaging into the foodstuff and be consumed. Therefore, diffusion processes out of packaging materials and the total amounts of migrants in the food should be minimized and are regulated by national and international authorities.

In the European Union, the European Food Safety Authority (EFSA) is the keystone of EU risk assessment regarding food and feed safety. EFSA produces scientific opinions and advice providing basic information to the European Commission, European Parliament, and EU Member States as well as allowing them to make (legislative) decisions. Due to the lack of regulations in the food packaging sector and as not all packaging materials are yet covered by European legislation, national legislation (and national recommendations, e.g., recommendations of the German Bundesinstitut für Risikobewertung (BfR)) have to be taken into account.

In the framework regulation 1935/2004/EC of the European Parliament and of the council (18) on materials and articles intended to come into contact with food, common and superior guidelines regarding demands on food packaging are laid down. Also a list of groups of materials and articles (e.g., adhesives, ceramics, rubbers, plastics, paper and board, inks, cellulose, etc.) is stipulated, which may be covered by specific measures. Until now only specific regulations exist for plastics (directive 2002/72/EC and its five amendments) (11), ceramics (84/500/EEC and its amendment) (19), and regenerated cellulose (2007/42/EC) (20). Most important is the "plastic directive" where several alternatives for verification of compliance of the food packaging materials are given. Therein measuring of the migration is possible by an adequate experimentation (see directives 82/711/EEC, 85/572/EEC, 93/8/EEC, and 97/48/EEC) (21–24) and by application of generally recognized mathematical diffusion models based on scientific evidence. Furthermore, a positive list of authorized monomers and additives with restrictions for certain substances (e.g., "specific migration limits" SMLs) was built up at the community level. The SML values are generally calculated based on ADI (acceptable daily intake) and TDI (tolerable daily intake) values, laid down by the Scientific Committee for Food (SCF). ADI and TDI values are derived from toxicological studies.

Hence, for a positive evaluation of a certain packaging, the migration results should meet the following limits:

- Global migration is less than 10-mg/dm^2 and 60-mg/kg food, respectively.
- The amount of each detected additive (listed in the positive list) is under its SML or the global migration limit.
- The amount of each detected additive, which is *not* listed in the positive list, is under 10 μg/kg food) (2007/19/EC) (25) when no toxicological data exist.

In addition, the packaging shall be manufactured in compliance with good manufacturing practice (GMP) and the additional general requirements laid down under article 3 of the directive 1935/2004/EC.

For evaluation and addition of a new substance to national or European positive lists, a petition has to be transmitted to the adequate authority, including identity and proposed use of the new substance, migration, and toxicological documents. As a general principle, the higher the exposure through migration, the more toxicological information is required (see Table 4).

Whereas EU authorities look at the identity and quantity of chemical substances detected in the food or food simulants, and list all substances, which are toxicologically evaluated and allowed to be used in all kinds of packaging material, the U.S. Food and Drug Administration (FDA) established a food contact notification process, whereby food additives are deemed to be safe for their *intended use*. That means that in comparison with the EU, substances evaluated by the FDA are only allowed to be used in special applications and concentrations, which are mentioned in their authorization processes (food contact notification, FCN). For using these substances in other applications, a new FCN has to be submitted to the FDA. The law governing food packaging in the United States is the Federal Food, Drug and Cosmetic Act of 1958 as amended and the Fair Packaging and Labeling Act. Regulated food contact substances can be found in title 21 of the Code of Federal Regulations (CFR) (26). This title is subdivided into parts covering specific regulatory areas (e.g., indirect food additives: polymers; indirect food additives: adjuvants, production aids and sanitizers, etc.). Sometimes there are substances "generally recognized as safe" (GRAS; e.g., ascorbic acid). Such substances are allowed to be used in packaging materials, if a consensus is reached by scientists that the substance is GRAS, and if

Table 4. Required toxicological information for evaluation by EFSA

Migration of substance	Tests	
<0.05 mg/kg food	3 mutagenicity tests	• induction of gene mutations in bacteria • induction of gene mutation in mammalian cells *in vitro* • induction of chromosomal aberrations in mammalian cells *in vitro*
0.05–5 mg/kg food	• 3 mutagenicity tests • 90-day oral toxicity study • data to demonstrate the absence of potential for accumulation in human being	
>5 mg/kg food	• above mentioned tests • further studies (e.g. on reproduction, absorption, distribution)	

there are experimental data and published studies that support this opinion.

In addition, if the estimated daily intake (EDI) from the proposed use of the substance is less than or equal to 0.5 μg per kg food and 1.5 μg per person and day, respectively ("threshold of regulation" TOR), and if the substance has not been shown to be a carcinogen in humans or animals and presents no other health or safety concerns, an exemption from the notification process can be granted by the FDA. If not, the petitioner has to send roughly the same toxicological and migration data to the FDA as to the EFSA. Whereas the European SMLs are calculated from toxicological values that are compared with migration data, the FDA calculates from migration data the EDI, which is compared with the corresponding ADI and TDI values. The EDI is calculated as the product of the migrant concentration $<M>$ in the total daily diet, based on consumption factors (CF) and food type distribution factors (f_T), and the factor 3, assuming that one person consumes 3 kg of food (liquid and solid) per day:

$$\mathrm{EDI} = 3\,\mathrm{kg\ food/person/day} \cdot \langle M \rangle \cdot \mathrm{CF} \tag{8}$$

$$\langle M \rangle = f_{aqueous\ and\ acidic}\ (M_{10\%\ Ethanol}) + f_{alcohol}\ (M_{50\%\ Ethanol}) + f_{fatty}(M_{fatty})$$

CF describes the fraction of the daily diet expected to contact specific packaging materials. It represents the ratio of the weight of all food contacting a specific packaging material to the weight of all food packed. These values were derived using information on the types of food consumed or the types of food contacting each packaging surface. The factor f_T considers the nature of food that will likely contact the food contact material containing the migrant. Both factors, CF and f_T, are published in certain guidances (e.g., (27)).

FUTURE TRENDS IN PACKAGING AND EVALUATION

The majority of the just off-the-shelf produced materials and articles intended to come into contact with foodstuff are passive materials mainly made out of plastics, (recycled) paper, and metal. In the future there will be a shift to the development and increased usage of active and intelligent packaging materials. These active and intelligent materials can, for example, indicate the edibility of the food and prolong the freshness and the shelf life of food. Also nanotechnology will be used in the food packaging sector to increase the functionality of materials (e.g., protection and indication of freshness). The development of more sustainable and environmentally friendly packaging is an ongoing trend, and new sustainable and biodegradable packaging materials will be developed and used.

However, legislative authorities will still have to evaluate the impact of food safety of these new materials on the health of the consumer. Authorities also still have to evaluate the safety of "nonplastic"-layers (e.g., coatings, adhesives, etc.) in multilayer materials that have not been taken into account yet.

As mentioned, the experimental measurement of migration is closely linked to certain directives, e.g., 85/572/EEC (22). But some problems arose in this system as implemented with the use of food simulants and not foodstuffs to measure migration in a simple and reproducible way. Therefore, the European Union and (industry) partners have launched the project "Food Migrosure" to overcome these weaknesses. The EU foresees that in order to show compliance, the migration into foodstuffs and not into food simulants is crucial and the exposure evaluation has to be based on migration values in food. Migration values are obtained by experiments and by modeling. In addition, other (proposed) projects like FACET ("flavours, additives and food contact material exposure task") are aimed at collecting deeper knowledge about both consumer exposure by packaging components and the physical properties of each layer of the multilayer packaging materials.

MILITARY FOOD PACKAGING

RAUNO LAMPI
Consultant,
Food Science, Engineering,
Food Service Systems,
Westborough,
Massachusetts

INTRODUCTION

The packaging requirements for military food service range from: prevailing commercial practice for food prepared and consumed on permanent state-wide stations, stabilized foreign theater sites, and shipboard; to highly durable concepts for mobile combat troop usage for both groups and individuals. This review will emphasize those packaging practices required for the initiation and conduct of a significant combat campaign. For the United States, historically and currently, these have been overseas and have represented a wide range of package challenging environments and food usage conditions.

Since hostilities may occur anywhere in the world and it is impractical to design specific packaging for large volume use for any defined geographic and/or climatic region and it is propitious to pre-position selected rations around the world for immediate local availability, military food packaging must be basically selected and designed for any and all climates or geographic regions. The packaging must also provide long-term protection to make prepositioned war reserves feasible. Further general requirements include compatibility with the mode of use: feeding in groups, singly, or during patrols. Specialized packets or supplements are needed for emergency use or unusually extreme climates. Organoleptic acceptability is essential, and packaging plays the key role in assuring that this desirable characteristic exists at time of food consumption.

Doctrinally, the practice is to use combat rations (as individually packaged meals or packets) for an initial period, say three weeks, followed by the introduction of bulk shelf-stable foods (currently termed B rations) to be prepared in company-sized mobile or temporary field kitchens. As utilities become available and as operations in the theater become stabilized, the master menu for group feeding will include perishables—vegetables, frozen meats, eggs, and so on (the A-ration). Of course, this means that climate controlled storage and freezer storage have become available. The type of packaging is partially changed to be less protective. For example, solid fiberboard becomes replaced with weather-resistant corrugated fiberboard and, for some items, standard commercial packing. The rigors of transportation and handling have, accordingly, become less strenuous. Combat rations for patrols and similar combat excursions and for remote outposts remain an essential part of the subsistence mix.

In actuality, based on informal yet direct feedback, the doctrine is rarely followed. Combat rations are used beyond the Surgeon General's recommended time limit. Standard mobile kitchens are underutilized. Much recent operational theater food service has been contracted to civilian concerns. So the packaging level, that is, the level of protection prevalent, with the exception of combat rations, varies.

THE REVOLUTIONARY WAR TO WORLD WAR II

Koehler (1) and Conference and Notes on Rations, QMS, January 1949 (2) have presented comprehensive reviews of military rations from the Revolutionary War era (1776) to the World War II era (1945). Moody (3), also starting with the Revolutionary War, has extended the review, excellently, to status and development effort to the year 2000. Military packaging, up to 1936, was primarily limited to common practices that defined commercial quantities and some protection from weather elements and dirt. Food preservation, with the exception of some canned items, was the result of curing, salting, and/or dehydration. There was minimal reliance on packaging to preserve edibility. The military diet was supplemented by live animal slaughter and foraging where possible.

In the early 1800s, Nicholas Appert established that heating food in a hermetic container preserved the container's contents, an initial event where the package was vital for high moisture food's safe storage and retained edibility. Canning was born; however, it was not evident in military rations until the Civil War era (1860s on) when some canned items were introduced, but with many defects and complaints. The high level of spoilage of both fresh and canned foods continued into the 1890s, according to reports from the Spanish-American War.

Again following Koehler's treatise, canned items finally became standard ration components in World War I. At this time, it was also recognized that rations needed to be categorized according to their intended field usage. This resulted in design of a menu for group feeding and an organization of components for individual's to carry and consume in the field. These were (1):

1. Reserve ration: food allowance for one man for one day consisting of
   a. One 1-lb (usually cylindrical) can of meat
   b. Two 8-oz cans of hard bread
   c. 2.4 oz of sugar
   d. 1.12 oz of ground coffee
   e. 0.16 oz of salt
2. Trench ration: food for 25 men in the field for one day consisting of
   a. Sufficient canned meats (roast beef, corned beef, salmon, and sardines) to feed, heated or cold, 25 men
   b. Supplemental items that included salt, sugar, soluble coffee, solidified alcohol, and cigarettes

All components were packed in large galvanized containers that protected the contents from poison gas.

3. Emergency ration: food to sustain a soldier when no other sustenance was available consisting of
   a. Three 3-oz cakes of a mixture of beef powder and cooked wheat
   b. Three 1-oz chocolate bars
4. Packaging consisted of an oval lacquered can to fit into a soldier's pocket. Ration categorization evolved so that in the late 1920s, the American Army listed four types of rations:
   a. Garrison
   b. Travel
   c. Reserve (replacing the emergency ration)
   d. Field (in essence, the first true emergency ration)

This categorization exercise surfaced the need and efficacy of designing rations to fit the major modes of theater of operations activities—personnel on attack, in garrison, on patrols, and in unanticipated situations. These basic definitions were the foundation of military food service until the current categories of A, B, and combat rations came into official use. Ensuing developments within the categorization have been impacted by packaging improvements integrated with innovative processes, reliable refrigeration, freeze-drying, irradiation, high-barrier packaging materials, container ship and aircraft delivery, an acceptance of flexible packaging in lieu of rigid cans for shelf stable foods.

WORLD WAR II AND KOREAN CONFLICT

Although the need for organized ration development, including significant packaging, packing, and unitization improvements, was surfaced in World War I, no meaningful action was taken until the advent of World War II became obvious in the late 1930s. This peacetime lack of urgency and support for military readiness is typical and recurring. At this time, among the first steps forward were the establishment of the Quartermaster Subsistence Research and Development Laboratory and, later, to facilitate technical assistance from the commercial food sector (then centered in the mid-west) and to accommodate the needs of all service elements, the establishment of the Food and Container Institute for the Armed Forces on Pershing Avenue in Chicago, IL. Moody (3) covers the evolution of the integration of commercially available technology and food industry support as mutual benefits surfaced. Frequently the military's research and development efforts provided industry with commercially viable products.

As subsistence research and development intensified, the Research and Development Associates (a technical organization of industry and government technologists) and various Technical Committees of the National Research Council were used to recommend, to contribute, and to analyze the military's needs and technical performance. Packaging and Packing interests were active participants and contributors.

An initial output from this concerted ration development was the D ration: three 4-ounce bars of chocolate, sugar, dry milk, cacao fat, oat flour, and flavoring meant to support a person for one day. Packaging, since there is no specific discussion, was probably aluminum foil for individual bars packed in Kraft board cartons for shipment and handling. The D ration was convenient and termed tenuously the first modern emergency ration.

The D ration had a short yet voluminous procurement span, 600,000 rations in 1941 and 170 million through its final procurement in 1944. Misuse as a combat food and its non-provision of three full, familiar nutritionally balanced meals per day found it being relegated to being a supplement and an emergency ration.

The experience with the D ration, reinforced by the evolving recognition of adequate nutrition and menu variety in assuring ration acceptance and combatant performance, resulted in the development and fielding, predominantly for World War II, of the K and C rations. Both were used throughout World War II.

There is some disparity as to when the C ration assumed an identity. Basically, the components of the C ration, in 12-oz, three-piece heavily tinned metal cans, evolved from World War I individual items. In 1939, the Adjutant General of the Army announced adoption of field ration C to consist of three cans containing meat and vegetable components and three cans, termed B units, containing crackers, sugar, and soluble coffee. In early 1944, separate component specifications were consolidated into a single document, "Ration, Type C, Assembly, Packaging, and Packing" where three canned meat entrees and three B unit cans were supplemented with a flexibly packaged accessory packet of sundries that included a small folding can opener, essential to open the durable, thick-tinned, three-piece double-seamed cans. Ration components were packed in Kraft board cartons, which in turn were packed six to a solid fiberboard shipping case.

The C ration easily met the shelf-life requirement of three years at 80°F, as evidenced by reports of rations issued far beyond their procurement dates. Organoleptic acceptability and variety were lacking.

The K ration was developed to provide an individual, easy-to-carry ration, initially requested by the U.S. Air Force, and as its acceptance grew, it was, in 1942, adopted for all service use, termed Field Ration, Type K. Per Moody (3) it became the ration of choice in World War II and for a while was quite popular. However, as noted by Koehler (1), an improved C ration diminished the K's usefulness and popularity; it was declared obsolete in 1948.

The K ration went through seven revisions/improvements, including packaging, before the final specifications were published. Menus were divided into breakfast, dinner, and supper units. Aside from minor variations, each meal menu consisted of a can of meat or cheese, two biscuits, and what would best be called an accessory bag (fruit or chocolate bar, beverage powder, confections, chewing gum, spoon, and key can opener). For each meal assembly, cans were held in a chipboard sleeve-type box; the remaining cans were held in a laminated cellophane bag. These two units were assembled and sealed in a waxed carton that was, in turn, enclosed in a non-waxed outer carton suitably labeled with the K-ration design and color. Twelve complete rations were packed in a fiberboard box that was overpacked in a nailed wood box (1).

DEVELOPMENTS LEADING TO CURRENT RATIONS

Because of (a) both actual and perceived deficiencies with the C ration and its clone-like successor, the Meal, Combat, Individual (weight, variable acceptability), (b) issue of many of these rations to troops after the ration's intended shelf life had expired, (c) need to explore the applicability of newer technologies in both food processing and in packaging materials and designs, and (d) accommodation to the military's highly mobile combat tactics, in the late 1950s the Army issued a request (Qualitative Materiel Development Objective) to improve combat rations. The Army's needs were supported by the U.S. Marine Corps and acceded to by all DOD elements under the jurisdiction of the Joint Formulation Board of the DOD Food Research, Development, and Engineering Program.

The significance of a DOD-level program and funding bears mention. It provides greater assurance that funding support will not be siphoned off prior to its reaching the working level and acknowledgment that all service personnel basically eat the same food. The implementation of the program was assigned to the then-titled U.S. Army Natick Research, Development, and Engineering Center, Natick, Massachusetts (commonly referred to as Nlabs). This progressive doctrinal and regulatory support was steady and consistent as needed for aggressive, thorough, and inevitably long-term (10–15 years) developments and their implementation.

Among the desired improvements for combat rations established under the aegis of the DOD Food Program and further detailed in an Army Combat Development Objective Guide (CDOG) in 1956 were lighter weight, ease of use and carrying by the individual, long shelf life, universal organoleptic acceptability, durability during transport and use in any geographic area or climatic condition, and adequate survivability on free-fall air drop.

During this time frame, mid-1950s to the late 1960s, three food technological areas were identified that could possibly be responsive to the military's combat ration needs. These were: freeze-dehydration, irradiation sterilization, and substitution of flexible packaging for rigid containers for both the preceding preservation techniques and its application to thermoprocessed foods. All three areas were amenable to the consideration of flexible packaging in lieu of traditional rigid metal cans.

FREEZE-DRIED RATIONS

For the military, freeze-dried (lyophilized) foods had obvious advantages: extremely light weight, excellent retention of organoleptic characteristics, long shelf life (if properly packaged to exclude oxygen), rapid rehydration, and suitability for flexible packaging in configurations that could be carried in the combatant's gear or clothing.

During the Vietnam conflict (1960s and early 1970s), a Packet, Long-Range Patrol (aka LRP) was fielded and highly accepted by personnel, primarily during reconnaissance missions and combat excursions. Entrees were "ready-meals"—a high-protein component, meat mostly, combined integrally with starch and/or vegetables and a sauce. Beef stew would represent such an item. Initially, and for most of the Vietnam campaign, components were individually freeze-dried and combined just prior to packaging. It was established that pre-packaging combination and cooking into partitionable servings improved acceptability, and later packets were so prepared and packaged.

During the active years of the Vietnam conflict, LRPs remained popular and elicited much positive feedback on quality and usage. Anecdotal comments, however, did include (a) reluctance by combatants to use water that they had to carry (canteen-full) in any way other than direct consumption and (2) some reports that when, for convenience, water was added to the packet at the start of a patrol; that is, several hours before consumption, microbial growth occurred and caused problems after entree consumption.

As the Vietnam conflict neared its end, the use and popularity of the LRP declined. High-quality entree components became more difficult to procure and costs rose. The LRP remained in the system at a low interest level. Then, in the 1990s, improvements were re-energized by the U.S. Marine Corps' need for a ration for extreme cold environments, and the U.S. Army Special Operational Forces' need for a long shelf life restricted calorie ration (back to the original LRP concept) for initial assault, special operations, and long-range reconnaissance missions. This reborn ration is now termed the Meal, Cold Weather/Food Packet, Long-Range Patrol (MCW/LRP), expanded as a meal to include crackers, spreads, cookies, sports bars, nuts, candy, and powdered beverages, and packed in a white (MCW) or a beige (LRP) outer polyethylene meal bag. There are 12 meal menus. Sixteen ounces of water (preferably heated) is required for all meals except those with eggs, which require 8 ounces. Another 12–24 oz of water are required for beverages.

The package for the entree is brick-shaped (Figure 1) when full and is designed for in-package rehydration and food consumption. Beverages can be prepared in the canteen cup; heat tablets are furnished.

Freeze-dried products require protection from water vapor (products are strongly hygroscopic) and air (oxygen) because of extensive exposed surface areas, and they also require some protection of structural integrity (to some degree, provided by immobilization in flexible, vacuumized packages). From the user's aspect, the ration package must provide a shelf life of a minimum of three years at 80°F and 6 months at 100°F. It must retain its form to serve as an easily opened rehydration and consumption container.

Two film structures are specified in Table 1.

Bonding of the sealant layer to the aluminum barrier layer (film 1) is to be by lamination or by extrusion coating. The barrier is in turn bonded to an outer layer of biaxially oriented nylon layer with 10 pound per ream low-density polyethylene. For film 2, the sealant ply is laminated or extrusion-coated to a nylon ply, followed by lamination to the foil that is bonded to an external polyester (usually polyethylene terephthlate) ply. The requirement for heat seals mentioned that the low-density heat sealant layer shall be capable of forming a fusion seal or shall be heat sealable and peelable. A peelable seal would suffice for the outer polyethylene meal bag, but the seals of the component brick-shaped pouch are more critical and should be fusion seals. As summarized by Lampi et al. (4), nonfusion seals can meet tensile and

	Film 1	Film 2
Inner scalant layer	0.0035-in. linear low-density polyethylene	0.0035-in. linear low-density polyethylene 0.0006-in. biaxially oriented nylon
Barrier	0.00035-in. aluminum foil	0.00035-in. aluminum foil
Outer abrasion protection	0.006-in. biaxially oriented nylon	0.0005-in. polyester

burst test criteria at time of creation yet fail with time and exposure to rough handling.

Pouch construction, filling, and final sealing follow standard practice. Some major requirements are:

1. Minimum heat seal width: 0.25 in.
2. Fusion seal tensile strength: 7 lb per linear inch
3. Vacuum level, at which filled pouches are sealed: 23 in. of mercury

Defects and acceptance standards and criteria are given in detail in the “Packaging Requirements and Quality Assurance Provisions for Dehydrated Product in a Brickpack Pouch.”

IRRADIATED FOODS

During the gestation period of freeze-dried food development and early feasibility probes into flexible packaging for thermoprocessed foods, the preservation (i.e., to commercial sterilization standards) of foods, including combat ration entrees, by ionized radiation warranted exploration. The anticipated advantages included very high quality shelf-stable entrees with minimum destruction of nutritive value, compatibility with a range of packaging options from flexible pouches to rigid metal containers (in other words, from combat rations to B, and possibly A ration usage), and commercial viability to provide a basis for reasonable costs during procurements.

For military rations, irradiation treatments (X ray, gamma, and electron beam) were applied at high enough levels to provide commercial sterility—that is, doses up to 60 kGy, the universal criterion for long shelf-life storage. To assure achieving this long-term stability, multiple-ply foil containing materials were used—not radically different in composition and structure from those for freeze-dried or thermoprocessed foods. Irradiation was performed with packaged items.

Packaging materials for irradiation have some singular requirements, namely:

1. In final filled package configuration, retention of integrity when frozen to temperatures as low as −50°F and held at those temperatures during the irradiation step.
2. Minimal chemical changes and/or creation of undesirable extractives in the packaging materials as the result of irradiation. These changes might be cross-linking, which could beneficially reduce migration; or, inversely, they might be degradation to lower-molecular-weight elements (radiolysis products) with increased migration into the food.
3. Retention of package performance criteria—heat seal integrity, absence of delamination, survivability through the transportation and field-handling trail, and retention of these properties over the desired shelf-life time span.

The effect of high-dose irradiation on food, candidate packaging films, and packaged irradiated foods (i.e., the final product) has been extensively investigated and the findings periodically scientifically and conscientiously reviewed. The first materials (5) approved for high-dose (up to 60 kGy) packaging of irradiated foods in 1965 and 1967 were:

1. Vegetable parchments
2. Polyethylene film
3. Polyethylene terephthlate (PET) film
4. Nylon 6 film
5. Vinyl acetate–vinyl acetate copolymer film

Radiation-preserved packaged food items were technically established as totally safe and nutritionally adequate, and consumer-oriented taste testers found items acceptable.

However, the progression of high-dose irradiated foods to either full-scale military or commercial usage is yet to occur. Reasons implicated are: the existence (at least in the United States) of an extensive established refrigerated and frozen-food chain; the reluctance of investors to establish costly manufacturing facilities without assurance of a desirable, potentially flourishing market (the old paradoxical question, What comes first, the chicken or the egg?); significant consumer reluctance to believe that the process is safe, in spite of the massive data proving it safe; and limitation of the process to meat items.

Although irradiated foods are suitable for inclusion in military rations, none, with the exception of South Africa, are currently included. No adequately sized production capability for the volumes that would be required exists.

However, the U.S. Army Soldier Systems Command (Natick, Massachusetts) has been furnishing (in lots of 200 or so) irradiated meat entrees (beef, poultry, pork, and lamb) to NASA for space applications. Earlier regulatory agency approvals listed above, because of the development of newer materials and material analysis techniques, are no longer valid. Loveridge and Milch (6) reflect the current status of packaging for NASA programs. They evaluated five commercially available film structures, all without current formal FDA approval for irradiated food entrees, but exempt for sole NASA usage and suitable for similar food process applications. Of the five materials, the two most readily commercially available were:

1. A new MRE pouch material (termed Quad since it now had four plys) – fabricated from outer to inner ply of polyester/nylon/aluminum foil/polypropylene.
2. The material used by South Africa – outer to inner ply: nylon/aluminum foil/polyester/linear low density polyethylene.

Three other multi-ply film constructions were also evaluated; these had some potential for use with irradiation – sterilized foods.

NASA-specific entrees were put through the entire process: filling, vacuum evacuation, sealing, cartoning, dry ice freezing and shipping, irradiation at 44 kGy, thawing, and return shipment.

Testing included seal strength, leak tests, drop and vibration tests, frozen pouch abuse, and internal pressure resistance. Criteria were those of the now massively produced Meal, Ready-to-Eat, combat ration. If high-dose irradiation of foods, already proven safe, becomes prevalent and costs are reasonable, packaging materials for military entrees would require re-approval and would likely be constructed with aluminum foil and the polymers or their successors listed above. Bonding of plies would be by coextrusion. A possible variant would be the inclusion of sealable polyethylene terephthlate (PET) as the inner layer. In short, flexible packaging for irradiated entrees to enter the Meal, Ready-to-Eat matrix would in all likelihood be readily approved and available.

THERMOPROCESSED FOODS IN FLEXIBLE PACKAGES

While packaging (predominantly the use of multi-ply flexible films) was being defined for freeze-dried and irradiated foods that were intended for combat use, studies were initiated with the aim of replacing the traditional cylindrical metal cans for standard thermoprocessed combat ration entrees with high barrier flexible polymeric films. The first probings to do this were probably in the late 1940s; however, the first formal publication of experiments with thermoprocessing common foods in flexible films was by Hu in 1953. The military, noting potential functional advantages (per their CDOG) for combat rations furthered these studies, initially reported by Keller in 1959 (cited in reference 3). After initial positive indications, these studies grew into a major development project culminating in the procurement of a new combat ration, the Meal, Ready-to-Eat, Individual (MRE) initially procured in 1979 (3). It is now the basic U.S. combat ration.

Some initial decisions and considerations that drove the direction that the development effort would take were as follows:

1. An aseptic processing and packaging approach would have alleviated the burden of performance on the film and its formed package (specifically resistance to process temperature as high as 265°F), but aseptic systems had no industry acceptance; and to undertake its technical development (to include solids) and gain processor, regulator, and consumer trust was felt to be prohibitive at that time. The decision was to proceed with the traditional post-fill-and-seal thermoprocessing.
2. Although conceivably prematurely at that stage of the state of the art, the manufacturing system was visualized as a blend plus modification of equipment already in use for forming, filling, and sealing for the frozen food industry and thermoprocessing principles and equipment for "canned" foods; that is, the need for radically new equipment was not anticipated. A need to tighten performance was accepted. As a result, a new technology evolved.
3. The military could not replicate the technology existing in the flexible film formulating and converting industries and would have to entice those industries' support by cooperatively revealing commercial opportunities and/or providing monetary support.
4. The package design would be a flat four-seal pouch—no gusset or vertical center seam (pillow pack) design—that is, avoidance of unnecessary loci for leakage. If a horizontally drawn form–fill–seal package concept were to evolve, it would be considered. It was assumed that on-line pouch forming or the use of preformed pouches would be suitable.
5. If successful, the replacement of the can with a pouch (retort pouch) would offer significant advantages; this provided a strong mission-oriented incentive to proceed. Briefly, these included:
   a. lighter weight: 1.5 pounds per meal in the shipping case
   b. easy to open: side seam tear notch or two
   c. improved palatability: flat thin shape precludes overcooking the periphery to assure sterility of the geometric cold spot
   d. easy to carry: fits field clothing pockets; flat in the rucksack
   e. durable:
      - during combat field movement
      - for air drop
      - all forms of transport
      - all climates
   f. storable: shelf life suitable for war reserve materiel usage
   g. producible:
      - materials
      - form, fill, seal process
   h. heatability: in water in canteen cup (*Note*: A flameless ration heater was later developed and incorporated into each meal.)

From the earliest feasibility and field performance tests, the packaging film producing and converting industries responded with proprietary film developments and participative support effort with the military researchers. Among these firms were: Reynolds Metals, Flexible Packaging Division of the Continental Can Company, Dow Chemical, American Can Company, and Morton Chemical Company. Reynolds Metals went so far as to establish a pilot production line for vegetables. A tangible recognition of this military–industry cooperation was the receipt of the Institute of Food Technologists' Industrial Achievement Award in 1978 jointly by Reynolds Metals, Continental Can Company, and the U.S. Army Natick Research, Development, and Engineering Center.

There were foreign developments, more or less paralleling those by the U.S. military. Although some of the developments were proprietary, there was considerable interchange of experiences through visits and joint technical sessions. Among those nations known to be probing flexible packaging for thermoprocessed foods were Japan, United Kingdom, Italy, Sweden, Germany and Canada. These foreign developments were oriented more toward commercial markets than toward military. Japanese and Italian representatives cited commercial successes.

The U.S. military's program can be visualized in four general development phases. During all phases the program was supported by laboratory activities to develop quality assurance tests and performance criteria. Overall, as previously stated, from concept acceptance to ration fielding (i.e., the four phases) took 20 years. Early in the program, field tests revealed that if made properly, the retort pouch performed well, but the tests also revealed that the form–fill–seal–process system and product formulation required technical and engineering modifications and improvements. This was to be truly an integrated product-package development. This took time. The development phases were as follows.

Feasibility Testing

This phase included selection of candidate films; laboratory and small pilot plant size preparation of entrees (Figure 2); informal field evaluation via such activities as carrying carton-enclosed pouched items in combat clothing pockets over a clothing-wear obstacle course (including prone position crawling over obstacles); initiation of storage tests; vibration and drop test cycles simulating transport abuse; and initial organoleptic acceptability evaluations. Extractives studies to meet Food and Drug Administration regulatory standards were performed, submitted, and accepted. The basic structural requirements of the film were established: a 0.004-in. sealant and basic strength layer, a 0.0005-in. aluminum foil oxygen/water vapor barrier, and an outer 0.0005-in. protective layer. The pouch at this initial stage of development enclosed and adhered to a kraft board envelope-folder.

The initial sealant layers were polyvinyl chloride (PVC) or a medium- to high-density polyethylene (HDPE) modified with polyisobutylene, each film bonded to the foil ply by an isocyanate adhesive system. As the result of occasional off-flavor transfer and delamination, the PVC material was replaced by the proprietary HDPE blend.

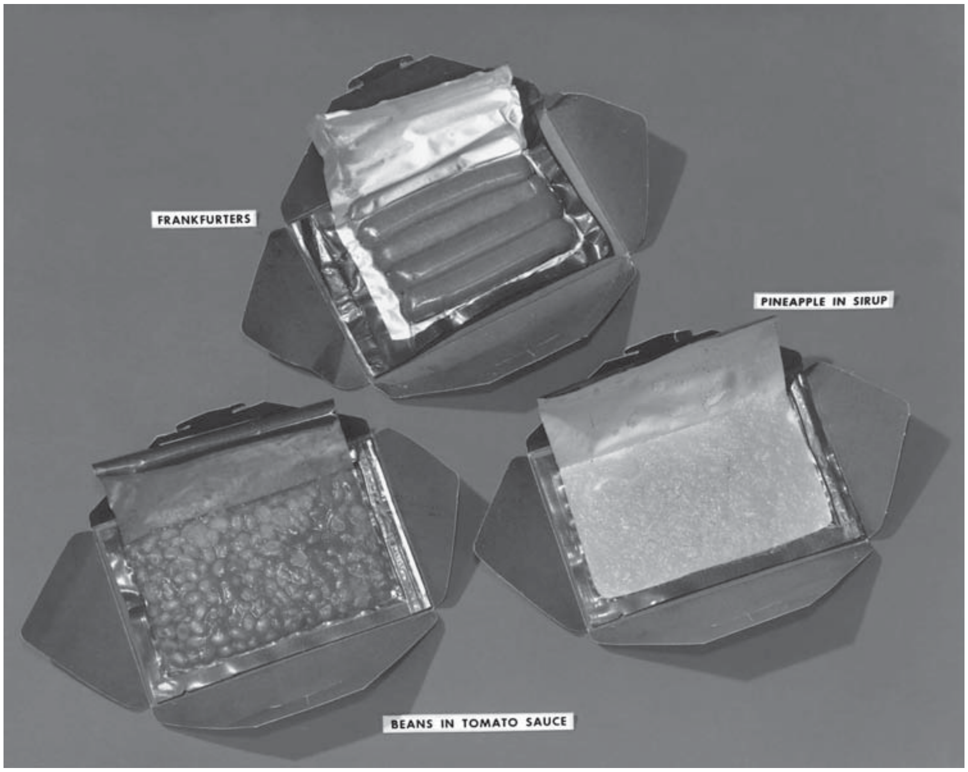

Figure 2. Thermally processed items. Early retort pouch items (for the MRE), opened to display typical items. Current ration of 24 menus contains 40–42 thermoprocessed entrée items in flexible pouches.

Where feasible and comparatively valid, pouch performance was compared to MCI canned entrees. The pouch performed well.

Initial Field Tests

The limited feasibility tests were promising enough that more extensive troop usage field tests were carried out—in Louisiana, Georgia, Arizona, and Alaska. These tests were more formal; that is, they were carried out independently by the Test and Evaluation Command (TECOM). The Nlabs, the developer, could only act as observers. Based on TECOM test personnel and user-documented assessments, the retort pouch performed satisfactorily. The material used featured the HDPE blend as the sealant ply. Failures were few and mostly related to closure seal defects; that is, irregularities and leaks caused by product caught in the seal area.

Palatability was assessed by ratings on a 1–10 (inedible to highly liked) hedonic scale by the users. The control for all aspects of these tests was the can in the Meal, Combat, Individual (MCI). Perhaps the most valid indication of acceptability was the free choice of the pouch over the can following tests in Alaska—that is, a choice with no hint of a Hawthorne effect.

The overall conclusion was that the retort pouch was acceptable for combat rations, but the failure rate (primarily defects in the closure seal area) was too high for a thermoprocessed food package.

Production Capability

Based on the field test revelation that filling and sealing flexible pouches with original high water content fluid, semisolid, and one-piece solid foods remained a significant performance and reliability problem, a decision was made to establish a pilot line of full-sized equipment, alter and/or add functions to improve performance, and run diverse representative food items in adequate amounts to provide valid reliability data (in terms of low percent failures). This approach would also provide future production monitors an experience base for assisting contractors in start-ups and in correcting production deficiencies. It would also test quality assurance sampling and test protocols. Under contract, a so-called Natick–Swift production Reliability Program was established. This program was carried out by a consortium headed by Swift and Company, with membership by Continental Can Company, Pillsbury Company, FMC Corporation, and Bartelt packaging machinery company. The package design was the four-side seal and was formed online from a roll stock of 75-μm-modified polyolefin (blend of polyisobutylene with medium- to high-density polyethylene) as the sealant ply, a 9-μm aluminum foil barrier, and 12-μm polyethylene terephthlate (Mylar) as the outer layer. Six diverse products were run: covering those considered pumpable into formed pouches (beef stew, pineapple); solids termed placeable (beefsteak, four frankfurters in one pouch); and viscous items termed extrudable (fruitcake, combination ham and chicken loaf). Overall results were a 0.002% seal-failure rate and a 0.016% closure-seal-contamination failure rate for 298,971 packages.

As reported by Lampi et al. (4), the Natick–Swift Reliability program revealed an overall outgoing seal defect rate of 0.017%. Tsutsumi (7) reported a final pouch defect rate of 0.02% in Japan. Nughes (8) reported similar rates in Italy. If one accepts a failure rate of 0.1% as published for the ordinary can, the pouch appeared to meet commonly accepted reliability standards.

The description of the line and results of its usage to pack six diverse products are described in the Proceedings, Symposium on Flexible Packaging for Heat Processed Foods (1973) sponsored by the National Academy of Science, National Research Council. Each participant detailed their task and its results. Overviews of results are included.

As briefly stated earlier, other pilot and manufacturing lines had been established. Systems, circa 1977, are summarily described by Lampi (9). Tsutsumi (10, 11) covers a Japanese approach. Goldfarb (12, 13) describes the Reynolds Metals system, the use of which is covered by Mermelstein (14). Although these production systems were not directly oriented to military use, their successful functioning reinforced confidence in the feasibility of the pouch for U.S. military rations.

As mentioned previously, laboratory tests and other supporting activities were ongoing during the general development phases. These were conducted with two films: One of them was used in the comprehensive Reliability Program; which was modified high-density polyethylene (HDPE), the other had polypropylene (PP) as the sealant layer. The latter had surfaced as an applicable film in usage paralleling the use of HDPE in separate but similar activities. Details of the many tests and developments are covered by Lampi (9), and those associated with seal performance are discussed by Lampi et al. (4). Among the activities and findings are

Extractives Studies. Extractives studies were carried out to establish that no meaningful contaminants were migrating from the packaging materials into package contents. Initial approvals were obtained; and in a later general review (15) of the status of the program submitted to regulatory agencies before fielding, no extractives problems were identified. However, just before the military was to start procurement, the FDA reported the presence of 0.3 to 3.0 ppb of toluene diisocyanate migrating into products. This caused a roughly five-year delay (1975–1980) while coextrusion as a bonding technique was finalized, assessed for migratory safety, and put into use. Then, procurement of the MRE began.

Storage Stability. Storage studies were carried out on representative products, such as ground beef in barbeque sauce, pork sausage, and ham and chicken loaf (containing ingredients apt to penetrate polymeric films), and with two films (HDPE and PP) to assess product organoleptic stability and to measure the effects of time and temperature on package seal tensile strengths and seal and body area bonding. Storage temperatures were 71.6°F and 100.4°F. Criteria at that time (1969–1973) were four years at 71.6°F and six months at 100.4°F (currently three years at 80.6°F).

The foods passed storage organoleptic stability criteria on the basis of periodic hedonic ratings and in some comparisons with like products in traditional cans. Seal area tensile strengths and laminate bondings held up very well over 27-month-long storage at 71.6°F and 100.4°F (16).

Resistance to Rough Handling. Retort pouches with HDPE and PP sealant layers and containing fluid and semifluid products were compared to like products in cans when exposed to a rough handling cycle. The cycle was vibration in case lots at 1 G for one hour followed by a series of 10 drops from a height of 46 cm (18 in.) (ASTM D-775-68, Objective B). The treatments were followed by visual examination and microbiological testing via a bio-tester (17). Neither film nor type of product had failures exceeding the can—a tentative performance standard for this type of testing could be 2% or fewer leakers as detected by microbiological testing.

In addition, free-fall airdrop of cases of rations in a field test demonstrated that the pouch met the recovery criterion of 75% useable items.

Indication of Spoilage (Leaking or, More Likely, Underprocessing). With metal cans, swelling (i.e., a convex lid shape) has been traditionally used as a proven indication of microbiological spoilage. Cans and pouches were equally inoculated with gas-producing bacteria through silicone sealant septa and monitored visually for swelling. Obvious swelling of the pouch was doubling of its thickness, easily judged by any user. The pouch showed gaseous swelling in 48 h, while it took the can 72–120 h.

Definition of a "Good" Seal. Based on production experience, early field tests, storage tests, and controlled laboratory tests, the criteria for defining a high-performance seal for retort pouches was established as follows:

1. Fusion must exist.
2. Internal pressure level
    - 20 psig
    - Hold time: 30 s
    - Maximum seal yield: 1/16 in.
    - Restrained pouch thickness: 1/2 in.
3. Tensile strength level
    - 12 lb/in.
    - Crosshead speed: 10 in./min
    - Sample width: 1/2 in.
4. Visual—No visible aberrations.

Fusion exists when the opposing seal surfaces form a weld where neither surface is visually distinguishable when seal area is tensioned beyond the point of failure. The presence of fusion cannot be understated. A polymeric film heat seal can pass all requirements, including tensile and burst tests and general appearance, at the time of formation but based on experience that was not good, such a nonfusion seal will fail on storage. To assist visual judgment of seals, a table of photographs has been assembled showing acceptable and nonacceptable seal surfaces and characteristics (4, 16).

Seal Defect Scanner. In cognizance of the vagaries of human leak defect assessment, an automatic seal defect detection apparatus was devised, built, and tested. The procedure used infrared radiometric scanning of heated seal surfaces. One surface of a seal was heated, and any heat impeded by defects in the seal area was detected on the opposite side by the infrared scanner. Both the heat source and scanner were stationary; the package seal was aligned and passed between these two elements, and packages with defective seals were diverted. Scanning speed was 6 in./s. The apparatus cost was considered high. Another deterrent to its use in the mid-1970s, ironically, was that a criterion for acceptance/rejection was a problem. It was too sensitive, rejecting pouches with very minor seal deformations that did not negatively affect seal integrity.

Leakers. The pouches are currently scanned by humans visually for defects including leaks during and immediately following production. Subsequent leakers are detected by transportation handlers and users visually and discarded. Swollen pouches including those possibly caused by product caking and plugging leak sites are discarded. This procedure fortunately works as evidenced by the 22 years of successful reasonably cost-effective production and use of the MRE at the current rate of 46 million meals per year.

Since the initial consideration of using flexible packaging for thermoprocessed foods, there has been concern over the presence, significance, and reliable detection of leaks. The deficiency of visual inspection (even multiple ones, loss of acuity with time-related fatigue) has been cited as justification to develop online detection devices. A prerequisite to exploring objective leak detection concepts is establishment of criterion (i.e., the smallest leak that needs to be detected).

Finding leaks, on the pouch body or through seals, is governed by two specific characteristics. First, whereas a rigid can exhibits a pressure difference between the outside atmosphere and its contents that could suck contamination through any void into the can, a pouch, on the removal of headspace air, collapses around the contents to a point where no external to contents pressure drop exists. A bio-tester (18) was constructed to create a momentary pressure difference and has been used as the primary bacteria penetration detection apparatus.

Secondly, fluid contents can plug defects and greatly reduce the sensitivity of such detection devices as the Mead Test (pulling a vacuum on a container submerged in water). With dry products, a 5-μm-diameter defect could be detected, while with a pouch filled with distilled water, even a 68-μm hole was not detected. The accumulated knowledge on pouch leaks starting with tests on films per se and ending with production, handling, and field experience through 1979 (the active development period) included:

1. Single plies of polymeric materials contain pinholes that could permit passage of bacteria. A three-ply

construction does not; the statistical chances of three holes coinciding to allow bacterial passage are extremely rare. Candidate polymeric films are not degraded by direct exposure to bacterial concentrations.

2. Manipulation of foil containing laminates results in minute breaks in the thin foil; these breaks do not result in film failure or microbial hazards. The total area exposed by such foil breaks is insignificant in that their effect on water vapor and oxygen transmission is nil.
3. Using a laser (crudely because of their technical infancy) to "drill" minute holes in a three-ply retortable laminate and exposing filled pouches made with this material, each having a "laser hole" to a bacterial "soup" in a tester, a tentative minimum, laboratory-created defect was listed as a 11-μm diameter hole. In perspective, such a hole/defect size is roughly 1/10th the thickness of the packaging material. Because of the small number of samples, no statistically valid conclusion was possible.
4. In one series of tests, retortable materials were subjected to multiple flexing, punctured by a fine sharp needle, and abrasion on a raised peak. Flexing resulted in a porous area that permitted gas flow but could not be defined even microscopically. Puncture by a fire-hardened fine-tip needle resulted in relatively large defects (greater than 100-μm size) that were visually detectable. Abrasion caused a variety of hole sizes, the smallest of which was equal to a 24.4-μm diameter round hole.
5. Pouches that failed during a rough handling cycle, as established by biotesting, were examined microscopically to try to define the size of leak sites. The smallest was $20 \times 15\,\mu m$, the next largest was $20 \times 40\,\mu m$, six were in the 100- to 999-μm range, and 24 were 1000 μm or larger.

Nine defects were undefined or destroyed during pouch opening.

At the time the MRE was accepted as the standard combat ration, the best estimate on leak occurrence was that one package in 100,000 could have a leak smaller than 100 μm.

Leak Detection Methodology. In this Production Capability development time frame, a concerted effort was made to determine if any nondestructive online- or line-associated leak test method could be made to apply to the retort pouch. Spencer and Bodman (19) surveyed 24 conceivably applicable concepts. Criteria were a 30-μm channel through the seal area and a 10-μm defect on the pouch body. For fluid foods, the best candidate was a change in the conductivity of deionized water by product forced out of the package by compression. For solid foods (i.e., beefsteak), a helium tracer gas procedure detected holes as small as 30 μm.

In each case, however, the design of an apparatus to cover handling, preparation for analysis, performing the analysis, and recharging or resetting for the next pouch would have approached the size and complexity of the basic production line.

Implementation and Field Improvements

The Meal, Ready-to-Eat, Individual (MRE) replaced the Meal, Combat, Individual (MCI, commonly and belatedly still referred to as the C ration) in 1975 with the caveat that testing be continued with the U.S. department of Agriculture to confirm that insect penetration would not become a problem. Reportedly, after further exposure to gnawing and chewing insects, there is no problem. Also, at roughly this same time, as cited previously, notice was received from the Food and Drug Administration that 0.3 to 3.0 ppb of toluene di-isocyanate was determined to be extracted by products from adhesives systems used in the lamination of the desire films. Rather than try to cope with adhesives, film suppliers developed coextrusion techniques with approved polymers, and current films are so currently formed.

The MRE, as it is currently configured (Figure 3), consists of entree/starch, crackers, spread (cheese, peanut butter, jam, or jelly), desert/snack, accessory packet (beverages, condiments, matches, gum, toiletries), and flameless ration heater (FRH).

There are 24 menus/12 meals to a case. Each meal provides 1300 kcal. Water requirement is approximately 23 oz to rehydrate beverages. The FRH has been in each meal bag since 1993. Each meal weighs 1.5 lb and takes up 1/12th of a cubic foot in volume.

The first four or five procurements surfaced the need for technical assistance to suppliers, a need for coordinated support by the procurement agency, and the engineering support function of the developer. The production of retort pouched items, although based on a blend of frozen and canned food capabilities, required a higher level of flexible package performance, and new inspection standards, and it was viewed by its proponents as essentially a new technology.

From this rather tenuous start, with strong institutional review, assessment, and support, the MRE has been improved in both individual item quality and menu configuration. Through the year 2004 procurement, MRE XXVI, the ration has been expanded to 24 menus including four vegetarian meals. Since 1993, 150 new items have been approved; 35 least acceptable items have been eliminated. Over 75% of ration components are now non-developmental items—that is, adapted directly from commercially prevalent items. At this time, the ration usage rate is such that storage stability is not a factor of concern. Providing combatants that represent a country-wide demography is paramount. Currently, the MRE usage rate is 46 million meals per year.

Nutritional adequacy, related directly to combatant performance, has been periodically measured. For example, Lichton et al. (20) evaluated the nutritional value of the MRE during a 34-day field exercise (at an elevation of 1800 m). Compared with a control group, those fed only MREs lost weight. Neither group appeared to be dehydrated. Both groups displayed normal values of serum

Figure 3. Meal, Ready-to-Eat, Individual. The large bag, labeled "Meal," contains the rest of the items shown. The light-colored bag is the flameless ration heater.

proteins, vitamins, and zinc, denoting acceptable nutritional status.

The old C-ration cans were heated in water, in an inverted combat helmet, in a canteen cup using heat tablets, or in bulk in water in any large barrel or tank. The advent of the Kevlar helmet removed one common field heating method. Subsequently, after some user skepticism, an effective flameless ration heater was developed and has been in each MRE meal bag since 1993. This 22-g flat card-like heater can heat 200 g of retort-pouched food in roughly 10 min. Any water can be used to activate the heating action. An initial version discharged a small amount of hydrogen, innocuous during use, but considered a possible hazard when multiple cases were transported in a closed container. A new hydrogen-free ration heater has been developed.

After all the technical effort and testing, the MRE, plus the engineering support it requires, has now supported the military person for over 20 years (Figure 4). The current packaging materials and the ensuing pouch used to prepare thermoprocessed ration items are given in Performance Specification MIL-PRF-44073F (Figure 5), Change 3, November 2006.

The skeleton requirements as abstracted from the specification are:

1. Pouch material (from the inside to the outside)
   a. Preformed pouches: 0.003- to 0.004-in.-thick polyolefin, 0.00035- to 0.0007-in.-thick aluminum foil, 0.0006-in.-thick biaxially oriented polyamide-type 6, 0.0005-in.-thick polyester.
   b. Drawn pouch; tray-shaped body of a horizontal form-fill-seal system, tray-shaped body: 0.003- to 0.004-in.-thick polyolefin, 0.0006 inch thick biaxially oriented type-6 polyamide, 0.0015- to 0.00175-in.-thick aluminum foil, 0.0010- to 0.0014-in.-thick oriented polypropylene Lid, 0.003- to 0.004-in.-thick polyolefin, 0.00035 to 0.0007 inch thick aluminum foil, 0.0005- to 0.00075-in.-thick polyester.
2. Pouch configurations are shown in Figure 5, and dimensions are shown in Table 2.
3. Performance requirements are:
   a. Material must be capable of being formed into pouches.
   b. Oxygen transmission rate must not exceed 0.06 cc/m^2/24 h/atm; Water vapor transmission rate must not exceed 0.01 g/m^2/24 h.
   c. Residual gas volume shall not exceed 10 cc for fruit or 20 cc for non-fruit items.
   d. Filled pouches shall withstand a pressure of 20 psig for 30 s.
   e. Postprocessed pouches must withstand abuse at 28°F with a survival rate of 75% and a survival rate of 100% at 160°F.
   f. Pouches including seals must be free of visual defects.
   g. The carton enclosing each pouch needs to conform to Specification PPP-B-566, Boxes, Folding, and Paperboard.

The MRE is constantly being improved and updated—menus and materials. As of 2006, the MRE is destined to continue to be the combat ration for the foreseeable future.

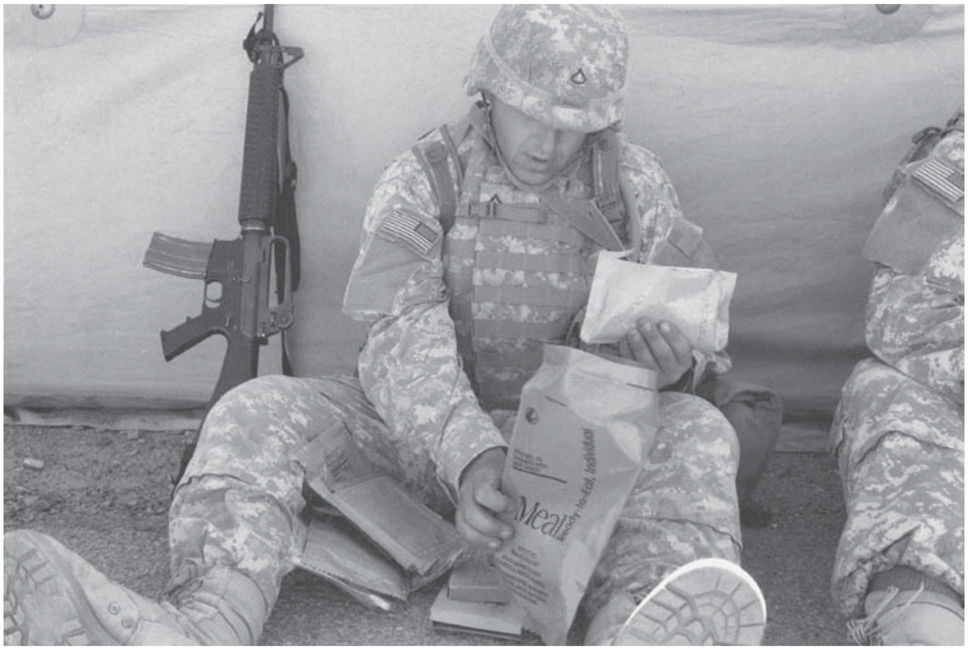

Figure 4. Combatant in the field preparing to eat the MRE.

UNITIZED GROUP RATION (UGR)

When field conditions permit group feeding in small units or even larger congregations, the unitized group ration (UGR) has been designed, tested, and fielded for such situations. The basic objective was to simplify the logistics for supporting small group feeding. The traditional procedure had been to order a slew of food items via individual requests and, similarly, to assemble preparation, serving, and dining ware. That is, for each field operation, a multitude of individual issue requests were submitted and, on receipt of items, rather haphazardly assembled. The UGR is a pre-assembly of all the preparation, dining, and consumable items into a single unit to support a designated number of personnel.

The unitized group ration (UGR) is a program designed to provide the highest-quality group meals to troops in the field by increasing variety, consumption, acceptability, and nutritional intake. It is an efficient method to provide breakfast, lunch, and dinner by packing 50 meals together. There are about 7 breakfast menus and 14 lunch and dinner menus, depending on options, for selection. The pre-mixed selection of menus ensures variety and maximizes consumption by avoiding repetition and ennui. The unitized ration also includes disposable trays, cups, flatware, and trash bags. There are four different group ration options, namely, unitized Group Ration Heat and Serve (UGR-H&S), unitized group ration A (UGR-A), unitized group ration B (UGR-B), and the recently fielded addition to the UGR concept, the UGR-E ("E" for express) featuring self-heating.

UGR-H&S. This option is available for military personnel who are in the worldwide operations and

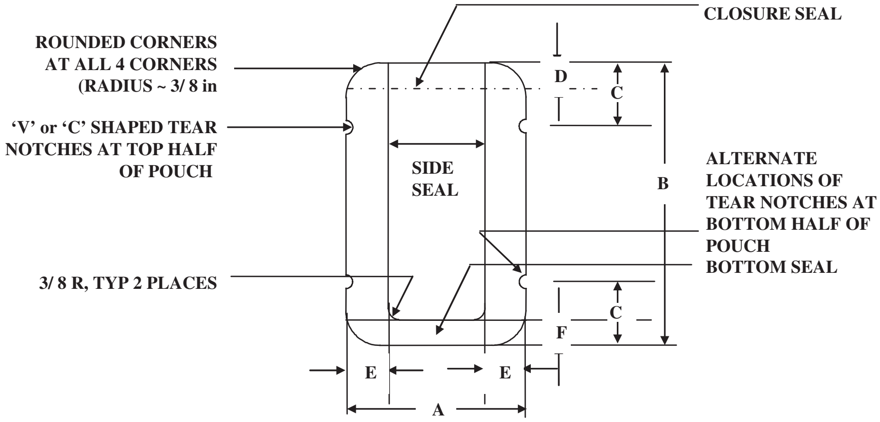

Figure 5. Pouch configuration.

Table 2. Pouch Dimensions

Pouch Sizes	Dimensions (inches)					
	A	B	C	D	E	F
5-oz size	$4\frac{3}{4}$ ($\pm\frac{1}{16}$)	$6\frac{1}{6}$ to $6\frac{1}{4}$	1($\pm$ $\frac{1}{16}$)	$\frac{3}{4}$ max.	$\frac{7}{32}$ min.	$\frac{1}{8}$ min.
		$6\frac{1}{6}$ to $7\frac{3}{8}$	$1\frac{1}{2}$ ($\pm$ $\frac{1}{16}$)	1 max		
Primary 8-oz size	$4\frac{3}{4}$ ($\pm$ $\frac{1}{16}$)	$8\frac{1}{8}$ (+ $\frac{1}{8}$, $-\frac{1}{16}$)	$1\frac{1}{2}$ ($\pm$ $\frac{1}{16}$)	1 max	$\frac{7}{32}$ min.	$\frac{1}{8}$ min.
Alternate 8-oz size	$5\frac{1}{4}$ ($\pm$ $\frac{1}{16}$)	$7\frac{1}{4}$ (+ $\frac{1}{8}$, $-\frac{1}{16}$)	$1\frac{1}{2}$ ($\pm$ $\frac{1}{16}$)	1 max	$\frac{7}{32}$ min.	$\frac{1}{8}$ min.

have organized food service facility. It includes a complete 50-person meal except for milk, cereal, bread, fruits, and vegetables. The breakfast includes a combination of egg, pork, beef, juice, dessert, and others. The lunch and dinner includes a combination of vegetable, meat, rice, pasta, juice, dessert, and fruits. Each menu, including other enhancements, provides about 1450 kcal per serving. The UGR-H&S Option has a pallet containing 4 tiers, and each tier provides about 100 meals assembled at government depots. They have a shelf life of 18 months at 80°F.

UGR-A. The UGR-A is similar to UGR-H&S except that this includes perishable/frozen type entrees (A-Rations) along with commercial-type components. Currently, there are 7 breakfast and 14 lunch/dinner menus available, and they provide around 1450 kcal of energy per serving. Each pallet contains about 12 modules or 600 meals built-to-order with direct vendor delivery. The average shelf life is around 3–6 months for frozen entrees.

UGR-B. The UGR-B ration includes dehydrated food and also commercial type items. Currently, it offers 7 breakfast and 14 lunch/dinner menus, with each meal providing an average of 1300 kcal of energy per serving. Each pallet contains around 8 modules or 400 meals assembled at government depots. They have a shelf life of 18 months at 80°F.

UGR-E. As cited in Natick PAM 30–25, 7th edition, November 2006, “The UGR-E includes separate group-serving polymeric trays and/or institutional-sized pouches that contain a shelf stable entrée,

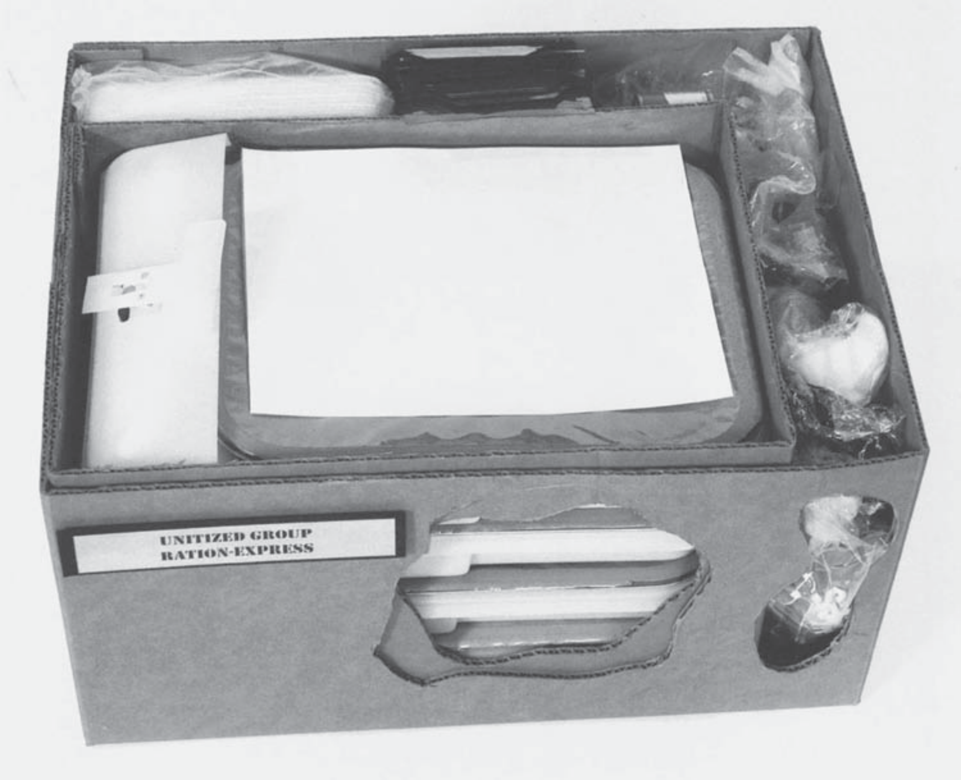

Figure 6. Case containing components of the Unitized Group Ration—Express (UGR-E) ; section cut open to display arrangement of contents.

Figure 7. Components of the UGR-E; food and utensils to prepare and feed 18 combatants.

vegetable, starch, and dessert (Figure 6). Additional items include drink pouches, snacks/candies, compartmented dining trays, disposable eating and serving utensils, condiments, beverage bases, napkins, wet-naps, and a trash bag (Figure 7). The UGR-E will be available in up to three breakfast and six lunch/dinner menus. Each UGR-E will provide 18 complete meals. The self-heated meal modules may be pre-positioned or carried by operational units. The UGR-E has a minimum 18-month shelf life at 80°F. Each pallet contains 18 UGR-Es or 324 meals. When a remote unit requires hot food, a tab is pulled to activate the heaters. In 30 to 45 minutes the module is opened and hot food is ready to be served in trays/pouches to Warfighters, like a cook prepared meal. After opening, the heaters continue to provide heat, keeping the foods hotter longer."

SUMMATION

Current developments and support to combat feeding emphasize improvements in quality, responsiveness to menu likes and dislikes, ration designs compatible with high mobility field tactics, and minimizing the time and complexity of individual and small group food preparation. In many instances, as opposed to activities prior to World War II, the military is pioneering food product and packaging development. At the same time, they utilize applicable commercial items when advantageous. The criticality of adequate nutrition to combatant performance seems to be finally recongnized and institutionalized.

Acknowledgments: The administrative and technical contributions of all who delved into the myriad of concepts and requirements to support the satisfactory feeding of combat troops merit special acknowledgment. The historical reviews by F. A. Koehler and S. M. Moody were keys to coverage to World War II. I also wish to acknowledge the encouragement plus the editing and organizational support of Professor Kit L. Yam of Rutgers, the State University of New Jersey, without which this contribution would not have been completed.

MILITARY PACKAGING

BACKGROUND

Developing food packaging to withstand the military logistics system poses both unique and difficult challenges. There are unusual supply constraints caused by the worldwide presence and the complex requirements of the Military Services. Current and future logistical complexities resulting from widely dispersed joint service operations, multinational deployments, and humanitarian missions have significantly changed the operational and organizational strategies in recent years. Even during peacetime—such as for humanitarian relief or disaster assistance—the military must satisfy its essential supply needs, anywhere in the world, at any point in time, and in the face of potentially severe and extreme environmental conditions. Moreover, the products inside must arrive in a usable condition, with very low levels of damage. Unless the rations retain the properties that make them suitable and desirable for consumption, they will be ineffective—or worse, they could pose a health hazard. Consequently, packaging technologists and engineers must design packaging systems in anticipation of worst-case supply situations.

The current military policy necessitates readiness to counter aggression or to provide disaster assistance wherever it occurs, thus requiring the prepositioning of rations for subsequent mobilization anywhere in the world. Consequently, military rations must be shelf-stable across a wide temperature and humidity range over prolonged periods of time. The current shelf-life requirement of many fielded rations is a minimum of 3 years at 80°F and 6 months at 100°F. In addition, air drop delivery of some rations is to be expected. During development of the military's primary individual combat ration—the Meal, Ready-to-Eat (MRE)—cases of meals were dropped free-fall from an aircraft flying at 110 knots indicated air speed and at an absolute altitude of 150 feet. Based on those tests, the required recovery rate of the MRE components was set at a minimum of 75% and remains the requirement even today.

CURRENT PACKAGING SYSTEMS

As in the commercial market, plastic materials are ideally suited for military food packaging. Plastic materials offer advantages such as material strength, light weight, corrosion resistance, and versatility. Through lamination technology and the use of plastic materials, the military has significantly improved the quality of operational rations.

These improvements have resulted from decreased thermal process times, decreased overall weight, and reduced volume. The development of multilayer structures allows one to tailor a packaging structure for a specific product, thus relying on the synergism of the various materials. Such materials are currently being used to package the MRE, which is used to sustain individuals during operations that preclude organized food service facilities, but where resupply is established or planned. Each meal contains an entrée/starch, crackers or snack bread, a spread (cheese, peanut butter, or jelly), a dessert/snack, beverage powders, an accessory packet, a plastic spoon, and a flameless ration heater (FRH). The flexibly packaged entrées are thermally sterilized, or retorted, at temperatures up to 250°F to ensure shelf stability. The entrées are packaged in a retortable pouch, which is a quad-laminate material constructed, from the inside out, of 0.003- to 0.004-in.-thick polyolefin, 0.0035- to 0.0007-in.-thick aluminum foil, 0.0006 inch thick biaxially oriented polyamide-type 6, and 0.0005-in.-thick pigmented polyester. The polyolefin used for the sealant layer is typically cast polypropylene (cPP) because it provides good heat sealability, flexibility, and low taste and odor transfer properties. The aluminum foil provides sufficient barrier to moisture and oxygen to meet the shelf-life requirements. The polyamide layer was incorporated into the structure in order to address handling and cold weather issues. The outside layer is typically biaxially oriented polyethylene terephthalate (BOPET) because it provides good strength and toughness. It also has excellent dimensional stability and heat resistance, which is ideal for the elevated sealing temperatures that it encounters.

Tri-laminate, high-barrier structures are also used to package various components in the MRE that are not retorted. For example, for the crackers and snack bread, the packaging materials may be constructed, from the inside out, of 0.003-in.-thick ionomer, 0.00035-in.-thick aluminum foil, and 0.0005-in.-thick oriented PP. These items are typically vacuum-packaged to prolong shelf life and to facilitate the use of horizontal form/fill/seal (FFS) equipment. However, this type of vacuum-packing often introduces problems with pinholes and flex cracks in the aluminum foil. The ionomer resin is used to alleviate this problem due to its outstanding puncture and impact resistance. Ionomers have ionic interchain forces that stiffen the polymer chain without hurting the melt processability, and, because of melt strength, are ideal for FFS applications such as the MRE crackers and snack bread. The ionomer layer may be substituted with a blend of linear low-density polyethylene (LLDPE) and low-density polyethylene (LDPE). A major difference between this structure and the retort pouch is that the adhesives used to bond the layers of the retort pouch are more heat-resistant. Other commercially packaged components (e.g., commercial candies) are typically overwrapped in similar tri-laminate pouches if their primary package does not provide sufficient O_2 and H_2O protection or rough handling survivability.

In 1993, the FRH was incorporated into the MRE. The FRH consists of a chemical heating matrix composed mainly of magnesium and iron enclosed in a heat sealable nonwoven polyester scrim material and sealed in a high-density polyethylene (HDPE) heater bag. The HDPE is pigmented olive drab to address battlefield signature concerns. The electrochemical heaters are activated by the addition of less than 2 oz of water, and the exothermic reaction raises the temperature of an 8-oz entrée 100°F in 12 min or less. It also keeps the entrée warm for approximately 1 h if the tactical situation prevents the user from eating immediately. HDPE was selected as the heater bag material due to its chemical resistance, good moisture barrier properties, good thermal properties, and good mechanical properties. The film is processed by blown film extrusion and, because of the orientation of the polymer chains in the direction of flow, it tears evenly in one direction only. This is important to facilitate opening of the bag, since tear notches are incorporated into the design. Due to its excellent thermal properties, it is able to withstand the temperatures encountered during the heating reaction. Its moisture barrier properties adequately prevent the permeation of water vapor into the bag during storage, which further prevents accidental activation of the heater pad. In some instances, when FRHs are pre-positioned onboard ships, the FRHs are further overwrapped in foil pouches to eliminate moisture ingress.

Another addition to the MRE is the water-activity controlled, shelf-stable pouched snack bread. In order to retard potential oxidation of the bread, a ferrous-based oxygen scavenger sachet was added to the package. The scavenger itself is packaged in a pouch constructed from spunbonded polyolefin, which allows the passage of oxygen molecules into the sachet, thus extending the shelf life of the bread product.

MODIFIED ATMOSPHERE PACKAGING

Jeffrey Brandenburg
The JSB Group, LLC,
Greenfield, Massachusetts

Modified atmosphere packaging (MAP) is a term applied to a range of food packaging technologies that rely on mixtures of the atmospheric gases oxygen (O_2), carbon dioxide (CO_2), and nitrogen (N_2), in concentrations different than those in air, to retard deterioration processes in foods. Such atmospheres, sometimes with the addition of small amounts of other gases such as carbon monoxide (CO), ethanol (EtOH), sulfur dioxide (SO_2), or argon (Ar), maintain foods in a “fresh” state for periods of time necessary to move them through extended distribution and marketing chains.

The majority of these technologies rely on a combination of MAP and rigorous refrigeration to forestall microbial and chemical deterioration. The key to the technologies lies in the different concentrations and application of the common atmospheric gases and the beneficial effects conferred by specific concentrations of various gases. Thus, the technologies, rely on gases that are safe, common, cheap, readily available, and usually not considered chemical additives. Different combinations of these gases are appropriate for different foods, package types, and situations. The proper marriage of food, gas mixture, and package type has been the subject of most of the developmental efforts in the area.

Vacuum packaging (VP) is a form of MAP that establishes an atmosphere by drawing a partial vacuum to remove the ambient gases inside a gas barrier package and then sealing the package with the purpose of excluding atmospheric gases, principally O_2. A complete vacuum is never established under practical conditions but the exclusion of gases is the aim.

MAP/VP are employed to delay deterioration of foods that are not sterile and whose enzymatic systems may still be operative. Thus, these techniques differ from traditional methods of food preservation, such as cooking, canning, drying, salting, or freezing, but rather are methods to maintain foods in a “natural” condition while slowing specific deterioration processes. Rigorous temperature control is often necessary for the packages to work properly. For this reason, the capabilities of the distribution system or “cold chain management” define the degree to which MAP can be used. These packaging technologies have fit very well into the vertically integrated, geographically restricted distribution systems in Western Europe. Although they have been more difficult to implement in the more fragmented and longer distance distribution systems of North America, they are now used commonly in all types of food packaging.

GASES USED IN MAP

Oxygen (O_2)

Most of the reactions with food constituents involving oxygen are degradation reactions resulting in the oxidative breakdown of foods into their constitutive parts. Oxygen combines readily with fats and oils and causes rancidity. In addition, most spoilage microorganisms require O_2 to grow and will cause off odors in the presence of sufficient oxygen. Oxygen is necessary to the normal respiratory metabolism of fresh fruits and vegetables, and normal atmospheric concentrations of O_2 contribute to senescence and degradation of produce quality. Oxygen is implicated in staling of bakery goods and pasta. It oxidizes the pigments of red meats to an undesirable brown color. In the absence of O_2, meats will take on a purplish color that some consumers find objectionable.

Oxygen permeates through plastic polymers at rates depending on the polymer, but it generally permeates more slowly than carbon dioxide. The permeability rate of oxygen (and all gases) in plastics increases as temperature increases. Similarly, the chemical reactivity of oxygen with food constituents increases as temperature increases.

Carbon Dioxide (CO_2)

Carbon dioxide is present in the atmosphere at low levels ($\sim 0.03\%$) but is a product of combustion and so is easily produced. It is very soluble in water, especially in cold water (179.7 cm^3/100 mL at 0°C), and will thus be readily absorbed by high-moisture, refrigerated foods. Carbon dioxide is soluble in fats and oils, as well as in water, and this solubility can lead to package collapse, off flavors, excess purge by muscle foods, and discoloration of fresh produce. Carbon dioxide permeates most packaging materials more rapidly than other atmospheric gases.

When CO_2 dissolves in water, it has an acidifying effect. This acidification, as well as direct antimicrobial effects of $CO_2 > 10–15\%$, can suppress the growth of many spoilage microorganisms and for this reason it is an important component of MAP.

Carbon dioxide also suppresses the respiration of some fresh fruits and vegetables and thus can help extend their shelf lives. In addition, CO_2, concentrations above about 1% can render many plant tissues insensitive to the ripening hormone ethylene and thus slow their senescence and deterioration. However, too much CO_2 can be damaging to plant tissues and individual fruits and vegetables differ in their tolerance of CO_2.

Nitrogen (N_2)

Nitrogen is the most abundant component in air ($\sim 78\%$) and can be used in either gaseous or liquid form. It is physiologically inert in its gaseous and liquid forms and is used in packaging primarily as a filler and to exclude other more reactive gases. It is sparingly soluble in water (2.33 cm^3/100 mL at 0°C).

Carbon Monoxide (CO)

Carbon monoxide is a colorless, odorless, tasteless, very toxic gas that is effective as a browning and microbial inhibitor. In concentrations as low as 1%, CO will inhibit the growth of many bacteria, yeasts, and molds. It can also delay oxidative browning of fruits and vegetables when combined with low O_2 concentrations (2–5%) and has found limited use commercially for this purpose. By adding minute amounts of CO to red meat packages, products such as ground beef can maintain their natural appearance throughout their shelf life, since CO reacts with the meat pigment myoglobin to create carboxymyoglobin, a bright red pigment that masks the natural aging and spoilage of meats. However, the benefits and risks of using CO in MAP remain controversial, and due to the toxicity of the gas and its explosive nature at 12.5–74.2% in air, it must be handled using special precautions.

Sulfur Dioxide (SO_2)

Sulfur dioxide has been used to control growth of mold and bacteria on a number of soft fruits, particularly grapes and dried fruits. It has also found use in the control of microbial growth in fruit juices, wines, shrimp, pickles, and some sausages. Sulfur dioxide is very chemically reactive in aqueous solution and forms sulfite compounds, which are inhibitory to bacteria in acid conditions (pH <4). However, a significant minority of people display hypersensitivity to sulfite compounds in foods and the use of sulfites has come under public and regulatory scrutiny in recent years.

Ethanol (EtOH)

Ethanol has antifungal activity and has been used with some baked goods in Japan to reduce microbial spoilage. In addition, research results have shown ethanol to enhance firmness of tomatoes and may act as a flavor enhancer for other fruits.

Argon (Ar)

Argon, a noble gas, is not known to have any chemical or biological activity. Nevertheless, reports from one company suggest that it may have antimicrobial effects. Argon comprises 0.9% of the atmosphere and so is relatively abundant.

PACKAGING MATERIALS

Most MAPs rely on flexible monolayer, multiplayer, and multilayer laminate films and/or composite trays to maintain product and atmosphere integrity. Polymer-paper and polymer-foil laminations, as well as metal cans and glass jars, are also used in such packaging. Many types of polymers and composite materials are available for these uses, and more are appearing every day. Polymers probably comprise upwards of 90% of the materials used in MAP, with paper, paperboard, aluminum foil, metal, and glass accounting for the remainder. However, for each product category, relatively few kinds of materials are used. The selection of materials depends on technical considerations of performance, strength, sealability, printability, and recyclability as well as aesthetic, safety, and cost considerations.

The most commonly used polymers are polyethylene (PE), polypropylene (PP), polyester, polycarbonate, polystyrene (PS), nylon, ethylene–vinyl alcohol (EVOH), polyvinylidene chloride (PVDC), ethylene vinyl acetate (EVA), cellophane, rubber, and butadiene. In addition, sealant layers of ionomer or other polymer materials are sometimes used.

Barrier Properties

The function of many MAP systems is to exclude O_2 and moisture from the packaged food and thereby retard oxidative rancidity (baked goods, *Sous Vide*, nuts, and pasta), retard growth of spoilage microorganisms (meats, pasta, baked goods), maintain crispness (baked goods and snack foods), and maintain proper color (red meat). In other packages, the aim is to prevent egress of CO_2 to retard growth of microorganisms (meat, baked goods and pasta). These packages require the use of gas barrier materials that allow very litle permeation of gases.

MAP for fresh produce, on the other hand, must allow entry of a controlled amount of atmospheric O_2 to maintain the aerobic metabolism of the product. In addition, controlled amounts of CO_2 must also exit the package to avoid buildup of injurious levels of the gas. These packages rely on the use of polymer films with either relatively high gas permeability characteristics or microperforations.

The barrier of a polymeric film to a gas is inversely proportional to the permeability of the film (i.e., the higher barrier, the lower permeability). Gas permeation involves three sequential steps: adsoprtion of the gas molecules onto one side of the film, diffusion of the gas molecules across the film, and desorption of the gas molecules from the other side of the film (1). The first and third step, adsorption and desorption, may be described as Henry's Law:

$$c_s = Sp$$

where c_s is gas concentration at the film surface (moles/cc), p (atm) is partial pressure of the gas, and S is solubility coefficient (moles/cc/atm). The second step, diffusion, may be described the Fick's First Law:

$$J = -D\frac{\mathrm{dc}}{\mathrm{dx}}$$

where J (moles/cm^2/s) is diffusion flux, D (cm^2/s) is diffusivity or diffusion coefficient, c (moles/cc) is gas concentration, and x (cm) is distance in the flow direction.

Sometimes, small holes or microperforations are incorporated in the film structure, which have the effects of increasing the values of permeabilities and decreasing the permeability ratio of CO_2 to O_2.

When calculating the permeability of a multilayer polymer laminate, the following equations may be employed (1, 2):

$$\frac{L_T}{P_T} = \frac{L_1}{P_1} + \frac{L_2}{P_3} + \frac{L_3}{P_3} + \cdots$$

where P is the permeability, L is the film thickness, the subscript T refers to the total film, and the subscripts 1, 2, 3 refer to the individual layers in the film.

Gas barrier properties of plastic films are sensitive to temperature and, in a few cases such as for EVOH or nylon, relative humidity. As most film permeability testing occurs at room temperature and low relative humidity, it is often difficult to predict barrier performance under the high humidity refrigerated conditions typical of extended shelf life fresh foods. As a rule, both WVTR and gas transmission rates increase with increasing temperature (see also Barrier Polymers).

ACTIVE PACKAGING

Besides gas flushing, gas injection, and wrapping in packages that mediate or obstruct gas movement, there are a growing number of supplementary materials that can be added to MAPs or used with those packages to further alter and control the package environment. These include absorbers, emitters, scavengers, scrubbers, and desiccants that, when added to a package, alter the package structure, function, or properties. Their purpose is to extend product shelf life, usually through the control of atmospheric gases and moisture, without the use of "preservatives." These materials are diverse and their claims in the marketplace may sometimes outpace their capabilities. But there is no question that this is a rapidly growing area of packaging that is likely to move into the mainstream of food packaging in the near future (3).

Oxygen Absorbers

For packaging applications that involve oxygen-sensitive products, gas flushing with nitrogen or carbon dioxide often is insufficient to remove residual oxygen. Because low concentrations of oxygen can participate in the degradation of fatty foods, accelerate staling of baked goods, and facilitate other forms of deterioration, the use of oxygen absorbers as an adjunct to gas flushing has become an important methodology. Most commercially available O_2 absorbers use metallic reducing agents such as powdered iron oxide, ferrous carbonate, or metallic platinum. Iron powder is the most common active ingredient. These products often utilize powdered FeO, which becomes Fe_2O_3 and Fe_3O_4 and their hydroxide forms after absorption of O_2. The lower the temperature, the lower the O_2 absorption speed (4, 5).

Reduced iron is listed as GRAS (generally regarded as safe by the FDA) with no limitations on its use other than good manufacturing practices. It should be pointed out that the use of O_2 scavengers reduces O_2 to levels that may be conducive to the growth and toxigenesis of certain anaerobic pathogens, notably *Clostridium botulinum*, and thus should be used with great care with nonsterile fresh foods.

Carbon Dioxide Absorbers

Some of the absorbents that are currently being used to remove excess CO_2 from CA storage rooms could be adapted for their utilization in MAP. They include lime (calcium hydroxide $[Ca(OH)_2]$ + sodium hydroxide or potassium hydroxide), activated charcoal, and magnesium oxide (5).

Moisture Regulators

The stability and shelf life of many food products depends, in part, on the maintenance of an appropriate water activity inside the package. Inappropriate moisture levels can lead to shortened shelf life, reduced quality, and, in the worst case, unwanted microbiological activity. While many films are available that will provide an excellent moisture barrier to prevent the ingress or egress of unwanted moisture, often the food product itself can contribute unwanted humidity within a package. Several products are available that will aid in the regulation of proper moisture within the package. Most rely on physical absorption of moisture, though a few rely on actual chemical bonding to the water molecules. The most common desiccants currently used are based on silica gel, montmorillonite clay, calcium oxide, activated carbon, or glycerol. Of these, silica gel is the most common.

Silica gel is a partially dehydrated colloid of silicic acid. Its structure is such that it forms interconnected micropores that form a vast surface area that can attract and hold water through adsorption and capillary condensation. Silica gel is most efficient at temperatures below 25°C where it can adsorb up to 40% of its weight in water. Its efficiency falls off at higher temperatures. Silica gel is nontoxic and noncorrosive. Montmorillonite clay is less efficient at moisture adsorption than silica gel and also slower.

Alternatively, saturated salt solutions can be employed to maintain a desired equilibrium relative humidity within the package. Individual salts, if present in sufficient quantities, will maintain a characteristic relative humidity (RH) at a given temperature. For example, NaCl, at 5°C, will maintain a RH of 75%. For a higher equilibrium RH, K_2SO_4, at 5 °C, will maintain an RH of 98.5% (6, 7). Selection of the proper salt can result in almost any desired RH.

Absorbers/emitters of Ethylene and Other Volatiles

Because ethylene gas is a plant hormone with powerful physiological effects at very low concentrations, it is sometimes removed from the environment of sensitive commodities. Ethylene gas (C_2H_4), in part per million concentrations, can induce rapid ripening and senescence in many fruits, yellowing of leafy vegetables, and physiological injury of selected produce items. Potassium permanganate has long been used to remove ethylene from controlled atmosphere apple storage rooms. The same compound, adsorbed on various inert substrates, is available commercially in sachets, on pads, or in granular form. Many other compounds have ethylene adsorbing capacity, including various hydrocarbons, silicones, glycols, and clay materials (8).

In addition, many other volatile compounds can be responsible for off-odors in foods but can be reduced through the use of absorbers. Potassium permanganate and activated charcoal are the most important and can absorb many volatile gases other than ethylene.

Active Films

While the above methods of active package modification have their virtues, they all suffer because they have to be utilized in addition to the packaging itself. As such, they represent an added expense and, in some cases, the addition of a potentially hazardous material. A number of innovative approaches to avoiding these problems have emerged in the past few years. There are now several plastic films that incorporate some of the functions described above into the film itself. Thus, the package itself may absorb O_2, ethylene or CO_2, or control decay (3).

There are several new films, mostly from Japan, that are reputed to have ethylene-adsorbing capabilities to improve the shelf life and freshness of fruits and vegetables. These films are typically made of common plastic polymers (usually low-density polyethylene) with one or several clay materials (zeolites, cristobilites, etc.) embedded in the film matrix. These ceramic materials have putative ethylene-adsorbing capacity. However, investigators have found little ethylene adsorbing capacity by porous ceramic materials (8, 9). Urushizaki (10) tested one such ceramic material and detected adsorption of less than 1 μL/g of ceramic material after exposure to 500 ppm of ethylene. Such adsorptive capacity is insufficient to be of benefit in a modified atmosphere package of fresh produce.

Some films containing ceramic materials are claimed to aid in the preservation of produce through the emission of farinfrared radiation. Such radiation normally is effective mainly in heating an absorbing body, in this case the fresh produce. This is antithetical to the usual aim in preserving produce. The reputed beneficial effect is that the infrared radiation excites the plant cell membranes, thereby rendering the cells more resistant to microbial invasion. Such claims are as yet unsubstantiated in the scientific literature.

Films that will pass ultraviolet radiation have been suggested for reduction of ethylene and for control of microorganisms. Ultraviolet radiation reacts with oxygen to form ozone which scavenges ethylene and also kills microorganisms. Unfortunately, ozone is also very damaging to most plant tissues. In addition, the reaction may not be very efficient in low oxygen environments such as those found inside MAP.

A promising approach to reduction of oxygen content inside a package is based on imbedding in the plastic film a photo-sensitizing dye and an electron-rich oxidizable compound termed a singlet oxygen acceptor. When irradiated with ultraviolet, visible, or near-infrared radiation of appropriate wavelengths, the excited dye molecules sensitize oxygen molecules by converting them to the singlet state. Such oxygen molecules then more readily react with oxygen acceptor molecules that are also embedded in the film (11).

Other workers are making progress in incorporating antimicrobial agents into plastic films so that the package itself controls bacteria and fungi. Technical hurdles surrounding a percentage of products in contact with the packaging material exist. In addition , the incorporation of pesticides in films may meet resistance in the current regulatory climate.

Temperature Switch

Temperture switch polymers, which are relatively new technologies, are unique polymers that respond to temperature changes in a controllableand very predictable way. Temperature switch polymers can significantly change their permeability, adhesion, viscosity, or volume when heated or cooled by just a few degrees above or below a preset temperature switch (12). Temperature switch polymers can be very advantageous in packaging applications when significant temperature variations occur within the distribution channel.

MAP OF RED MEAT

Deterioration of Fresh Meat

Fresh meat undergoes both oxidative color deterioration and microbiological deterioration. The color of red meat is determined by the oxidation state of the pigment myoglobin. The reduced form, deoxymyoglobin, is a purple color. Oxygenated oxymyoglobin is a bright red color associated with freshness in the minds of many consumers. Atmospheric O_2 slowly converts myoglobin to the dull brown metmyoglobin that many consumers associate with poor quality. Deoxymyoglobin is more susceptible to oxidation than oxymyoglobin, so metmyoglobin forms more readily at low O_2 concentrations than at higher concentrations (13).

Fresh meat is contaminated on the surface with spoilage bacteria from the slaughtering process. The presence of O_2 encourages the growth of aerobic spoilage bacteria, particularly species of *Pseudomonas*, which will produce putrid, malodorous compounds.

Vacuum Packaging

The exclusion of atmospheric O_2 prevents the oxidation of myoglobin to metmyoglobin as well as suppressing the growth of malodorous *Pseudomonas* bacteria. The delay of these two primary forms of deterioration through packaging can significantly extend shelf life of fresh red meat.

Vacuum packaging has been applied to 2–9 kg primal and subprimal cuts of meat for distribution to stores. Appropriate films for such packaging must have good gas barrier properties, generally admitting $<50\,\mathrm{cc}\,O_2/\mathrm{m}^2/24\,\mathrm{h/atm}$ (13). In addition, they must resist puncturing by protruding bone and must be flexible enough to form a tight “skin” over the meat and prevent pockets of air from forming where aerobic deterioration could rapidly occur. Films made of polyamide–polyethylene laminates and EVA copolymer–PVC/PVDC copolymer laminates, as well as ionomer–polyamide–EVA copolymer, among others, have been used for this purpose (17).

When vacuum-packaged meats reach the store, they are unpacked, cut into appropriate consumer units, and placed in polystyrene foam trays of PVC trays and overwrapped with O_2 permeable films. The ingress of O_2 causes the deoxymyoglobin to “bloom” into red oxymyoglobin.

Vacuum packages for meat are formed in four basic ways: (i) through heat-shrinking a flexible bag around the primal cuts, (ii) Using a preformed plastic bag in an evacuation chamber, (iii) Thermoforming trays in-line from a base web, or (iv) Vacuum skin packaging in which the product acts as the forming mold. Vacuum-packaged beef of normal pH and kept at chill temperature can be stored for 10–12 weeks. Lamb, because it tends to have more neutral pH exterior adipose tissue than beef, will keep 6–8 weeks in vacuum packages (14).

Case Ready Meats

A further evolution of vacumm-packaged meats are case-ready meats. Case-ready meats are packaged at plants and delivered to retailers ready to be placed in the retail case. Case-ready meats employ a combination of MAP technologies including vacuum packaging as well as low and high O_2 MAP (15). Examples of growing case-ready meats include poultry, beef, veal, pork, and ground meat products.

High O_2 MAP

High O_2 MAP employs 40–80% O_2 to extend color stability as well as 20–30% CO_2 to delay microbial spoilage. However, the presence of O_2 can lead to off odors and rancidity and so high O_2 MAP has not been suitable for prolonged storage of red meat.

Low O_2 MAP

Combinations of low O_2 and high CO_2 have been achieved through gas-flushing packages with N_2 and CO_2. The absence O_2 retards formation of brown metmyoglobin and the CO_2 suppresses growth of spoilage bacteria. However, because CO_2 is very soluble in both water and fat, excess CO_2 must be added to the package to allow for the solubility. Package collapse can result unless N_2 in the headspace of the package significantly exceeds the amount of CO_2 that solubilizes. Such packages have resulted in shelf lives of 3–4 months for pork and lamb.

MAP OF POULTRY

Poultry is usually contaminated with a large bacterial population that consists primarily of spoilage bacteria. Poultry is high pH compared to red meat and so provides a good environment for growth of these bacteria. Vacuum packages are difficult to form around poultry because of the irregular shape and sharp edges commonly encountered. Consequently, shelf life in vacuum packages is usually short, limited to about 2 weeks before putrid odors develop.

Low O_2 combined with high CO_2 has been extensively used with bulk packaged poultry. Oxygen is removed by drawing a vacuum and CO_2 and N_2 are introduced. Despite the presence of some residual O_2, shelf lives of 2–3 weeks can be achieved (13). Case-ready MAP is also expanding in poultry, including chicken, turkey, and duck.

MAP OF FRESH FISH

Fish encompasses a great diversity of species and habitats. In general, fish differ from terrestrial foods in that the interior of their muscles are not sterile, they undergo rapid enzymatic breakdown of their proteins even in low O_2 environments, and they are often not raised in controlled environments. Fish are only as clean as the water they were taken from. Thus, fish can be carriers or several pathogens such as *Clostridium botulinum* non-proteolytic types E and B, *Vibrio parahaemolyticus, Listeria monocytogenes*, and others (16).

Fish rapidly spoil due to the activity of gram-negative spoilage bacteria and they undergo enzymatic breakdown. Vacuum and MAP employing high CO_2 have been used to extend the normally limited shelf lives of various kinds of fish. Gas mixtures of 30% O_2, 40% CO_2 and 30% N_2 have been used for nonfatty fish, while 40% CO_2 and 60% N_2 have been used for smoked and fatty fish, (17).

The use of MAP and vacuum packaging are not capable of preventing growth and toxin production by *C. botulinum* (18). Maintaining the temperature below 3°C throughout distribution is the only barrier to the growth of this pathogen. While commercially packaged raw fish have not been implicated in food poisoning incidents, MAP of fresh fish should only be undertaken with extreme caution.

MAP OF BAKERY AND PASTA PRODUCTS

Pasta and baked goods are subject to moisture loss, oxidative rancidity, and microbiological breakdown, primarily due to growth of molds. MAP has been used extensively in Europe and, less so, in the United States to prevent deterioration and extend shelf life. Vacuum packaging has been used for some baked goods to remove headspace O_2 and inhibit oxidative rancidity and growth of aerobic spoilage microbes. Packaging in a combination of N_2 and CO_2 has been used more commonly to replace O_2 and suppress growth of bacteria and molds due to the presence of the CO_2. Oxygen absorbers, CO_2 generators, and ethanol emitters have been used to extend the shelf life of baked goods in Japan and other parts of Asia (19).

Because the exclusion of O_2 is so crucial to MAP of pasta and baked goods, packaging materials must provide a good barrier to O_2. Rigid trays with nylon/LDPE or PVC/PVDC lidstocks have been used. Alternatively, laminated films made from nylon/polyethylene, nylon/PVDC/PE, or nylon/EVOH/PE have also been used. All maintain a reasonable moisture vapor as well as an O_2 barrier.

Baked goods have been packaged in atmospheres of 50–100% CO_2 plus 0–50% N_2, which can result in shelf lives up to several months for some products. Fresh pasta will stay fresh in MAP up to 2 weeks if not pasteurized or, in some cases, 3 months if pasteurized (20).

MAP OF PREPARED FOODS

Chilled, prepared foods are perhaps the fastest growing area of all food categories, and many of these foods are being shipped and marketed in MAP. As with all MAP applications, use of top-quality ingredients, strict adherence to temperature control, and careful sanitation are prerequisites to entering this market. The most rapidly growing areas of this sector include such prepared foods as pasta, pizza, precooked meats, sandwiches, precooked French fries, and complete prepared dishes such as "*Sous Vide*."

Most chilled, prepared foods are packaged in combinations of N_2 and CO_2 with little or no O_2 in the package. Such atmospheres confer several benefits including reductions of oxidative rancidity, lack of growth of aerobic spoilage microorganisms, suppression of growth of molds by CO_2, little moisture loss through the film package, and reduced oxidative breakdown of flavor and aroma volatiles.

The packages for these products are generally high-barrier polymer coextrusions or laminations. Packaging formats can include bags, top- and bottom-forming and nonforming webs, stand-up pouches, or multilayer lidding materials sealed onto rigid trays. Most packaging is run on form/fill/seal machines using with either PVC or EVOH polymers to provide the barrier properties.

Sous Vide involves vacuum packaging of foods, usually in multilayer polymer pouches, cooking the vacuum packaged product in a water bath, moist steam or pressure cooker, cooling rapidly in cold water, and then storing under refrigeration. These products will have a shelf life of 2–3 weeks under refrigeration. Cooking under vacuum protects the flavors from oxidative breakdown as well as preventing the growth of aerobic spoilage microorganisms (21).

While the food is not sterile, it will have low microbe counts and refrigeration should prevent growth of those few microbes that survived the cooking process. Because the cooking process will not kill spore-forming bacterial pathogens, the inclusion of barriers to pathogen growth, such as low pH, reduced water activity, or the introduction of lactic acid bacteria, in addition to refrigeration, has been suggested. *Sous Vide* was developed in France and has found widespread acceptance there. Acceptance has been slower in the United States but continues to grow, particularly in the food service sector.

MAP OF FRESH FRUITS AND VEGETABLES

The primary effects of MAP of fruits and vegetables are based on the often observed slowing of plant respiration in low O_2 environments. Reduced respiration leads to reduced depletion of carbohydrate reserves, slower ripening of fruits, and longer shelf life. This suppression of respiration continues until O_2 reaches about 2–4% for most produce. If O_2 gets lower than 2–4% (depending on product and temperature), then fermentative metabolism can replace normal aerobic metabolism and off flavors, off odors, and undesirable volatiles can be produced. Low O_2 can also reduce enzymatic browning of injured plant tissues. As CO_2 increases above the 0.03% found in air, a suppression of respiration results for some commodities. Reduced O_2 and elevated CO_2 together can reduce respiration more than either alone. In addition, elevated CO_2 suppresses plant tissue sensitivity to the effects of the ripening hormone ethylene. For those products that tolerate high concentrations of CO_2, suppression of the growth of many bacteria and fungi results at $>10\%$ CO_2 (22).

Although package O_2 permeability increases somewhat as temperature increases, product respiration (demand for O_2) increases much faster. Thus, O_2 will rapidly be depleted if package temperature increases. Because package performance can only be specified within a particular temperature range, it is important that packages be used within that range. If the temperature gets outside of that range, product quality will suffer (7).

The rapid growth of the fresh-cut produce industry, including retail salads, vegetables, and fruits as well as many fruits and vegetables produced for food service, has been possible largely due to the improved quality and shelf life of cut produce in MAP. Products are packaged in a wide variety of modified atmosphere packaging including laminated and/or coextruded copolymers of polyolefins such as LDPE, EVA, PS, and PP. Packaging formats include bags, stand-up pouches, lidded trays, and microwaveable trays. The choice of the correct polymer or combination of polymers is often determined by matching the strengths of particular polymers with the requirements of the packaging system, while at the same time minimizing or masking particular polymer disadvantages (2). Package atmospheres can be created passively by sealing the bag and allowing the product respiration to decrease the O_2 concentration and increase the CO_2 concentration until equilibrium is reached. Alternatively, the atmosphere can be initially rapidly modified by reducing the package headspace by drawing a vacuum and, sometimes, by injecting a desirable gas mixture into the bag. In any case, the equilibrium package atmosphere is determined by the respiration rate of the product or product blend, the final target modified atmosphere, and the gas permeability properties of the package, not by the initial atmosphere in the bag. Once all of the parameters have been defined, mathematical models can be used to determine appropriate film breathability characteristics that will deliver a beneficial atmosphere at the anticipated processing, storage, and distribution temperatures.

An effective mathematical model to estimate appropriate film breathablity for a desired atmosphere is as follows (23):

$$WR_{O_2} = \frac{AP_{O_2}}{L}(O_{2,air} - O_{2,\mathrm{pkg}})$$

$$WR_{CO_2} = \frac{AP_{CO_2}}{L}(CO_{2,pkg} - CO_{2,\mathrm{air}})$$

where

R_{O_2} = respiration rate (O_2 consumption rate of product)
R_{CO_2} = respiration rate (CO_2 evolution rate of product)
W = product weight
L = film thickness
A = film surface area
P_{O_2} = permeability to O_2
P_{CO_2} = permeability to CO_2
$O_{2,\mathrm{pkg}}$ = desired O_2 concentration in package
$O_{2,\mathrm{air}}$ = O_2 concentration in air (typically 21%)
$CO_{2,\mathrm{pkg}}$ = desired CO_2 concentration in package
$CO_{2,\mathrm{air}}$ = CO_2 concentration in air (typically 0.03%)

Campden and Chorleywood
Food Research Association,
Chipping Campden,
Gloucestershire, United
Kingdom

INTRODUCTION AND MAP MARKET INFORMATION

In the last few decades there has been a dramatic growth in the chilled foods market in Europe. This growth has been stimulated by an increasing consumer demand for fresh, convenient, and additive-free foods. This consumer demand has stimulated the growth of modified-atmosphere packaging (MAP) as a technique to improve product image, reduce wastage, and extend the shelf-life quality of a wide range of foods. Also the added benefits of improved transportation and distribution chains and longer product shelf life have enabled widespread use of modified atmosphere packaging.

The prepared chilled foods market in Western Europe is worth approximately 14.62 billion euros. The United Kingdom leads the way, with 54% of the chilled food market, equating to nearly 8 billion euros, followed by France with 18%. Other countries with increasing sales of chilled prepared foods include Germany, Italy, Spain, Belgium, and the Netherlands (1). Figure 1 illustrates the segmentation of the chilled food market. Proportionally more retail area is being devoted to chilled foods at the expense of frozen and ambient-stable foods. The main

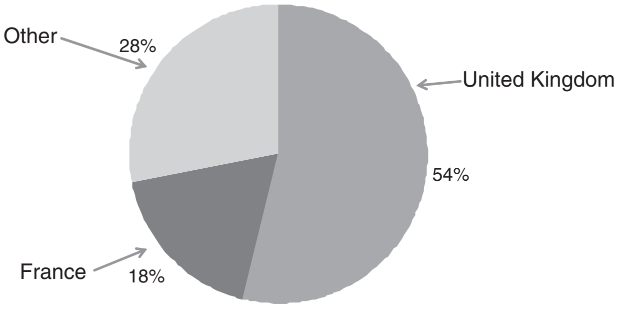

Figure 1. Segmentation of the chilled food market, Europe.

reason for this development is that the concentration of retail power in the United Kingdom is the highest in the world, led by Sainsbury, Tesco, Morrisons, Asda, Waitrose, and Marks & Spencer. Their operations are increasingly being focused on centralized distribution and a quality image that they feel is enhanced by an expanding chilled-foods sector (2).

As MAP grows in popularity across Europe, some of the more established MAP areas such as raw red meats, will see their growth rates slow down. Centralized packing of these types of products will become more common rather than retailers cutting and packing the product in the back of the store. MAP can allow a wider area for distribution across Europe, thereby reducing costs, but packers need to ensure that the product can outlast the distribution time to the store. There has been a surge of interest of MAP in the chilled ready meal market with products such as sandwiches, salads, and cooked–chilled products. It is predicted that the MAP chilled ready meal market will dramatically increase in volume and value, and this strong growth will cause it to overtake the frozen ready meal market, particularly in the United Kingdom.

BACKGROUND INFORMATION

Modified-atmosphere packaging (MAP) is a popular food preservation technique, whereby the composition of the atmosphere surrounding the food is different from the normal composition of air, which consists of oxygen (20.9%), carbon dioxide (0.03%), and nitrogen (79%). These gases can be used on their own or in combination to enhance the shelf life and quality of the packaged product.

Vacuum packing (VP) is the removal of most or all of the air within a package without deliberate replacement with another gas mixture.

Active packaging can be used in conjunction with MAP, whereby certain additives are incorporated into the packaging film or within packaging containers and are capable of altering the atmospheric composition surrounding the food. Active packaging devices include oxygen and carbon dioxide scavengers and ethanol and carbon dioxide emitters.

Controlled-atmosphere storage (CAS) is yet another food-preservation technique similar to MAP; but unlike MAP, where there is no way of controlling atmospheric constituents at specific concentrations once a package has been hermetically sealed, in CAS the atmospheric constituents are precisely adjusted to specific concentrations throughout the storage and/or distribution of perishable foods. CAS is used primarily for the warehouse storage of whole fruit and vegetables and for the road or sea-freight container transport of perishable foods (3).

Gases Used for MAP

The gas mixture used in MAP must be chosen to meet the needs of the specific food product (3), but for nearly all food applications this will be some combination of either carbon dioxide (CO_2), oxygen (O_2), or nitrogen (N_2). For example, raw red meats are often packed in a high oxygen environment to maintain the red color, bakery products will be packed in a combination of carbon dioxide and nitrogen to prevent mold growth and pack collapse, and dried goods are packed in nitrogen to prevent oxidative rancidity.

Novel Gases

Novel gases such as carbon monoxide, ozone, nitrous oxide, helium, argon and high oxygen have been used to extend the shelf life of a number of food products. For example, carbon monoxide has been shown to be very effective at maintaining the color of red meats, maintaining the red stripe of salmon, and inhibiting plant tissue decay. However, carbon monoxide is not permitted in the EU, due to its highly toxic and explosive nature. Argon and nitrous oxide are known to sensitize microorganisms to other antimicrobial agents (4). Argon has been shown to inhibit tissue fermentation in sliced tomatoes, inhibit protein breakdown in seafood, and extend the shelf life of prepared fruit (5) and has been used as a replacement for nitrogen. Research has also indicated that argon is biochemically active, probably due to its enhanced solubility in water compared with nitrogen and oxygen and its possible interference with cell membrane fluidity and enzymic oxygen receptor sites (4). Nitrous oxide is being used as a propellant in whipped cream cans. The commercial use of most of these gases is severely limited in the United Kingdom because of regulatory constraints, safety concerns, negative effects on sensory quality, or economic factors (3). However, argon (E938), helium (E939), nitrous oxide (E942), and sulfur dioxide (E220) are now permitted for food use in the EU (4).

Research into high oxygen applications other than with meat products has resulted in some commercial applications. High oxygen has been found to be particularly effective at inhibiting enzymatically mediated discoloration, preventing anaerobic fermentation reactions and inhibiting aerobic and anaerobic microbial growth. Under high oxygen MAP it is hypothesized that reactive oxygen species damage vital cellular macromolecules and thereby inhibit microbial growth when oxidative stresses overwhelm cellular antioxidant protection systems (6). Research carried out at Campden and Chorleywood Food Research Association (CCFRA) found high oxygen MAP to have beneficial effects on the sensory quality of the vast majority of the fresh produce items studied. These items included a number of different types of lettuce, potatoes, coriander, raspberries, and strawberries (7).

Products Packed Under MA

The United Kingdom is undoubtedly leading the world in terms of the range of food products packed under MA (8). These product developments have been prompted by the major retail chains, which have considerable influence in the British food industry (9). Established products packed under MA include red meats, poultry, cooked and cured meats, fish and seafood, pasta, cheese, bakery goods, pizza, quiche, ready meals, dried foods, fruit, and vegetables. Newer modified atmosphere products include sandwiches, as well as fresh chilled combination products with meat/fish and vegetables. Further developments include products being modified atmosphere packed, stored frozen, and then thawed to chilling for retail sale. However, there is little background information on the effects of freezing on the gases used in modified atmosphere packaging.

Nitrogen and/or carbon dioxide are also used with a number of beverages such as beer, lager, fruit juices, and carbonated soft drinks.

Although retail products have tended to attract most of the publicity in relation to MAP developments, bulk MA technology is being used for products such as pork primals, poultry, and bacon (8). In addition, this technology is presently being used to gas flush conventionally packaged retail products, such as overwrapped trays of red meats, into large bag-in-box master packs. Excellent opportunities also exist for using MAP technology for supplying the catering, food processing, and wholesale industries with bulk packs of many dried commodities, such as tea, coffee, cocoa, herbs, spices, and nuts, as well as chilled perishable foods (8).

MAP DEVELOPMENTS

High-Permeability Films for Produce

Unlike other foods that are MA packed, fresh fruit and vegetables continue to respire after harvesting, and consequently any subsequent packaging must take into account this respiratory activity. The depletion of O_2 and the accumulation of CO_2 are natural consequences of the progress of respiration when fresh fruit or vegetables are stored in a hermetically sealed package. Such modification of the atmospheric composition results in a decrease in the respiration rate, with a consequent extension in the shelf life of fresh product. However, packaging film of the correct permeability must be chosen to realize the full benefits of MAP for fresh produce.

Typically, the key to successful MAP of fresh produce is to maintain an equilibrium MA (EMA) containing 2–10% O_2 and CO_2 within the package. For highly respiring produce such as mushrooms, beansprouts, leeks, herbs, peas, and broccoli, traditional films such as LDPE, PVC, EVA, and OPP are not sufficiently permeable. Highly permeable microperforated films for highly respiring produce are more suitable. P-Plus film can be microperforated to match the permeability of the film with the product's respiration rate.

Intellipac® technology is a means of providing different permeabilities to maintain the optimum atmosphere within a pack even with changing temperatures. The membrane patch that is attached to a hole in the film controls the flow of gases in and out of the pack by altering the properties of the polymers within the membrane (10).

Seal Integrity of MA Packs

Seal integrity is important to maintain a safe and good-quality product. A number of methods can be used to detect leaks in MA packs. Offline methods include the following:

1. *Dye testing.* A penetrative dye is sprayed or painted onto the seal area. This indicates if a leak is present and also identifies the position.
2. *Gas Analysis.* This can be used on flexible packs to determine whether there is a leak in the sealing area (11). EMCO has established a European company that has the distribution rights of Oxysense O_2 technology. This can also be used as a noninvasive detection device. The O_2xysense™ 4000 is a portable oxygen analyzer that utilizes a noninvasive optical method that determines oxygen concentration by measuring the fluorescent energy released from an illuminated oxygen-sensitive sensor (O_2xyDot™) (11).
3. *Indicators.* This is a nondestructive method for detecting leaks in MA packs. Indicators give a visual indication (e.g., a color change), if a leak is present. For modified atmosphere packs the indicators used are oxygen or carbon dioxide, depending on the gas composition of the pack.

Carbon dioxide leak detectors can also be used where at least 10% of the packs gas composition is CO_2. These systems can be offline or online and use CO_2 as a trace gas to detect leaks.

Easy-Opening/Resealable Systems

A visit to any European supermarket will illustrate the enormous growth in convenience foods. Clearly, the ease of opening of these products is a key attribute. Also as the population ages, and consequently their abilities to read and/or handle food packages decreases, there is a need to understand how consumers manage so-called easy-to-open packaging and also to have an understanding of how reducing seal strengths to make packs of all types easier to open may compromise the quality and safety of the products on sale. Easy-open features are not only important for the convenience food market but are essential for the elderly and those with disabilities. Easy opening and resealable systems are very different. Easy opening systems are designed to aid consumers when opening packaging, whereas resealable packs are designed to help extend food shelf life in the consumer's home. However, once the primary seal is broken, the major benefit of MA to extend food shelf life is lost. The resealable features such as slider/zipper will just provide the convenience benefit to the consumer and will prevent moisture loss of the product.

There are a variety of systems now available, including peelable films for easy opening and zips/slider (single- or dual-track zipper) to reclose bags after opening.

Valle Spluga Two-Phase MAP

When packing high-moisture/high-fat foods such as meat, poultry, and seafood, the high solubility of CO_2 in these foods can lead to pack collapse, due to the decrease in headspace volume (10). In conventional retail MA packs, pack collapse is minimized by limiting the proportion of CO_2 to less than 40% and having a large headspace volume above the food. However, these procedures limit the shelf-life extension potential since lower levels of bacteriostatic CO_2 are maintained within MA packs. Additionally, the larger headspace volume required results in a decreased packing density, with associated higher costs of production, storage, and distribution (8).

An innovative process for solving the problem of pack collapse is now widely used. This two-phase process is based on the use of solid and gaseous CO_2 in MA packs (7). A weighed tablet of solid CO_2 is dispensed into a thermoformed tray containing the food product, just before gas flushing and sealing. The solid CO_2 sublimes to gaseous CO_2 after sealing and causes the semirigid package to swell. However, after a few hours, an equilibrium is established between the gaseous CO_2 in the headspace and the CO_2 absorbed by the food, and hence the package reverts to its original shape. Valle Spluga patented the process and has successfully used this process to market spring chickens in MA packs that maintain high levels of CO_2 with a minimum headspace (8).

GUIDELINES FOR THE MANUFACTURE AND HANDLING OF MA PACKED FOODS

MA-packed chilled foods have been marketed in Europe for many years, and during this period they have maintained an excellent safety record, providing the consumer with high-quality, safe, and fresh products. It is important, however, for all those involved in the manufacture and handling of MA-packed chilled foods to be vigilant about possible food safety hazards, especially in the light of increased regulatory and consumer concern about the perceived rise in food poisoning incidents. It is imperative that the food safety of such products not be compromised by complacency and poor manufacturing or handling practices. Such a situation would seriously compromise the safety of MAP technology and hence its further application as a preservation technique for chilled foods (3).

REPORT ON VACUUM PACKAGING AND ASSOCIATED PROCESSES

The UK Advisory Committee on the Microbiological Safety of Food (ACMSF) has published a report on the potential hazards of vacuum packaging and associated processes such as “sous vide” and MAP (12). Emphasis is placed on the safety aspects of chilled foods, with particular reference to the risks of botulism. Preventative measures have been identified, and possible mechanisms for control have been detailed. Among the many recommendations is one which states that chilled prepared food packed under reduced O_2 levels with an assigned shelf life of more than 10 days should contain one or more controlling factors in addition to chill temperatures to prevent growth and toxin production by *Clostridium botulinum*. Controlling factors include heat treatment, acidity and salt levels, and water activity. The UK government endorses this recommendation and has drawn it to the attention of appropriate trade and professional bodies.

CONCLUSIONS

MAP is still one of the most exciting and innovative areas of the packaging industry. New developments in both packaging materials/machinery and food product applications are being described at an ever-increasing rate. The biggest growth areas are likely to be in easy-opening MA packs and methods for measuring integrity. The MAP chilled-food market in Europe is substantial and has enjoyed considerable growth in recent years because of the important benefits it provides to food manufacturers, retailers, and consumers alike. Although MAP has been used primarily for red meats, tremendous opportunities exist for the MAP of other foods.

MOLECULAR WEIGHT OF PACKAGING POLYMERS

Kit L. Yam
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

An important characteristic of packaging polymers is their molecular sizes relative to the much smaller organic or inorganic molecules. The molecular weight of a packaging polymer, a measure of its molecular chain length, can significantly affect the physical properties of the polymer. As molecular weight increases, tensile and impact strengths increase sharply before leveling off, while melt viscosity increases slowly and then sharply (Figure 1).

When selecting molecular weight for a specific application, the strength and melt viscosity should be compromised. The molecular weight should be high enough to acquire adequate strength, but low enough to avoid high melt viscosity, which makes the polymer difficult to process, such as flowing into a mold or through an extruder die. Typically, the practical molecular weight range for packaging polymers is between 50,000 and 200,000 as mentioned above.

Unlike small molecules such as oxygen or water, a polymer does not have a single molecular weight. This is because polymer molecules of different sizes are formed during the polymerization reaction. The relative fraction of different sizes may be characterized using a plot of frequency versus molecular weight, known as molecular weight distribution (MWD), as shown in Figure 2.

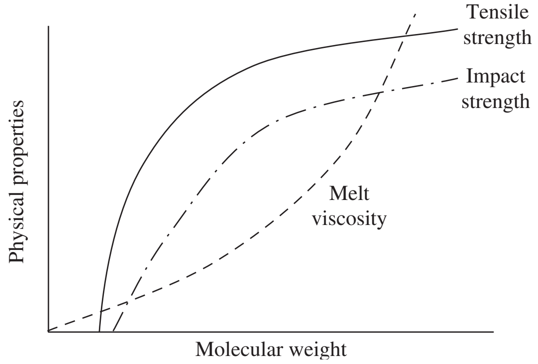

Figure 1. Effects of molecular weight on polymer properties.

Two average molecular weights are often obtained from the MWD. The number-average molecular weight $\overline{\mathrm{M}}_\mathrm{n}$ is defined as

$$\overline{\mathrm{M}}_\mathrm{n} = \frac{\sum_\mathrm{i} \mathrm{N_i M_i}}{\sum_\mathrm{i} \mathrm{N_i}} \tag{6.1}$$

where $\mathrm{N_i}$ and $\mathrm{M_i}$ are the number and molecular weight of polymer molecule i, respectively. The weight-average molecular weight $\overline{\mathrm{M}}\mathrm{w}$ is defined as

$$\overline{\mathrm{M}}_\mathrm{w} = \frac{\sum_\mathrm{i} \mathrm{w_i M_i}}{\sum_\mathrm{i} \mathrm{w_i}} = \frac{\sum_\mathrm{i} \mathrm{N_i M_i}^2}{\sum_\mathrm{i} \mathrm{N_i M_i}} \tag{6.2}$$

where $\mathrm{w_i}$ is weight of polymer molecule i.

The polydispersity index (PDI) is defined as

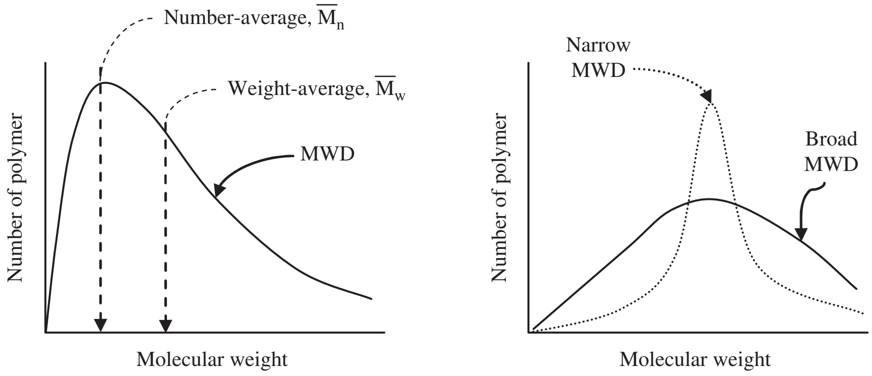
$$\mathrm{PDI} = \overline{\mathrm{M}}_\mathrm{w}/\overline{\mathrm{M}}_\mathrm{n} \tag{6.3}$$

which is a measure of the spread of the molecular weight distribution. The value of PDI is always ≥ 1. PDI = 1 means that all the polymer molecules have the same molecular weight and thus $\overline{\mathrm{M}}_\mathrm{n} = \overline{\mathrm{M}}_\mathrm{w}$ However, PDI = 1 is difficult if not impossible to achieve; most commercial packaging polymers have PDI greater than 2. A higher PDI is associated with a broader MWD (Figure 2(b)), meaning more variation in molecular weights among the polymer molecules.

A broader MWD tends to decrease the tensile and impact strengths of a polymer but increase its ease of processability, due to the smaller molecules in the distribution acting as a plasticizer or processing aid.

Chain Entanglement

A unique characteristic associated with large molecular weight of packaging polymers is chain entanglement, the ability of polymer chains to become entangled with one another. The degree of chain entanglement increases with length of the polymer chain or molecular weight of the



(a) (b)

Figure 2. Molecular weight distribution.

polymer. Polymers consisting of short chains are weak and brittle but become strong and ductile above some critical length. A minimum of 1000 to 2000 repeating units, for example, is necessary for polyethylene to acquire the strength adequate for packaging foods.

Chain entanglement is important for packaging polymers. For example, during thermoforming or blow molding of a thermoplastic, the polymer is in molten state with its molecular chains resembling cooked spaghetti (or, more vividly, wriggling long worms) tangled up on a plate. Chain entanglement holds the polymer chains together but also allows them to slide pass one other, thereby providing both the necessary strength and the pliability for the polymer to be molded into a film, bottle, or other shapes. After cooling, sliding between polymer chains is more difficult and chain entanglement makes the polymer strong and resilient.

Summation of Intermolecular Forces

The physical properties of a material are greatly influenced by the forces (such as dipole–dipole forces, hydrogen bonding, and dispersion forces) between its molecules (see Structure/Property Relationships of Packaging Materials). Although intermolecular forces exist between all molecules, their influences are more pronounced for polymers. Summation of intermolecular forces refers to the total force between neighboring molecules—this total force is particularly significant for packaging polymer molecules due to their long molecular chains.

The effects of summation of intermolecular forces may be observed in the physical states of large and small molecules: for example, polyethylene of solid versus ethane of gas. Except for the difference in size, the chemical structures are the same and weak nonpolar intermolecular forces operate on both compounds. Although weak nonpolar forces are operating in both compounds, the summation of intermolecular forces is much greater for the long polyethylene chains of solid than for ethane gas. Yet polyethylene molecules are held more strongly together due to greater summation of intermolecular forces.

Summation of intermolecular forces and chain entanglement can significantly influence the mechanical, thermal, rheological, and other properties of thermoplastics.

MULTILAYER FLEXIBLE PACKAGING

Thomas J. Dunn
Printpak Inc., Atlanta,
Georgia

Multilayer flexible packaging offers packaged-goods manufacturers the opportunity to match the functional needs of their products precisely to the materials used to package them. The same materials used as complete, sealed flexible packages are also suitable for use as lidding on rigid containers, film covers on carded and blister packs, and wrapping materials. These functional needs, broadly defined, are (a) package appearance, (b) package barrier, and (c) product containment.

Multilayer flexible packaging consists of combinations of metal, plastic, or cellulosic substrates (foils, films, and paper), individually ranging in thickness from 0.0001 in. (0.1 mil or 2.5 μm) to about 0.005 in. (5 mils or 125 μm). The aggregate thickness of the combination is defined by convention to be less than 0.01 in. (10 mils 250 μm). (Thicker composites are typically considered "sheet" materials.) This material is fashioned into various container formats (pouch, bag, wrapper, etc.) that hold a product.

The manufacture of multilayer flexible packaging is known as *converting*. In producing material for a particular application, specific text and related graphic information (e.g., pictorials and use suggestions or bar codes) are typically printed onto one of the substrates. Several processes—*coating, laminating*, and *coextrusion*—then combine this printed layer with others to provide the overall material functionality.

Packaged-goods manufacturers usually buy the composite directly in roll form. They use various types of integrated packaging machinery to form the material into a pouch or bag-like container, fill it with a premeasured product amoount, and finally seal it. Alternately, the converter will fabricate bags or pouches from the composite material. The packaged-goods manufacturer then fills and seals these containers using a variety of manual or automated means.

PACKAGE APPEARANCE

Consumers and industrial users require various visual cues and information on the packages of products they use. Multilayer flexible packages must communicate to these users specific information about the product within: product identification (including for example, name, ingredients and specific type), product quantification (e.g., count, volume, or net weight), manufacturer's identity and address, and warnings about any hazards presented by the product. In addition, manufacturers will usually provide product-use information (with text, icons, and/or pictorials) on the package. If the product is branded, the package must effectively communicate trademarks, logos, and brand colors. The appearance of a multilayer flexible package may also be used to communicate a variety of marketing claims for the product/package (e.g., new formulations, new packaging types/formats nutritional positioning, and compliance with certain religious requirements), promotional efforts of the manufacturer intended to stimulate sales, or linkages to other products. Multilayer flexible packaging provides abundant options to fill these needs.

Materials Options

Multilayer flexible packaging ranges in opacity from totally opaque to completely transparent. In the opaque form, it serves to deliver light-sensitive photographic and

X-ray films to users. When transparent, it can merchandise a variety of consumer products, allowing the would-be buyer to directly view them before purchase. Aluminum foil historically served as the most effective material for blocking light. With mirrorlike spectral reflecting properties, composite materials with foil have come to connote product quality and freshness (1). Metallized plastic films with vacuum-deposited aluminum coatings have been effective in imitating this shelf appearance, but they typically do not provide all the light barrier or other preservative qualities of foil.

A variety of plastic films combine to make transparent multilayer flexible materials. Cellophane, the earliest transparent film, is a cellulosic product; however, as a plain, uncoated material it had severe limitations (2). This material was first used as an unsupported (single-layer) packaging material. In fact, much of the product–process development in multilayer flexible packaging over the past 50 years derives from the need to overcome various use limitations of cellophane (e.g., brittleness from cold-temperature or low-humidity storage). Modern transparent films include polyethylene, polypropylene, polyesters, and nylons, among others. These films can also be pigmented with white, black, or various hues to complement colors printed on the package.

Printing Options

Multilayer flexible-packaging materials are printed using primarily rotogravure and flexographic processes. Unlike traditional lithographic printing process, both flexible material processes lend themselves to the effectively limitless choice of package size available with flexible packaging. These high-quality, high-speed methods provide a full range of textural, machine-readable, and pictorial information. Some materials are printed on their outside surface (surface printing). In such cases, a protective coating is often applied over the ink to protect it from scuffing, chemical destruction, or other abuse. In contrast, the more common practice for multilayer flexible materials is to print on the inner surface of an outer, transparent layer of the multilayer flexible material (reverse printing). The surface is then laminated to the other layers. The outside layer itself then serves to protect the ink from abuse. It also usually presents a very glossy appearance to the package as it is displayed (see also Printing).

PACKAGE BARRIER

Multilayer flexible-packaging materials provide documented levels of barrier to environmental factors: light, moisture vapor, and oxygen (Table 1). These factors can interact with and impair packaged products for which multilayer flexible films provide protection. The materials are generally considered impervious to microorganisms, although packaging shelf-stable processed foods in them requires confirmation of this barrier function down to the level of a submicrometer void (3).

Oxidation of oils fats and vitamins in foods and other products can be retarded by barrier multilayer flexible materials if the oxygen-rich atmosphere within the package is replaced with an inert gas such as nitrogen (gas flush) or evacuated and then sealed under vacuum. Interaction with water vapor can be more dynamic. Dry food (moisture content $<3\%$) and hygroscopic granular products need protection from moisture migrating from a humid exterior into the package. Moist products, including aqueous solutions or suspensions, need moisture-barrier materials that will prevent the loss of product moisture into a low-humidity exterior. Recent advances in controlled and modified atmosphere packaging systems utilize the barrier of flexible multilayer packaging materials to nitrogen, carbon dioxide, and flavors/aromas as well. These barrier functions and standard methods for quantifying them are not generally established in the industry.

Extended Shelf Life

Flexible multilayer packaging is successfully used for retort processing of various food formulations. These "retort pouches" are capable of preserving their contents for 48 months. The primary barrier properties are provided by a layer of aluminum foil or, in a few cases, by a transparent layer of saran (polyvinylidene chloride, "PVDC") film or aluminum-oxide/silicon-oxide-coated plastic films.

Industry-standard practices are established for the safe and reliable production of these packaged products (4).

Shelf-life extension is also achieved in practice by aseptic packaging of sterile products. In this process, a sterilizing technique, such as a steam or hydrogen peroxide bath, or exposure to an electron beam, is used to clean the product-contact surfaces of the flexible multilayer material

Table 1. Typical Transmission by Selected Flexible Materials[a]

			Transmission Rate	
Gauge (mil)	Material	Optics: Haze or Optical Density	Moisture vapor	Oxygen
1	LDPE	6% (haze)	0.8	>100
1	HDPE	30% (haze)	0.35	>100
0.7	Oriented polypropylene	1.6% (haze)	0.49	90
0.5	Oriented polyester	2.5% (haze)	2.8	6
0.5	Oriented nylon	3.0% (haze)	24	4
0.7	Metallized-oriented polypropylene	2.3 (OD)	0.02	8
0.5	Metallized-oriented polyester	3.0 (OD)	0.05	0.08

[a] Values as supplied by various commercial film suppliers. Moisture-vapor values: g/(100 in.^{2} · 24 h) at 100°F and 90% RH. Oxygen values: ml/ (100 in.^{2} · 24 h) at 100°F and 90% RH.

in a sterile environment. Then, while still in a sterile environment, a commercially sterile product is packaged in this material and hermetically sealed.

The barrier properties of flexible multilayer packaging materials are typically not as dependable as that of rigid packages (e.g., metal cans and glass bottles) traditionally used for extended shelf-life packaging. This is the result of (a) imperfections in the thin layer of materials involved, (b) measurable transmission of oxygen through fabricated multilayer polymeric containers, and (c) voids in heat-sealed (i.e., welded) areas of the fabricated containers. Ongoing research is directed toward developing reliable, nondestructive testing of 100% of flexible pouches containing long-shelf-life processed foods (3) (see also Shelf Life).

Material Barrier Properties

The barrier presented by a plastic film to migrating gaseous molecules is a complex property of that film (see also Barrier Polymers). It is considered to be a mass-transport phenomenon in which the gas first dissolves into the polymer; then, it diffuses through small voids in the polymer in response to the net gas concentration differences on either side of the polymer; and finally, desorbs and leaves the polymer on the side of lower concentration (5). In practice, the industry uses an equilibrium (isostatic) technique in which a constant concentration gradient for the permeating gas is maintained across the film. In this steady-state condition, transmission of the permeant is expressed as a mass (or standard volume) of the permeant per unit area in a 24-h period. Ambient temperature and film thickness are also reported (6). Table 1 provides a summary of barrier performance for commonly used films.

The barrier to migrating gaseous molecules presented by aluminum foil is not characterized by this plastic film model. Foil, free from small voids as in polymers, is a perfect barrier to migrating molecules. With the inevitable pinholes in foils (representing $<0.001\%$ of the surface area), however, the transport mechanism is one of flow through orifices (7). At the point of flow, the polymeric model applies, if the foil is laminated to a plastic film.

Barriers to Organic Volatiles

Food and nonfood products often contain volatile components critical to the utility and purpose of that product. Inside a sealed flexible multilayer package, these components can volatize into the headspace of the container. In this mobile form, they can dissolve and diffuse through a polymer film, much like environmental gases. If the solubility and transmission rates are of sufficient magnitude, product shelf life can be significantly decreased. Similarly, volatiles from the enviroment external to the package or from packaging materials themselves can desorb into the package headspace and contaminate products inside. While a variety of proprietary studies have been reported, attempts to develop standardized methods and measures for typical volatiles have gained the support of industry participants only very recently.

Table 2. Materials Properties of Interest

Density	ASTM D1505

PRODUCT CONTAINMENT

This function of multilayer flexible packaging is the most complex, and perhaps the most critical. If the material fails to contain its product properly, its intended appearance and barrier performance are quickly compromised. Containment relies on the physical strength of the composite material to deliver a product securely to its intended market. It also depends on the ability to “seal” packages by using heat and/or pressure to weld opposing surfaces of a two-dimensional leaf of material into the three-dimensional container (e.g., pouch, bag).

Physical Strength

Standard physical measures of material strength are used to characterize films, foils, and papers. Table 2 summarizes typical properties of interest. The specific product to be packaged dictates the level of strength (as measured by any particular physical property) that a composite flexible material must have. For example, dried soup mixes and ground coffee contain small, sharp, granular particles that can readily puncture or rub through a material unless “puncture resistance” is adequate. The actual environmental contexts within which punctures take place are complex and dynamic—so much so that traditional strength of materials measurements taken alone are not sufficient predictors of success in a given application. The pouch of dried soup mix, for example, is typically sold as a multipack inside a paperboard carton. Through distribution and storage, any pouch face in direct contact with the paperboard will experience abrasive forces greater than ones rubbing against other pouches. To satisfy the need to specify materials without the time and expense of dynamic simulation or actual field testing, a variety of specialized tests with associated testing apparatus have been developed to discriminate among the relevant performance levels of various materials (Table 3). Many of these have been adapted from the paper industry where analogous

Table 3. Specialized Materials Properties

Bond strength	ASTM F904

needs for distinguishing among materials in nonpackaging uses have long been recognized.

The growing interest in packaging relatively large volumes of liquids (i.e., >200 mL) demands a new level of strength in multilayer flexible-packaging materials. Linear low-density polyethylene (a copolymer of ethylene and longer-chain α olefins, typically octene) is the material of choice for such applications. Its tensile strength and elasticity can withstand the surges of hydraulic pressure as liquids in pouches are compressed during shipping and handling. Laminating this film to oriented-polyester film with its high tensile strength provides a reinforced composite material with the ability to contain several liters of liquid. This film laminated to oriented-nylon film for its high puncture strength might be the choice if the package must withstand small diameter puncture abuse.

Heat-Seal Strength

Obviously, the container made of a multilayer flexible material can be no stronger than the seals that weld it together. Seals are typically made by applying pressure with heated surfaces to opposing faces of the composite materials, melting the thermoplastic material of the contacting surfaces. The two surfaces then fuse together as the thermoplastics cool.

Cohesive coatings are the major exception to heat sealing. Such coatings are similar to pressure-sensitive ones in that they will adhere when they are applied with pressure to another surface. Unlike pressure sensitives, cohesives adhere only to surfaces coated with similar coatings. In practice, cohesive coatings are applied in a perimeter pattern on the inside surface of a packaging film. The cohesive property allows this pattern-coated film to be unwound from roll form on a packaging machine. The package is formed around a product using only pressure to adhere the opposing cohesive surfaces. Heat-sensitive products, such as chocolate bars, can be wrapped in this manner without melting. Packaging line speeds can also be increased as the sealing pressure can be transmitted to the interface essentially instantly (8). Heat sealing, in contrast, requires time to raise the interface temperature to the melting point because the heated surfaces can contact only the opposite side of the surface to be sealed.

The process of making heat seals relies on the basic thermoplastic properties of the polymers on the inside of a multilayer flexible package (the "seal" layer) (9). In theory, this welding process involves a dynamic fluid material moving under pressure. However, heat-sealing practice for the most part ignores the rheological properties of the molten polymer and uses a static set of temperature, pressure, and time variables to control the heat-sealing process on packaging machinery. A matched pair of sealing "jaws" is maintained at constant temperature and brought together with the packaging material between them. Assuming that the packaging machine's pressure settings are correct, the thickness of the material and the minimum distance between the jaws dictate the pressure at the sealing interface. The "dwell" time during which maximum pressure is maintained is dictated by the line speed of the machinery. The process assumes that the outer layers of the multilayer flexible-packaging material are themselves sufficiently heat-resistant to avoid melting. Paper and cellophane can easily withstand sealing temperatures, typically 250–350°F. Heat-set oriented-plastic films of nylon, polyester, or polypropylene are the usual thermoplastic options. Pressure effects at the interface of seal layers can be enhanced by using serrated or ridge surfaces on the seal jaws that mate with complementary patterns in the closed position. (In theory, such shapes can be used to impart shear forces to the molten polymers. This would cause stronger welds more quickly.) Various preheating techniques (e.g., infrared lamps or heated guide surfaces) have been developed to speed up the process of melting the interface layers. New grades of "metallocene polyethylene'" (linear low-density polyethylene, polymerized using catalyst systems made of metallocene materials) have densities lower than traditional grades. As a result of this combination of density and chemical composition, such products have strength and the ability to seal faster and/or at lower temperatures. (See Sealing, Heat)

While the integrity of the package itself depends on reliable seals, consumer access to the packaged products can require that the seals be broached with relatively little effort. Such "easy-open" seals have been accomplished by a variety of means (Figure 1). One major technique ("seals") involves using a thin layer of low-melt-point polymer as the seal layer. This is welded to itself in the sealing process. As the consumer pulls on the seal to open the pouch, the thin layer breaks away from the other layer(s) of the multilayer material. This allows access to the interior of the package past a layer that was previously buried within the composite material. Alternatively, the seal layer can be contaminated with an immiscible material that is blended into the polymer that will actually melt to form the weld. This can be either an inorganic material or an immiscible polymer with a higher melt point. When the seal is made, the welded area is decreased by the amount of interface area comprised of the "contaminate." This is designed to be large enough to allow access to the package interior by

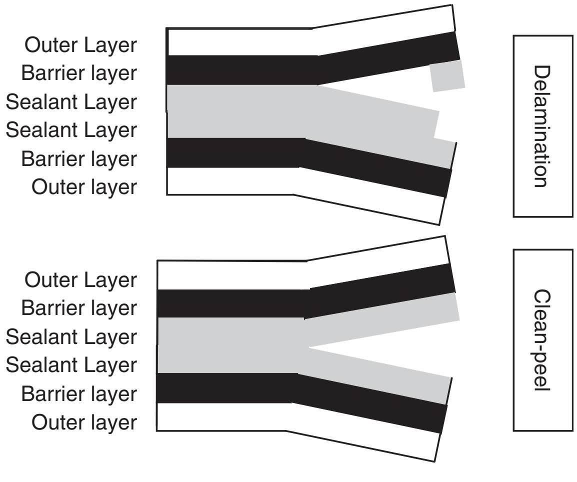

Figure 1. Easy-open seal types.

using a specified force to separate the original seal interface ("clean-peel seals").

Reclosing flexible packages remains an industry challenge. Dry products (e.g., cereals, snacks, cookies, crackers, and pharmaceutical products) can quickly lose their crispness in an opened package. And moist products, such as shredded cheese, can dry out, particularly in refrigerated air. Pressure-sensitive tapes and interlocking plastic ridges (plastic "zippers") are used in several applications at present. Widespread adoption of recloseable features for flexible packages awaits a reliable, low-cost technique. Alternatives to separate pieces of pressure-sensitive tapes have been developed that actually incorporate pressure sensitive layers into the multilayer structure (10). Recloseable zippers for packages have been enhanced with rigid "sliders" that are easily gripped and reliably press the zipper "ridges" together into the closed position (11).

MANUFACTURING MULTILAYER FLEXIBLE PACKAGING

The converting operations for manufacturing multilayer flexible packaging are printing, laminating, and finishing processes. Such operations are designed and equipped to convert a variety of raw materials into many kinds of customized products. Even within a specific category of packaged product, the actual multilayer flexible packaging specified by one customer may differ dramatically from that purchased by another. Differences in product formulations, packaging machinery, distribution systems, and marketing approaches combine to require different levels of appearance, barrier, and containment. These functional differences, in turn, dictate differences in specified raw materials.

Printing

Flexible packaging printing involves both flexographic (images on rubber plates that stamp ink onto a substrate) and rotogravure (images etched into metal cylinders that release ink to a substrate from small engraved cells) printing processes. The choice between processes is now primarily one of customer preference. Historically, converters specializing in foil and opaque packaging were rotogravure printers. Until the 1980s, this process was the only one capable of reproducing quality continuous tone (pictorial) graphics. Flexographic printers were more common among cellophane and plastic-film converters, where transparent packaging required only basic text printing. Flexographic continuous-tone printing has become much more acceptable for high-quality graphics over the past 10 years. With consolidation of converters within the industry and internal diversification by the remaining suppliers, this distinction of capabilities along opaque and transparent substrate lines has virtually disappeared.

Both printing processes use liquid inks comprised of colored pigments, a polymeric "vehicle" (binder), and a volatile solvent. The solvent (an organic liquid or water) is evaporated from the printed substrates as the vehicle solidifies and adheres to the printed substrate. Each of these three ink components must be selected to meet various functional and environmental requirements (12).

When the printed surface is to be the outside of the outer layer of the multilayer flexible package, a protective layer, or overprint varnish, is often applied over the ink to prevent scuffing and to provide a high-gloss effect. This coating must also be resistant to hot sealing jaws that will contact it as heat seals are made. In contrast, when the printed surface is on the inside of the outer layer, the ink must be formulated to adhere to the material that will be used to bond it to the next layer. It must also have an internal strength sufficient to support the overall strength requirements of the entire multilayer material. These properties must be maintained at the temperatures that the ink will experience during heat sealing and any thermal process of the product in the package.

Adhesive Laminating

The majority of adhesive laminations in multilayer flexible packaging are manufactured using the dry-bond process. In this technique, a liquid adhesive is applied to one substrate. Any one of a number of web-coating methods (e.g., direct, offset, or reverse gravure; wirewound rods; air knife) is used to meter and apply the adhesive onto the substrate. The adhesive coating is then dried with hot air. This dried surface can be adhered to a second substrate using heat and pressure at a nip point. The newest generation of flexible packaging adhesives involve 2 or more liquids comprised of reactive prepolymeric chemicals. When mixed, these so-called 100% solids adhesives undergo chemical reactions that essentially bind up all of the applied coating materials into a solid layer of cross-linked adhesive. No volatile diluents need be evaporated from the coatings to achieve the solid layer.

The adhesive formulations themselves represent a reactive chemistry (typically urethanes or acrylics) that is chosen to withstand the processing and distribution environment of the filled product. This can be high temperatures of retort processing (280°F), migrating volatile organics that can redissolve adhesive solids, or other packaging components that can interact to discolor components of the lamination. Because the adhesives are reactive chemicals that are expected to polymerize and/or crosslink when coated, government food-additive regulations control the presence of any unreacted residuals in the composite materials (13). (See also Adhesives.)

Extrusion Lamination

Extrusion lamination involves using a thin (as low as 0.3 mil or 9 μm) layer of plastic (typically low-density polyethylene (LDPE) or a copolymer of LDPE) to bond together two layers of film, paper, and/or foil. The method has the advantage over adhesive laminations of adding substantial thickness to a multilayer lamination as well as contributing to the overall strength of the material. It grew out of the process of coating paperboard with low-density polyethylene (an alternative to wax coatings for such packages as milk cartons) (14). At present, the technique accounts for the majority of printed multilayer flexible packaging.

The process enjoys significant cost advantages over the alternative of producing separate thin layers of polyethylene and using dry bond adhesives to adhere the separate layers together. It has no environmental emissions and permits the processing of thinner layers of plastic than can be handled otherwise. The intrinsic adhesive affinity of low-density polyethylene (LDPE) toward other substrates is limited. However, a variety of LDPE copolymers, adhesion primers, and processing aids have been developed to broaden the applicability of the method (15).

Coextrusion

The cost advantages of extrusion laminations are exploited in the extreme in the coextrusion process. This method entirely eliminates the use of any separately manufactured substrates. It simultaneously extrudes several layers of molten plastic into a single multilayer material. Each plastic maintains its identity as a separate layer in the film and can contribute various functions accordingly. For example, a coextruded film of nylon, ethylene vinyl alcohol, and ionomer provides, respectively, heat resistance, oxygen barrier, and low-temperature sealing for the material used to vacuum-package processed meats. Of course, a pure coextruded film precludes the use of (a) reverse-printed substrates and (b) paper and foil entirely. However, hybrid processes in which a multilayer extruded curtain is used to "coextrusion-laminate" or "coextrusion-coat" traditional substrates have been developed.

Coextrusion has proven to be a powerful option for achieving a mix of functional features in ultra-thin-base films. In effect, base-film suppliers can mix and match materials in a manner analogous to a converter's lamination processes. For example, a current standard seal layer for snack food packaging is a coextruded oriented-polypropylene film comprised of a $\sim 0.05\,\text{mil}$ (1-μm) bonding layer for metal adhesion, a core layer of $\sim 0.6\,\text{mil}$ (15-μm) of homopolymer polypropylene, and a seal layer of $\sim .01\,\text{mil}$ ($2\,\mu$m) of propylene–ethylene copolymer. This film is vacuum-metallized and extrusion-laminated to a reverse-printed 0.7 mil ($18\,\mu$m) oriented-polypropylene film to provide a strong, easy-open package with excellent light and moisture barrier and sufficient oxygen barrier to maintain an internal nitrogen-flush headspace for about 3 months.

Finishing

The converter will print and laminate multilayer flexible-packaging materials in typical widths of 40–60 in. (1–1.7 m). These are usually wider than the rolls that a packaging machine can form, fill, and seal. The converter then slits the wide rolls into several narrower lanes suitable for the customers' machines. This product is then sold in roll form to the customer in very compact form. A typical 0.003-in. (75-μm)-thick multilayer material wound on a core 3 in. (75 mm) in diameter can be delivered in 18-in. (450-mm)-diameter rolls containing about 7000 packages 12 in. (300 mm) long.

An alternative to multilayer flexible packaging in rolls is the premade bag or pouch form. For this product, the front and back of the pouch are printed side-by-side. This single package is folded longitudinally and heat-sealed inside-to-inside along the fold and two of the other three sides. These flat pouches are sent to the customer, who fills them with product and seals shut or otherwise closes the fourth side.

CURRENT TRENDS IN MULTILAYER FLEXIBLE PACKAGING

Innovation has been a reliable characteristic of flexible packaging over past decades (16), and significant development efforts continue to introduce new flexible films and composites that improve package functionality in essentially all of the areas discussed here. Recently, two emergiing issues, packaging sustainability and active/smart packaging, have emerged to further drive industry inovation.

Appearance

New technical processes for achieving appropriate quality for the graphical images reproduced on flexible packaging materials are being actively developed in the first decade of the 21st century. Increasingly, graphics origination, review, and appproval efforts are accomplished using Internet-based exchange of digital files. Such files are in turn used to generate digital printing media (flexo plates or cylinders). Techniques exist to actually drive digital print engines to print flexible packaging materials, but are not widely used at this writing because of ink costs and limited throughput.

Advanced digital controls on printing presses permit the adoption of "expanded color gamut" printing. This technology tracks the color value and printed density of six or seven standard colors (compared to the four traditional "process colors": cyan, magenta, yellow, and black) in order to provide specific colors and color effects with regularity and consistency between production lots.

Criminal efforts to market counterfeit branded goods have stimulated the development of various appearance techniques to authenticate the source of packaged goods in the market place. These include overt (visible to the consumer) methods as holographic reproductions. Covert means (such as fluorescent inks) support scrutiny of wholesale or retail stocks by trained agents of producers or buyers of the packaged goods.

Barrier

Transparent alternatives to opaque foil and metallized multilayer barrier materials increasingly find their way into commercial packages. The most common of these are ceramic or metallic oxides (for example, silicon and aluminum oxides) that are deposited on plastic films in vacuum coating operations comparable to those used to produce widely used metallized barrier materials. The oxide vapors are produced with evaporative methods from solid forms of the compounds or with reactive methods in which precursors of the oxides are introduced into a chamber and plasma or chemical reaction energy used to form the oxides. Other transparent coating techniques have been developed to combine the oxygen barrier properties of polyvinyl alcohol with the moisture barrier properties of a metallic-compound-containing material (17).

Nanotechnology in flexible barrier materials is most evident in attempts to disperse nanometer-thick platelets of naturally occurring clay minerals in polymers. The objective is to arrange the platelets so as to form a "tortuous path" for gaseous molecules that would permeate through a polymer layer. The technology is now best practiced with polymers, such as nylon and ethylene vinyl alcohol, that have regions of relativlely strong electrostatic polarity distributed throughout them. Nonpolar molecules, especially polyolefins, are unable to break apart the natural clay particles to achieve the needed distribution of platelets in the polymer. Research into the use of surfactants (with their distinct polar and nonpolar ends) has shown promise in effectively dispersing platelets into polyolefins.

Containment

Ironically, flexible packages seem to be trying to become more rigid, at least stiff enough to stand up. The Doyen standup pouch concept has been used for hot-fill juice containers for over three decades (18). European and Japanese consumers are exposed to many other commercial examples at present. In the United States, many domestic market introductions have succeeded. The format is now a mainstay for consumer products in the States. In the 2007 Flexible Packaging Association (FPA) Achievement awards and Innovation showcase, 13 Doyen-style pouches were recognized (19). Further evolution includes pouches shaped to suggest their prior rigid package formats, such as (a) bottles or jars (three such examples were included in the 2007 FPA awards) and (b) pouches fabricated with flat bottoms perpendicular to distinct side panels (six such examples included in the 2007 FPA awards).

Ease of opening for flexible packaging has emerged as a significant challenge to growth for the industry (20). An aging population with decreasing manual dexterity has come to demand easy-opening flexible packaging and can recognize the differences, as "Consumer Reports" found with three different brands of ready-to-eat cereal with flexible coextruded film liners in folding cartons (21).

Packaging Sustainability

By nature, multilayer flexible packaging contains many materials intrinsically bonded together. This fact mitigates against recycling the component materials, as has been possible for many monomaterial packaging systems (e.g., HDPE merchandise bags and milk bottles, PET beverage containers, aluminum cans, and glass bottles; note that some progress has been made in separating at least some components of multilayer materials for economic recovery) (22). Rather than minimizing packaging residuals after use by recycling, the flexible-packaging industry has been urging consumer and regulatory consideration of the advantages of using less packaging material for a product as it is put into commerce (23). Flexible-material packaging systems offer significant reduction of both waste volumes and weights when compared to traditional systems. A few of these are summarized in Table 4.

Table 4. Flexible-Packaging Source Reduction

Packaging System		Reduction (%)	
Baseline	Reduced	Weight	Volume
Coffee can	Brick pack	70	55
Detergent bottle	Concentrate pouch	85	84
Diaper carton	Film bag	85	86
Soup can	Soup pouch	93	97
Glass bottle	Flexible pouch	96	82
Glass bottle	Drink box	90	70

Source: Flexible Packaging Association.

Other strengths regarding sustainable industrial development practices exhibited by flexible packaging come from the ability to use "biopolymers," polymers from carbon sources grown in contemporary farming, forestry, or aquaculture systems, rather than from fossil fuels. Modified starch has been extruded into film and fabricated into bags. Lactic acid has been extracted from corn and then polymerized into polylactic acid. Numerous flexible barrier packages have incorporated this material into commercial packages at this writing.

Active/Smart Flexible Packages

"Active packaging" (packaging that changes conditions and/or environment in the package to extend shelf life,

enhance sensory properties, and/or improve food safety) and "smart packaging" (packaging that senses change and/or changes package properties) technologies have long been recognized in the packaging industry as possible, but for a variety of commercial and legal issues have not been widely adopted in the U.S. consumer market. The European Union, in contrast, has actively encouraged commercialization of the technologies. The European "FAIR" Project CT98-4170 sought "[t]o enable the application of active and smart concepts throughout Europe and to establish and implement these concepts in the current relevant regulations for food packaging in Europe." In their view, "Active packaging … will likely emerge as the preservation technology of the twenty-first century" (24).

Cooksey reported on commercial applications of active and smart packaging technologies in 2006 (25) A summary of these examples is given in Table 5. The table also indicates whether the technology is "integral" to the packaging material or a "separate" label, sachet, or other device incorporated into the package.

As is apparent here, much of the commercial and proposed application of active/smart packaging technology intends the use of separate and additional components in or on the package (along with the product itself) rather than a packaging material that inherently provided the functionality itself. Such merged material performance is the subject of much current research (26).

NANOCOMPOSITES CURRENT INTEREST AND APPLICATIONS IN FOOD PACKAGING

Nanotechnology is by definition the creation and use of structures with at least one dimension in the nanometer-length scale that creates novel properties and phenomena otherwise not displayed by either isolated molecules or bulk materials. Since Toyota researchers in the late 1980s found that mechanical, thermal, and barrier properties of nylon-clay composite materials improved to a significant extent by reinforcement with less than 5% of clay (1), extensive research work has been performed in the study of nanocomposites for packaging application. The term “nanocomposite” refers to composite materials that contain typically low additions of some kind of nanostructured materials. Most nanocomposites being considered in the packaging sector are based in low additions, typically 1 to 7 wt.-%, of modified nanoclays.

Nanoscale structures display a high surface-to-volume ratio, which becomes ideal for applications that involve composite materials, chemical reactions, drug delivery, controlled and immediate release of substances in active an functional packaging technologies, and energy storage, for instance, in intelligent packaging (2, 3).

Until recently, the most interesting packaging technology based on blending to generate barrier properties was the so-called oxygen scavengers. This technology is known to lead to relatively low levels of oxygen in contact with the food because it traps permeated oxygen from both the headspace and the outside. However, in carbonated beverages for instance, a barrier to carbon dioxide is also a requirement. As most commodity plastic packaging materials, e.g., polyethylene terephthalate (PET) and its main sustainable counterpart the PLA, are not sufficient barrier to these gases, multilayer structures had to be devised in which one layer (made of Ethylene vinyl alcohol copolymer (EVOH), MXD6, polyethylene naphthalene (PEN), and nanocomposites of PA6) needs be high barrier to carbon dioxide and to oxygen. An alternative, technology is the use of oxygen scavenger but these only reduce O_2, and not CO_2, at the packaging headspace. The nanobiocomposites technology can overcome this in monolayer solutions because barrier properties are usually not only to oxygen but also to other gases and low-molecular-weight components such as water vapor and food aroma components (4).

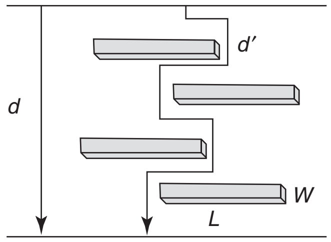
In general, the rationale behind the interest of the nanocomposites is that with low additions of the nanofiller, many relevant properties can be enhanced without a significant drop in interesting properties of the matrix such as transparency or toughness. As stated above, one property that has attracted more interest in the food-packaging area, because of its direct implication in food quality and safety issues, is the possibility of increasing the barrier properties to gases and vapors of plastics and bioplastics. Thus, by simple application of models such as the one of Nielsen, and for the case of laminar structures with high aspect ratios (L/2W of 180), the model predicts permeability reductions of the matrix of up to about one order of magnitude for fractional volume (φ) layered clay additions of ca. 0.05 (see Figure 1).

In this technology, it is reckoned that the presence of exfoliated layers of clay in the polymer results in enhancement of the so-called tortuosity (or detour) factor. The equation in Figure 1 shows a simple formalism to model permeability of systems comprising impermeable plates of a layered filler oriented perpendicular to the permeant transport direction and evenly dispersed across the polymer matrix. The use of other models such as the one of Cussler predicts even higher permeability reductions but most experimental data with barrier improvements below 10-fold fit better the above Nielsen model (5).

Numerous studies in the literature report that experimental improvements in barrier properties to water vapor, i.e., about 60% permeability reduction in polyvinyl alcohol (PVOH) (6) and even larger in gluten at 11% relative humidity (RH) (7), and to oxygen [above 75% in EVOH (8–10) and up to 64% in polylactic acid (PLA) (11, 12)], can be achieved via polymer nanocomposites. It is therefore a proven fact that the integration of ceramic nanoparticles with tailor made modifications in plastics matrices does help increase the barrier to oxygen and vapors and reduce the water sensitivity of biopolymer matrices.

There are several technologies to achieve nanodispersion, namely, in situ polymerization, dispersion in solution, and dispersion by melt blending. The latter route is perhaps the most interesting methodology from an applied view point because it can be used more widely to convert most plastics into final articles (13–15).

Nanoclays are currently being considered as barrier layers in multi-layer packaging to improve barrier



$$\frac{P_{nano}}{P_{matrix}} = \frac{1-\phi_{clay}}{1+\dfrac{L}{2W}\phi_{clay}}$$

Figure 1. Schematics showing the tortuosity effect imposed by nanolayered clays to the transport of low-molecular-weight components through a film and a typical model equation that takes this effect into account in the permeability coefficient.

properties and extend shelf-life (16). The fastest growing barrier application for nanoclays is bottles for beer, carbonated soft drinks and other carbonated beverages (17) and film applications (18).

Most nanocomposite technologies make use of chemical or otherwise modifications of layered 2:1 phyllosilicates (19). The modification is needed both to compatibilize highly hydrophilic clays with the more organic apolar chemical constitution of most plastic materials and to increase the clay intergallery space (basal space between adjacent layers), which facilitates both intercalation and exfoliation of the clays laminar components in the matrix during compounding. In the food chain, specific caution should be taken because the applied modifications should be harmless, comply with migration regulations, and make use of food contact approved substances as valid modifiers. Unfortunately, for most technologies and producers, this is not the case, and it will limit the implementation of the nanocomposites in the food packaging sector.

In this context, it is well known that most nanocomposite formulations (first generation nanocomposites) in the market are currently making use of some not European union (EU) listed ammonium salts as organophilic chemical modifiers, which have been devised to enhance the properties of engineering polymers in structural applications. However, as mentioned above, for food-packaging applications, only food contact approved materials and additives should be used, and they should do so below their corresponding threshold migration levels. In this respect, Nanobiomatters S.L., Paterna (Spain) and its second-generation nanocomposite products traded as NanoBioTer® claim to comply with the current food contact legislation. Second-generation nanocomposites are therefore referred to as nanocomposite technologies, which are specifically designed to comply with current regulations and at the same time are cost effective and specifically formulated to target specific materials (including biopolymers), materials properties, or production technologies. In essence, second-generation nanocomposites are materials with targeted specifications rather than wide-spectrum generic formulations.

Despite the fact that multilayer solutions are currently needed in many food-packaging applications including the above-mentioned carbonated beverages, a monolayer solution would be of great interest for many reasons, including recyclability, a technology, and material costs. The nanocomposites technology can also make this possible by simple melt or solution blending routes. The reason why in PET bottles, nanocomposites are still devised to be used in multilayer systems (such as Imperm™ nanocomposites of PA from Nanocor) is because PET nanocomposites are extremely difficult to obtain in a monolayer case because of the high temperature needed to process the polymer, which causes degradation of the organophilic chemical modification of the layered clay particles.

Companies are already developing packaging materials based on nanotechnologies that claim to extend the shelf life of foods and drinks. Several large beer makers, including South Korea's Hite Brewery and Miller Brewing Company, are already offering the technology. However, nanocomposites for packaging have been developed for a limited number of polymers, e.g., PAs, thermosetting epoxies and, to some extent, PET (20), and their food contact status remains unclear.

Table 1 summarizes the companies and the barrier technologies that have been developed for improving the properties of thermoplastics materials. From Table 1, nanoclay companies developing nanocomposite materials in the food-packaging sector are NanoBioMatters S.L. and Nanocor (part of Amcol International). Nanobiomatters S.L. (Paterna, Spain) offers a wide range of commercially available food contact compliant nanoclays and plastic masterbatchs for enhancing physical properties such as barrier to gases, vapors, and ultraviolet (UV) light and thermal and mechanical properties, as well as specialty grades that can exhibit active properties such as antimicrobial, oxygen scavenging and antioxidant performance (21). The Nanocor company is currently producing nanocomposites for use in plastic beer bottles that give the contents a 6-month shelf life (22). TetraPak and Eastman are developing nanocomposites of PET materials (23–26), and ICI is developing also nanocomposites of PET (27). Ube (Allied Signa Bayer) (28) and EMS Chemie is developing nanocomposites of PA-based systems (29).

Table 1. Summary of suppliers and of the barrier nanotechnology they are developing or offering at a commercial level

Company	Material	Application	Development status
NanoBioMatters S.L.	Nanocomposites/EVOH/PET/LDPE/PLA/PHB/PCL	Film	Commercial
NanoBioMatters S.L.	Active nanocomposites	Biocide, antioxidant Film	Commercial
Nanocor/Amcol Int.	Nanocomposites		Development
EMS Chemie	Nanocomposites/PA	Film	Commercial
Ube	Nanocomposites/PA	Film	Commercial
Allied Signal	Nanocomposites/PA		Development
Bayer	Nanocomposites/PA		Development
Honeywell	Nanocomposites/PA		Commercial
ICI/DuPont	Nanocomposites/PET	Film	Development
Eastman	Nanocomposites/PET	Bottles	Development

ICI	Nanocomposites/melamine	Bottles	Development
PPG Industries	Nanocomposites/epoxy	Bottles	Development

PA, polyaniline; PCL, polycapro lactone; PHB, polyhydroxybutyrate.

NANOCOMPOSITES RESEARCH DEVELOPMENTS TO ENHANCE BARRIER PROPERTIES

Several research studies published in the scientific literature detail barrier improvements for plastic-clay nanocomposites. Table 2 summarizes the most relevant works reporting barrier improvements in nanocomposites of plastics of interest in food-packaging applications.

PET is one of the most widely studied materials regarding nanocomposites, Sánchez-García et al. (30) reported improvements in oxygen permeability of about 55% in melt mixed nanocomposites of PET with 5 wt.-% nanoclay (based on a food contact approved montmorillonite (MMT) traded as NanoBioTer), with regard to the pure PET. Limonene permeability improvements of about 68% for composites containing 5 wt.-% of nanoclay and a water vapor permeability improvement of about 43% in nanocomposites containing 1 wt.-% of nanoclay were also reported. Ke et al. (31) reported a 25% oxygen permeability reduction for PET containing 1 wt.-% of organically modified montmorillonite [organical montmorillonite (OMT), containing an interlayer agent comprising a –COOH group in its structure] by using an in situ interlayer polymerization route. More recently, Choi, W.J et al. claimed to have obtained a 94% oxygen permeability reductions in PET containing 5 wt.-% of MMT (MMT-Na-with chlorotitanium triisopropoxide used as a catalyst) nanocomposites by an in situ polymerization process (32). Fifty percent oxygen permeability reduction for PET–MMT nanocomposites obtained by melt blending in a rheometer was also reported by Vidotti, et al. (33). Lai et al. (34) studied amorphous films of poly(ethylene terephthalate-co-ethylene naphthalate) (PETN) and PETN/Cloisite 30B (MMT-$(OH)_2$; MMT modified with methyl bis(2-hydroxyethyl) (hydrogenated tallowalkyl) ammonium cation)) nanocomposites prepared in a twin screw extruder. The PETN containing 2 wt.-% of the MMT-$(OH)_2$ clay showed a 50% reduction in O_2 permeability compared with the neat PETN. So, to enhance the polar interactions between the organoclay and the PETN matrix, the organoclay surface was treated with a diepoxide, diglycidyl ether of bisphenol A (DGEBA). Therefore, with the addition of epoxy (by melt intercalation and the weight ratio of epoxy to PETN was (0.75/100) in the finished composite), a permeability reduction higher than 88% was obtained with compared the neat PETN (34).

For the case of polyamides, Yano et al. (35) reported that the polyamides have a reduction of the water permeation coefficient of about 54% with only 2 wt.-% of an OMT (MMT-intercalated with an ammonium salt of dodecylamine) compared with the unfilled polymer. Picard et al. (36) measured that the diffusion rate slowed down by about 55% going from neat PA to polyamide 6 containing 13 wt.-% OMT (organically modified with a dihydroxy methyl tallow quaternary ammonium) nanocomposite prepared by melt mixing. Pinnavaia et al. (37) reported that the rate of water absorption in PA6 nanocomposites was lowered by 40% compared with the neat polymer.

Table 2. Relevant reported reductions (%) in oxygen and water vapor permeability of nanocomposites of some widely used polymers

Matrix	Type of clay	Clay content	O_2 Permeability	H_2O Permeability
PET (30)	MMT	5%	55%	
PET (30)	MMT	1%		43%
PET (31)	MMT	1%	25%	
PET (32)	MMT	5%	94%	
PET (33)	MMT	5%	50%	
PETN (34)	MMT	2%	50%	
PA (35)	MMT	2%		54%
PA (36)	MMT	13%		D 55%
[38]Nylon6	MMT	6%	28%	
[38]Copolyamide-Nylon6	MMT	6%	54%	
[40]LDPE	MMT	7%	24%	
[41]LLDPE	MMT	5%	15%	
[42]LDPE	MMT	5%	30%	
[43]EVOH	MMT	5%	75%	
[45]PP	$CaCO_3$	3%	30%	
[47]PP	MMT	4%	50%	
[48]PP	MMT	5%	57%	
[49]PS	MMT	7%	60%	
[51]PI	MMT	5%	69%	
[52]PI	MMT	0.5%	46%	48%
[53]PI	MMT	4%		82%
[54]Natural Rubber Latex	MMT	2%	66%	
[56]PVC	SiO_2	3%	40%	45%
[57]Resin Epoxy	Zirconium phosphate/phosphonate	5%	59%	
[58]PU	Natural Unmodified MMT	5%	41%	
[59]PU	MMT	3%	30%	50%
[60]PSF	MMT	3%	72%	30%

PA, polyaniline; pp, polypropylene.

Russo et al. (38) reported an oxygen barrier improvements for the PA6 (nylon 6) with 6 wt.-% of Cloisite 30B of about 28% compared with the pure PA6. They also study the copolyamides of PA6 containing 6 wt.-% of Cloisite 30B, and the oxygen permeability reduction was of about 54% compared with the pure copolyamide (38). Moreover, Jiang et al. (39) published that the barrier performance of exfoliated PA6 with an OMT (OMT was synthesized by a cation-exchange reaction between Na-montmorillonite and octadecylammonium salt) was improved markedly by adding a small amount of the clay, having a toluene and ethanol permeation rate in the composite sheet 3–4 times slower than in neat PA6.

Regarding polyethylene, Supong Arunvisut et al. published that a low-density polyethylene LDPE containing 7 wt.-% of OMT (MMT was mixed with Di(hydrogenated tallowalkyl) dimethyl ammonium chloride) exhibited a decreased oxygen permeability of 24% compared with the pure material (40). Ali Durmus et al. (41) measured a reduction in the oxygen permeability of ca. 15% with the addition of 5% OMT traded as Cloisite 20A [MMT modified with dimethyl dihydrogenated tallow quaternary ammonium salt, MMT(2Me$_2$HT)] to linear LDPE (LLDPE). Finally, Zhong et al. (42) reported that incorporating 5 wt.-% of the MMT(2Me$_2$HT) clay, the oxygen permeability of an LDPE maleic anhydride grafted polyethylene (MAPE) system prepared by melt mixing decreased by 30%.

Lagaron et al. (43) reported many significant results where nanotechnology was satisfactorily applied to improve packaged food quality and safety by increasing the barrier properties to oxygen of an ethylene-vinyl alcohol copolymer (EVOH) under dry and humid conditions using nanoclays (MMT and kaolinite). The authors measured a reduction in oxygen permeability of more than 75% in dry conditions and a reduction of 71% for the nanocomposites of EVOH at 85% RH.

Regarding poly(ethylene-co-vinyl acetate), Muralidharana et al. (44) reported the characterization of ethylene vinyl acetate (EVA)/MMT (natural sodium MMT clay) nanocomposite membranes with different clay loadings. The solvent uptake was minimum for composites with 3 wt.-% of the nanoclay and increased with increasing filler content, presumably because of aggregation of the clay filler at higher loading. They claimed a reduction in the diffusion coefficient of benzene, toluene and xylene of about 50%, 48%, and 40% for the nanocomposite with 3% clay, respectively.

In regard to propylene, Avella et al. (45) measured a reduction in barrier properties both to oxygen and to carbon dioxide of about 30% on nanocomposites of polypropylene containing 3 wt.-% of CaCO$_3$. Giuliana Gorrasi et al. (46) reported that samples of polypropylene containing 1 and 2 wt.-% of organomodified fluorohectorite showed a linear decrease in the diffusion coefficient until about the 3% of solvent sorbed dichloromethane vapor. Mittal et al. (47) prepared polypropylene nanocomposites containing different volume fractions of an OMT (MMT modified with an dialkyl imidazolium salt) and measured oxygen permeability reductions of about 50% for samples containing 4 wt.-% of the nanofiller (47). Finally, nanocomposites of polypropylene with 5 wt.-% of an OMT (a MMT modified with a nondisclosed alkyl ammonium salt) also showed a reduction in the oxygen permeability of about 57% and a reduction in the dioxide permeability of about 48%. The composites were prepared by a solvent blending method by Frounchi et al. (48).

In the case of polystyrene, Meneghetti et al. (49) synthesized polystyrene (PS)/clay nanocomposites via in situ polymerization with an OMT (the MMT was ion exchanged with zwitterionic surfactant (C18DMB)) that resulted in an intercalated morphology. The oxygen permeability decreased by more than 60% over pure PS for the intercalated nanocomposite containing a 0.07 volume fraction of clay.

Regarding polyimides, Yano et al. (50) claimed that only a 2 wt.-% addition of a synthetic mica led to a decrease in the gas permeability coefficient to a value less than one tenth that of the pure polyimide. Huang et al. (51) reported a decrease in the oxygen permeability of about 69% with a 5 wt.-% of OMT clays (MMT modified with alkylammonium ions) in a polyimide prepared by in situ polymerization. Yeh et al. (52) reported that a polyimide prepared by solvent casting containing an OMT (MMT modified with an alkyl ammonium salt) (0.5 wt.%) exhibited about a (53) 48% and 46% decrease in H$_2$O and O$_2$ permeability, respectively (52). Jin-Hae Chang et al. obtained an 82% reduction in the water permeability coefficient with the addition of 4 wt.-% of OMT (Na–MMT modified with an ammonium salt of hexadecylamine) in a polyimide (PI) nanocomposite film, as compared with the same PI film without nanoclay, both prepared by solution casting.

In the case of the natural rubber latex prepared by casting, the addition of 2 wt.-% of natural sodium MMT yielded a reduction in oxygen permeability of about 66% compared with the unfilled material (54). Liang et al. (55) discussed a reduction in nitrogen permeability of ca. 22% in an isobutylene–isoprene rubber (IIR) containing 5 wt.-% of OMT (MMT modified with butyl alcohol).

Concerning poly(vinyl-chloride) (PVC), Zhu et al. (56) reported the barrier properties to O$_2$ and H$_2$O of nanocomposites of PVC prepared by melt mixing as a function of nanofiller content. The PVC nanocomposites containing 3 wt.-% of SiO$_2$ led to an oxygen permeability reduction of about 40% and for the case of water of 45% compared with the same unfilled material.

In the case of epoxy resins, Tsai et al. (57) reported the preparation of novel nanocomposites of an epoxy resin containing zirconium phosphate/phosphonate derivative (Zr-P). The oxygen permeability decreased by about 59% and the nitrogen permeability decreased by about 53% for the nanocomposite containing 5 wt.-% of Zr-P compared with the unfilled material.

For polyurethanes, Choi et al. (58) claimed to have obtained a reduction in the oxygen permeability of about 41% for the PU containing 5 wt.-% of OMT (clay modified with hydroxyl end group) obtained by a film-casting method. Osman et al. (59) reported a reduction of the oxygen transmission rate of about 30% and a reduction in the water permeation of 50% for a polyurethane (PU) containing 3 vol.-% of OMT [the inorganic cations of the MMT were exchanged with the organic ammonium ion bis(2-hydroxyethyl) hydrogenated tallow ammonium].

Regarding polysulfones (PSF), Yeh et al. (60) developed and characterized PSF containing OMT (MMT modified with intercalating agent dodecylamine) nanocomposites, which were prepared via a solution dispersion method. Compared with the neat PSF, membranes of nanocomposite PSF materials containing low nanoclay loading (3 wt.-%) showed about 30% and 72% reductions in H_2O and O_2 permeability, respectively.

Even though many studies in the literature report about barrier enhancements in polymer and biopolymer matrices, it is clear from the modeling results (see Figure 1) that the expected improvements are not yet experimentally attained or reproducible. This is the result of lack of (a) complete exfoliation of the nanofiller, (b) good compatibility between the filler and matrix, and/or (c) good purification and appropriate selection of raw materials and surface modifications. In general, there is still a need for a deeper understanding of the composition-structure-processing-properties relationships in nanoclay-based nanobiocomposites both at a laboratory and at an industrial scale. Moreover, because most extensive studies related to nanoclays have been carried out using few nanoclay grades (based mostly on MMT), in many cases from the same commercial supplier, there is still a lot of room for variation and maturation in the nanoclay-based composites area.

Most applications of nanocomposites in plastics have made use of laminar clays and in some cases of carbon nanotubes. However, other types of reinforcing elements such as biodegradable fibers obtained by electrospinning are promising in several application fields (61, 62). The electrospinning method is a simple and versatile technology that can generate ultrafine fibers, typically in the range from 50 to 500 cm^3, of many materials. The produced fibers have large surface-to-mass ratios (up to 10^3 higher than a microfiber), excellent mechanical strength, flexibility, and lightness. The obtaining procedure is not mechanical but electrostatic and is applied to the polymer in solution or to polymer melts. As a result of the latter, it is a suitable technique for the generation of ultra-fine fibers of biodegradable materials, which are in general easy to dissolve. It has been reported that around 100 different polymers (including biopolymers) and polymer blends have been nanofabricated by electrospinning. Even though significant body of literature report about the characterization of nanofibers, not many studies exist that examine the properties of nanocomposites of materials containing these fibers. One of the most interesting aspects of the electrospinning methodology is the possibility of the incorporation of various substances, including fillers such as clays as well as bioactive agents in the electrospun fibers. This advantage has already been considered in the controlled release of bioactive principles in the pharmaceutical and biomedical fields (62) and can also be applied to the controlled release of active and bioactive food-packaging applications (3).

NANOTECHNOLOGY AND PACKAGING

SUSAN SELKE
Michigan State University
School of Packaging, East
Lansing, Michigan

WHAT IS NANOTECHNOLOGY

In recent years, a lot of public attention has been given to nanotechnology, with both claims and fears making headlines. What may easily be obscured in all the hype is just what nanotechnology is and isn’t. The simplest definition of nanotechnology is that it is technology involving structures with one or more dimensions that lie between 1 and 100 nanometers (1 nm = 0.000000001 m). It has been discovered that at these very small sizes, particles of “ordinary” materials can have properties that are significantly different from those the material has when its particles are larger. Among these properties can be differences in reactivity, color, the ability to move through barriers, and so on. The underlying reason for the change in properties is that atomic properties such as quantum effects and wave-particle duality that do not have observable effects at larger scales do have profound impacts on behavior at these tiny sizes. Furthermore, nanoscale materials have much larger surface areas than similar amounts of larger particles, so their potential for interaction with surrounding materials is much greater.

Some effects associated with nanoscale structures have been known for a very long time. Medieval stained glass windows and ancient pottery get some of their colors from nanopigments. Gold particles, for example, can impart an orange color, a red color, or even a greenish color, depending simply on the size of the particles incorporated. Other materials that we use have always had “particles” in this size range, so they behave as we’ve expected them to. For example, antioxidants in plastic films, sugar in water solution, and plasticizers in PVC blisters have components that are nanoscale in size. The key difference in the “nanotechnology” that is getting all the attention is related to materials that we normally use at large scale, but that have different properties when their particle size is reduced.

Perhaps in part because of this, some definitions of nanotechnology have tried to require more than just size. A common approach has been to require that to be “true” nanotechnology, the materials have novel properties and functions because of their small size, and/or that they involve the ability to control or manipulate materials on an atomic scale. Of course, one of the problems with such a definition is the vagueness of “novel.” Does something cease being nanotechnology once we become accustomed to it? Even controlling or manipulating materials on an atomic scale isn’t really new. All chemical reactions involve such phenomena to some extent.

To further complicate the issue of definitions, not all products that use nanotechnology explicitly state that they do so, and some products claim to use nanotechnology when they really do not. Furthermore, some products use nanotechnology in manufacturing, but there are no nanoscale structures in the finished product. So, it is understandable that there remains a degree of vagueness about what is and is not nanotechnology, in packaging as well as in other fields.

The official U.S. definition of nanotechnology comes from the National Nanotechnology Initiative: “Nanotechnology is the understanding and control of matter at dimensions between approximately 1 and 100 nanometers, where unique phenomena enable novel applications. Encompassing nanoscale science, engineering, and technology, nanotechnology involves imaging, measuring, modeling, and manipulating matter at this length scale.” This definition importantly recognizes that 100 nm is not a firm size line between “nano” and “not-nano.” Also, it is recognized that nanoscale materials and effects are not limited to synthetic substances, but are also found in nature. For example, spider silk is naturally reinforced by nanoscale crystals (1).

NANOTECHNOLOGY IN PACKAGING

Nanotechnology has applications in a vast array of fields. Our discussion here will be limited to those applications that are relevant to packages or packaging materials. By all accounts, this is a significant sector of packaging, and it is predicted to grow rapidly. A 2005 study by Helmut Kaiser Consultancy (2) reported that there was $860 million in U.S. sales of nano-related food and beverage packaging in 2004, with more than 250 nano-packaging products in the market. Furthermore, the study predicted that nanotechnology would affect 25% of the food packaging business over the next decade, reaching a value of $20.4 billion by 2010. Much of this is expected to be for the food products themselves. Packaging applications mentioned included improvement in material performance and extension of product shelf life, along with special features such as antimicrobial action, tailored permeabilities, and embedded sensors. A 2007 update reported that the 2005 "nano-featured food packaging" market had a value of $1.1 billion and was anticipated to reach $3.7 billion in 2010. Furthermore, the prediction was that the "nano-bio-info convergence" would influence over 40% of the food industry by 2015 (3).

Similarly, a 2004 report from Pira (4) reported that benefits of nanotechnology in packaging included (a) longer shelf life, (b) improved high-temperature performance permitting hot fill, (c) thinner flexible packaging films, (d) functionality of various types, including anticounterfeit, antitamper, and antimicrobial, (e) various types of sensors, and (f) integrated power for features such as self-healing containers and intelligent tags. The study also mentioned nano barcodes for track and trace and sensing, use of nanotechnology in the production process for paper, nanoscale pigments for inks, the use of nanomaterials to obtain colors without requiring dyes or conventional pigments, and electronic displays based on nanomaterials that provide the quality of paper.

While some of these early studies likely overplayed the impact and usefulness of nanotechnology in packaging, there are significant applications where nanotechnology provides real advantages. In this article, we will group these current and potential applications into three main categories: barrier, improved mechanical performance, and communication/sensing, with a fourth category of miscellaneous for applications that do not readily fit within these three. Please note that the discussion that follows is meant to be illustrative, rather than inclusive, because the number of applications of nanotechnology in packaging greatly exceeds the space available for discussion, and new uses, materials, and systems arise constantly.

Barrier

Use of nanomaterials to improve the barrier of packaging materials, generally plastics, was one of the earliest applications to be tagged with the "nano" identifier. It is also one of the areas where definitions are fuzzy. Metallized film, for example, is not generally labeled as "nano" yet the aluminum thickness is generally 40–50 nm, so it certainly could be so categorized. The primary function of the aluminum layer is to improve barrier, often especially to oxygen.

Similarly, SiO_x coatings, such as on film or on PET bottles, generally have a thickness of 40–60 nm. This glass-like coating, usually inside but sometimes outside the bottle, also acts to improve barrier. Aluminum oxide coatings are also used to improve barrier, and they are applied at nanoscale thickness. Usually, these coatings are not marketed as nanotechnology.

In contrast, the amorphous carbon systems, also used as coatings to improve barrier, have been marketed as nanotechnology in some cases. Sidel's Actis™ system applies a layer of 20–200 nm of amorphous carbon to the inside of PET bottles, Actis Lite™ provides a thinner layer. Kirin and Mitsubishi Shoji Plastics implicitly claim nanotechnology for their "Plasma Nano Shield" system, which provides a 20 to 40-nm-thick layer of amorphous carbon. This system was previously called "Diamond-Like-Coating" (5).

Most often, nanotechnology for barrier improvement is associated with the development of nanoclay composite structures. These are based on various types of layered clays, most commonly montmorillonite. When properly formulated and processed, the clay is exfoliated, splitting into platelets that are typically about 1 nm thick and 70–2000 nm in length and width. The clay particles are not mobile in the polymer, and they present a torturous path for the diffusion of gases, which cannot pass through the clay platelets. It is reported that 10% clay can cut permeation rates by as much as 75% (6, 7).

There are two major U.S. nanoclay suppliers. One is Nanocor (8), which produces the Nanomer brand for use with nylon resins, polyolefins, and other products. The other is Southern Clay Products (9), which markets under the Cloisite brand.

Mitsubishi Gas Chemical markets Imperm N™ PET bottles, films, and thermoformed containers that contain Nanocor nanoclay. The barrier layer is M9™, which is a nanocomposite with clay platelets in MXD6 nylon (10–12).

Similarly, Honeywell markets Aegis resins for multilayer PET bottles. These resins, available with and without oxygen scavenger, are also based on nanoclay from Nanocor. The clay particles are said to conduct the oxygen molecules to specific oxygen-capture sites in the nanocomposite (11–13).

Southern Clay Products' Cloisite nanoclay has been used to enhance the barrier of ethylene vinyl alcohol (EVOH) for long-shelf-life packaging, in a joint development effort by the U.S. military, NASA, and Triton Systems, Inc. (11, 12).

Alcoa filed for a patent on coextruded barrier liners for plastic bottle caps that contain a nylon 6/nanoclay composite, along with oxygen scavengers, to protect oxygen-sensitive products such as beer or juice. The liners are reported to be better than other barrier materials at very high humidities (11).

Other nanominerals can also be used to improve barrier or other performance properties. In 2006, Nanova, LLC was listed as a supplier of nanotalc and nanocalc, which consisted of magnesium silicate and calcium carbonate, respectively (14). However, as of late 2008 the company was evidently no longer in business.

The type of nanomaterial used to improve barrier is not always identified. Kuraray (Japan) markets a retort food packaging film, Kurarister™, which is reported to contain a 1-micron-thick barrier layer on both sides of a PET film. The barrier layer is a composite containing inorganic nanoparticles. The result is a highly transparent film that can be printed without surface treatment. The coating is reported to be highly durable, maintaining barrier properties even if stretched or flexed during processing. The barrier is also not much affected by moisture. A nylon-based film, Kurarister™ N, is also available and offers improved retention of mechanical properties after retorting, compared to conventional nylons. The materials are being marketed as an alternative to foil laminates in pouches for retorted foods, as well as for medical packaging and lidding film. Their microwaveability and the ability to use metal detectors on the packaging line are mentioned as two significant advantages (15).

Combustion chemical vapor deposition (CCVD) is used to produce 30 to 60-nm-thick barrier coatings on PET bottles in the nGimat system (formerly MicroCoating Technologies). The company also produces nanopowders and devices. The company's catalog in late 2008 listed 7 single-oxide nanopowders, 15 bi-metal oxides, 9 multimetal oxides, 2 phosphates, 2 hydroxyapatites, and 7 metal and metal-alloy nanopowders, along with the potential for special orders for others not listed. Barrier coatings for packaging are targeted at improving carbon dioxide and oxygen barrier in PET containers and PET/polyolefin films. The coatings are applied using nGimat's proprietary Nanomiser™ device. The resultant barrier layers are 30–60 nm in thickness and are transparent. Barrier performance is reported to be comparable to metalized film. The company claims that the shelf life of 20 oz PET bottles for carbonated beverages can be extended from the 10 weeks common for uncoated bottles to 30 weeks (16).

Researchers have even hypothesized the use of nanotechnology to control the permeability of a packaging system by using a molecular "switch" such as a change in pH to open or close pores in a nanoporous film layer (17).

Improved Mechanical Performance

Addition of nanoclay also increases the stiffness and strength of polymer materials. While most applications specifically targeting improved mechanical performance are in products, rather than packages, PolyOne was reported in 2004 to be nearing commercialization of their nanoclay-reinforced PP, Maxxam LST™, in pallets and dunnage (9). The 2008 information from the company indicates that two grades of nanoclay-reinforced PP, now called Nanoblend™ LST, are currently available (18).

Addition of nanoscale nucleating agents in foams results in smaller cell size and higher cell density, along with improving the performance of the foam (11). Researchers have also investigated the use of nanotechnology to produce foams that can be tuned to protect the contents from specific frequencies (17).

Nanoscale silica and alumina particles have been found to increase the scratch and abrasion resistance of coatings, while not interfering with transparency (17).

Conductive polymers can be made by using carbon nanotubes as a reinforcing filler. The carbon nanotubes also offer significantly improved tensile strength and greater thermal conductivity. Other carbon-based nanomaterials can provide similar improvement. Pyrograf Products produces vapor-grown carbon nanofibers that are reported to cost significantly less than carbon nanotubes, while providing similar benefits (11). Fiber diameters are 70–200 nm, and lengths are 50–100 microns. The company does not currently list packaging applications as typical uses, but they do have potential (19). Potentially even less expensive but with similar performance are graphite nanoplatelets (11).

Addition of nanoscale inorganic alumina platelets to plastics is reported to provide sizeable improvements in rigidity, strength, and thermal stability. Some researchers are currently working on development of synthetic alumina platelets. Others are developing large organic molecules in the form of rigid disks, with the idea that the chemical properties can be adjusted by attaching functional groups to the uniformly shaped disks (20).

Communication/Sensing

The communication category includes RFID tags incorporated into or onto packaging materials. While the tags themselves are not nano-sized, nanotechnology is used in manufacture of the embedded computer chips, and RFID tags have been the target of groups outraged at what they see as potential invasion of privacy (21). The potential advantages of RFID for inventory control, track-and-trace functionality, and so on, have led to a steady increase in its use.

Other communication functions related to nanotechnology include embedded sensors, to detect and/or record changes in temperature, pressure, concentrations of chemical substances, shocks, vibration, and so on (17, 22). One example is "nano ink" for detection of oxygen as an indication of faulty packaging or product tampering. The ink contains light-sensitive nanoparticles that are "switched on" with ultraviolet light. The UV light changes the ink color to white, but it changes back to blue under normal room light if oxygen is present. The dye is encapsulated in polymer, allowing it to be coated only on surfaces. Coupled with MAP packaging, it will change color if oxygen is present in the package but remain colorless if oxygen remains absent (23).

Strathclyde University has developed a film, based on nanocrystalline semiconductor technology, that changes color with oxidation of food inside the package. The color and sensitivity can be changed, and the sensor is printable on paper, plastic, or metal (12).

Some sensors are designed to detect substances other than oxygen, such as ethylene, which is associated with ripeness in many fruits. Sensors for fresh pears are already marketed (24). Dublin University is developing printable oxygen and carbon dioxide sensors. Sensors can also be targeted at detection of microbial contamination or toxins, resulting either from contamination or spoilage or from terrorism. While not all of these sensors involve nanotechnology, many do (22).

Detection of counterfeiting is the target of another nanomarking system. IDGlobal has a forensic marking technology in which packaging materials, including inks, adhesives, and varnish coating, are tagged with nanomolecular markers. Hand-held scanners then use spectrometry to read the chemical signatures imparted by the nanomarkers. The information from the bar codes or RFID tags is matched to the product signature in the marker. Any disagreement may mean counterfeiting. Furthermore, the markers cannot be detected visually, and the cost per label is less than one cent (25).

Similarly, Microtrace produces taggants that act as "fingerprints" for product identification and authentication.

While the particles themselves are larger than nano, at 20 microns or larger, the structures within the particles are often nanoscale. In fact, each encoded particle may contain multiple nanotaggant technologies. Packaging applications of the taggants include holographic and laminate films and shrink sleeves, among others (26).

5In 2001, researchers at Pennsylvania State University reported the development of a method to form nano-sized rods that could be used to produce nanoscale bar codes, which could have use as covert anticounterfeit measures (17).

Another potential packaging application of nanotechnology is in printed electronics, which might be used, for example, to provide displays on packages themselves (17, 27). In 2006, Pliant and NovaCentrix announced an alliance to develop "unique film and packaging solutions" by combining Pliant's film expertise with NovaCentrix's expertise in nanoparticle based inks and coatings (27). While no recent reference to this alliance was found, NovaCentrix continues to develop printed electronics with potential applications to advanced packaging systems (28).

Similarly, Siemens in 2005 developed color displays that can be printed on paper or foil, suggesting that the displays could be printed on packages to show information about products or to show operating instructions. They were even working on the ability to show moving pictures, suggesting that it would be possible even to have small computer games printed on packages, powered by printable batteries (29). It was anticipated that the first displays would become available in 2007, but no current reference to them was found. However, the potential remains.

Other

Nanoclays are also being used to act as flame retardants in plastic materials. The nanoclay acts to form a char coating that delays the polymer degradation and reduces the heat output. It also increases the heat-distortion temperature (11, 12).

Nanomaterials can also be used to provide antimicrobial properties, for either packages or products. One common system uses silver, either incorporated into zeolites or, in the case of nGimat, deposited as a layer of "adherent silver nanodots" which have antimicrobial activity against fungi and bacteria in the presence of moisture (30). Other systems use tethered bioactive compounds on surfaces, such as peptides linked to amines that in turn were attached to polyethylene (31). While these are not usually tagged with the "nano" label, they are nanoscale in size.

Organic/inorganic nanocomposite coatings were developed as part of the EU Solplas project, which began in 2002, for antimicrobial activity as well as for barrier improvement. This process uses aerosol-assisted atmospheric plasma (AAAP) coating, in which the film precursor is introduced into a plasma adjacent to the substrate as aerosol droplets. In the nano-alternative, an electrospray process is used to decrease the size of the aerosol droplets to the nanoscale, making the process more effective (31).

Nanopigments can be used to provide colors for packaging materials without the use of conventional dyes or pigments. The color is created by dispersion of uniformly sized nanoparticles. Such nanopigments can also be used in inks. A different type of nanomaterial, hyperbranched polymers, can also be used to allow the same ink formulation to be used to print on both polar and nonpolar surfaces. BASF reportedly estimated that 10% of its ink sales already involve nanotechnology (32).

Nanoscale additives have found use in papermaking. Colloidal silica sols and cationic polymers have been used in papermaking for many years, without being labeled as "nano," to aid in fiber retention and drainage systems. Newer technologies use highly structured nanoparticles for this purpose. Inorganic/organic hybrid materials, mineral-based coatings, and polymer-encapsulated nanoclay hybrids have all been used as paper coatings (32).

One company is now marketing a nano-dispersed biopolymer that is intended to be a substitute for wax emulsions for manufacturing water-resistant paper and paperboard. TopChim claims its technology maintains the water barrier of wax emulsions while improving repulpability and recyclability. The biopolymer contains a "monodisperse distribution of nanoparticles with a regular shape" (33).

Similarly, the SustainPack project in the EU has a goal of reducing the environmental impact of packaging materials. One target is to increase the strength, including wet strength, of fiber-based packaging materials through the use of nanotechnology. Researchers are using nanoclays modified with chitosan derived from crustacean shells (34).

Greenbox Systems claims nanotechnology is the basis of their Thermal-Lok™ panels that provide "unparalleled resistance to heat transfer" and permit the Greenbox containers, with appropriate phase-change materials, to provide temperature stability for extended periods for sensitive products such as pharmaceuticals, blood, and biologics. Details of the technology are proprietary, other than it uses a carbon-silica material in a nanotechnology-based process that results in an insulating capacity ten times greater than typical foams (35).

Hybrid organic–inorganic nanocomposites based on titania siloxane have been developed for glass bottles in both Japan and Europe. The coatings provide a wide variety of colors while improving the mechanical properties of the bottles. Furthermore, the bottles can be easily recycled as uncolored glass (12).

Nanotechnology can also be used to release desired substances. In 2003, researchers in the Netherlands were working on use of nanotechnology to develop intelligent packaging in which a bioswitch would send a command to the package to release a preservative if the food within began to spoil (17).

Researchers at the University of Leeds have worked on incorporation of oils and oil-soluble sensors for fragrance release, color change, and anticounterfeiting applications. NaturalNano reported in March 2008 that the company won an award for innovation from a Fortune 500 company for its work in extended release capability. The desired components are loaded into nanotubes, which release the material slowly over time (36). While it appears that the current target is consumer products, applications to packaging are obvious.

Nanotechnology can also play a role in something as simple as starch-based adhesives. In 2004, EcoSynthetix Inc. developed a nanostarch powder adhesive that has advantages over conventional starch adhesives used for manufacture of corrugated board. The 50 to 100-nm starch particles in the EcoSphere adhesive could be used at lower water content than conventional starch adhesives, meaning that less energy and shorter times were needed for drying, allowing ovens to run at lower temperatures (37). Evidently the higher cost proved prohibitive, at least for now, since the company no longer lists this adhesive as a product. However, they do market a binder coating for paper and paperboard, EcoSphere™ 2202, that reportedly consists of crosslinked biopolymer nanoparticles. The company also manufactures a variety of pressure-sensitive adhesives; it is not clear whether these also involve nanotechnology (38).

On a more high-tech level, researchers at the Polymer Centre at Sheffield University have used nanotechnology to develop an adhesive that can be turned on and off, which they termed “molecular velcro” (17).

Regulations and Public Concern

Regulations for nanotechnology are still developing. Regulatory systems in place for “ordinary” materials are not always appropriate for nanoscale versions of those materials. For example, for materials that are categorized as GRAS (generally recognized as safe), the differences in behavior that appear when size is reduced to the nanoscale may result in differences in toxicity. On the other hand, if the migration or other safety testing was done with materials already dispersed at the nanoscale, simply applying the “nano” tag to the product or system obviously does not change its properties.

An additional concern is that we are still early in learning how nanoscale materials behave. We do not yet have a full understanding of how variations in particle size within the nanoscale, the presence of contaminants, dispersal into the environment after use, and so on, affect the behavior of the materials. In 2008, the Woodrow Wilson International Center for Scholars Project on Emerging Nanotechnologies, in collaboration with the GMA, published an analysis of key regulatory issues for use of nanomaterials in food packaging (39).

NETTING, PLASTIC

JIM OHLINGER
Tipper Tie-Net, West Chicago,
Illinois

INTRODUCTION

Today there are two popular manufacturing methods to produce plastic netting: knitting and extrusion. Both methods produce a tubular or sheeted netting product in a wide variety of mesh sizes, diameters, widths, and colors. Plastic netting is purchased as individual pieces, in continuous rope form, or sheared onto cardboard mandrels.

The primary materials used to produce plastic netting are high-density polyethylene (HDPE) and polypropylene. Ultraviolet inhibitors can be added to the resin to give the netting extra durability in direct sunlight applications. HDPE has a high elongation value and must undergo the process of orientation to achieve its maximum tensile strength. The process of orientation is when the material is heated and then stretched to the point just before breakage. This process also keeps the netting from drooping when exposed to heat applications. The melt index of HDPE is 208°F. Polypropylene has a high melt index (325°F), and it is used when temperature requirements exceed 208°F. Polypropylene tensile strength is almost twice that of HDPE with the equivalent weight ratio. With the heat and strength attributes, polypropylene netting is widely used in the meat–poultry industry.

The process of extruding plastic netting was invented in the mid-1950s. Extruded netting is produced through counterrotating dies. As the inner and outer die rotate, small strands of molten plastic overlap each other, bonding themselves together where they overlap. The extruded plastic is then cooled by water; this material is called a *cast*. The next process is orientation. The cast is heated and stretched to the point just before breakage. After the cast is oriented and has become the final product, the net is transverse-wound onto large spools (1).

MANUFACTURE

The manufacturing process of knitted plastic netting offers the most versatile and variety of netting products. Knitting machines offer simple and sophisticated stitch patterns. The first knitting machine was invented by Reverend William Lee, an Englishman, in 1589. The first power knitting machine was introduced in 1832, in Cohoe, New York by Egberts and American (2). The knitting process is complex and varies by different types of machinery. To manufacture plastic netting via knitting, the plastic resin must be manufactured into yarn or tape. The yarn is then put onto a creel, with several individual packages consisting of a single thread, or beam, and several threads wound onto a large spool. The basic concept of knitting is to take the yarn or plastic tape from the creel or beam, and thread the set of needle guides in the knitter. A bed of latch hooks move up and down (vertically) as the needle guides move right and left (horizontally). The needle guides are directed by a pattern chain that controls the different mesh patterns; hexagon, diamond, or countless other configurations. Knitting allows the manufacturer to choose the style and the material to be used, allowing a multitude of products.

APPLICATIONS

Plastic netting is used in an array of applications. As a flexible material, it conforms to irregular products (toys, houseware products, etc.). Netting provides an excellent packaging forum as a decorative and protective overwrap. It provides the necessary air circulation for products such as plants (tropical and flowering) and various types of fruits and vegetables. Because of plastic netting's flexibility, it can be looped, making a convenient carrying handle for the consumer (fresh or frozen whole turkey and ham products). In the meat–poultry industry, netting is used as a transportation vehicle. The meat and poultry items are encased in the netting in the production area and then hung on smoke racks ready to go into the smoke house. The netting allows the meat and poultry products to receive smoke for flavoring and coloring during the cooking process. The netting leaves an attractive pattern on the products, giving them the "old world" look. The netting can be left on the product as a marketing tool for product identity.

Netting has a wide variety of uses in sheet form. It can be used to wrap pallets as an alternative to stretch wrap. The netting can be put up the same way as stretch wrap, to utilize modern equipment and hand applicators that are available. This is an important tool where ventilation or heat dissipation is needed (produce, bagged mulch, flowers, flour, etc). Because of its exceptional strength, netting can be used to wrap heavy loads such as bricks. In sheet form, netting has an abundance of uses. It makes a great fence for construction or snow applications. It can be used as a safety net in construction to catch debris and increase the safety of workers. It is widely used in the horticulture industry as shade cloth protecting plants from the harsh sun. It is also used as bird net, protecting fruit trees, berry bushes, and fish ponds from predator birds.

By using the knitted process to manufacture plastic netting, different-color strings or threads can be combined to form a multicolored netted product. An example is Candy-Cane (trademark) red and white netting used to package Christmas trees (3). This netted package allows the tree to be easily transported from the retail lot to the consumer's tree stand at home. Netting is also used by Christmas-tree growers to compress the tree. This gives the grower the ability to ship more trees, saving in transportation cost. The netting also protects the tree from damage, and it makes the tree much easier to handle. This packaging process also applies to other types of trees (white oak, maple, bamboo, etc.).

Knitted netting is soft, durable, and strong, making it an ideal packaging medium. The produce industry, which uses extruded netting primarily for consumer-sized packages, is seeing a trend moving toward knitted netting. Both styles of netting offer adequate ventilation needed for fruits and vegetables to reduce spoilage. The soft texture of knitted netting does not damage the delicate produce skin and makes an eye-pleasing package. A draw string can be automatically inserted during the knitting process, making a convenient closing mechanism as well as a carrying handle. Potato sacks are a good example of this process.

Plastic netting is a valuable packaging tool. It is resilient, strong, and flexible. Netting can be frozen and then heated, or vice versa, keeping its strength and flexibility. Plastic netting is very cost-effective compared to other forms of packaging and is recyclable. The applications and areas of usage keep growing as creative minds keep developing new and innovative ways to use plastic netting.

NITRILE POLYMERS

Paul R. Lund
Joseph P. McCaul
The BP Chemical Company,
Cleveland, Ohio

INTRODUCTION

Nitrile polymers are generally those that contain the cyano ($C\equiv N$) functional group, also called the nitrile group. The commercial development of these materials was due in large part to the 1957 discovery by BP Chemicals of a low-cost one-step process for acrylonitrile (AN) production (1). The pure nitrile polymer, polyacrylonitrile (PAN), is 49% nitrile. It is an amorphous, transparent polymer with a relatively low glass-transition temperature ($T_g = 87°C$) (see Polymer properties) that provides an outstanding barrier to gas permeation and exceptional resistance to a wide range of chemical reagents. Unfortunately, its combination of properties is not of commercial value in the packaging industry. Its primary deficiency is that it is not melt processable. It degrades at 428°F (220°C), which is below that required for melt processing. To overcome this handicap, nitrile polymers are produced using acrylonitrile ($CH_2{=}CHCN$) as the monomer with other comonomers that impart melt processability. Through this copolymerization process, the desirable properties can be retained and the undesirable properties can be suppressed.

COPOLYMERS

Styrene–Acrylonitrile (SAN)

Typical SAN polymers are made using a 3:1 ratio, by weight, of styrene to acrylonitrile. The copolymer has a combination of properties that reflect the processability of the styrene component and the chemical resistance of the AN. Gas-barrier properties are low because of the relatively low AN concentration. SAN is of relatively minor significance in packaging, used in applications where PS would suffice with an added measure of chemical resistance.

Acrylonitrile–Butadiene–Styrene (ABS)

ABS is a graft copolymer of SAN onto a polybutadiene backbone. The SAN forms a matrix phase, whereas the polybutadiene forms a discrete (dispersed) phase. A tough impact-resistance thermoplastic is produced by using the grafting mechanism to compatibilize the two phases. Although the polybutadiene is an excellent impact modifier with low T_g ($\cong$ 85°C), its refractive index is different from the SAN matrix polymer. Therefore, in contrast to PS (see Polystyrene), PAN, and SAN are not transparent. ABS is a major commercial thermoplastic, but it is rarely used in packaging because of its opacity, lack of gas-barrier properties, and economics relative to other commodity resins. However, thermoformed ABS (see Thermoforming) has been used, for example, to produce margarine tubs. This is an application in which PS would suffice if not for its limited resistance to stress cracking. A wide range of SAN ratios is used to achieve properties of value in nonpackaging applications.

Acrylic Multipolymers

Some acrylic multipolymers are produced using AN as a comonomer with methyl methacrylate (MMA). Refractive index matched rubber modifiers are incorporated to combine toughness with transparency. These materials are used in healthcare packaging (2) (see Medical packaging) and in some food packaging applications. Because the AN concentration is low, these materials do not have exceptional gas-barrier properties [18.7 $\mathrm{cm^3}$ mil/100 $\mathrm{in.^2}$ d atm at 73°F (23°C)].

High-Nitrile Resins (HNR)

As noted above, SAN is a styrene–acrylonitrile copolymer. Its gas-barrier properties are limited, however, by the low nitrile content. High-barrier melt-processable copolymers can be produced by raising the nitrile content above 25%. Over this threshold, copolymer properties begin to resemble those of PAN, particularly with respect to gas barrier and chemical resistance.

Acrylonitrile–Styrene Copolymers (ANS). High-nitrile copolymers can be produced by combining acrylonitrile and styrene in a 70:30 ratio. This was the approach taken by Monsanto Company (Lopac) and Borg-Warner (Cycopac) during the 1960s and early 1970s in their development of resins for carbonated-beverage packaging. Lopac's composition is 100% copolymer of 70% acrylonitrile and 30% styrene. Cycopac's composition is 90% copolymer of 74% acrylonitrile and 26% methyl acrylate plus 10% butadiene rubber graft (3). As serious commercial development began, toxicological problems with AN surfaced (4). The FDA banned the use of HNR in beverage packaging because of concern for potential AN-extraction from the bottle into the beverage. Since beverages are a major component of the diet, their treatment by FDA was most severe. The FDA continued to permit the use of HNR for direct and continuous nonbeverage-food-contact applications (5) with filling and storage temperatures less than 150°F (65.6°C); but because the principal commercial significance of ANS polymers was in carbonated beverage packaging, all commercial production of ANS polymers was eventually discontinued.

In 1984, the FDA amended its position on HNR-beverage applications (6). Monsanto Company had petitioned on behalf of their ANS high nitrile resin for approval. As described in their process patent (7), the bottle preform is irradiated with an electron beam prior to blowing of the bottle. Monsanto claimed that this process resulted in a bottle that, because of the thermodynamics of the extraction process, would have essentially no extraction of AN by the contained beverage. The FDA did not accept this claim, but it did decide that the extraction would be below the detection limit of 0.16 ppb. The agency ruled that AN concentrations at or below this detection limit would be considered acceptable, and it limited the residual AN content of the finished container of 0.1 ppm. This concentration is current (8).

Rubber-Modified, Acrylonitrile–Methacrylate Copolymers (AN/MA). High barrier properties can also be achieved by copolymerizing acrylonitrile and methacrylate in a 75:25 ratio onto a nitrile rubber backbone. This is the approach taken by BP Chemicals in the production of Barex (registered trademark) resins. Barex's composition is 90% copolymer of 74% acrylonitrile and 26% sytrene plus 10% butadiene rubber graft (3). This family of resins can be processed on almost all conventional plastic processing equipment including, but not limited to, injection, injection blow molding, injection stretch blow molding, extrusion, extrusion blow molding, extrusion stretch blow molding, profile extrusion, pipe extrusion, tubing extrusion, and thermoforming (see individual processing sections). Transparency is retained through the use of a refractive-index-matched rubber modifier.

The Barex family of resins are the only high-nitrile resins in commercial production today and are in full compliance with all applicable FDA regulations for direct food contact and meets all the known requirements of a USP Class VI plastic. Barex is now marketed by INEOS.

PROPERTIES

Among the commercial packaging polymers that have the physical properties required for monolithic structures, HNRs offer the greatest gas barrier [0.8 $\mathrm{cm^3}$ mil/100 $\mathrm{in.^2}$ d atm or 3.0 $\mathrm{cm^2}$ $\mu\mathrm{m/m^2}$ d kPa] and chemical resistance. Their gas-barrier properties (see Barrier polymers) are surpassed only by EVOH (see Ethylene–vinyl alcohol) and PVdC (see Vinylidene chloride copolymers), which are used as components of multilayer structures (see Coextrusions for flexible packaging; Coextrusions for semirigid packaging). Because of the polarity that the nitrile group imparts to the molecule, HNRs show an affinity for water. Water-vapor barrier is lower than that of the nonpolar polyolefins (e.g., polyethylene, polypropylene), but that same polarity imparts resistance to nonpolar solvents. The relatively high flexural modulus (combined with the lower specific gravity) means that for structures with identical geometry, the HNR parts can be source-reduced

Table 1. Properties of High Nitrile Resins

Property	ASTM Test	Units	Barex 210 Resin	Barex 218 Resin
Specific gravity	D1505		1.15	1.11
Yield		in.^{2}/lb at 1 mil	24,080	24,950
Brabender torque		meter-grams	950	1050
Notched Izod	D256	ft-lb/in.	5.0	9.0
Flexural modulus	D790	psi	490,000	400,000
O_2 permeability (73°F, 100% RH)	D3985	cm^3-mil/100 in.^{2} -24 h-atm	0.8	1.6
CO_2 permeability (73°F, 100% RH)	D3985	cm^3-mil/100 in.^{2} -24 h-atm	1.2	1.6
N_2 permeability (73°F, 100% RH)	D3985	cm^3-mil/100 in.^{2} -24 h-atm	0.2	0.4
WVTR (100°F, 90% RH)	F1249	g-mil/100 in.^{2}-24 h-atm	5.0	7.5
Heat deflection temperature	D648	°F	160	170
Heat seal temperature		°F	250–375	275–350

(down-gauged) and therefore designed with less material for equivalent stiffness compared to the polyolefins, PVC, PET, PETG, and many other plastic polymers. A summary of the properties of high-nitrile resins is shown in Table 1.

APPLICATIONS

HNRs are used in packaging in a variety of physical forms. These include: film, semirigid sheet, and injection-molded (see Injection molding) and blow-molded containers. Blown film (see Extrusion) is used in polyolefin-container structures to provide formability, chemical resistance, and gas barrier. Spices, medical devices, and household chemical products are example of such applications. Laminations with polyolefins and aluminum foil are used in applications ranging from food packaging to oil-drilling core wraps (9). These structures have exceptional barrier properties, as well as sealability and chemical resistance. Indeed, their use in sachet packaging is growing rapidly as individual dose and unit packaging become more popular.

The semirigid sheet market for HNR is primarily meat and cheese packaging in thermoformed (see Thermoforming) blister packages. With its excellent gas barrier, clarity, and rigidity, the HNRs are the premium packaging material. Of increasing importance in semirigid applications, however, is disposable medical device packaging (see Medical packaging). Here HNR can be sterilized by either ethylene oxide (ETO) or gamma radiation and is unaffected by plasticizers present in many devices, making it ideal for many medical packaging applications. As a result of its unique combination of properties, including source reduction and superior thermoforming, usage has been steadily increasing in this market area.

Blow-molding applications for HNR are dominated by chemical resistance requirements. Injection blow molding is the most widely used method for manufacturing small containers—for example, bottles for correction fluid, nail enamel, and other cosmetics. Larger bottles are generally extrusion blow-molded. Some important applications include: pesticides, herbicides and other agricultural chemicals, fuel additives, and hard-to-hold household chemicals. Extrusion stretch blow molding is gaining increasing acceptance for bottles 16 oz (473 mL) or larger. The orientation achieved during stretching greatly increases the drop-impact performance, and the walls can be relatively thin.

HNR has been coextruded with many different polymers, but the polyolefins have been of greatest commercial significance. Coextrusions are available in sheet, film, and bottle form. They typically gain gas barrier or chemical resistance from the HNR and water vapor barrier and economics from the polyolefin. In structures with polypropylene, the heat-deflection temperature (HDT) of the structure is increased by the higher HDT of the polypropylene. This permits the use of HNR in high-temperature environments such as microwave ovens.

The adhesive used to combine the layers in an HNR coextrusion are typically styrene–isoprene or styrene–butadiene block copolymers (see Multilayer flexible packaging). Scrap is reusable in the polyolefin layer if the nonolefin percentage in that layer is well-dispersed and of lower concentration than about 15%.

Chemical-resistant coextruded bottles containing HNR are now being commercialized. HNR is the inner contact layer enclosed by adhesive and polyolefin, typically HDPE. Use of a three-layer structure limits the cost and complexity of the machinery. It also places the solvent-resistant polymer in contact with the chemicals. Five layer or laminar structures (see Surface modification; Nylon) using other barrier resins place the polyolefin in direct contact with the aggressive contents of the container. The three-layer structure also allows visual inspection of the barrier layer and maximizes the sealing area of the barrier layer at the pinchoff of the bottle. HNR-coextruded containers offer high performance with economics superior to the other packaging alternatives (10). Thermoplastic coextruded films of 5–7 layers have been reported (11).

Alloying and blending also offer other unique properties that can be imparted to the base resins, typically polyolefins. Here they can be used to reduce ESCR as well as provide increased flexural modulus (stiffness) to polyolefinic resins (12).

The Barex family of resins offers a unique combination of properties to the packaging industry. Barex resins protect products from oxidation and are inert and resistant to chemicals. They meet United States and European regulations and, thus are available for a range of products, They eliminate the need for a separate heat-seal layer and are good against strong ingredients. As bottles, they keep fragrances and flavors in place. The following are applications of Barex (13).

1. *Medicinal Uses.* Catheter trays, sachets, assay trays, transdermic patches. These products are sterilizable.
2. *Personal Care.* Cosmetic packs, perfume, mouthwash, nail enamel, and bath gel bottles.
3. *Industrial Products.* Among many nonpackaging uses, criminal evidence bags and air fresheners.
4. *Food and Beverages.* Fruit juices, meats, and confectionary.

NONWOVENS

J. Robert Wagner
Philadelphia College of Textiles
and Science, Philadelphia,
Pennsylvania

INTRODUCTION

“Nonwovens are fabric-like materials consisting of a conglomeration of fibers that are bonded in some way or other” (1). The total world wide sales of nonwovens in 2006 amounted to 19 billion dollars ($5 \times 109\,t$) (2). Nonwovens may be sold by a yield or area basis, weight basis, or product unit basis. Because of their unique properties and high production rates, nonwovens offer a substantially high performance/price ratio. However, in order to appreciate the full range of products, properties, and end uses of nonwovens, it is necessary to consider the fibers, the web-formation method, and the bonding methods used to make them.

FIBERS

The primary ingredient of nonwovens are the fibers used to produce them. A fiber is substantially longer in length than in diameter. In nonwovens, fibers may vary in length from 1 mm to a continuous length. Short (1-mm) fibers are used in air-laid or wet-laid nonwovens. Spunbonded nonwovens use continuous-length fibers in their fabrication. The length of the fibers will affect both the uniformity of fiber distribution and the strength of the nonwoven. Short fibers tend to give good fiber distribution, but longer fibers tend to produce greater strength. However, the fiber length actually utilized is dependent on the nonwoven-web-formation process and the type of product being manufactured.

The diameter of the fiber affects the properties of the nonwoven considerably. If it was desired to produce a soft nonwoven facial wipe, baby wipe, or polishing cloth, a fine fiber should be used. If, on the other hand, it was desired to produce a scrubbing pad of the required stiffness for a frying pan, large-diameter fibers should be used. The latter would also give high incompressibility or resilience.

While many fibers are perfectly round, some are triangular, square, hollow, and of other shapes. In addition, they may consist of one or more generic type of materials in their makeup.

One major variable in nonwovens is the type of fiber used in its construction. Virtually any fiber can be utilized to make nonwovens. The principal natural fibers found in nonwovens are cotton, jute, and especially wood pulp. The majority of spunbonded fabrics are based on either isotactic polypropylene or polyester. Small quantities are made from nylon 6,6 and an increasing tonnage from flash spun high density polyethylene (3). Because of their far-reaching properties, the range of fiber types available offer great latitude in the performance characteristics of the final nonwoven. Because of their high hydrophobic properties, moisture-barrier properties are provided by polypropylene, polyethylene, polyester, and polytetrafluoroethylene (PTFE). High tensile strength may be obtained using Kevlar aramid, Spectra olefin, nylon, polyester, silk, and glass. High-temperature resistance or low flammability can be obtained with carbon, glass, Kynol novoloid, Kevlar and Nomex aramid, modacrylic, PBI, PTFE, ceramic, and metallic fibers. For composites, glass, carbon, Kevlar, and Nomex aramid may be used. Chemical resistance may be obtained with PTFE, glass, carbon, acrylic, olefin, and some metallic fibers. It should be apparent, therefore, that proper fiber selection is essential in order to ensure desirable end-use performance characteristics of the nonwoven.

NONWOVEN WEB-MANUFACTURING METHODS

Nonwoven webs can be produced in four primary ways: carding, air laying, wet laying, or spunbonding. Within each one of these, the process and resulting product will often vary considerably.

A carding machine feeds a mass of crimped fibers, opens, disentangles, and drafts the fibers and then delivers a thin wide web of uniformly distributed fibers to some form of delivery apron. The fibers used to produce carded nonwovens must have crimp and will usually have a fiber length ranging between 34 and 152 mm.The fibers exiting the card tend to be aligned in the machine direction, and, if used in this manner, the product is referred to as a *parallel-laid nonwoven*. Often it is necessary to combine the web from several carding machines to achieve the desired nonwoven weight. A parallel-laid nonwoven may be up to 11 times stronger in the machine direction or fiber-oriented direction than it is in the cross-machine direction. Also, the elongation in the machine direction is substantially less than that found in the cross-machine direction.

The web exiting the card may be laid back and forth across a moving apron to produce what is known as a *cross-laid nonwoven*. Because systems of fibers cross each other, the resulting nonwoven has more uniform strength and elongation properties than found in parallel-laid nonwovens.

Sometimes a parallel-laid web is combined with a cross-laid web to produce what is termed a *composite carded nonwoven*. The latter has the greatest uniformity in strength and elongation properties of carded nonwovens.

In *randomized carded nonwovens* the card is similar to that used for parallel laying, but the doffer roll is run in a direction counter to that of the main cylinder at the point of near-wire contact. Such a configuration deparallelizes the web, permitting more loft and greater uniformity of strength and elongation in the machine direction and cross direction.

Because of the great latitude in weight, thickness, fiber orientation, strength, elongation, and fibers utilized, carded nonwovens have a vast number of product end-use applications.

Air-laid nonwovens utilize fibers having a length ranging between 1 and 76 mm.The fibers are first opened, then conveyed with an air stream against either a condensing cylinder or a screen to form the web. The product produced tends to have an *x, y, z*-fiber orientation, and as a result the webs are soft and lofty. Such a web is especially useful in padding, insulation, filtration, and wipes.

Wet-laid nonwovens utilize papermaking equipment and technology. The fiber length ranges between 1 and 38 mm.The longer fibers are either glass for roofing shingles and felt or carbon for composites. Shorter natural and synthetic fibers are used in tea bags, automotive air and oil filters, coffee filters, bunting, hang tags, and composites. While flat-tabled fourdrinier machines have been used to make some nonwovens, the best machine for producing wet-laid nonwovens is the inclined-wire machine since long fibers are held in suspension in water at the time of formation on the moving wire. Often multiple headboxes are used to produce layered or stratified high-efficiency air filters and other products.

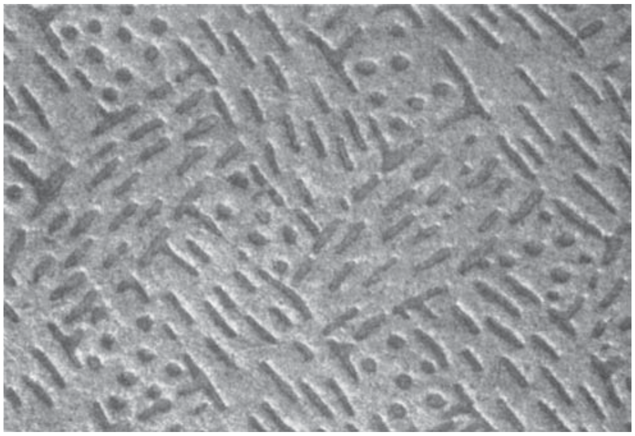

Figure 1. Illustration of a polypropylene melt blown nonwoven that is bonded using a heated pattern engraved calender roll. Such a product is manufactured using a fine oil-loving fiber and is excellent for use as a shop towel or wipe.

Spunbonded and melt-blown nonwovens (see Figure 1) are produced at the time the fiber is extruded from the spinneretts. Spunbonded nonwovens are produced with continuous filament fibers that are drafted with either multiple drafting rollers or high-velocity air used in combination with a venture to achieve molecular fiber orientation. Most spunbonded nonwovens are produced with polypropylene or PET. However, polyethylene, polyester, nylon, acrylic, and rayon are also used.

Melt-blown nonwovens are similar to spunbonded nonwovens but instead use a spinnerette in which both the polymer and hot air exit the spinnerette from different orifices simultaneously. The velocity of the air is sufficient to draft the polymer into very fine discontinuous fibers. Melt-blown nonwovens are used for thermal insulation, filters, padding, personal products, synthetic leather, and other products.

Flash spinning is a radical departure from conventional melt spinning. It begins with a 10–15% polymer solution prepared by dissolving a solid polymer, such as high-density polyethylene, with a suitable solvent. The solution is pressurized and then permitted to expand rapidly through a hole in a spinnerette. The solvent is instantaneously flashed off, leaving behind a three-dimensional film-fibril network called a plexifilament. These plexifilaments are substantially oriented and possess relatively high tenacities. Flash spinning is the most complex and sophisticated method for manufacturing spunbonded fabrics (3).

BONDING METHODS

There are four principal methods of bonding nonwovens: chemical, mechanical, thermal, and inherent or self-bonding. Chemical bonding may rely on binders, solvents, or hydrophilic fibers. Of these, binders are by far the most important. Binders act like adhesive and include acrylic, phenol, urea and melamine formaldehyde, poly(vinyl acetate), styrene–butadiene rubber, vinyl acetate–ethylene, poly(vinyl chloride), nitrile rubber, poly(vinyl alcohol), and other lesser binders (4). Such binders vary considerably in cost, properties, and performance characteristics.

Mechanical bonding includes needle punching, stitch-through, and hydroentangling. Needle punching may use either barbed or forked needles. Barbed needles interlock the fibers to provide mechanical strength to produce such products as papermaker's felts, blankets, geotextiles, synthetic shoe leather, thermal lining, and automotive trunk liners. The forked needles can produce velour and patterned products for use as institutional and automotive carpeting, and throwrugs.

Stitch through technology is a knitting-through process that may be accomplished either with or without yarns to stitch the nonwoven web together. The Mali and Arachne machines are most common and produce products such as carpets, upholstery, blankets, interlining, geotextiles, and automotive products.

The hydrogenating process was invented by E. I. DuPont and was first referred to as the *spunlace process*. It utilizes very fine water jets to mechanically entangle fibrous webs.

Thermal bonding may include the use of thermoplastic fibers, yarns, powders, or films. Often bicomponent fibers having differential melting temperatures in either a core-and-sheath or a side-by-side configuration may be utilized. Bonding is facilitated by through-air heaters, and smooth or patterned calender rolls.

Inherent or self-bonded nonwovens are bonded at the time they are produced. This might include film splitting, blow extrusion, or static-charge extrusion. However, because of their limited properties and aesthetics, nonwovens produced in this manner have limited uses.

Because of the fiber types available, the differences in web-manufacturing processes possible, and the various bonding methods, a cost-effective nonwoven product can be produced with properties that will perform in almost any application. However, adequate performance characteristics are ensured only if a nonwoven incorporates the proper fibers, web manufacturing process, bonding method, and proper finishing and fabrication to produce the final product for the end-use application desired.

PACKAGING APPLICATIONS

Packaging applications for spunbonded fabrics are for the most part a specialty area in which paper products or plastic films do not adequately perform. One of the largest packaging applications is high-performance envelopes.

The major use for spunlace fabrics is in medical products. In medical applications, great progress has been made in the substitution of traditional reuseable woven materials with higher-performing spunbondeds. Historically, flash spunbonded polyethylene was the first 100% spunbonded to find use in sterilzable packaging. Recently, structures of spubonded–meltblown–spunbonded polypropylene has gained acceptance in sterilizable wrap. Spunbonded fabrics with elastomeric properties are now commercial. An economical approach using polypropylene has recently become commercial and is used in medical and hygienic applications (5).

Medical devices or trays of devices are often sterilized after the nonsterile device is sealed in a package. A part of the package, such as the lid, is made from flashspun or spunbonded–meltblown fabric because it possesses the unique property of permitting the sterilizing gas of ethylene oxide to pass through while remaining impenetrable to bacteria (3).

NUTRITION LABELING

Jean Storlie
Nutrition Labeling Solutions,
Ithaca, New York
Karen Hare
Nutrition Services, Inc., Fort
Collins, Colorado

The regulatory issues associated with nutrition labeling of food products are complex and extensive. Specific nutrition information must be included on most food products following particular design requirements. The regulations also delineate what nonmandatory nutrition information may be included and how it can be presented. Professionals involved in food processing, manufacturing, marketing, and packaging need to be aware of nutrition labeling regulations and understand how they affect food packaging and marketing.

The purpose of this article is to provide a broad understanding of the nutrition-labeling regulations, explain why they were developed, and describe some of the approaches that may be used for developing nutrition labels. A heavier emphasis will be placed on the issues related to design and format, rather than those pertaining to the content of the nutrition label. Because the regulations are extensive and detailed, it is not possible in the scope of this article to cover all the issues necessary to make this a “how to” reference. In order to apply the regulatory requirements to specific packaging issues, it is necessary to consult with regulatory source documents, regulatory guidebooks, and/or legal or regulatory advisors.

HISTORY OF NUTRITION LABELING

Although the history of food labeling laws reach back as far as 1906 with the Pure Food and Drug Act, it was not until after World War II that consumer interest in and need for nutrition information became evident (1). During the war, food preparation shifted from the household to large-scale food processing. The extended shipping times for delivery of goods needed in war encouraged the development of additives to extend shelf life. Wartime health problems led to the recognition of the relationship between nutrition and diseases, spawning interest in nutrition research and food labeling. Scientists recognized the need for vitamins and minerals to prevent certain diseases such as beriberi and pellagra.

By 1969, there was significant public interest in the relationship between diet and health. As a response to this interest, President Nixon convened the White House Conference on Food, Nutrition, and Health, addressing malnutrition in America (2). He told Congress of the need to ensure that the private food industry serves all Americans well and that people are educated in choosing proper foods. As an outcome of this conference, along with Congress’ effort to mandate nutrition labeling, the Food and Drug Administration adopted a voluntary nutrition labeling program in 1973 that required the labeling of nutrition information whenever a nutrient claim was made or a product was fortified (3). At this time, the voluntary nutrition label focused on key vitamins or minerals known to cause deficiency disease.

Proponents of mandatory nutrition labeling were not satisfied with the limitations of the voluntary program—typically, only products with a good nutrition story included nutrition labeling. Throughout the 1970s, mandatory nutrition labeling continued to be addressed by legislators—in particular, Senator George McGovern, who chaired the Senate Select Committee on Nutrition and Human Needs. This Committee investigated a number of nutrition issues affecting Americans and was responsible for issuing the U.S. *Dietary Goals*, the first government report setting prudent dietary guidelines for Americans (4). In 1978, McGovern initiated a series of hearings to explore nutrition labeling and information, where he is quoted: “It appears from all I have heard and read to date that the present labeling system is not useful or appropriate. Therefore we must determine what nutrition information the public wants and needs, and how best to convey that information” (5). Although the hearing displayed the bipartisan nature of the issue, it took Congress another 13 years before the Nutrition Labeling and Education Act of 1990 (NLEA) was passed.

With the election of President Reagan in 1980, the thrust to adopt mandatory nutrition-labeling legislation came to an abrupt halt (1). Deregulation limited available resources, causing FDA to focus on food-safety issues and to deemphasize economic issues such as food labeling. Despite this shift in legislative priorities, there were major advances in science that documented the link between nutrition and health. Several reports issued by the federal government (6–8), in addition to reports released by nonprofit agencies, such as the American Cancer Society (9) and the American Heart Association (10), clearly showed the growing consensus about the relationship between dietary imbalances and chronic diseases, specifically the overconsumption of calories, fat, saturated fat, cholesterol, and sodium and the underconsumption of dietary fiber. As a result of extensive media coverage of these findings, consumers began to demand healthier food products and more information about the fat, cholesterol, and fiber content of foods. Food manufacturers responded by introducing nutrient-focused products—products lower in fat, cholesterol, and sodium and high in fiber proliferated. Unfortunately, there were no guidelines for defining “low” or “high” or for labeling nutrients such as dietary fiber, saturated fat, or cholesterol. As a result, manufacturers’ efforts to produce and market such products without consistent rules led to incidence of abuse, and consumer groups complained of food-labeling deceptions. By the end of the 1980s, the food industry, as well as regulators and consumers, were frustrated by the contradictions that prevailed on grocery-store shelves.

It was not until President Bush took office in the late 1980s that legislative and regulatory efforts again focused on nutrition labeling. Senators Metzenbaum, Kennedy, and Hatch and Representatives Waxman and Madigan renewed the spirit of the 1970s with nutrition labeling regulations that ultimately resulted in mandatory labeling, nutrient content and health claim definitions, and federal preemption, now known as NLEA. While these legislators were lobbying for mandatory nutrition labeling laws, the National Academy of Sciences’ Institute of Medicine (IOM) issued a report entitled *Nutrition Labeling: Issues and Directions for the 1990s* (11). The IOM report recommended changes in food labeling to assist consumers in implementing the recommendations of the Surgeon General (7) and the National Research Council (8). The FDA responded by working with all concerned parties, including industry, consumer groups, and the states, to define regulations that would meet the goals set out by the IOM report.

On November 8, 1990, President George Bush signed into law the Nutrition Labeling and Education Act (NLEA) of 1990 (12), which dramatically changed the way that food products were labeled in the United States. The NLEA represents a comprehensive mandatory nutrition-labeling system, designed to help consumers meet the U.S. *Dietary Guidelines* (6) and reduce their risk of chronic diseases. The intent of these regulations was to the provide guidance to food manufacturers and package designers needed to ensure consistent presentation of nutrition information and to prevent erroneous nutrient content and health claims.

The only significant change that has been made to the Nutrition Facts panel since the implementation of NLEA in the early 1990s was on July 9, 2003, when FDA issued a regulation requiring manufacturers to also list trans fat on the Nutrition Facts panel of food products. This regulation was the result of growing scientific reports confirming the relationship between trans fat and an increased risk of coronary heart disease.

REGULATORY AGENCIES

Regulation of food labeling falls primarily under the jurisdiction of two federal agencies: the Food and Drug Administration (FDA) and the United States Department of Agriculture (USDA) (13). The USDA's Food Safety and Inspection Service (FSIS) oversees food labeling of products containing meat or poultry ($\geq 2\%$ or more cooked, $\geq 3\%$ raw). All other food products fall under the jurisdiction of the Center for Food Safety and Applied Nutrition (CFSAN) of FDA. FDA regulations are governed by the Federal Food, Drug, and Cosmetic Act (FDCA) and the Fair Packaging and Labeling Act (FPLA). [The Nutrition Labeling and Education Act of 1990 (NLEA) is an amendment to the FDCA.] The USDA's regulatory role and responsibilities are defined by the Federal Meat Inspection and Poultry Products Inspection Acts. Because the two agencies are governed by separate laws, they have different missions, philosophies, and approaches to food labeling. This results in subtle differences throughout the regulations.

The USDA's primary regulatory role has been to prevent public health hazards resulting from improper handling of meat and poultry during production and packaging. The USDA's network of field offices are responsible for conducting frequent plant inspections, and the national office administers a label preapproval program. Through these mechanisms, the USDA tightly controls food labeling during the production process. Unlike the USDA, the FDA has not been funded to function as an inspection service; therefore, the agency does not have the staff resources to play a hands-on role in label development and approval. The FDA relies on postmarket surveys to enforce the regulations.

As discussed above, Congress passed the NLEA in 1990, mandating the FDA to initiate extensive changes in the content and format of the nutrition label. FDA responded by issuing final rules in January 1993 (14). Nutrition labeling of USDA products was not included in the Congressional mandate; however, the USDA decided to follow suit in order to prevent consumer confusion arising from two different nutrition labels (15). In most of the significant aspects of nutrition labeling, the USDA regulations mimic the FDA's; however, the regulations diverge in a few areas. For example, the USDA has different exemption criteria, more relaxed rules for use of the "Simplified" format, and less extensive requirements for statements that accompany nutrient content claims.

NUTRITION FACTS PANEL

The Nutrition Facts panel presents the nutrient profile of a food product on a per serving basis. Since a goal of NLEA was to make nutrition information easy for consumers to locate, read, and understand, both the content and layout of the Nutrition Facts panel were studied extensively before the regulations were finalized. The Nutrition Facts panel focuses on the nutrients important to the health of Americans (e.g., calories, fat, saturated fat, trans fat, cholesterol, sodium, fiber). The nutrient content of the food is presented in absolute terms (e.g., grams, milligrams) and as a percentage of the Daily Value (% Daily Value) for those nutrients where FDA has establised a Daily Value. Percentages provide a method for comparing the nutrient profile of the food to recommended nutrient intakes. Larger food packages are also required to include a list of the Daily Values at two calorie levels (i.e., 2000 and 2500) in a footnote at the bottom of the Nutrition Facts Panel. The serving size information has been standardized to make it easier to compare similar products. Serving sizes are presented in common household measures (e.g., cups, tablespoons) to help consumers visualize portion sizes, as well as metric units (e.g., grams), to encourage familiarity with the International System of Measures (13).

To maintain a consistent look from package to package, both FDA and USDA regulations explicitly define the layout of the Nutrition Facts panel (Figure 1). A hairline box surrounds the nutrition information, which is presented in a required order. The type size and leading (spacing between lines of type) of each line is specified. Boldface type is used to enhance certain nutrients, and other nutrients are indented. Heavy-, medium-, and lightweight rules are incorporated in specified places.

To provide some flexibility in tailoring the Nutrition Facts panel to various food packages, the regulations allow for several variations of the Nutrition Facts layout pictured in Figure 1. These variations are not a random choice; they each have explicit usage criteria (13). Format options are based on the nutrient profile of the food. Display options are available to accommodate different package shapes and sizes, as well as special situations (e.g., variety packages, foods for children, bilingual labels). In addition, the regulations allow for modification of the Nutrition Facts on packages that have limited space for labeling.

Format Options

The format of the Nutrition Facts panel refers to the nutrients listed on the panel (13). The regulations define 14 mandatory nutrients for inclusion in the Nutrition Facts panel; the "Full" format includes these 14 nutrients (Figure 1). In addition, the regulations allow for inclusion of certain nonmandatory nutrients, on either a required or voluntary basis. The Extended format accommodates the inclusion of nonmandatory nutrients in a specified order. An example of the Extended format is presented in Figure 2.

When a food product has one or more mandatory nutrients at an insignificant level (e.g., nutrient declaration of 0), an abbreviated format may be used. The "Shortened" format is available for FDA products that have between one and six insignificant nutrients. With this format, insignificant nutrients may be listed in a footnote stating, "Not a significant source of [list of

Figure 2. Extended Nutrition Facts format.

insignificant nutrients].” FDA products with seven or more insignificant nutrients may bear the Simplified format that allows insignificant nutrients and the Daily Values table in the footnote to be omitted. However, if nonmandatory nutrients are declared, then a variation, called the “Simplified Extended” format, is used. USDA employs a different approach to the Simplified format. The Simplified format is available for products that have one or more noncore, mandatory nutrients at insignificant levels. With all these abbreviated formats, five core nutrients (viz., calories, total fat, sodium, total carbohydrate, protein) must be listed, even if they are insignificant. Figure 3 presents examples of the abbreviated formats.

Display Options

The “Standard” display (vertical column) pictured in Figure 1 is the “model” Nutrition Facts layout from which all others are derived (13). On packages with limited vertical space, the “Modified” (footnote to the side) display may be used. If neither the Standard nor Modified displays will fit, then the “Tabular” (horizontal) display may be used. Figure 4 presents the Modified and Tabular displays.

To accommodate special packaging and labeling situations, other displays are allowed. The “Dual Column” display provides for listing nutrients on an “as prepared” as well as an “as packaged” basis. The “Aggregate” display

allows for presentation of nutrition information for a variety of products contained within one package (e.g., variety package of cereal). Figure 5 pictures the Dual Column and Aggregate displays.

A "Bilingual" display accommodates inclusion of a second language in the Nutrition Facts panel. Special labeling requirements apply to foods intended for young children, so the Nutrition Facts panel is modified for these products.

Package-Size Considerations

For packages with <40 in.^{2} of "available space to bear labeling," any of the displays can be modified to create a smaller Nutrition Facts panel. Specifically, the Daily Values table may be omitted from the footnote and abbreviations may be used. Figure 6 illustrates these modifications of the Standard and Tabular displays.

On packages with <12 in.^{2} of available space that contain no other nutrition information and make no claims, the Nutrition Facts panel may be replaced with an address or phone number where nutrition information can be obtained. The "Linear" (paragraph) display is provided to accommodate nutrition labeling of these small packages when claims or nutrition information is present (Figure 7). (A larger display may be employed at the manufacturer's discretion.) If no other display will fit, then the Linear (paragraph) display also may be used on packages with 12–40 in.^{2} of available space.

Table 1 summarizes what display options are available to various package sizes and the modifications that can be made.

Figure 5. Dual Column (**a**) and Aggregate (**b**) displays.

CLAIMS

The regulations define two categories of claims: nutrient content (or descriptors) and health claims (13). Nutrient-content claims are statements about the level of a nutrient in a food. Health claims, on the other hand, link the nutrient profile of a food to a health or disease condition. Nutrient content claims are used widely by the food industry. Since the regulations governing health claims are more complicated and restrictive, health claims are not as common.

Nutrient-Content Claims

Nutrient-content claims (sometimes referred to as "descriptors") characterize the level of a nutrient in a food. Only defined terms can be used on the label to describe a food's nutrient content. When these terms are used, a product must meet specific criteria. Nutrient-content claims may be implied or expressed, comparative or absolute (Table 2).

When a product bears a nutrient content claim (whether it is implied or expressed), certain information must be incorporated into the design of the package. Depending on the type of claim and whether the product is governed by FDA or USDA, the requirements for claims-related information will vary. FDA mandates more extensive information than USDA (i.e., the inclusion of either a Referral or Disclosure Statement), and both agencies require additional information on products bearing comparative claims. All required statements must adhere to placement and typesetting requirements that are defined by the regulations. Table 3 summarizes the

Figure 7. Linear display.

required statements that must accompany nutrient-content claims.

When an FDA-regulated product bearing a nutrient-content claim contains excessive levels of key nutrients that are associated with health risks, FDA requires a Disclosure Statement that flags the nutrient(s) of concern and directs the consumer to the Nutrition Facts panel. The statment must be appear next to the largest claim on each panel unless the claim is on the same panel as the Nutrition Facts statement.

Both FDA and USDA product labels that bear a comparative claim must include a Nutrient Claim Clarification statement and Quantitative Information. On FDA products, this information is required in addition to a Referral or Disclosure Statement. The Nutrient Claim Clarification statement identifies the comparison food and states the percentage (or fractional) difference in the subject nutrient(s) between the product and its comparison food [e.g., 50% less fat than (comparison food), ~33% fewer calories than (comparison food)]. The Quantitative Information provides the absolute amounts of the subject nutrient(s) in the product and the comparison food. This required information can be presented in a chart or narrative format.

Health Claims

FDA has defined nine health claims and created very strict criteria for use of these claims. No other nutrient-disease associations can be made in food labeling. Written statements, third-party references (e.g., "American Heart Association"), use of certain terminology in a brand name (e.g., "heart"), symbols, and vignettes may be considered a health claim if the context in which they are presented either suggests or states a relationship between a nutrient

Table 1. Display Options Based on Package Size

[a] Per labeled serving.

and a disease. When a statement, symbol, vignette, or other form of communication suggests a link between a nutrient and a disease, it is considered an implied health claim, and it is subject to all the requirements for health claims. The USDA has proposed regulations that parallel the FDA's.

The regulations governing health claims are very complex. When a product bears a health claim, very specific language must be used on the label. The regulations pertaining to each health claim outline the assertions that can be made and any additional required statements. When a claim is implied through graphic representations, a complete claim statement must be included on the label.

Since the required statements can be quite lengthy, the complete claim may appear on a back or side panel. When this approach is taken, a reference statement may be placed on the front panel, flagging the claim and directing the consumer to the location of the claim (e.g., "See ——— for information about the relationship between ——— and ———." The first blank contains the location of the health claim (e.g., back panel, attached pamphlet); the second blank should state the nutrient; and the third blank, contains the disease or health-related condition. Products bearing health claims must undergo careful review by legal and/or regulatory experts to make certain that the language is accurate and any graphics are acceptable.

NUTRITION-LABELING RESOURCES

Although this article summarizes the evolution of nutrition labeling and provides an overview of the nutrition-labeling regulations, it is not a sufficient resource for implementing the regulations. Understanding and complying with nutrition-labeling regulations requires a detailed working knowledge of the regulations and continuous monitoring of regulatory changes. Regulatory guidebooks, such as those listed in the Bibliography at the end of this article, can be expedient; however, consulting the regulatory source documents is the most accurate approach.

All federal regulations are compiled and updated annually in the *Code of Federal Regulations* (*CFR*). Each federal agency is assigned a numerical title of the *CFR* in which the agency's regulations are published. The FDA regulations are published in Title 21, which includes eight volumes of regulations, pertaining to foods, drugs, and other products administered by the FDA. The first three volumes contain the regulations related to foods (Part 1 through 99, Parts 100 through 169, and Parts 170 through 199). USDA's food labeling regulations can be found in the second volume (Parts 200 to end) of Title 9 of the *CFR*.

Since the *CFR* is updated only on a annual basis, other sources must be consulted to identify recent regulatory changes. The *Federal Register* releases proposed and final regulations for all federal regulations on a daily basis. Regular monitoring of the *Federal Register* is the most accurate method of staying current. Many trade publications include columns that summarize regulatory updates of importance to their readers. *Food Labeling News*, a weekly newsletter, is another source for obtaining current information on regulatory aspects of food labeling, advertising, and packaging.

NYLON

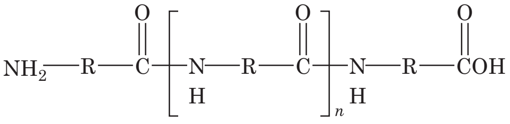
Updated by Staff

INTRODUCTION

Nylons are selected for applications in the packaging industry mainly for their functional contributions. In general, they offer clarity, thermoformability, high strength and toughness over a broad temperature range, chemical resistance, and barrier to gases, oils, fats, and aromas. For most packaging applications, nylons are used in film form, as single components in multilayer structures (see Films, plastic; Multilayer flexible packaging). Multilayer coextruded thermoformable structures containing polyester and nylon layers have been reported (1).

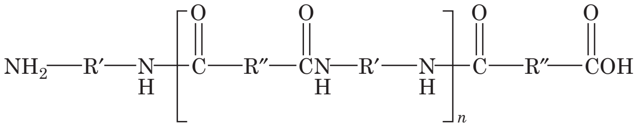
Nylons, or polyamides, are thermoplastics characterized by repeating amide groups (–CONH–) in the main polymer chain. The various types of nylon differ structurally by the chain length of the aliphatic segments separating adjacent amide groups. The combination of hydrogen bonding of amide groups and crystallinity yields tough, high-melting thermoplastic materials.

Polyamides can be described as long-chain molecules with amide functionalities (–CONH–) as an integral part of the repeat unit. Film-forming nylons are usually linear and conform to either of two general structures.



$$NH_2{-}R{-}\overset{O}{\overset{\|}{C}}{-}\left[\underset{H}{N}{-}R{-}\overset{O}{\overset{\|}{C}}\right]_n{-}\underset{H}{N}{-}R{-}\overset{O}{\overset{\|}{C}}OH$$

(1)

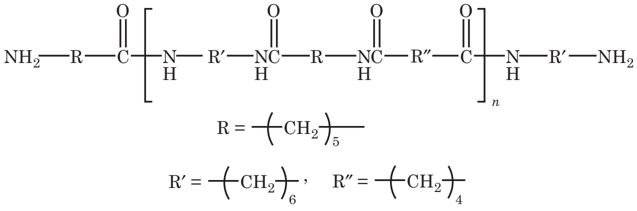


$$NH_2{-}R'{-}\underset{H}{N}{-}\left[\overset{O}{\overset{\|}{C}}{-}R''{-}\overset{O}{\overset{\|}{C}}\underset{H}{N}{-}R'{-}\underset{H}{N}\right]_n{-}\overset{O}{\overset{\|}{C}}{-}R''{-}\overset{O}{\overset{\|}{C}}OH$$

(2)

Examples of the first polymers are nylon 6 [R = $(CH_2)_5$], nylon 11 [R = $(CH_2)_{10}$], and nylon 12 [R = $(CH_2)_{11}$]. Here, the nylon type corresponds to the total number of carbon atoms in the repeat unit. Examples of the second-type nylons are nylon 6,6 [$R' = (-CH_2-)_6, R'' = (-CH_2-)_4$], and nylon 6, 10 [$R' = (-CH_2-)_6, R'' = (-CH_2-)_8$]. In the case of the second-type polymers, R′ refers to the number of methylene (CH_2) groups or carbon atoms between the nitrogen atoms and the R″ refers to the number of methylene groups or carbon atoms between the CO groups. The *n* in the formula is the degree of polymerization and its value determines the molecular weight of the polymer.

Nylons can also be prepared as copolymers. For example, a nylon 6/6, 6-copolymer might have the formula



$$NH_2{-}R{-}\overset{O}{\overset{\|}{C}}{-}\left[\underset{H}{N}{-}R'{-}\underset{H}{N}\overset{O}{\overset{\|}{C}}{-}R{-}\underset{H}{N}\overset{O}{\overset{\|}{C}}{-}R''{-}\overset{O}{\overset{\|}{C}}\right]_n{-}\underset{H}{N}{-}R'{-}NH_2$$

$$R = \left(CH_2\right)_5$$

$$R' = \left(CH_2\right)_6, \quad R'' = \left(CH_2\right)_4$$

If the amounts of the nylon 6 and nylon 6,6 monomers are varied, many combinations of the comonomers are possible. This would give rise to a series of nylon 6/6,6 copolymers with different properties (2).

PROPERTIES

The flexibility of aliphatic chains permits film orientation to further enhance strength (3). As the length of the aliphatic segment increases, there is a reduction in melting point, tensile strength, water absorption, and an increase in elongation and impact strength. Copolymerization also tends to inhibit crystallization by breaking up the regular polymer chain structure and likewise yields lower melting points than the corresponding homopolymers (4). The selection of a particular nylon for an application involves consideration of specific physical requirements (mechanical properties, barrier properties, dimensional stability), processability (melting point), cost, and so on.

Recent research efforts have been focused on producing multilayer packaging films to improve their photostability and recycling. The technology of blending represents a potentially relevant new approach to barrier films with improved recyclability as compared to multilayers. Theses films are made on nylon 6 blended to ethylene-*co*-vinyl alcohol (EVOH) in the presence of carboxyl-modified EVOH (5). Due to environmental issues, increased efforts have been made in developing barrier polymers for food packaging that guarantee degradability. A potentially degradable polymer based on the modification of nylon 10/12 was reported (6). The chemical modification consisted of the replacement of two C–C linkages with two ether linkages. A remarkable effect due to the ether linkage produced an increase in water solubility and diffusivity. A pronounced increase in water permeability was detected. Nylon treated with UV light has been examined as to its antimicrobial activity. Observed activity is presumed based on the formation of surface amines (7).

Table 1 lists comparative properties of commercial nylon films.

PROCESSING METHODS

Extrusion

Nylons are melt-processable via conventional extrusion, but some parameters differ from those used in extruding other resins (see Extrusion). Since the quality of extruded film is sensitive to raw-material defects, nylon resins should be clean and free of gel particles. Selection of resin viscosity depends on use. Low-viscosity resins are used in extrusion coating to allow rapid drawdown rates, whereas medium- to high-viscosity resins are preferred for film production. Because nylons are hygroscopic, special care is required to ensure sufficiently low water content (<0.10 wt%) for the extrusion process. Unless properly packaged and stored, nylon resins absorb moisture from the atmosphere and inevitably pose processing difficulties (8). In any extrusion operation, continuous production of uniform-quality film as well as maintenance of a safe work environment is best achieved by monitoring and tightly controlling all machine variables (temperatures, head pressure, extruder drive load, screw rpm, etc.) (9, 10).

Many film converters have been successful in producing nylon film on conventional polyethylene extruders, making only small modifications. The most important factors to consider are temperature control and screw design. The extruder must be equipped with adequate heaters for the required processing temperatures (9). In addition to heating capability, temperature control should permit little fluctuation ($\pm 3^\circ$C) to ensure delivery of a proper and consistent melt. Typical temperature profiles are shown in Table 2.

Although a variety of screws have been used successfully for processing nylon resins, not all screws are optimum for the nylon being processed. In general, a nylon screw is thought of as a rapid-transition metering-type screw. A compression ratio (volume of a feed flight relative to the volume of a metering flight) of 3:1 to 4:1 is acceptable for most nylons. Most nylon screws are 40% metering, 3–4 turns transition, and the remainder feed zone. Length to diameter ($L:D$) ratios of 20:1 and 24:1 are common and acceptable. In designing a screw for a specific nylon, factors that must be considered include melting point of the resin, melt viscosity characteristics, machine type, extrusion rate, and so on (8).

Film Manufacture

Nylon film can be produced by either the cast-film process or the blown-film process. Semicrystalline polymers like the nylons can be made “amorphous” by rapidly quenching the melt via the cast-film process. That is, the polymer chains are prevented from aligning and organizing into regular, three-dimensional “crystalline” structures. Thus, by varying quenching rates, nylons are capable of existing in a low-order or amorphous state and in a highly crystalline state. The properties of the final film are highly dependent on the crystalline state of the polymer. By a rapidly quenching the melt, favorable properties of transparency and thermoformability are induced.

In producing nylon film by the blown-film process, the cooling rate is much slower than for the cast-film process: The film is allowed to crystallize and film clarity is generally sacrificed. Blown films are used in applications requiring tubular film, or films of higher strength or better gas-barrier properties than yielded by the cast process. A chrome-plated bottom-fed die with a spiral mandrel is generally recommended for blown-film processing to minimize weld lines and polymer degradation due to stagnant hold-up of melt in the die. Because of their stiffness, nylons pose wrinkling problems in the bubble-collapsing phase of production. Special care is required to properly align the collapsing frame and nip rolls, minimize gauge variations, and limit drag force in the collapsing assembly. It has been suggested that the lower-density nylons show less-severe wrinkling problems (8).

Oriented Nylon Films

The high strength and toughness properties of nylon films can be further enhanced by orientation. The increased alignment and tighter packing of polymer chains resulting from the process also yields improved barrier properties. Table 3 lists property comparisons for unoriented versus biaxially oriented films. Preferential orientation, typically machine direction, improves strength and toughness in

Table 1. Properties of 1-mil (254.4-μm) Nylon Films

			Value				
Property	ASTM Test		Nylon 6	Nylon 6,6	Nylon 6/6,6	Nylon 6/12	Nylon 6, Biaxially Oriented

the direction of orientation. Biaxial orientation yields films with balanced properties. Market development efforts in this area are concentrated on critical packaging applications requiring soft films that permit tight package conformation and offer improved impact strength and reduced pinholing, superior burst strength, and flexcrack resistance. As with most other flexible substrates, oriented films permit further conversion, (e.g., printing, lamination, metallization, etc.).

Three processes are used to manufacture biaxially oriented nylon film.

One-Step Tenter Frame. This process simultaneously draws cast nylon film in both the machine and transverse direction (11).

Two-Step Tenter Frame. This is a two-step orientation process in which a nylon film that has been modified with a plasticizer is first drawn in the machine direction and then drawn in the transverse direction (12).

Blown Bubble. Nylon film extruded from a circular die is oriented in the transverse direction by controlled internal air pressure, and it is also oriented in the machine direction by regulating the bubble takeoff speed (13).

Coextrusion

Nylons used in film extrusion are often combined with other plastic materials via coextrusion. In most cases, polyolefins are used as coextrusion partners for nylon to provide heat sealability, moisture barrier, and good economics. As in single-layer-film extrusion, nylons can be processed by cast-film coextrusion and by blown-film coextrusion (see Coextrusion, tubular). The combining-adapter technology is generally the preferred method for joining layers in cast film coextrusion of nylon, although multimanifold-die systems are also used. Special care in matching resin viscosities is required when using the combining-adapter system in order to produce films of uniform layer profile. For both systems, nylon 6 is the most common and preferred polyamide used in cast film coextrusion.

Because the blown-film coextrusion process employs air as the cooling medium, the melt is cooled slowly, permitting spherulite formation in semicrystalline nylon homopolymers (i.e., nylon 6, nylon 6,6) and film transparency is sacrificed. For this reason, less-crystalline nylon copolymers such as nylon 6/12 and nylon 6/6,6 are gaining acceptance in blown-film coextrusion.

Applications for nylon/polyolefin coextruded films include vacuum packaging of meat products, cheese-

Table 3. Comparative Properties of Unoriented, Uniaxially Oriented (MD), and Biaxially Oriented Nylon-6 Films (1-mil or 25.4-μm Films)

		Values

ripening pouches, consumer packaging of cheese and fish products, and several nonfood packaging applications including containers for chemicals, fertilizers, and animal foods.

Extrusion Coating

Nylons with lower viscosity permit rapid drawdown rates for extrusion coating (see Extrusion coating). Typical substrates range from heavy-duty paperboard to intermediate aluminum foils and papers, to thin polyethylene films. Published literature describes the nylon extrusion coating process in detail (8, 14). As in cast-film production, annealing the nylon coating is necessary to impart dimensional stability when a flexible substrate is used.

Blow Molding

Nylons of ultrahigh viscosity are commonly used in blow molding (see Blow molding). Because of their excellent impact strength, chemical resistance, toughness, and wide temperature use properties, nylons are ideally suited for several blow-molded applications, including industrial containers, moped fuel tanks, and automotive oil reservoirs. A recent development for nylon in blow molding has been in the area of blow-molded hydrocarbon-barrier containers. The process employs a blend of a modified nylon barrier resin and a polyolefin, extrusion blow molded under controlled mixing conditions to produce a barrier container competitive with surface-treated HDPE bottles (3, 4, 14). Packaging applications include containers for charcoal lighter fluids, general-purpose cleaners, waxes, polishes (see Surface modification) and those described in several patents (15).

Secondary Conversion

Thermoforming. Nylon films are readily thermoformed by conventional methods (see Thermoforming.) Ease of formability is affected by nylon type (melting point), molecular weight, degree of crystallinity, and machine variables. In general, nylon films offer excellent thermoformability due to their high elongation. Furthermore, the high elongation facilitates deep draw, and flex- and stress-crack resistance of nylons minimize film breaks during and after forming. Current applications include (a) vacuum and gas packaging of meats and cheeses and (b) thermoform/fill/seal packaging of disposable medical devices (see Controlled Atmosphere Packaging; Healthcare packaging; Thermoform/fill/seal.)

Heat Sealing. Because of their high melting points, nylons are typically coextruded with, laminated to, or coated with a polyolefin heat seal layer (PE, EVA, EAA, ionomer, etc.). However, unsupported nylon films are heat sealed for applications that require heat-seal integrity under high-temperature exposure (e.g., oven “cook-in” bags). By properly balancing the variables of time, temperature, and pressure, unsupported nylons can be heat-sealed at relatively low temperatures. For most commercial applications, however, it is necessary to heat the films to temperatures that closely approach their melting points. This factor, compounded by the relatively narrow melting range of nylons, necessitates precise temperature (±3°C) and pressure control. By making necessary modifications to conventional machinery, nylons are successfully heat-sealed by thermal impulse and constant-heat techniques.

Adhesive Lamination. Nylon films are combined with other flexible materials via adhesive lamination to produce multiple structures, each ply contributing to the requirements of the end product (see Laminating; Multilayer flexible packaging). Typical substrates include sealant webs (PE, EVA, ionomer, etc.), and aluminum foils. Converters may choose to laminate rather than coextrude nylon to minimize scrap losses for short runs. Lamination is also necessary when combining non-coextrudable or incompatible plastics. The lamination process is described in detail in published literature (16). The adhesive is generally applied to the nylon web which has been corona treated (see Surface modification) to assist wettability, as the high melting point of nylon provides suitable stability in solvent-drying ovens. Adhesive systems are typically two-component types that vary for nylon types and substrates. Nylon film suppliers recommend adhesives for specific substrates (see Adhesives).

Vacuum Metallizing. Applications for metallized oriented nylon films are expanding in the packaging industry. Metallization offers functional contributions of improved moisture, oxygen, and light barriers and unique aesthetic appeal at the consumer level (17). The resultant film offers excellent flexibility, oxygen barrier, flex-crack resistance, antistatic properties, and printability. These properties meet the necessary requirements for use in such applications as institutional coffee pouches, metallized balloons, and liquid-box containers (see Bag-in-box, liquid product; Metallizing).

PACKAGING APPLICATIONS

Although nylons are not generally considered commodity-packaging resins, the added material cost is easily justified in specific demanding applications where the nylons’ physical properties provide added protection, extended shelf life, or reduced losses of expensive contents. The combination of excellent thermoformability, flexcrack resistance, abrasion resistance, gas-, grease-, and odor-barrier, and tensile-, burst-and impact-strength over a broad temperature range make nylons well suited for many packaging applications. For most applications, nylons are combined with other materials that add moisture barrier and heat sealability, such as low-density polyethylene, ionomer, EVA, and EAA.

Most nylon-containing packaging films are used in food packaging, principally in vacuum-packing bacon, cheese, bologna, hot dogs, and other processed meats (18). A variation of this package includes a carbon dioxide flush prior to heat sealing to remove traces of oxygen, thus prolonging shelf life for foods such as poultry, fish, and fresh meat (19). Poly(vinylidene chloride) (PVDC) coatings are offered for improved oxygen-, moisture vapor-, or UV light-barrier properties (see Vinylidene chloride copolymers).

Nylon 6 is the nylon resin used most frequently for packaging applications because of the balance of cost, physical properties, and process adaptability. For blown or cast extrusion as well as cast coextrusion, nylon 6 resins are favored by most converters, while lower-melting nylon copolymers (nylon 6/6,6 or nylon 6/12) have been developed primarily to aid blown-film coextruders (lower melting points permit lower process temperatures for faster melt quenching). In addition to lower melting points, the nylon copolymers are less crystalline than their corresponding homopolymers and provide better clarity and thermoformability. On the high end of the melting-point scale, nylon 6 and nylon 6,6 resins are appropriate for use in oven-cooking bags, where high-temperature tolerance is a key requirement. A ready-to-bake fish fillet product is possible using an ovenproof film of nylon 6,6 for packaging during storage (20).

Medical-packaging applications, such as packaging of hypodermics and other medical devices, are a relatively new and expanding area for the nylons. The combination of toughness, puncture resistance, impact strength, abrasion resistance, and temperature stability make nylons appropriate for protecting sterile devices during shipping and storage. Although ethylene oxide and steam have always been appropriate means of sterilization for nylons, modified-nylon resins have recently been introduced that permit radiation sterilization as well (21).

Biaxial orientation of nylon films provides improved flex-crack resistance, mechanical properties, and barrier properties. These films have new applications in packaging foods such as processed and natural cheese, fresh and processed meats, condiments, and frozen foods. They are used in pouches, in bag-in-box structures, and in a box for wine (22) (see Bag-in-box, dry product; Bag-in-box, liquid product). In other areas (e.g., cooked meats, roasted peanuts, smoked fish) the nylons compete with biaxially oriented polyester (see Film, oriented polyester). Although oriented nylons offer better gas barrier, softness, and puncture resistance, oriented polyester offers better rigidity and moisture barrier.

Other uses for nylon film include a nylon-6 shrink film (see Films, shrink) for meat and fresh-vegetable packaging (23), a nylon composite film used in a system to produce greaseless fried chicken (24), a uniaxially oriented nylon-6 film for food packaging (25), a nylon-6 film with improved thermoformability (26), and a nylon film as an outer protective layer for aluminum foil in cookie and vacuum coffee packages (22). Laminated structures containing nylon provide an oxygen barrier for packaging liquid and dry products. These structures are used for packaging fruits, citrus juices, tea, and other beverages (27).

INTRODUCTION

Off-odor and off-flavor compounds that are responsible for the sensory response are detected by the taste and olfactory systems. The challenge for analytical instrumentation is to detect and identify those compounds most responsible for the off-odor or off-flavor. This task is further complicated by the fact that the compounds with the highest sensory response have very low odor thresholds. That is, they can be present at part per million (ppm) or part per billion (ppb) levels. The analytical methodology must be able to separate, identify, and quantitate these off-odor compounds at very low levels in the package.

Since the 1970s, there have been excellent advances in the instrumentation, experimentation, interpretation, and application of measurement techniques, that have increased the separation and lowered the detection limit of compounds that have low odor thresholds and high human sensory response. Much of the off-odor references for investigation are derived from the flavor and aroma chemistry field, in which the analytical methodology has been centered on isolation and identification of the volatile compounds known to give the organoleptic human response. Because of their volatility, these compounds are predominantly analyzed by some form of gas chromatography (GC). Capillary GC can be tailored to give the separation and sensitivity needed for the analysis of off-odor compounds. It is easily amenable to various sample introduction techniques, and specific, universal, or confirmatory detectors.

ANALYTICAL INSTRUMENTATION FOR DETERMINING THE CHEMICAL COMPOSTION OFF-ODOR COMPOUNDS

Gas chromatography (GC) is the separation of a mixture of compounds that are put into the vapor state, carried through a chemically coated column, selectively separated based on a physical or chemical property, and identified with a specific detector. GC was developed using a packed metal column of about 2 m, with a stationary support that was coated with a nonvolatile liquid phase. It is now predominately performed with high-resolution GC (HRGC), using capillary columns ranging from 15 to 100 m long. The type of GC detectors most often employed in aroma and flavor analyses are; flame ionization detector (FID); mass spectrometry—full scan (or total ion) mode MS-TIC; mass spectrometry in selective ion monitoring mode (MS-SIM); GC—olfactometry (GC-O). The selection of the detector depends on the complexity of the volatile mixture being separated, the properties of the compounds in the mixture, and the levels at which those analytes of sensory response interest exist.

The methodology chosen for off-odor and off-flavor compound isolation is a critical step in ensuring that the entire mixtures that cause the sensory response are analyzed. Solid-phase extractions (SPE) and SP-micro-extraction (SPME), headspace (HS) extractions, thermal desorption (TD), and purge and trap (P&T) are common techniques employed to facilitate the extraction of the compounds and then analyzed by the GC instrumental system.

Gas Chromatography—Olfactory (GC-O)

Gas chromatography—olfactometry (GC-O) is a true hyphenated analytical and sensory technique. It is widely applied to confirm the actual olfactometric property of a suspected off-odor, off-flavor, or off-aroma compound. The isolated mixture is injected into a GC, the compounds in the mixtures are separated, and the effluent vapors from the column are usually split to an instrumental detector and a sniff port (Figure 1). The sniff port is conditioned with humidified air to protect the nasal passages of the analyst (or panelist) and the vapor compounds separated from the mixture by the column elute out of the sniff port and are detected by the human nose. An electronic signal is generated by the analyst

Figure 1. Gas Chromatograph equipped with a sniff port.

upon detection of the odor. A descriptor is also recorded for each compound. The final olfactogram is reconstructed by averaging the individual olfactograms of the replicate samples, identifying the odor-active compounds in the odorant areas (1). GC-O was successfully used in conjunction with triangle tests to determine the effects of oxidation of critical flavor active compounds during wine processing (4).

Gas Chromatography–Flame Ionization Detector (FID)

GC-FID is the most widely used GC system in many different environments from production quality control to fragrance research. There is an abundance of published literature and application notes using this technique in a wide variety of fields where the analysis of volatile compounds is important (e.g., environmental, petroleum, industrial solvents, food packaging, flavors and fragrances). The identification of a compound is based on the retention time on a particular column, compared to a known standard. They can also be compared to a series of n-paraffin hydrocarbons, which determines their retention index (RI). This comparative retention index of a compound allows comparison with different instrument configurations to published data, as was done in the wine research of Le Fur et al. (1). In the wine industry, GC-FID is used in conjunction with GC-MS to quantitate the chemical composition of the volatile aroma compounds in foods (2, 3). The GC-FID is also commonly used in-line concurrently with GC-O, where the column effluent is split to the FID and sniff port at the same time (5). These techniques used in the food and wine industry have been adapted to off-odor analysis by the authors of this article.

Gas Chromatography–Mass Spectrometry (GC-MS)

The improvement of the mass spectrometer since the 1980s has made it readily available to a wide variety of industries. It is the most appropriate analytical tool to enable the detection, identification, and quantitation of flavor aroma active compounds with odor thresholds in the very low ppb range. The utility of the MS is in its generation of a third dimension of the mass spectral identification to the chromatographic separation of column retention time in the column and response at the detector. There are many examples in the literature search for the utilization of GC-MS in the confirmation and identification of sensory significant compounds (1–8). The ability to generate a mass spectrum that is consistent and predictable to the chemical structure has led to large ($>$500,000 compounds) commercial databases of compounds that can be used to search and identify unknowns. The specific GC–mass spectrum of the individual off-odor and off-flavor compounds allows for their detection, identification, and quantitation at ppm or very low ppb levels (2).

Static Headspace Gas Chromatography–Mass Spectrometry (HS-GC-MS)

Static HS-GC-MS is used to obtain an overview of the volatile aroma compound mixtures. It is the simplest of the volatilization techniques, reproducing the natural volatilization of the aroma and flavor compounds in the sample. A liquid sample is heated in a closed container, and the volatile mixture of compounds present in the headspace above the liquid is sampled and analyzed by GC-MS. This technique is effectively used in food packaging and wine profiling to compare acceptable and unacceptable samples (i.e., off-odor and off-flavor). Its limitation is that the concentration of some off-odor or off-flavor compounds with very low odor thresholds are at levels below the detection limit of this method (i.e., ppb). The instrumentation available on the market allows for automated sampling of up to 100 samples, facilitating analysis of replicate samples to generate statistical significance of the results.

Purge and Trap Gas Chromatography–Mass Spectrometry (P&T-GC-MS)

Purge and trap (P&T) is a dynamic headspace volatile concentration technique. The volatiles are purged from the sample and trapped on an absorbent material (i.e., Tenax™). P&T is also used to prepare samples for concentrated GC-O (1) analysis. The trapped volatile compounds are then desorbed into the GC-MS, and the mixture is separated by the GC column and identified using the MS. P&T has been mostly done off-line, where the volatiles are trapped onto an absorbent material (i.e., Tenax). The trap is then installed onto a desorption apparatus, which sits over the injection port of the GC-MS, and the volatiles are desorbed at high heat (e.g., 300°C) and analyzed. P&T was used as a sample preparation on many of the experiments performed in the author's laboratories.

Thermal Desorption–Gas Chromatography–Mass Spectrometry (TD-GC-MS)

Thermal desorption (Figure 2) can be used to extract trapped volatiles that have been captured onto a chemical trap, as stated above in P&T-GC-MS. It has been used for the identification of off-flavors from food packaging materials (9). One way it is used is by trapping the outgassed volatiles P&T, which are then desorbed into the injection port of the GC-MS or GC-O (1). Another approach used is by direct thermal analysis (TA-GC-MS) of the plastic polymer film used for the food packaging, to release trapped off-odor compounds from the polymer matrix (11, 12). In that work by one of the authors, the cause of an off-odor in a polypropylene food packaging made from recycled resins was determined. Two compounds out of 175 chromatographic peaks were identified as the most organoleptic significant.

Electronic Gas Sensor Array (Electronic Nose)

The electronic nose (e-nose) is a measurement device that combines chemical sensing with electronic processing. Two of the most popular designs of e-nose sensors used in flavors and aromas are based on a conductive organic polymer sensor array and piezoelectric gas sensor. In the conductive organic polymer sensor array, the polymers swell to different degrees upon response to a volatile compound, changing their resistance. The resistance patterns of the array of

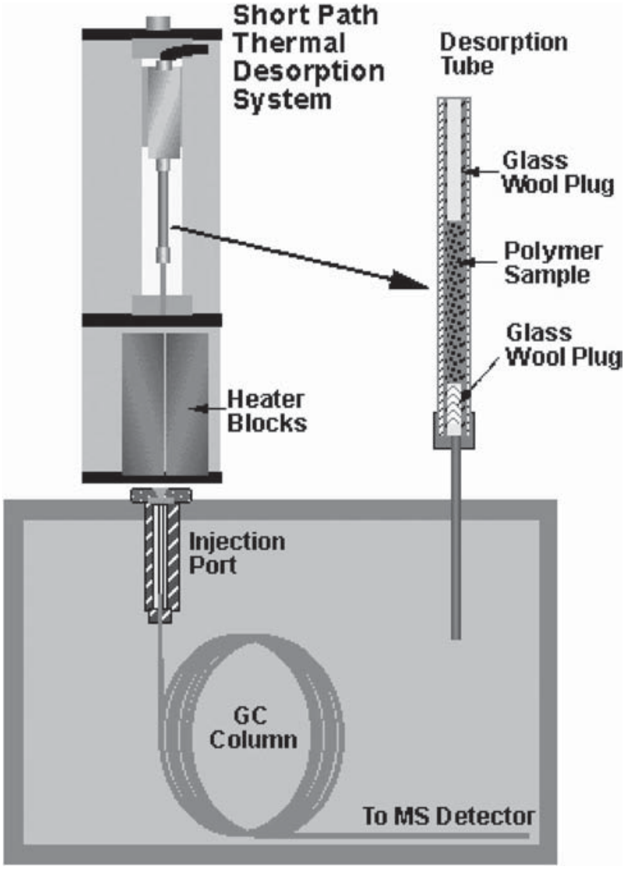

Figure 2. Thermal Desorption/Analysis System.

polymers are unique for each type of compound. The pattern display resembles the cross fiber pattern theory of taste, although the response mechanism is much different. The signal pattern generated by the e-nose sensor are downloaded to a chip (for handheld models), and also analyzed by computer. To be successfully applied, it is critical that the e-nose is "trained" with the compounds and volatiles of interest. This sensor was used in food quality control (6). It was shown that once the e-nose is trained with the standard, it is successful in detecting deviations and changes. The e-nose's portability make it an excellent in-line production screening tool, capable of identifying foods that fall outside of the calibrated, acceptable range. Another type of e-nose made from a piezoelectric gas sensor was applied to record and reproduce the odor of citrus to manufacture artificial citrus flavors (10). The array output pattern from the sensor was compared to the ten essential citrus oil standards. The multi-component mixtures were treated as single components, allowing successful duplication of typical orange flavor. The e-nose can be trained to identify if a food or package is different that the standard, but is less capable to identify and quantitate an off-odor or off-flavor compound as well as GC-MS.

OXYGEN SCAVENGERS

STANISLAV E. SOLOVYOV
Multisorb Technologies, Inc.,
Buffalo, New York

Oxygen scavengers comprise the most commercially important subcategory in active packaging applications and are a part of a much broader category of absorbers or sorbent materials for gases, vapors, liquids, and volatile organic compounds. Depending on their physicochemical nature, such absorbers can either reversibly or irreversibly remove an undesirable gaseous or liquid species from environments contained within a package. Common reversible absorption processes include physical adsorption of gas molecules to solid surfaces, bulk dissolution, and molecular diffusion of mobile species in solids and liquids. Mobile species absorbers, whose action is irreversible at the conditions of use, are generally referred to as scavengers of such species. Irreversible absorption (scavenging) generally proceeds via chemical reactions of the mobile species with the components of a scavenger system to form stable compounds. Oxygen scavenging processes include, for example: oxygen chemisorption, catalyzed oxidation of hydrogen gas to form water: catalyzed oxidation of ethylenically unsaturated hydrocarbons and organic polymers to aldehydes, ketones, and carboxylic acids; and oxidation of reduced transition metals to form stable oxides.

Molecular oxygen (O_2) is a highly reactive diatomic gas that forms about 20.9% of the earth atmopshere (1) and is necessary for sustaining organic lifeforms, but at the same time it causes many types of food and beverage spoilage, degradation of pharmaceutical formulations, and oxidation and corrosion of metals, electronic components, and various other products. Internal volume of any package is necessarily limited and contains a limited amount of oxygen; therefore it is possible to reduce or essentially eliminate the oxygen present inside the package by using oxygen scavengers. In food packaging, removal of oxygen trapped inside the package allows us to control aerobic microorganisms such as mold and many bacteria, slow down enzymatic activity, and reduce detrimental color and flavor changes due to oxidative deterioration (2, 3). The use of individually packaged oxygen scavenger formats, which are inserted in a package but do not form a part of food formulations, also allows food processors to reduce or eliminate less desirable direct food additives such as antioxidants and preservatives.

Individually packaged oxygen scavengers are produced in the form of packets or sachets containing a sacrificial compound that is formulated to rapidly oxidize and thereby eliminate free oxygen by chemically binding with it before it reacts with the packaged product (4). In addition to sachets, oxygen-scavenging internal labels applied with pressure-sensitive adhesive backings and oxygen-scavenging liners in bottle caps and crowns are marketed. Oxygen-scavenging polymeric films that appeared in the early 1990s allow us to eliminate loose sachets from the package and add an oxygen-scavenging functionality to the entire packaging structure or its part. The resulting hermetically sealed packages have a dual function, simultaneously providing for oxygen removal from the package interior and preventing ingress of atmospheric oxygen through otherwise permeable container walls by forming a reactive barrier to oxygen permeation. Applications of reactive barrier technology include oxygen scavenging plastic bottles for beer, juices, ketchup, and so on, pharmaceutical blister packs, plastic lidstocks, and thermoformed food trays.

The majority of all oxygen scavengers in commercial use are based on the oxidation of iron powders, although systems based on other oxidizable transition metals such as copper, zinc, magnesium, manganese, aluminum, titanium, and so on, have been proposed and patented. In recent years, multiple patents have been issued, describing organic oxygen scavenging chemistries with and without use of metal-based oxidation catalysts, specifically for the use as active barriers in plastic packaging applications. In this case the low oxygen permeability of polymer matrix is combined with high reactivity and substantial reactive capacity of oxidizable substrate to create an efficient and long-lasting active barrier to oxygen permeation (5). Organic oxygen scavengers are often preferable due to their transparency and compatibility with polymeric matrices that make it possible to produce optically clear oxygen barrier films and structures. Several formulations have been claimed as having zero effective oxygen transmission rates through the reactive barrier films for periods ranging from 1 to 3 months up to 2 years, thus outperforming glass packaging with essentially permeable seals and closures. In such cases the essentially zero oxygen transmission rates are achieved for reactive barrier systems characterized by a high degree of diffusion control of the overall forward rate of oxygen scavenging reaction. Diffusion-controlled reactions refer to the reactions of dissolved oxygen with the scavenging agent immobilized in a solid matrix, where the rate of oxygen removal by the reaction is much faster than the rate of oxygen diffusion through the solid matrix of the barrier layer (6).

Performance and packaging requirements to enclosed oxygen savengers differ substantially from those for reactive barrier applications. Enclosed scavenger formats are designed for a controlled mode and rate of activation, rate of oxygen absorption, and specific overall reactive capacity to absorb oxygen. Scavenging chemistries that are initially stable and inactive but can be activated on demand are preferable because they reduce the possibility of premature reaction and loss of scavenger activity before application. Scavenging systems are generally designed to be activated by external fields and penetrating agents such as UV radiation (photoreducible organic compounds) or moisture diffusion (oxidation of transition metals). Scavengers that are immediately active upon their manufacture are less desirable since they generally require high levels of protection from environmental oxygen before use. To rapidly deoxygenate a package, an oxygen-scavenging chemistry has to be readily accessible to both activating agent and oxygen. Therefore the scavenger packets are often made from microperforated or otherwise highly permeable film substrates. Numerous sizes and formats of packaged oxygen scavengers with varying oxygen absorption capacity and activated at different RH levels have been developed for specific applications.

Oxygen-scavenging capacity of the packaged scavenger unit as well as the mode and rate of its activation are critical for packaging system design. The rate of oxygen absorption by the scavenger, determined by its format and chemistry, and overall oxygen transmission rate (OTR) of the package wall determine the minimal attainable oxygen concentration in the package headspace. OTR of the package, together with the overall reactive capacity of the scavenger, control the overall duration of protection from ingress of ambient oxygen. In well-designed oxygen-scavenger/package systems, attaining and maintaining 100 ppm or less of residual headspace oxygen is considered to be the norm. At 100 ppm, effective control of the detrimental effects of oxygen on foods has been demonstrated (7). Oxygen scavengers are often used in conjunction with modified atmosphere packaging (MAP) techniques, such as vacuum packing and flushing headspace with inert gas before sealing, to reduce residual oxygen amounts. The gas flush reduces the scavenger reactive capacity requirement per package and is a more economic means of reducing the oxygen down to as little as 0.5%, but flushing alone is not capable of reaching the oxygen levels possible with the use of the scavenger (4).

The oxygen-scavenging technologies constitute a major part of active packaging techniques and methods, and they have been extensively patented worldwide, especially in Japan. Commercial use of oxygen scavengers started in 1976 in Japan and in 1984 in the United States. UK-based consulting and media concern Pira International Ltd. estimated the global value of the total active packaging market in 2005 to be worth more than US$1.5 billion and has forecasted this market to be worth more than US$2.6 billion in 2010. The global market for packaged oxygen scavengers was estimated to be 12 billion units in Japan, 500 million in the United States, and 300 million in Western Europe in 2001. This market was forecast to grow to 14.4 billion units in Japan, 4.5 billion units in the United States, and 5.7 billion units in Western Europe in 2007.

HISTORY

In 1869 Virgil Blanchard of Vermont obtained a U.S. patent for “improvement in preserving fruits, meats, and other substances” (8) by placing an insert with an alkaline solution of pyrogallic acid into an air-tight vessel. Removal of both headspace oxygen and oxygen leaked through the seals was claimed via reaction of pyrogallic acid with oxygen. In 1938 Henrik Tallgren of Finland was granted a British patent for “keeping food in closed containers with water carrier and oxidizable agents such as zinc dust, iron powder, manganese dust, etc.” (9). F. Isherwood of the Low Temperature Research Station at University of Cambridge obtained a patent for “removing oxygen from a container containing vacuum or gas packed food in which a metal absorbs oxygen to form an oxide” in 1943 (10). This early activity was followed by attempts to use powdered metals to purify industrial gases and the development of a system to scavenge oxygen by use of palladium catalysts in a hydrogen-flushed package by American National Can in the 1960s. In 1969, Mr. Fujishima attempted to market a hydrosulfite-based oxygen scavenger that reacted very quickly, causing problems with lost capacity, and also had a propensity to react with food volatiles to form noxious sulfur-containing gases. None of these early developments resulted in any significant commercial activity. Mitsubishi Gas Chemical Co. (MGC) of Tokyo, Japan has been issued a patent for a ferrous-iron-based scavenger formulation in 1977 and was the first company to start marketing of their Ageless® brand sachets in 1976.

The early success of oxygen scavengers in Japan appears to be tied to the tradition of gift-giving and the importance of flawless presentation and quality (11), especially in the hot and humid summer climate of Japan. When the gift was a food item, the quality assurance provided by an oxygen scavenger was a reasonable precaution. Several confectionery items given as traditional gifts also suffered from short shelf life due to mold growth. For foods such as Japanese rice cake, the shelf life and quality improvements afforded by a combination of a barrier package and an oxygen scavenger allowed for a longer distribution cycle and made Ageless® a commercial success. Competitors followed in Japan and other Asian countries, and today there are more than a dozen, although MGC is still leading the industry. Metal-based oxygen scavengers are not the only option, because many organic scavenging systems have been proposed with the goal to alleviate the possibility of food contamination by metallic compounds, prevent setting off metal detectors, and allow making microwaveable containers. Toppan Printing Co. has marketed an ascorbic-acid-based oxygen absorber since 1979. A catechol-based scavenger has been marketed by Oji Kako Co. under the Tamotsu™ name. Since early 1990s, many scavenger-based oxygen barrier films and structures have been developed with the goal of preventing oxygen ingress into the sealed package.

In the United States, oxygen scavengers were first used in 1984 when General Foods began to ship ground roast coffee with their “Fresh Lock,” an oxygen scavenger formulation supplied by MGC. Multiform Desiccants Inc. (currently Multisorb Technologies, Inc.) of Buffalo, New York entered the U.S. market with their Freshpax® brand oxygen scavengers in 1988 and an initial application for “Meal, Ready-to-Eat” (MRE) rations as developed by the U.S. Army Natick Research, Development and Engineering Command. The Aquanautics Corp. introduced “SmartMix and SmartCup” technology for compounding into packaging such as bottle-cap liners in the late 1980s (12). In addition, CMB Technology (France) introduced their Oxbar® oxygen barrier system, which used a cobalt salt catalyst to accelerate oxidation of MXD-6 nylon blended with PET (13). The original Oxbar® did not become a commercial technology; however, its later reincarnations as MonOxbar® and optically clear DiamondClear® technology, currently a part of Constar International (USA) portfolio, have gained significant publicity and resulted in several commercial applications.

A wide acceptance of oxygen scavengers by the Japanese food industry has not yet been repeated in other markets. Food is more expensive in Japan than in the United States; thus the cost of an oxygen scavenger versus the value of preservation afforded a greater incremental packaging expense in the Japanese market. The U.S. food industry has had other reservations, especially regarding the liability of loose scavenging sachets and potential food contamination by their contents. The acceptance is growing in the United States and Europe as the technology has matured and adapted to specific applications that make economic sense in the U.S. and EU markets. Notably, food stores at Walmart supercenters in the United States started switching from high-oxygen packaging for case-ready meats to low-oxygen master packs with enclosed oxygen scavengers in late 2007 to improve preservation and shelf life of red meats such as beef steaks and ground beef.

SPOILAGE CONTROL WITH SCAVENGERS

Preservation of foods and other products with the use of an oxygen scavenger will be improved only when an oxygen-related spoilage is the primary pathway of quality deterioration. The economic significance of the various spoilage types attributable to oxygen also varies and should be factored into any decision to employ a scavenger. In situations where control of oxygen is warranted, the observable advantages include greatly reduced losses and returns due to spoilage, improvement in consumer confidence and relations, increased distribution radius due to a longer shelf life with correspondingly increased sales expectations, and improved plant scheduling due to longer product runs taking advantage of the longer shelf life.

Primary use of an oxygen scavenger is to control aerobic microorganisms. While both MAP and vacuum packaging have the capability to aid in control of aerobic bacteria and mold, it has been reported that mold colonies may grow in even 0.4% residual oxygen in as little as 10 days (7). Both vacuum and MAP techniques may not be able to effectively deliver or maintain such low initial residual oxygen concentrations, although an appropriate concentration of carbon dioxide may also effectively suppress mold growth. However, Powers and Berkowitz (14) noted that an oxygen absorber prevented mold growth in specially formulated and packaged bread for up to 3 years, and oxygen scavengers are also reported to control mold growth on crusty rolls for at least 60 days (15). In commercial practice, use of an oxygen scavenger to control mold is a major use in Japan but has been of minor importance elsewhere in the world. Use of barrier packaging for baked goods appears to be more prevalent in Japan than in the United States, and oxygen scavenger use makes sense only where a suitable barrier to oxygen permeation is employed. In the United States, the MRE, beef jerky, and fresh pasta industries have adopted packaged oxygen scavengers to control mold growth on their products. Permeation of oxygen into the package over time, which leads to mold growth, is the major concern that can be addressed with either enclosed scavengers or reactive barrier packaging.

Another oxygen related mode of food spoilage is through oxidation of various pigments in the food itself (16). This generally takes the form of a darkening of color—for example, due to enzymatic browning reactions (17). While color change does not in and of itself make the food product inedible, consumers appear to perceive that such darkening is an effective indicator of other spoilage problems that may have occurred simultaneously. Therefore, such pigment darkening may effectively end the shelf life of the packaged product. The smoked/processed meat industry is especially aware of the problems of discoloration and consumer reluctance to purchase packages exhibiting a color darker than other packages in the same retail case. Oxygen scavengers, more than any other packaging method, excel at reducing headspace oxygen to such low levels that pigment oxidation does not occur for extended periods of time (16, 18). Color preservation is often cited as a reason for using oxygen scavengers in the United States and Europe.

Another mode of oxygen related deterioration of foods is through oxidation of fats and oils in the product (7, 16, 19). This process is commonly referred to as the rancidity of lipids and yields organoleptic changes in them that are usually considered undesirable even though rancidity is commonly accepted in some food products such as fried fish and nutmeats. The byproducts of this type of oxidation may include peroxides, aldehydes, ketones, and carboxylic acids. The presence and undesirable odor of many aldehydes and ketones is detected by humans at levels well below 1 ppm, and this fact presents a major problem for food processors. Use of an oxygen scavenger has been shown to positively control this type of oxidation (20) because peroxide values have remained essentially unchanged over time in packages protected by the scavenger. Conversely, reduction of headspace oxygen to the low ppm range tends to preserve vitamin and nutrient content of foods.

Another example of a type of food spoilage, related to oxygen in the package headspace, is insect infestation. Many grains and flour products suffer losses due to weevils and the like, and it has been shown that these can be controlled by use of an oxygen scavenger (21). While an infestation may have been suppressed during the storage of the bulk grain, either a later hatch or a reinfestation may occur during packaging or distribution. Insect eggs, larvae, or pupae may be present, but all need some amount of oxygen to survive. Elimination of the headspace oxygen will eventually kill all forms of the infestation and prevent further damage, although it may take as long as 12 days to kill the eggs of some of the more resilient insects. There have been limited uses of this concept in the United States for bird seed and preservation of museum artifacts, but it is an accepted practice in Japan.

When the product to be protected is not a food product, oxygen scavengers can also provide significant benefits. Some pharmaceutical formulations are easily degraded by oxygen: In particular, vitamin C, vitamin E, and β-carotene employed as antioxidants are commonly packaged with an oxygen scavenger. Many newer hormone replacement therapies and similar drugs are unstable in the the presence of oxygen and will not meet common pharmaceutical shelf-life requirements without reactive oxygen barrier packaging. Closely related to the food industry, pet food and pet snacks are often protected with an oxygen scavenger as rancidity and mold appear to be a problem for pets. Protection of metals from corrosion in demanding applications such as electronics often requires the use of oxygen scavengers. In the meantime, the food industry remains the dominant worldwide consumer of oxygen scavengers.

CHEMISTRY

Applications of scavenging technology are complex primarily because of different chemistries involved, their activation mechanisms, the endpoints of oxidation, the reaction byproducts, and the interactions between the scavenger and the product. The iron-based oxygen scavengers are the most prevalent and they are examined first.

The iron technology is based on rapid oxidation of iron powders to prevent headspace oxygen from reacting with foodstuff components or to reduce oxygen permeation rates through container walls. Reduced iron powders (zero-valent iron Fe^0) are highly reactive and possess a higher capacity to react with oxygen than partially oxidized ferrous iron (Fe^{2+}) compounds. Large exposed surface area of iron powders per unit weight, which increases with reduction in mean particle size and especially when using highly porous "sponge" iron morphologies, promotes simultaneous oxidation at multiple reactive sites, resulting in faster rates of oxygen scavenging. Presence of electrolytes and an aqueous interface to facilitate electron transfer during oxidation is known to accelerate oxidation reactions of transition metals. This is exemplified by rapid rusting of ferrous metals and steels exposed to road salt and salted seawater, in contrast with slow rates of corrosion in the dry climates. Ferrous and ferric iron oxides and hydroxides produced by oxidative reactions are basic. As a result, acidic environments promote oxygen scavenging by shifting equilibrium to iron oxides. At low pH values, oxidation of reduced iron proceeds in humid environments even in the absence of oxygen, by deoxygenizing water molecules and resulting in hydrogen gas formation.

Since low pH values and aqueous interfaces require the presence of water, water vapor diffusion and variation in relative humidity of the environment can be used to control activation of oxygen scavenging capacity of iron powders. The specific formulations are designed to trigger the activation at desired RH levels, control the reaction rate, achieve the full oxidative potential of the iron powder, maintain compatibility with various products, and ensure food safety. The reaction formula for complete oxidation of reduced iron to eventually form ferric oxide trihydrate complex (commonly known as rust) is

$$4Fe^0 + 3O_2 + 6H_2O \rightarrow 4Fe(OH)_3 \rightarrow 2(Fe_2O_3 \cdot 3H_2O)$$

Many transition metals are recognized as being sufficiently oxidative to become candidates for an oxygen-scavenger formulation; however, iron does offer unique advantages that have driven the industry to general use of this medium. Iron has a relatively high affinity to combine with oxygen on a per unit weight basis compared to most alternatives. Complete oxidation of 1 g of reduced iron removes 300 cm^3 of oxygen at STP conditions. Elemental candidates that exceed it have drawbacks such as the odor problems with the use of sulfur and the propensity of aluminum to form an almost impermeable oxidized skin layer that limits further oxidation. Iron rust, on the other hand, flakes off as it forms and it is highly permeable to further duffusion of water and oxygen. Of great importance is the food safety of iron powders, which are recognized as nutrients important for healthy blood and commonly used as food enrichments in milled flour, breads, breakfast cereals, and baby foods. The same cannot be said about copper, zinc, aluminum, and many other transition metals. The abundance and relatively low cost of producing elemental iron are also important, especially in comparison to choices such as palladium and platinum metals and catalysts based on them. Then there is the ready ability to manipulate reactive capability of iron powder formulations to adapt to a wide variety of applications for both the rate of oxygen scavenging and the activation by the moisture in a package headspace. One of the few drawbacks is that the oxidation of iron is a temperature-dependent reaction and normally slows dramatically as the temperature approaches freezing.

Electrolytes and acidifying agents in a scavenging formulation are commonly supplied by metallic salts (22). The practical considerations of food safety have dictated that common table salt (NaCl) is often the best choice for the electrolyte, while various metal and organic salts of strong acids are often used to increase the acidity of the formulation. Another important factor in oxygen scavenging chemistry is the desired control of activation or triggering the scavenging reaction on demand in every application. When the packaged product does not have a required water activity to fully activate an iron-based scavenger and provide the desired reaction rate, premoisturized silicas, zeolites, and activated carbons are used as self-contained water carriers in various proprietary formulations to provide a reliable activation.

There are two broad categories of iron-based scavenger formats, commonly described as "moisture-dependent" type and "self-reaction" type. For the moisture-dependent chemistries, either no moisture or insufficient moisture is present in the sachet or label formulation and the chemistry must have the capability to absorb moisture from the headspace of the package. A significant advantage of these formulations is that they are stable in ambient environments until sufficient moisture has been absorbed to allow reaction to occur. The package into which they are inserted must provide a moisture source, which limits the use of these formulations to food products with relatively high water activity. For the self-reaction type, the necessary moisture is added right into the sachet on a suitable carrier. These carriers must carry a high percentage by weight of moisture and must bind the moisture strongly enough so that the formulation powder remains free-flowing, yet they must release the moisture as needed for the reaction. This type of formulation has to be protected from environmental exposure because it will start scavenging oxygen immediately and can exhaust its capacity if exposed for extended periods. An additional disadvantage is that the preloaded moisture is subject to desorption and equilibration in the package over time, which means that with extremely dry products, the moisture will leave the sachet. The loss of preloaded moisture means that the oxygen scavenger will eventually stop working even though it may still contain unoxidized iron.

It should be noted that since oxygen scavengers are routinely used with MAP, there will be situations in which the application dictates gas flushing of the package headspace with gas mixtures containing carbon dioxide. This is an area for caution because many iron-based formulations are unsuitable for use with carbon dioxide because they will absorb it preferentially over oxygen. Many of these formulations have a capacity for about five times as much CO_2 as O_2 and will thus fail to remove enough oxygen to prevent spoilage. Furthermore, these formulations can also reduce the beneficial effects of carbon dioxide by reducing its intended concentration in the headspace. However, formulations are available that both scavenge oxygen and release carbon dioxide (CO_2 emitters), and one of these should be used when gas flushing with CO_2 is used.

Sulfites, bisulfites, and their analogues have been suggested and used as oxygen scavengers for a long time (23). Sulfites are commonly added to bottled wines to preserve their quality. Desirable oxygen scavenging action is produced by oxidation of sulfites to sulfates. The reactive capacity of such scavengers is rather small to be used as a reactive filler in barrier structures, therefore, their use was limited to sachets and liquid sulfite layers (24).

Use of iron-based oxygen scavengers can create problems with metal detection because there is enough iron in most sachets and labels to set off a metal detector. This is generally overcome by using metal detectors just before the scavenger insertion to assert that no extraneous metal is present and then another just after to assert that the scavenger has been added. In situations where this has not been possible, organic oxygen scavenging chemistries can be successfully used. Organic scavengers are also beneficial for making polymeric barrier films and structures due to often improved compatibility with matrix resins and higher achieveable levels of dispersion compared to dispersion of inorganic powders, generally insoluble in plastics.

Ascorbic acid and other ascorbates are known organic antioxidants because they oxidize to dehydroascorbic acid in the presence of transition metal catalysts, preferably copper. Pillsbury Co. (now a part of General Mills, Inc.) holds a patent to use ascorbic acid as a reducing agent. A combination of ascorbates and sulfites was used as an oxygen scavenger embedded in plastic closure liners by the Darex Container Products division of W. R. Grace & Co. The technology has only achieved minor acceptance in the United States, but it does have unique advantages and disadvantages. Due to a lower capacity to scavenge oxygen, it generally requires a larger sachet and weight of reactant to accomplish the same oxygen removal as for the iron-based technology. Carbon dioxide is also released as a byproduct of oxidation.

Other proposed organic oxygen scavengers included gallic acid, *n*-propyl gallate, butylated hydroxyanisoles (BHA), butylated hydroxytoluene (BHT), and dihydroguaretic acid, which can serve as reactive barriers when added to plastic packaging structures rather than being used as food additives. Migration of these low-molecular-weight chemicals as well as byproducts of their oxidation into the product cannot be completely prevented. To overcome this problem and increase the available activated capacity of scavengers, more recent developments focused on oxidizable polymers that can be used as barrier resins or blended with common packaging polymers to create reactive barriers to oxygen permeation. Ethylenic unsaturation in linear hydrocarbon polymer backbones and pendant groups as well as in polyunsaturated fatty acids is subject to auto-oxidation, especially in the presence of transition-metal-based catalysts:

$$-CH = CH- + O_2 \rightarrow -CH = C(OOH)-$$

The resulting hydroperoxides can decompose to produce free radicals, which can in turn combine by crosslinking, can initiate free radical polymerization of other double bonds if enough of them are present, or can cleave the double bonds in the course of successive oxidation reactions. Such reactions can be catalyzed by salts of transition metals (e.g., cobalt is most common). Rearrangement and cleavage of the hydroperoxides to aldehydes and ketones result in low-molecular-weight byproducts that adversely affect odor and flavor of packaged foods in very low concentrations. These effects limited the use of unsaturated hydrocarbons in food packaging. Oxygen Scavenging Polymer (OSP) developed by Chevron-Phillips Chemical Co. gets around this problem by including the double bond in a pendant cyclohexene ring (25). This way pendant carboxylic acid groups are formed on the polymer backbone as a result of oxidation rather than free low-molecular-weight byproducts.

Rapid rates of oxidation of certain polyamides in the presence of transition metal catalysts have been exploited to produce reactive oxygen-scavenging barriers. MXD-6 nylon with a cobalt salt catalyst has been the primary system patented by MGC and is targeted for incorporation into the inner layers of polymeric packaging structures. Having a large reactive capacity and high reaction rates, MXD-6 nylon-based scavengers can provide nearly zero oxygen transmission rates through nylon barrier layers. However, their use is limited by layer delamination issues, the potential migration of low-molecular-weight reaction byproducts into the packaged product, relatively high cost, and a lack of regulatory approval for direct food contact. Oxygen-scavenging barrier systems based on MXD-6 nylon and cobalt salts have experienced some limited success when multiple producers started blending them as minor additives to reduce migration and improve barrier properties of PET and other packaging resins.

CSIRO Australia has introduced photosensitive dyes as oxygen scavengers independent of transition metal catalysts (26). Functionalized anthraquinone-based chemistries can act as singlet oxygen acceptors after being excited by UV light. Excited dye molecules sensitize ground-state oxygen molecules that diffuse through a polymer in a singlet state. Singlet O_2 molecules react with the dye and are consumed. $ZerO_2^{®}$ is a CSIRO line of UV-activated oxygen scavengers incorporated into reactive barrier films. Despite lower capacity than that provided by metal-based scavengers, $ZerO_2^{®}$ scavengers have advantages such as efficient low-energy activation on demand and their reactivity being independent of moisture diffusion and transition metal based catalysts.

Biochemical reactions in living cells are accelerated by biologically specific organic catalysts called enzymes. Certain enzymes can function as oxygen scavengers within barrier structures. To act as scavengers, enzymes must be first immobilized within the polymer matrix. Although many enzyme candidates can be thought of as oxygen absorbers, few systems have been attempted in practice. Oxygen removal by a combination of glucose oxidase and catalase is a primary example (27). It should be noted that oxygen-scavenging enzymes and coupled enzyme systems cannot act without water and are very sensitive to changes in pH, water activity, temperature, salt content, and other factors. On the other hand, common thermoplastics such as polyethylene and polypropylene are good substrates for enzyme immobilization. Stability of immobilized enzymes in the film is not fully analyzed. Other food-grade enzymes can potentially be used for oxygen scavenging: One example is ethanol oxidase, which oxidizes ethanol to acetaldehyde. Bioka Ltd. of Finland commercially produces enzyme-based scavenging sachets.

Some organometallic complexes known as ligands are capable of trapping free oxygen in a manner similar to that of blood hemoglobin (containing Fe^{2+} ligand in heme) and other peptides with metal-containing prosthetic groups. When immobilized on a solid support such as silica, these ligands have been demonstrated to form a highly reactive oxygen-scavenging medium (28). Such systems anchored to an insoluble support can be dispersed in polymer matrices as powders to form reactive barriers. Advanced Oxygen Technologies, Inc. (New York, NY) has developed a series of oxygen scavengers based on synthetically produced ligands. Incorporation of ligands into plastic film structures has also been claimed.

APPLICATIONS

Individually packaged oxygen scavenger formats are now found in multiple applications with packaged foods being the primary use. Fresh refrigerated pasta is a major user of oxygen scavengers to maintain quality during its distribution cycle. The smoked/processed-meat industry has several segments that rely on oxygen scavengers to maintain color or prevent mold during distribution. Both presliced pepperoni in thermoformed packages and bacon bits in glass and plastic jars use an oxygen scavenger for color retention. In Great Britain and the United States, sliced deli meats are often produced with very low levels of preservatives and are thus susceptible to rapid discoloration under retail lighting. These are now increasingly packaged with oxygen scavengers to prevent discoloration for up to one month. Beef jerky is commonly packaged with an oxygen scavenger for reasons of both color retention and prevention of mold growth. Case-ready meat master packs often include oxygen scavengers to extend distribution time through deoxygenation. The individual cases are then exposed to ambient oxygen before placing them on the shelves to reoxygenate the meat and restore its original red color. Roasted nuts are often protected from rancidity by scavengers, especially where the product will be used for export or for upscale packages. The MRE military rations remain a major U.S. application that is being adopted by other military organizations around the world. Freeze-dried products often have an elevated oxygen sensitivity, and items such as backpackers' trail foods are now packaged with scavengers. Pizza crusts are also being packaged for some markets with a scavenger to prevent mold during fresh distribution. Baked goods and confections are often packaged with scavengers to prevent mold. Oxygen-scavenging liners in juice and wine bottle caps have been introduced with limited success in some markets. Oxygen scavengers with simultaneous humidity control (e.g., StabilOx® from Multisorb Technologies) are used for protection of pharmaceuticals, dietary supplements, diagnostic tests, and other medical supplies. Other uses include prevention of metal corrosion in archeology, art storage, and electronic components, as well as conservation of oxygen sensitive products such as rubber, plastics, and greases.

Reactive oxygen barrier packaging is another rapidly growing market. Beer, wine, and fruit juices in PET bottles, ketchup in plastic containers, and oxygen-sensitive pharmaceuticals and nutraceuticals in oxygen-scavenging blister packs are some of the current and emerging applications. Sulfur-containing components in beer originating from hops are particularly subject to oxidation and, when oxidized, adversely change beer taste profile. Reaction with 1–2 ppm of oxygen is often enough to cause a beer taste unacceptable to many consumers. Protection of beer in plastic packaging is a major application of oxygen-scavenging barrier technology.

PRODUCTS

Sorted by application format, the following oxygen-scavenging products have been offered by major manufacturers:

Sachets and Labels. Ageless® sachets and labels (Mitsubishi Gas Chemical Co., Japan), Freshmax® labels, Freshpax® and StabilOx® sachets (Multisorb Technologies, USA), ATCO® sachets and labels (Standa Industrie, France), O-Buster® sachets (Desiccare, USA), Bioka sachets (Bioka Ltd., Finland), Freshilizer® sachets (Toppan Printing Co., Japan), Keplon™ sachets (Keplon Co., Ltd. Japan), Tamotsu™ sachets (Oji Kako, Japan), Oxyeater® sachets (Ueno Seiyaku, Japan), Vitalon® sachets (Toagosei Chemical Industry Co., Japan), Secule™ (Oxysorb™ in the U.S.) sachets (Nippon Soda Co., Japan), Sansocut™ sachets (Finetec Co., Japan), and several other Japanese, Korean, and Chinese sachet producers.

Closure Liners. Pureseal® (W. R. Grace and Co., USA), DarExtend® (Darex Container Products, USA), Tri-SO2RB® (Tri-Seal International, USA), Oxycap® bottle crowns (Standa Industrie, France).

Oxygen Scavenging Plastic Packaging Materials. OS 2000® (Cryovac, USA), OSP® (Chevron-Phillips, USA), Shelfplus® (Ciba Specialty Chemicals Corp., Switzerland), Oxyguard® (Toyo Seikan Kaisha Ltd., Japan), Amosorb$^{®}$ (Amoco Chemicals, currently a trademark of Colormatrix, USA), ActiTUF$^{®}$ (M&G Polymers, Italy), ZerO$_2$$^{®}$ (CSIRO, Australia), DarEval$^{®}$ (Darex Container Products, USA), ValOR$^{®}$ (Valspar, USA), Oxbar$^{®}$, Mon Oxbar$^{®}$, and DiamondClear$^{®}$ (Constar International, USA).

SIZING AND CHEMISTRY SELECTION

Rapid removal of headspace oxygen and preventing oxygen ingress through packaging for the longest possible time constitute two different design targets in scavenger applications. Simultaneous attainment of these goals usually requires the use of more than one scavenging solution and chemistry. Combination of rapidly absorbing sachets or labels with high oxygen barrier passive or reactive packaging often provides the best possible performance.

For iron-based sachets, the major factors to consider are the water activity (A_w) of the food product or the equilibrium relative humidity in the package headspace in contact with the product, the total volume of the package, the total weight of the food or other product in the package, the temperatures that the package will experience, whether carbon dioxide will be present in the headspace, the percentage of oxygen initially present in the package, the permeation rate of oxygen into the package, and the total shelf life desired. Water activity, temperature, and presence of carbon dioxide will determine the proper chemistry while the rest determine the proper sizing (4).

The objective of the sizing calculations is to determine actual volume of the oxygen that must be scavenged over time (including both headspace and ingress oxygen). Once the package volume and headspace volume are known, then the percentage of oxygen in the initial headspace gas mixture is used to calculate the actual volume of oxygen that must be scavenged. If the product has a relatively short shelf life, removing this initial oxygen may be all that is required. However, for many packages, more oxygen permeates through the package over its distribution life than the oxygen initially present in the headspace. If this is the case, then the surface area of the package should be multiplied by the oxygen permeation rate (OTR) of the barrier in use and by the expected shelf-life duration to determine the amount of oxygen ingressing over the shelf life. The initial oxygen amount and the oxygen ingress over the shelf life are then added to determine the total capacity necessary for the proper oxygen scavenger for that application. Sachet sizing has been standardized such that most of the chemistry designations are available in sachets of 20, 30, 50, 100, 200, 300, 500, 1000, and 2000 mL of oxygen capacity (measured at STP conditions). Since oxygen is approximately one-fifth of the atmosphere, these oxygen capacities can be used to deoxygenate five times the stated capacity of ambient air.

As better oxygen barrier packaging materials and structures become available, the oxygen permeation rates through packages can be reduced and smaller-sized scavengers are needed to offset the ingress of oxygen. For nearly absolute barriers like aluminum foil, only the initial headspace oxygen has to be removed by enclosed scavenger. Reactive barrier packaging solutions allow us to eliminate loose sachets from the package. Design of reactive barriers to reduce oxygen ingress rates is complicated due to inapplicability of steady-state permeation assumptions, nonuniform activation of scavenger capacity across the barrier, and continuous inhomogeneous depletion of this capacity in the course of scavenging reaction (5). These effects are combined to produce transient nonzero permeation rates (oxygen leakage) over the shelf-life duration, unless the barrier reactivity with oxygen is high enough to result in a zero measured permeation rate. As a rule of thumb for uniformly reactive monolayer barriers, the overall reactive capacity of the film should be twice that of the enclosed scavenger to obtain the same time to complete depletion of the scavenger capacity, provided that the OTR of the passive barrier package and OTR of the inactivated reactive barrier are the same. In both cases of enclosed sachets and reactive barrier films, the scavenger capacity needed to consume the headspace oxygen has to be added to all sizing calculations.

TESTING

One common difficulty experienced by many first-time users of individually packaged oxygen scavengers is the difficulty of determining quantitatively just how well the scavenger is working. The ability to accurately measure 1% residual oxygen in a package headspace is quite common. The difficulty arises when there is only 0.01% because the partial pressure of oxygen is far less inside the package than outside, causing atmospheric oxygen to rapidly equilibrate through any tiny aperture and contaminate many samples (4). Septa and sampling syringes that are entirely adequate at 1% will prove inadequate at 0.01%, as many labs have learned. It is common to use a gated or valved syringe with tight-fitting gaskets and natural-rubber septa to overcome the propensity for leakage. One manufacturer recommends that the sample be taken, the valve closed while the syringe is still in the package, and thumb pressure be maintained on the syringe plunger as it is withdrawn and until the syringe needle is actually inserted into the oxygen meter, and only then is the valve actually opened. By so doing, the sample consistency can be improved. It is also difficult to obtain accurate repeat samples from the same package unless great care is exercised with the septa.

For testing reactive barrier films, the standard carrier gas OTR test methods are suitable (29), provided that the film sample is active or can be activated during the test. Ox-Tran permeation analyzers by MOCON, Inc. (USA) and 8000 series oxygen permeation analyzers by Illinois Instruments (USA) are commonly used to measure OTR with controlled relative humidity on both sides of the film. Since no steady-state permeation can be observed in reactive films until the scavenger capacity is depleted by the reaction, waiting for the establishment of the steady-state (passive) permeation pattern does not provide a measure of the barrier performance. Commonly measured performance properties include: the reactive lag time (or the time after which the steady-state passive permeation pattern across the film is resumed), the initial barrier improvement (or the initial rate of oxygen leakage through the activated reactive film versus OTR of the inactive film), and the induction period (or the duration of full scavenger activation across the film during which the OTR drops to its minimal measurable value). To prevent inaccurate results, OTR measurements shoud be started as soon as the film is loaded into the test chamber and the downstream side is purged of oxygen. This way, no reactive film capacity is wasted on equilibration and the transient OTR profile will provide full information about the film barrier performance. For films with a low oxygen permeability of the polymer matrix material and a large scavenging capacity, the OTR testing even with 100% oxygen at the upstream film side can take a long time. Even longer times will be needed when ambient air is used. Thinner films and lower scavenging capacities incorporated into the film can be used to accelerate OTR testing, quantify barrier properties, and scale-up the barrier designs. The film reactive capacity to scavenge oxygen can be tested separately by placing the activated film sample in a sealed chamber and monitoring oxygen levels in it until equilibration.

FOOD SAFETY AND REGULATORY CONCERNS

Ingestion of iron-containing sachets has been cited as a concern, however, no evidence has been presented regarding physical harm due to such ingestion. Mitsubishi Gas Chemical Co. reports that they have tested the acute oral toxicity (LD_{50}) of their formulations in rats and find it to exceed 16 g per kilogram of body weight (30). LD_{50} values of various food-grade iron powders generally exceed 5–15 g/kg of body weight. Multisorb Technologies, Inc. reports that their oxygen scavenger components are either food- or pharmaceutical-grade materials. Therefore iron-based oxygen scavengers can be used with confidence. Iron toxicity has been recognized as a problem among infants in the United States as related to accidental ingestion of dietary iron-supplement products. Reports of iron ingestion by persons of low body weight can be routinely handled by poison control centers (31). Because of body weight, it is highly unlikely that an adult could ingest enough iron powder from commercially available sachets to cause harm. Additionally, by the time a food package reaches a consumer, the iron would no longer be in a very reactive elemental form but partially oxidized. Use of adhesive oxygen-scavenging labels and oxygen-scavenging films, trays and lidstock eliminates the danger of accidental ingestion.

There is also a necessity to prevent the use of oxygen scavengers in applications where anaerobic bacteria may grow. The food industry employs a number of precautions to control anaerobes. Among these is to use oxygen scavengers only when (a) the water activity of the product is below the point at which *Clostridium botulinum* bacteria will grow (32), (b) the food has been acidified to have sufficiently low pH values, or (c) appropriate curing salts have been used to prevent botulism. Temperature control is generally discounted as a botulism prevention agent where retail packages are concerned, but HAACP systems have been employed for some products. Specific limits have not been given because they will vary from product to product. There is some evidence that the concern over oxygen scavengers and botulism may be overstated. An examination of the oxidative reductive potential in packages with and without oxygen scavengers has been reported to show that the scavenger does not increase the reductive potential (11), and thus does not enhance the risk of outgrowth.

TROUBLESHOOTING

Because oxygen-scavenging technologies are not as prevalent as MAP and are somewhat complex, many users have a need for a diagnostic tool to help evaluate the oxygen scavenger performance. The following points can be helpful for troubleshooting iron-based scavenging sachet and label applications:

1. Is the package hermetically sealed? If not, a hermetically sealed package must be used.
2. Does the package provide sufficient oxygen barrier (as a measured steady state OTR) at the conditions of use? If not, the scavenger will be exhausted prematurely and the product shelf-life expectations will not be met.
3. Are the contents of the sachet or label rusty, or some agglomeration is noticeable? If an evidence of reaction is present, then examine the following factors.
   a. Is the test method capable of measuring ppm oxygen levels? Insufficiently accurate method may indicate high oxygen concentrations when the actual values may be significantly lower.
   b. Is there carbon dioxide present in the headspace? If so, use a scavenger chemistry compatible with carbon dioxide that will scavenge oxygen instead.
   c. Does the scavenger have enough capacity for the product and package headspace? Recheck the sizing calculations and use a larger format as indicated.
   d. If the scavenger is a self-acting type, was it left in the atmosphere for too long before being placed in the package? If so, it may have exhausted part or all of its capacity. Limit the preapplication exposure.
4. If the contents of the sachet or label are not rusty or agglomerated:
   a. Verify that the water activity range of the scavenger chosen matches the water activity range of the food or other product being packaged. If not, change scavenger specification to match the product.
   b. Check to make sure that the scavenger was not blocked off from the headspace by being placed under the food or a tray, or trapped tightly between the product and the barrier film. If so, alter the scavenger placement.

P

PACKAGE-INTEGRITY IN STERILE DISPOSABLE HEALTHCARE PRODUCTS

Fritz Yambrach
Rochester Institute of
Technology, Rochester,
New York

The manufacturers of products used in healthcare activities are referred to as the medical device industry in the United States. Healthcare products include tongue depressors, cardiac pacemakers, artificial joints, and hospital beds and range from highly technological products patented for unique design features, employing a variety of technologies, to commodity products sold for a variety of applications, healthcare being just one. The firms represented by the industry present an example of a business that by its nature is an integration of technical activities by various actors: biological sciences, mechanical engineering, material science, and entrepreneur behavior, to name a few. Unique to this industry is the high performance requirement placed on the package and packaging process. A failure in the package or process is viewed by the Food and Drug Agency (FDA) as a critical defect equal in gravity with a product design failure (1).

Sterile disposable medical products are a relatively new product group, in existence only since the 1960s. The arrival of this new product group created an increased healthcare quality by utilizing single-use sterile medical products. The development of these one-way products has reduced the risk of contamination from previously used products that were sterilized after each use in the hospital where there existed a probability of error in the steriliztion process. The advent of this product group, based on the "Kleenex" principle, eliminated the cost and risk of in-hospital sterilization. This product group has been growing, with more products being introduced in the healthcare industry each year. These products have a new set of protective requirements that their packages have to meet. Because the products are disposable after one use, the packaging cost must not significantly increase the cost of the product, so along with functional protective requirements the packaging is frequently restricted by cost constraints. This is not true of all sterile disposable products, because there are many that may cost several hundred dollars and these can afford to have higher package costs.

PACKAGE REQUIREMENTS IN HEALTHCARE PACKAGES

The basic requirements of a package are to protect the product from the producer to the consumer. The definition of "protection" is to prevent any activity from taking place during the distribution channel that could render the product useless or significantly reduce its usefulness. It is beneficial to understand the basic requirements and applications of a package prior to a more thorough discussion of specific functional requirements. The main requirements of a disposable device package include the following:

1. *Maintain Sterile Barrier around the Product*. The first and most important functional demand of a device package is for the package to maintain a sterile barrier around the product. This sterile barrier is accomplished mostly by flexible packages or blister packages. The simple, low-cost devices that require little physical protection are usually packaged in flexible bags or pouches. These simple packages provide excellent barriers to microorganisms when the correct materials are chosen, and they are very material efficient. Complex devices such as implants or multiple channeled IV (intravenous) sets require more protection and often additional product-use functions. These products are often packaged in blister trays that offer more physical product protection and other features for product use, such as separate areas in the package for holding items before or after their specific use (see also Skin packaging). If the sterile integrity is compromised by a hole in the package or a ruptured seal, the product is regarded as contaminated and determined unusable. The potential contamination of a patient from a nonsterile product due to package failure is a very real concern with serious outcomes. The maintenance of a sterile barrier is a result of keeping anything in the external environment from breaching the package and keeping the product from breaching the package integrity. The breach does not have to be more than a few micrometers in size for a microorganism to enter the package. This barrier function relies solely on material and package seal integrity.
2. *Allow for Sterilization*. The second major functional demand that a package may have to meet is the ability to allow for the product to be sterilized. This demand translates into the package having to survive the stress of a sterilization process and allow for complete sterilization of the product within that package. This is a necessary demand on the package system in most products because the products are sterilized after they have been packaged. Sterilization occurs after the product has been sealed in the primary package and the primary package has been packaged into the corrugated shipper. Four main sterilization processes are used to sterilize medical devices, gamma radiation, ethylene oxide gas, electron-beam radiation, and steam. Gamma radiation and ethylene oxide are responsible for about 85% of the disposable market, with each currently having

approximately one-half of that group. The electron-beam system is gaining market share because of several new developments in that process that make this sterilization technology particularly beneficial to the medical-device industry. Other sterilization systems are used to sterilize devices, including gas plasma, vapor-phase hydrogen peroxide, peracetic acid, and X-ray, but each has limited applications due to certain factors and limitations in each system (2). Certain products have unique needs that are satisfied by these other sterilization systems, but presently they represent minor applications for device sterilization.

3. *Aid in Aseptic Removal of Product.* Another requirement of these packages is that they must allow for an easy opening of the package by the medical personnel. The opening of the package must not compromise the sterility of the product. The package must facilitate sterile, struggle-free opening without the use of nonsterile opening devices. Low-aggression opening of the package allows for easy removal of the sterile product and reduces the risk of contaminating the product by struggling with the package and touching sterile areas on the product or dropping the product on a nonsterile area. This requirement is particularly problematic in that the package, to accomplish an easy opening, must have a low resistance to force applied to the seal areas while remaining intact. This low resistance to physical stress increases the difficulty of the package to remain intact through the physical stresses occurring during sterilization and distribution cycles. The easy-opening feature is generally accomplished through the use of a heat-seal material that has low cohesive strength. Ethylene–vinyl acetate (EVA), a copolymer of polyethylene and vinyl acetate, has a low cohesive strength and allows for a thermoplastic heat seal that gives the required microbial barrier (see Aseptic packaging).
4. *The Package Should Not Add to Airborne Contamination.* The package material should remain intact and not tear and create airborne fiber that can settle down and recontaminate the product during opening. This translates to having packaging materials that are higher in cohesive integrity than the heat-seal materials used. When a package is opened, the package material should not tear but the adhesive will come apart. Additionally, heat-seal adhesives should not be prone to particulate generation. The adhesive should separate and remain on the package materials. This particulate concern also includes dust that has settled on the exterior of the package becoming airborne through a vigorous opening action. The dust problem can be solved by low-cohesive-strength heat-seal materials, designing a flat package with few folds to allow for dust collection, and the use of materials with smooth surfaces.
5. *Aid in Product Identification.* The product should be easily identifiable while still in the unopened package. This eliminates the opening of a package, with the consumer erroneously thinking that another product or variation of the product was inside. Ease in product identification is a particularly important feature where numerous products or product variations need to be distinguished. In the case of erroneously opening a package, the entire product would be thrown out because the sterility was compromised. Transferral of product-specific information can occur in many ways in the unopened package. Use of clear packaging materials can allow for product inspection through the unopened package. The package can display an illustration of the product with specific items highlighted on the exterior of the package. The package can be color-coded so that a line of similar products with different specific features could be graphically identified by the colors used for copy.
6. *Evident Opening Features.* The opening feature of the package should be designed to clearly indicate that the package has been opened. There should be no reclosable feature on the package that would allow for the package to be opened, contaminated, and then resealed. The package seals should, when opened, visually alert hospital personnel that the package had been opened and sterility had been compromised.

PACKAGE AND MATERIAL REQUIREMENTS FOR STERILIZATION PROCEDURES

Generally, the maximum physical stress to which a package will be exposed is during transportation and distribution, including truck shock and vibration, the drops in handling, and finally the twist and compression of handling the packages by hospital personnel. A current issue in the device industry is the increased practice of using flexible packages to contain products that are relatively heavy. These heavier products will severely stress the package materials and particularly the seals as they are moved against the seals during transportation shock and vibration stress. This is basically a package design issue which must be addressed by utilizing more rigid packages that “isolate” the product during distribution. When the product is isolated in the package and not allowed to move, it will not push against the seals and force the package to open. This is accomplished by using blister packages with design elements in the blister to hold the product imobile.

A medical package will face all these stresses, but additionally the package will be exposed to stress during product sterilization. The particular sterilization process used exerts a unique set of stresses on the product and also on the package. Ethylene oxide sterilization, for example, will stress the package integrity more than it stresses the materials. Both radiation and sterilization seem to have the most stressful effect on the material properties. The package and materials must withstand these demands and after these processes remain functionally intact throughout distribution and storage.

Since sterilization occurs after the product has been packaged, the package sees the same contact with radiation, chemicals, moisture, and heat that the product is exposed to during sterilization. The material properties may change as a result of the sterilization exposure, and some low level of change is acceptable. The package properties may change as a result of the material changes, but as a whole the package must maintain a high level of microbial barrier. What is not allowable is *any* loss of sterility. If the sterile integrity of the package is breached to any degree by seal rupture or stress cracks in the material, the product is considered contaminated and unacceptable.

Each sterilization system used requires that the package perform in some way in order to facilitate sterilization. Autoclave (steam) and ethylene oxide (EtO) sterilization both require a vacuum process in a chamber as a mechanism for the sterilant to pass through the package and contact the product and sterilize it. Autoclave sterilization requires that hot steam be allowed to pass through the package and contact the product. The package must not act as an insulator or be a barrier to the steam. An additional requirement for steam sterilization is for the package to tolerate high temperatures without losing intended properties. Ethylene oxide (EtO) sterilization requires a certain level of porosity in the package material for the EtO gas to pass through the package material, contact, and sterilize the product. Porosity is also necessary for removal of the EtO gas from the package at the end of the sterilization cycle. Gamma and electron-beam sterilization both require a tolerance for low-level energy without loss of mechanical properties. These packaging materials must also not shelter the product from energies required for an effective kill.

The stress a package must withstand in this industry may be compounded in two ways:

1. It is possible for a package to see multiple sterilization cycles. This occurs when a batch of product is sterilized and the batch fails to meet sterility requirements. If this occurs, the batch is allowed to be resterilized and retested. The sterilization effects on a package are cumulative, and package design must consider the worst-case challenge.
2. A single package design may be required to satisfy the requirements of two different sterilization systems. This occurs when a company has multiple manufacturing locations and different sterilization facilities are used at each location. The company does not want the product to be on the market in two different packages, so one package must meet the functional needs of two different sterilization procedures.

Steam and (EtO) Sterilization

Steam and EtO sterilization systems are similar in that they both use mechanical systems to deliver a sterilant to the product. In the case of steam, the sterilant is hot moist air; in the case of EtO, it is a warm gas. The mechanical systems designed to deliver the sterilants rely on the differences in pressure created by a vacuum in a vessel to move the sterilants through the package walls and then to contact the product. The packages are placed in a sealed chamber, and then a vacuum is pulled on the entire chamber. The sterilant is then released into the chamber; and because of the pressure difference, the incoming gas with the sterilant replaces the low-pressure areas, moving through the package and contacting the product. This is held for a period of time, and then another vacuum is pulled on the chamber to remove the sterilant. Figure 1 shows the pressure changes in a typical steam-sterilization cycle.

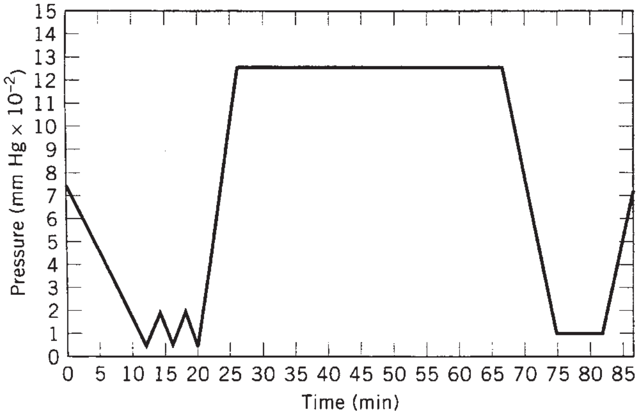

Figure 1. Changes in pressure in a typical steam sterilization cycle.

The back-and-forth changes in pressure contribute to package-seal rupture in these sterilization systems. The decrease then increase in interior gas volume causes the seals tbe stressed in a sort of “bellows” effect. This seal stress is increased by the warm to hot temperatures used during the cycle. The EVA heat seal is a low-melt-temperature thermoplastic, and elevating the temperature softens the material and weakens the seal strength. The amount of vacuum drawn, quickness of the evacuation and repressurization, package porosity, and temperature are the key variables to control in order to maintain package integrity. It would be possible for the pressure cycles to be very slow and gradual, but that would increase the processing times and add to the cost. In an EtO cycle, the temperatures may be lowered to lessen the effect of temperature softening the EVA heatseal, but to compensate a longer exposure time may be required. Figure 2 shows the pressure changes that occur during a typical EtO sterilization cycle. Steam sterilization requires a minimum temperature that cannot be reduced. These variables are balanced with the package’s ability to survive the sterilization system. If the need for improved package integrity outweighs the cost of a longer cycle, then the cycle could possibly be altered.

The mechanical similarities between the steam and EtO processes allow for some common solutions to the problems caused by the systems. The most serious common problem is the stressing and rupturing of the heat seals during the pressure changes in the sterilization cycles. There are package and package material variables

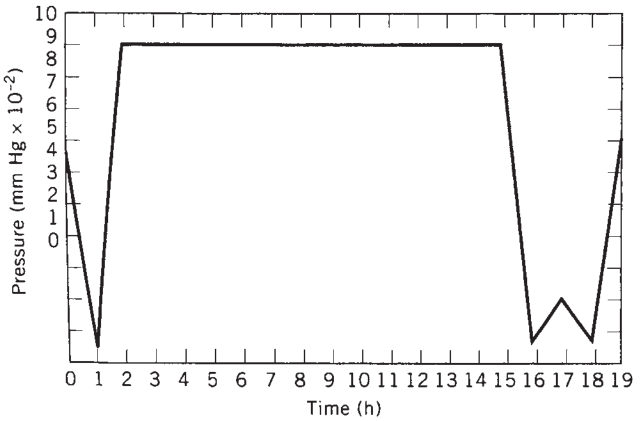

Figure 2. Changes in pressure in a typical EtO sterilization cycle.

that can be manipulated to alleviate the problem of package seal stress during sterilization:

1. *Porosity Rate of the Package.* The porosity rate of the package impacts on the stresses the seal face because, if the porosity is high, the change in relative pressures occur quickly and the package does not bellow out and stress the seals. If the package has a low porosity rate, the package tends to bellow out and stress the seal by the pressure exerted on the seal area. This property of the material can be measured by a porosity tester. Another solution is to increase the surface area of porous material and, by doing so, increase the total package porosity rate.
2. *Seal Aggression.* Another way to improve the seal's ability to survive stress is to increase the cohesive strength of the seal material. The aggressiveness of EVA seal material is designed so that the opening force of the package is low and the health-care professional does not have to struggle to open the package. The drawback of an easy-opening package is that the lower-aggression seals have a hard time surviving sterilizer stresses. It is possible to vary the vinyl acetate content of the copolymer from 14% to 40%. The higher the vinyl acetate content, the weaker the material's cohesive strength and the lower the seal strength. Another aspect of this seal-strength issue is that if the seal is too aggressive, it may cause the lidstock of the package to tear when opening, increasing the amount of airborne particle contaminants.

Steam Sterilization

The use of steam to sterilize devices is the oldest sterilization method and dates back to the time when devices were reusable and were sterilized in the hospital after each use. The process of using moist heat to kill microorganisms is a very effective system with a great deal of data available demonstrating its effectiveness. This process is very difficult to monitor because there are many variables to control, including temperature, moisture content, pressure, and time of exposure. This process is very similar to EtO in that the vacuum vessel is used and the differences in pressure are created to move the sterilizing agent into the packages. In this process the sterilizing agent is very hot steam, with temperatures in excess of 121°C. This process is common in most hospitals and in physicians' and dentists' offices. It is not used for many disposable devices because the temperatures required will soften and weaken most thermoplastic devices. Steam is most useful with glass and metal devices that can tolerate the extreme moist heat. Steam is not a major sterilization process in the disposable-device industry but is more an in-house system used by hospitals and medical offices on heat-tolerant products. The use of steam sterilization as an in-house system provides us with an example of packaging medical devices on a relatively small scale. This is accomplished by the hospitals purchasing premanufactured packages and loading the product into the three-sided pouch and sealing the pouch. This package must then withstand the rigors of a steam cycle and remain intact and provide a sterile barrier until the product is to be used. The advantages and disadvantages of steam sterilization are summarized in Table 1.

Table 1. Steam Sterilization

Advantages	Disadvantages
Highly effective	High heat exposure
Short product release time	Many variables
In-house process	High moisture
Low equipment cost	Package seal stress
	Package porosity requirements
	Labor cost to process

Effects on Materials. The materials used in packaging steam-sterilized items must be porous enough to allow for sterilization and be able to withstand high-moist heat. Steam has the ability to weaken papers because of the combination of heat and moisture, so paper packaging must be evaluated to determine the actual loss of material integrity. Steam does not have the problem of toxic residues found in packaging materials after sterilization because the mechanism of lethality to microorganisms is the high temperature rather than a toxic chemical. The greatest concern with thermoplastic packaging materials is their loss of physical properties on exposure to high temperatures during the cycle. Polyethylene and polystyrene have relatively low melt temperatures, so they soften at too low a temperature for usefulness. Polypropylene and polyesters have higher melt temperatures and may be more suitable for steam cycles.

Effects of Package. The package stress stems from exposure to pressure changes during the sterilization cycle. These stresses manifest themselves in the same package-seal problems occurring in EtO sterilization cycles. The difference in temperatures used between steam and EtO accounts for the greater severity of package stress with steam. Steam sterilization requires that the product reach a temperature of 121°C to be considered sterile. This high temperature weakens thermoplastic heat seals and packaging films. The required porosity eliminates most plastic films and makes paper a good choice. The one drawback with paper is that it will weaken when saturated with water and must be dried after sterilization.

Ethylene Oxide Sterilization

Ethylene oxide (EtO) is a chemical that, when in contact with biological systems, disrupts certain cellular activities interfering with the cell function, and in the case of small organisms, the result is death. The use of EtO in sterilizing medical devices is widespread, with approximately 45% of single-use devices using this method (3). This sterilization system is favored over steam for disposables because it employs a warm rather than hot environment and is not as temperature-aggressive to thermoplastics. The process involves, first, the prehumidification of the devices and packages prior to the sterilization cycle. This is done to activate any desiccated microorganisms because the chemical has a more effective kill rate on active microorganisms that are carrying out normal biological activities. This prehumidification process takes at least 9 h at 40°C and 65–80% relative humidity. After prehumidification, the devices are moved into a vacuum chamber. The products are still in their primary packages; and in most high-volume applications, corrugated cases of product are moved into the vacuum chamber still on pallets. In the vacuum chamber a vacuum is drawn and then held until the EtO gas is released into the evacuated chamber. The difference in pressure is the mechanism that draws the gas into the package and into the product where all surfaces that come in contact with the gas are sterilized. After a period of time, depending on the level of bioburden and complexity of the device design, another vacuum is drawn and the EtO gas is drawn out of the chamber. A series of vacuums and air flushes are performed to eliminate the EtO gas residuals from the product and the package. These pallets of products are then removed from the vacuum chamber and allowed to vent while samples are evaluated for sterility before the batch of product is released.

The effectiveness of this sterilization procedure relies on the package having the properties of porosity to EtO gas, heat and moisture resistance, and the ability to maintain a sterile barrier. The maintenance of a sterile barrier depends on the package material and heat seals remaining intact without breaches throughout the repeated vacuum and pressurization cycles.

Effects on Materials. The effect of EtO gas on materials is very well documented because this process has been widely used for years. The main concern has been the absorption of EtO and byproducts ethylene glycol and ethylene chlorohydrin by packaging materials (4). Medical papers and nonwoven materials such as Tyvek (manufactured by DuPont) are porous and do not retain EtO because they have ample surface area for the residuals to evaporate and elute. EtO residuals can be absorbed into plastics and exposure of the device manufacturer and healthcare workers to residual amounts of the chemical are a concern. There are differences between materials, but a basic rule is that thicker materials will tend to absorb more EtO than a thinner material and it is tougher for a thicker piece of material to elute EtO residuals.

Table 2. Ethylene Oxide Sterilization

Advantages	Disadvantages
Relatively effective	Toxic residuals
Relatively low heat (compared to steam)	Package porosity requirements
In-house process	Many variables to monitor
	Moderate heat
	Regulatory issues
	Moist process
	Long process time
	Long product release time
	Package seal stress
	Labor cost to process

Polyvinyl chloride will absorb twice the amount of EtO as polyethylene, polypropylene, and polystyrene (4). The longer the sterilization cycle (the longer a material is exposed to EtO), the greater the absorbency. The manufacturers who use EtO have designed aeration cycles during and after sterilization that reduce the residual problem. The residual issue continues to be monitored by the U.S. government regulatory agencies, and this issue has been instrumental in the increasing use of radiation as a sterilization process (3). The advantages and disadvantages of EtO sterilization are summarized in Table 2.

Effects of Package. The effects of an EtO sterilization cycle is more apparent on the package than on the materials used in that package. The package effects center on the ability of the package, as a combination of materials assembled together, to maintain a sterile barrier:

1. *Package Stress.* The package stress comes from the evacuation cycles during sterilization. The quick changes in pressure have a bellows effect on the heat seals. This effect is to blow the package up and stress the package seal. This stress is compounded by the fact that the plastic used for a heat-seal material is chosen for its low melt temperature and low cohesive force. The package must survive stress on the seals at temperature conditions that have already weakened the heat-seal material. The most challenging part of packaging for EtO-sterilized packages is that the package has to encounter stress when the heat seals are in a preweakened warm condition. The packaging engineer is caught between creating a strong, aggressive seal to withstand sterilization and creating a weak, easy-open seal to facilitate a sterile removal of the product from the package. The seal weakening from
