evacuation and pressure cycles is referred to as "CREEP." This is recognized by a scalloped area along the seal that reduces the seal width and also the seal strength at that point. The problem with a seal weakened during sterilization is that during normal distribution the seal may see additional stress that may exceed the compromised seal strength and cause it to open, compromising the sterile integrity of the package. The scalloped void in the seal can also actually be as wide as the seal, breaching integrity and creating an opening for microorganisms to enter.

2. *Packaging Design to Aid in Penetration.* The effectiveness of EtO sterilization lies in the ability of the cycle to drive the gas into the package and contact the product. It is difficult for the gas to reach sealed chambers in the product and other areas that do not allow for airflow. Also, packages utilizing foam inserts are particularly difficult to sterilize because the volume of air in the foam materials is difficult to remove and impacts on sterilizer effectiveness (5). The package can be designed with large areas of porous material to improve the air-flow characteristics of the package. This is necessary with blisters that have only one side that is porous, and "Schuster" or "header" pouches that reduce the surface area of porous materials used in the package because their design allows a minimal amountof porous material (6).

Radiation Sterilization

Currently there are two popular methods of generating radiation energy used to sterilize medical devices. Each delivers the same effect, but they differ in mechanism of delivering the energy. It is these differences that drive the specific applications of each system now and in the future.

Gamma Sterilization. With gamma sterilization the products are sterilized by action of exposing the packaged product to a decaying isotope, usually cobalt-60 (^{60}Co). The γ-photon particles bombard the item and excite electrons, causing them to break apart from their existing positions. These ionized particles break other chemical bonds, causing material and biological damage. This damage is what kills microorganisms by disrupting cellular systems. Gamma particles are large, and because of their size and mass, can travel relatively far distances. This means that the source can be located yards away from the product and still receive an effective dose. Gamma sterilization requires a large technical facility requiring a large capital investment. These facilities are generally owned by companies whose business it is to expose items to radiation through this process. The process can achieve either (a) lethal doses as in the case of medical devices or (b) sublethal doses as in the case of food products (7). The sublethal process is exposure to much lower doses. The process variables in this procedure are few and microbial kill effectiveness is high, accounting for high reliability in the procedure. The sterilization takes place at ambient conditions, so the effects of high temperature and humidity in steam and EtO sterilization cycles are not factors affecting package integrity. Gamma is characterized by very high penetration, which is one reason for its high reliability of kill rate. The time for a sterilization cycle is about 6–9 h at a normal dose rate of 4 kGy/h. The recognized average dose for sterilization is 2.5 Mrad or 25 kGy. A gamma cycle will guarantee exposure to at least 2.5 Mrad, but in order to do so, actual doses will exceed that minimum. The advantages and disadvantages of gamma sterilization are summarized in Table 3.

Table 3. Gamma Sterilization

Advantages	Disadvantages
Effective kill	Costly facility
Few variables	Degrades materials
High-volume cost-efficient	Facility location not always convenient
No residuals	Effects are cumulative
No heat	Variability in dose
Short product release time	Long process time

Electron-Beam (E-Beam) Sterilization. E-beam sterilization is a lower energy system than gamma and has particular advantages in particular applications. This system excites electrons in an electron accelerator and then bombards the package and product with these excited electrons. The free electrons then break other chemical bonds and cause biological damage. The similarity between gamma and E-beam is the use of electrons to effect sterilization; the difference is how the electrons are excited. A gamma particle is much heavier than an electron, so the gamma particle can travel farther and still have the energy left to excite and ionize compounds. Electrons, on the other hand, have very small masses and lose energy quickly, so the effective use of excited electrons occurs relatively close to the source. This distance is less than 12 in. for high-energy accelerators (8). The advantage of E-beam sterilization is that a large facility is not needed and consequently does not require as large a capital expense as gamma. The electron accelerator can be placed in a production line with appropriate shields employed.

The use of electron accelerators is not new in the device industry. Johnson and Johnson was one of the first to use this technique as far back as the 1960s (3). Currently the technology is used for such varied applications as (a) dosing polyester tennis strings to improve the tensile strength and (b) curing inks and varnishes. The latter is currently more common in Europe. There are currently electron accelerators capable of producing 2–12 MeV of energy. The lower energy is used mostly to cure inks and varnishes, but this energy level is capable of producing a sterile field within 1 in. of the source. This system has potential for sterilizing very low-profile medical devices (9). At these low energy levels, little shielding is required because the energy is lost over small distances. This fact, along with the short time required to dose the product, would make this process a possible in-line operation. The 10 to 12–MeV accelerators are being used currently in the industry to sterilize cases of products and have a penetration of roughly 1 MeV to 0.8 cm. These higher-energy systems require shielding, but this is being accomplished by subtle design changes to the production line so the product can be sterilized in-line. Figure 3 shows an E-beam accelerator being used in-line to sterilize medical devices. Figure 4 shows a high-energy electron accelerator sterilizing bottle caps. The advantages and disadvantages of E-beam sterilization are summarized in Table 4.

Effects on Materials. The material changes in packages exposed to radiation vary quite a bit. Some materials have little change even when exposed to large doses of energy, while other materials show profound effect with small energy levels. The effects of radiation on materials has been fairly well documented by research done by the U.S. government and different private device companies (10). The materials that are used in the majority of device packages are generally low-cost common plastics and papers, and consequently any method of limiting these effects must be cost-effective.

Plastics are affected several ways when exposed to doses of radiation. The polymer chains exhibit scission and cross-linking, gas elution, and discoloration. The dominant effect depends on the particular material. The effect on materials has been shown to be dose-dependent and cumulative. The effects are increased by repeated exposure from multiple sterilization cycles. Most packaging plastics are very resistant to radiation energies at the levels used for sterilization, but two common materials exhibit significant property changes. It is interesting that two different materials show profound changes at low-level energy exposure. Figure 5 shows the effects of different doses of energy on the tensile strength of plastic films commonly used as packaging materials. Polypropylene (PP) and polyvinyl chloride (PVC) are two common materials used to make devices and packages that exhibit acute reactions to low levels of energy. At very low doses, polypropylene will turn brittle, lose flexibility, and discolor, turning yellow. Polypropylene shows significant loss in mechanical strength at energy levels used in radiation

Table 5. Effects of Radiation on the WVTR of Packaging Materials Tested [g/(100 in.^{2} 24 h) at 100 °F, 90% rh]

Materials (Mrad)	0	2.5	5.0	7.5	10.0
PETG	1.42	1.52	1.57	1.76	1.73
PET/PE	0.46	0.48	0.50	0.55	0.57
PP	0.19	0.21	0.21	0.23	0.24
OPP	0.30	0.33	0.33	0.35	0.37
PE	0.12	0.13	0.15	0.15	0.13
PET	0.25	0.28	0.28	0.29	0.28
Nylon/PE	0.26	0.29	0.34	0.37	0.37

sterilization. Polyvinyl chloride shows a reaction to radiation at low levels by turning amber and eluting gas. The significant change in mechanical properties in PVC occurs at higher energy doses, around 100 Mrad (11).

In contrast, polyester films show change due to exposure by increasing tensile strength (12). The tensile strength increase is dose-dependent over 0–5 Mrad and then begins to reduce with increased exposure. Even at 12.5 Mrad the tensile strength of the sample is greater than the original, untreated sample as shown in Figure 5. This is a desirable property change in applications where tensile strength is desirable. Polyester tennis strings produced by a company named Gamma Gut are dosed by gamma radiation to increase their tensile strength, which is a quality necessary for tennis strings. The company even identifies the process in the corporate name.

In addition to the mechanical properties changing, the barrier properties of a material are also at risk. PETG, PP, and nylon show significant loss of water-vapor-barrier qualities when exposed to sterilizing doses of radiation. These effects have been demonstrated to be dose-dependent, so the greater the dose, the more pronounced the effect (13). It is speculated that the effect comes from the restructuring of the polymer chains, allowing more area for water molecule transport. Table 5 shows the WVTR values of various packaging films at different energy doses.

The stabilization of these polymers to the radiation levels seen in sterilization cycles is being accomplished by the use of various additives. The additives are designed to either react with the energy before it damages the material or absorb the energy before it energizes the material. These additives are specially formulated for the particular application because their compatibility with a product is a key consideration. PVC is modified with lead carbonate or organic tin compounds, and this change reduces the discoloration in the material (14).

Effects of Package. The effects on package integrity are secondary to the effects of material integrity. There is no elevated temperature to soften plastics, and there is no evacuation cycle to stress the package seals. The embrittlement of a material is the key issue because if a package material is flexed and cracks, the sterile integrity of the package is compromised and the product is viewed as contaminated and unusable. Stresses encountered during distribution take on greater importance when materials have become brittle, so effective distribution testing is prudent.

Shelf Life of Device Packages. The shelf life of a device package is expressed as the length of time the package will provide a sterile barrier. The shelf life has traditionally been defined as only an event-related process where events such as rough handling contribute to premature aging of the package. Current research has indicated that time is also a factor in device shelf life. There has been evidence to suggest that material changes may occur during poststerilization storage. These changes are the same as those that occur immediately after sterilization but seemingly increase over time. One study has shown that aged EVA heatseals on porous packages sterilized by EtO have significantly lower seal strengths than the same packages immediately after sterilization (15). Other observed effects are discoloration and increasing brittleness of materials sterilized by radiation. These few observations make a case for increasing attention on poststorage testing of the packages so that more can be learned about the impact of sterilization method on shelf life (see also Shelf life).

PACKAGING DESIGN AND DEVELOPMENT

INTRODUCTION

Packaging is ubiquitous, yet invisible to many who use it. It is present in almost all environments and facets of modern day life, though few people give it any purposeful thought. Hospitals, military outposts, construction sites, industrial manufacturing facilities, retail outlets, and restaurants (to name a few) all have personnel that interface with packaging. It permeates our homes, businesses, churches, and schools and utilizes nearly every material known, taking on many different forms and functions.

It is challenging, in a single chapter, to discuss effective package design in great detail due to the myriad of products in need of packaging and complexity of stakeholder desires. However, there are certain basic considerations that designers should contemplate, regardless of the product to be packaged or the packaging form to be employed.

STAKEHOLDER PERSPECTIVES ON PACKAGING

Effective designers consider multiple inputs and desires from varying stakeholders (see Figure 1), throughout the life cycle of a package (from ingredients through disposal), though many times these stakeholders don't even realize that their expectations for a product are achieved by thoughtful package design.

Converters and fillers expect that packages will be easy to produce, fill, process, evaluate, handle, ship, store, and track. The idea is to maximize production efficiencies (line speeds, cube efficiencies, inventory control, and the like) without imposing unnecessary burden on workers. Both groups wish for products and packages that will satisfy downstream customers' (particularly sellers and end consumers—see Figure 1) wants and desires, creating the opportunity for more orders and more profit. Perhaps one of the greatest motivators of package design decisions, particularly for fillers, is the need to effectively brand their products. With the fragmentation of traditional media sources and the advent of technologies like satellite radio and TiVo®, which allow consumers to filter advertisements, packaging takes on a more prominent role in attracting and retaining consumers. Distinguishing features such as logos, wordmarks, colors, and functionality are vital parts of this effort, and packaging is increasingly seen as a tool for adding value.

A variety of sellers (retailers, internet businesses, hospitals, pharmacies, restaurants, etc.) have many expectations as well. They expect affordable products that will arrive in a pristine, genuine, shelf-ready condition with maximum shelf life and features that make tampering evident. For many, packaging is part of loss prevention programs which are meant to deter and detect theft, a noted and costly problem (1). Certain sellers, like hospitals and other healthcare facilities, desire packages that readily identify contents when seconds count. They place emphasis on the directions, and in some cases warnings; designs that facilitate the safe and effective use of the contents within are a priority. Other sellers (retailers) still emphasize the importance of products that are easily identified, but with the purpose of attracting consumers for sale. Sellers also desire packages that are easily integrated into their systems which track inventory, so that billing, ordering, and, occasionally, recall, are efficient and cost-effective.

End consumers want to be able to easily identify a safe and affordable product that has arrived intact with maximum shelf life remaining. They prefer things that are easily opened, dispensed, and stored and express frustration when designers do not consider their needs. With increasing frequency, they express concerns regarding the sustainability of packaged goods. Many end-users desire products that have considered the social, economic, and ecological impact of design choices on the world, with designs that have zero or positive impacts being preferred. To further complicate the considerations, end-users come with preconceived notions about what packaging is appropriate for a given product. For instance, Americans were very slow to embrace the concept of wine in anything but a glass bottle with a cork until recently, and they are just

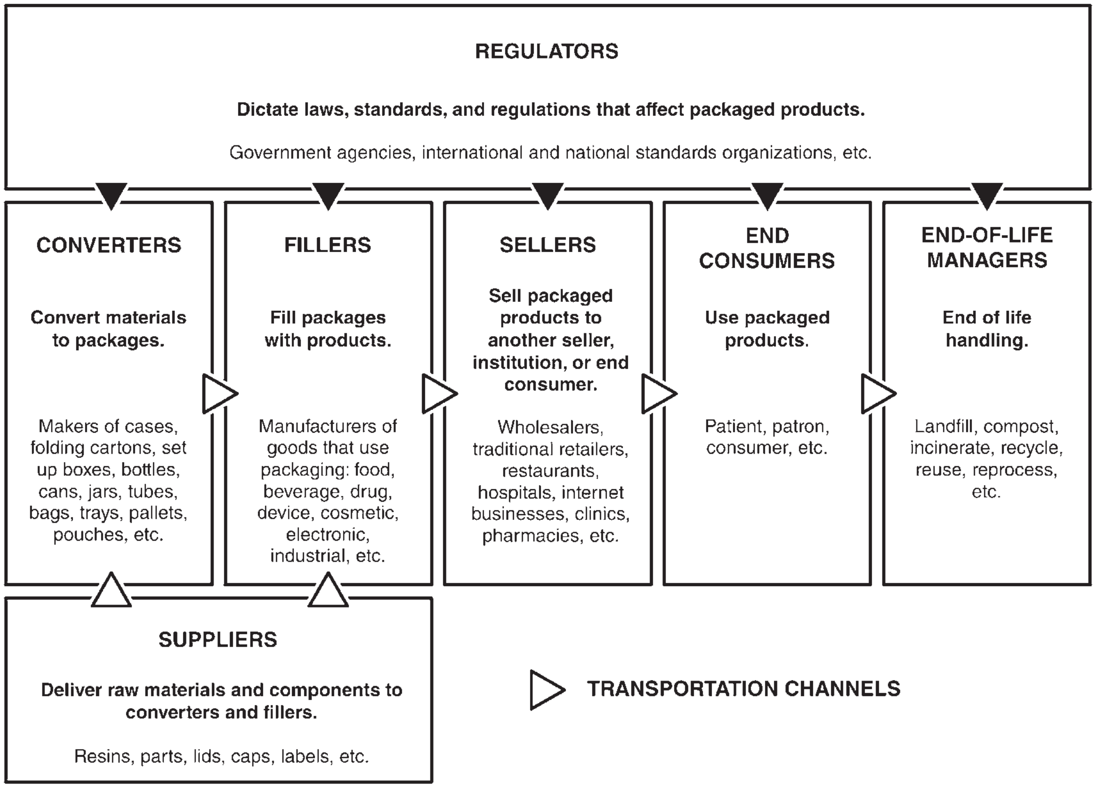

Figure 1. Packaging supply chain stakeholders.

beginning to accept bag-in-box systems and canned wine. These conceptions are filtered through a cultural lens, so as the marketplace becomes more global in nature, so, too, does understanding how a design will be perceived and embraced by the end-user. The rising globality of the marketplace further complicates design decisions, as the varying systems for distribution, storage, and handling are not standardized and large distances, coupled with multiple hand-offs, allow for problems with product security.

It is for this reason that, with increasing frequency, manufacturers, regulators, and standards organizations are integrating automatic identification (auto-ID) and authentication technologies into package designs. Frequently, technologies like bar codes and radio-frequency identification (RFID) are being included in package systems in an attempt to provide a complete history regarding the product's origin, location, and conditions of handling. Overt, covert, and forensic technologies are commonly imbedded into packaging components in order to deter and detect illicit activities (counterfeiting, up-labeling, etc.) as well as authenticate genuine product.

Finally, at the very end of the stream are those that deal with the issues of disposal, the end-of-life managers (see Figure 1). They, too, have desires for packaging. Packaging can end its life by being reused, either in the same fashion as it was used to begin with (a returnable, refillable bottle) or in a new way (a bottle that becomes a vase). Packages that are to be reused in the same way must be capable of withstanding the processing necessary to ensure that they are as safe and effective the second time around as they were the first. Those that are reused for different purposes must suggest to the end-user (either subtly or directly) that reuse of this item is an attractive option.

A number of systems exist where packaging is processed at the end of its life to become something else. Recycling reprocesses the materials present into new forms. Composting breaks the materials down into basic components. Incineration captures the energy released as the package is burned. Finally, packages may end up in the solid waste stream, where they are land-filled.

Regardless of the process employed, end-of-life managers desire package designs that can easily and safely be integrated into existing systems for the collection and processing of the materials. Designs must effectively utilize appropriate disposal mechanisms and convey to both the end-user and the disposal facility any necessary steps to be taken (e.g., the classification of the materials and separation of components).

Clearly, the considerations and decisions that astute packaging designers regard are vast, and different products and stakeholders require emphasis on varying aspects of the design.

THE LOCKHART PACKAGING MATRIX

The Lockhart Packaging Matrix is a tool that allows designers to consider numerous design decisions and

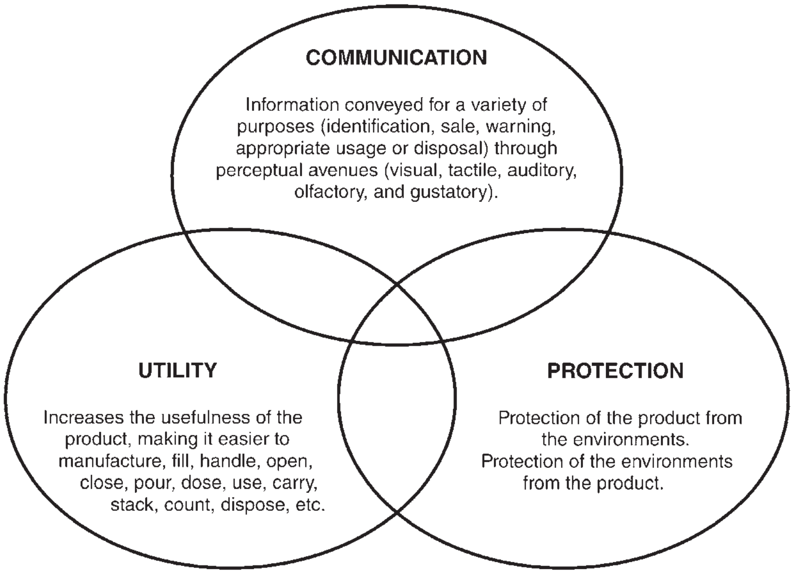

Figure 2. The functions that packaging must perform.

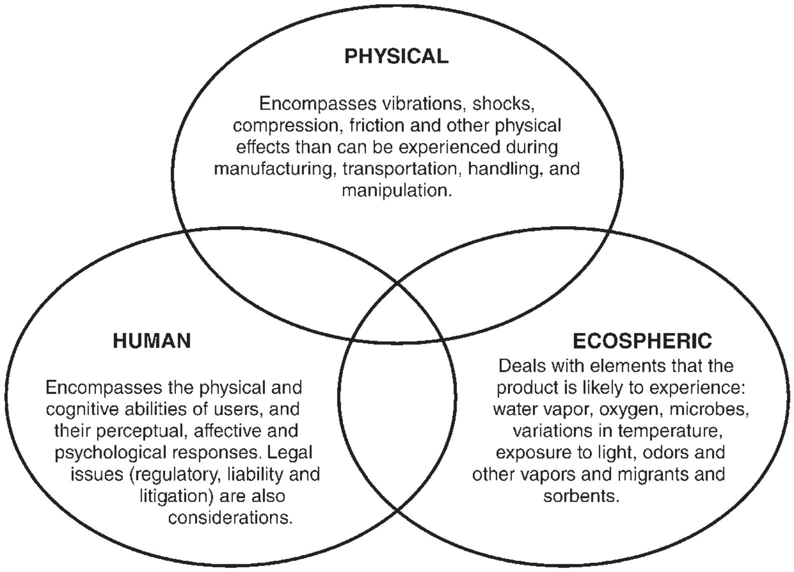

Figure 3. The environments in which functions must be performed.

stakeholder perspectives in an organized fashion (2). It considers packaging to be a socioeconomic discipline that must perform three main functions—protection, utility, and communication (see Figure 2)—in three environments: the physical, ecospheric, and human (see Figure 3). These functions and environments frequently exert their effects simultaneously, though the matrix separates them for ease of understanding.

When all functions and environments are considered, packaging is not just a means to protect or contain the product, but also has the potential to impact the decisions and lives of those interfacing with it throughout the chain (see Figure 1). The Lockhart matrix presents, visually, a way to manage the intersections of function and environment that occur (see Figure 4).

The challenge to designers when using the matrix is to simultaneously consider all nine intersections of the matrix from the perspectives of the many, varying members of the supply chain (see Figure 1); optimal decisions will maximize all intersections without suboptimizing others. For instance, consider a package that contains a prescription drug. By focusing solely on the category of human/protection, a child-resistant container that is impervious to all children might be created. The system is suboptimized, however, if this comes at the cost of any senior being able to access their medications; suboptimization of the human/utility interface of the matrix (see Figure 4).

HISTORICAL EMPHASIS OF PACKAGING SCIENCE

Because packaging is a fledgling discipline, not all areas of the matrix have received the same level of scientific

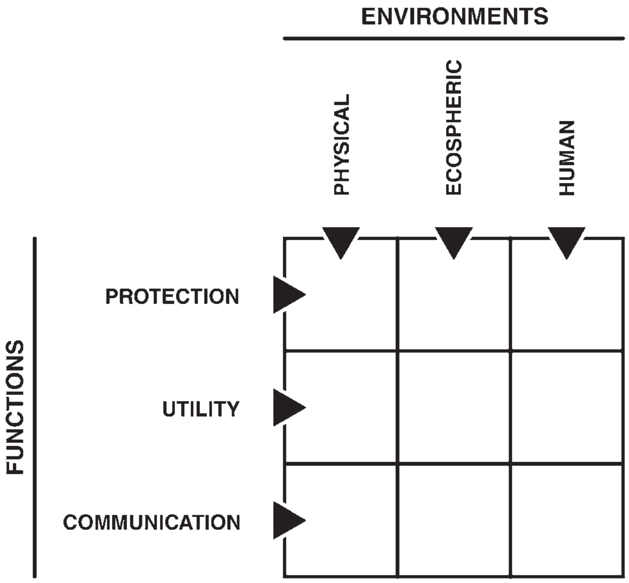

Figure 4. The Lockhart packaging matrix.

investigation. Consider the level of science that has been applied across the three environments (ecosphere, physical, and human; see Figure 4). The ecospheric environment and the physical environment each have a considerable history of scientific exploration which has resulted in standardized test methodologies, predictive models, and design innovations.

In the ecospheric environment, the role of packaging as a barrier to deterioration (from air, water, light, temperature, and living organisms) is well known. Material and packaging innovations in this arena have seen tremendous growth and development, and they range from the simple to complex. Society has been the benefactor of developments such as: amber glass and canning; the creation of polymers that allow for less breakage and lighter packages than glass or metal; the incorporation of additives that extend the shelf life of products by scavenging oxygen or killing microbes; and the emerging introduction of nanocomposites, to name a few.

Science was, and continues to be, used to catalyze and inform these innovations. Fickian models can be used to explain the transfer of molecules through barrier systems, and sorption moisture isotherms characterize product delicacies; this information can be coupled to predict and understand the resultant shelf life of products through the use of multiple test standards (see Shelf life, Testing, Permeation, and Leakage). Solubility parameters can be calculated to predict the likelihood of product/package interaction. "Active packaging" (3) manipulates and reacts to the internal and external environment to achieve a desired goal for the product (generally extension of shelf life). Chemical engineers and material scientists have worked to understand the "weak links" that can be manipulated in material chemistries in order to create polymers that are biodegradable or readily compostable.

Like the ecosphere, the physical environment has been the benefactor of attentive scientists and engineers during the years that packaging has been formally studied. Accelerometers that can "map" physical conditions and shock indicators that trigger a warning of potential damage have been developed to provide information to designers and end-consumers. Testing agencies and research teams are capable of estimating component fragility so that product and package design can be manipulated to mitigate the probability of damage. This information can be coupled with damage boundary curves and cushion curves in order to help designers maximize protection and minimize cost. All of these approaches rely on sophisticated equipment and test standards (see Distribution Hazard Measurement, Logistical/Distribution Packaging) that have been put in place over the years.

Obviously, packaging research has optimized performance by providing science that garners insights into the interactions between product and package when the ecospheric and physical environments are considered. However, the lack of this same degree of attention and quantification of the human environment represents a real opportunity for packaging designers, particularly as the global population ages.

We submit that optimal designs consider the product and the user (all three environments; see Figure 4) from all stakeholder perspectives (see Figure 1). This is not the traditional approach to design, which generally centers on either the product or user as the focus of the decision making process.

PRODUCT-CENTERED DESIGN (PCD) VERSUS USER-CENTERED DESIGN (UCD)

In a product-centered design (PCD) process, designers focus first on the technological development of the package while considering product and production requirements, after which point they address user functionality. The traditional approach to packaging design has been largely PCD, with concerns about the ability to efficiently fill, protect, and distribute products driving most design decisions.

By contrast, a user-centered design (UCD) process first considers the needs and wants of the user. The users' functional capabilities determine which product features are satisfactory. For instance, if it is known that a user can only exert a certain force, any design that requires a force beyond that limit will be disallowed from consideration.

We suggest that truly optimal designs consider all viewpoints, a combination of PCD and UCD processes. During the entire process the design team must attempt to balance requirements of the three environments (physical, ecospheric, and human) and the three functions (protection, utility, and communication) described earlier from varying stakeholder perspectives (see Figure 1–4). Though all intersections of the matrix may not be given equal credence for all products and stakeholders, all are considered and, if under- or disregarded, the decision to do so is deliberate.

PACKAGING DESIGN AND DEVELOPMENT—CONSIDERING ALL PERSPECTIVES

A packaging project is quite unique in the sense that it encompasses both the design of three-dimensional components and the design of two-dimensional elements to perform the functions of protection, utility, and communication in the varying environments. Usually, the end result takes the form of a multicomponent system that includes primary, secondary, and tertiary packaging. Because of its interdisciplinary nature, the development process affects all functions in an organization. Research, sales, finance, legal, and the general management are involved, but of particular importance are the functions of marketing, design, and manufacturing because of their continuous involvement along the entire process. It is for these reasons that it is assumed that the design team will have representatives from the latter areas.

There are many design and development processes described in the literature (4–6). Even though some of them do not specifically consider the design of packages, from a broad perspective they all have conceptual similarities. Regardless of the type of packaging system, a design project has four typical stages: research, design, development, and manufacturing. We present a six-phase, comprehensive methodology adapted from Ulrich and Eppinger (5) for developing packaging systems (see Figure 5).

The output of each phase is evaluated to determine what design features move forward in the process. Evaluations take the form of testing (mechanical and chemical), user assessment, and/or internal assessment. The process is iterative and usually bidirectional, meaning that information gathered in later phases can be used to modify and feed early stages (see Figure 5). The process' phases are defined in terms of the state of the packaging system being developed. They are as follows:

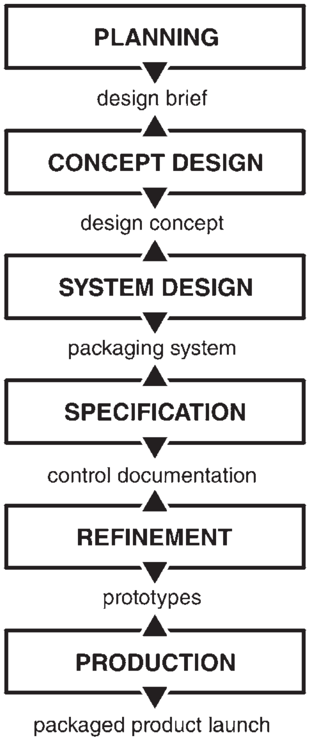

Figure 5. A generic packaging design and development process. (Adapted from Ref. (5).)

1. Planning
2. Concept design
3. System design
4. Specification
5. Refinement
6. Production

1. Planning. The objective of the planning phase is to formulate a *mission statement* or *design brief* that includes identification of target segments, businesses goals, stakeholders (see Figure 1), assumptions, and both product-centered and user-centered restrictions. The inputs of this phase take into account the corporate strategy, an assessment of available technology, and market objectives.

2. Concept Design. During the concept design stage, several packaging concepts are generated and evaluated, and one or more are selected for additional development and testing. A concept is a description of shapes, functions, and features which are intended to fulfill the expectations generated, as expressed in the design brief. Concept ideation is a complex task that implies several interconnected activities which include:

a. Identifying Product and User Needs and Requirements. The first activity is directed at recording the varying requirements, needs, and desires for the package system and communicating these to the development team and members of the organization. The packaging matrix (see Figure 4) can be used extensively in understanding and prioritizing these requirements. The output of this step is a hierarchical list of need statements with importance weightings.

Activities carried out at this point include:

- Identification of stakeholder needs
- Identification of product requirements
- Data gathering from stakeholders and product
- Prioritization of the stakeholder needs and product requirements
- Development of design parameters based on collected data
- Interpretation of raw data in terms of stakeholder needs and product requirements.

It is very important to identify the requirements of the product and the varying stakeholders. Be aware that product and stakeholder requirements may be juxtaposed and that varying stakeholders are likely to place emphasis on differing sections of the packaging matrix. As such, prioritization is a crucial piece of the process.

To illustrate this, consider a prescription drug. Product protection requirements may dictate the use of an opaque or amber package (ecospheric/protection), but manufacturing may desire a clear material so that a vision system can verify the presence of the pill in the blister cavity (physical/utility). Similarly, stakeholders may have different desires. Pharmacists have unique requirements in terms of cost, storage, labeling, and filling operations, but those needs may be very different from those of the end-users.

Once the product requirements (physical and ecospheric) and the stakeholders' needs and requirements (human) have been identified, the team must gather data in order to inform the design of the package. Product-driven data may include: isotherms; chemical assays that look at sensitivities; stability studies; fragility data; characterization of the distribution environment (relative humidity levels, typical temperatures, as well as shocks and vibrations likely to be encountered); and limitations imposed by the manufacturing process and distribution systems. End-user insights may include data collected from interviews, focus groups, ethnography, and use; end-users may also be characterized by demographics, psychographics, and anthropometrics, as well as in terms of their physical capabilities (strength, range of motion, visual acuity, etc.).

The next step is to design parameters from the raw data. At this point in the process, the parameters are described in terms of what the packaging has to do, as opposed to prescriptive solutions. Design parameters are then organized into a hierarchy and grouped in primary, secondary, and even tertiary priorities. To establish the relative importance of the parameters, the design team can rely on its own knowledge about the user and product; they can overpackage, or they can conduct fact-finding to gather further information. There is a natural tradeoff between the approaches: cost, speed, and accuracy. Relying on internal knowledge can aid in speed to market and be cost effective, but can be detrimental in terms of accuracy. Overpackaging, or overdelivering, can also aid in speed to market, but can be costly in the long term; mining more data to inform decisions can slow the process, but can result in a more informed, cost-effective solution.

b. Setting Target Specifications. Prioritized design parameters are then translated into target specifications. These are measurable and precise descriptions of what the packaging has to do. Target specifications represent goals that, later in the process, can be readjusted in the event of unforeseen constraints (i.e., technological, economic, etc.). The process of establishing specifications involves the selection of metrics, collection of competitive benchmarking data, and the setup of ideal and acceptable target values.

To illustrate this concept, consider a product that has a design parameter indicating it to be moisture-sensitive. In this step, the parameter is translated into a target specification, a specific requirement for the maximum allowable rate of moisture vapor transmission. The same type of transition occurs with design parameters that relate to user needs. The design parameter "easy opening" can be translated into target specifications relating to package diameter, maximum allowable torque, and coefficients of friction between cap and hand, or the team could just decide a percentage of opening success among the target population.

c. Concept Generation. Target specifications are synthesized into a set of packaging concepts from which the team will make a final selection. The basic idea is to exhaustively explore design solutions in order to reduce the probability of finding a better alternative late in the development process or, even worse, having a competitor find one.

d. Concept Selection. The design team will use some kind of method for selecting concepts. The approach to concept selection can be either intuitive or structured and can include:

- *An External Decision*. A customer or client makes the selection.
- *Product Champion*. A member of the team makes a selection based on personal preference.
- *Intuition*. A concept is selected by its feel.
- *Multivoting*. Team members vote for multiple designs (i.e., "vote for your top 3"). Each round, a pre-determined number of designs are forwarded for more voting, and votes are cast again ("vote for your top 2"). This process continues until the design(s) is chosen.
- *Pros and Cons*. The team chooses a concept based on a list of strengths and weaknesses of each concept.
- *Prototype and Test*. The team builds and test prototypes of each concept and makes a selection based upon test data.
- *Decision Matrices*. The team evaluates each concept with respect to a set of selection criteria. Criteria are based on previously discussed design priorities.

More structured methods provide objectivity throughout the concept design phase and help to evaluate concepts scientifically. Concepts are examined scientifically to determine if they meet or exceed the needs and requirements of the product and varying stakeholders and the selection is made based on objective results. New concepts are also evaluated and benchmarked against the existing competition.

e. Concept Testing. Selected concepts are evaluated by potential users in the target market and subjected to appropriate laboratory testing. These activities involve:

1. Defining the purpose of the test: the team needs to define what questions will be answered with the testing.
2. Selecting test conditions:
    - In the case of user focused testing, it is assumed that a sample population will reflect the target

population. Testing can be conducted in a variety of ways, including ethnographic research, surveys, face-to-face interviews, telephone interviews, postal or electronic mail, and over the internet. Concepts can be communicated in many ways with different levels of description. These include: verbal description, sketches, photos, videos, physical appearance models, and working prototypes.

- In the case of pilot scale manufacturing, it is assumed that incoming lots will reflect the variability of materials, line speeds, and other manufacturing parameters.
- In the case of stability testing, it is assumed that conditions of test will be carefully chosen to reflect, or accelerate, appropriate conditions of storage and use.
- As with the other testing, physical testing will be purposefully constructed so that conditions accurately reflect handling and storage throughout distribution channels.

3. Measurement of responses.
4. Analysis, interpretation of results, and selection of a final concept.

f. Setting Final Specifications. Based on the final concept, the team will be able to confirm or revise specifications. This is done by conducting a terminal evaluation which, again, considers the broad spectrum of stakeholder requirements with a heavy emphasis on technological restrictions and manufacturing costs. During this phase, the design team must perform a balancing act that considers the myriad of requirements from the varying user perspectives to arrive at the optimal package design for the entire system. As such, the final specification process calls for an active involvement of team members representing marketing, design, and manufacturing functions of the organization.

3. System Design. This phase includes the definition of all packaging system components and parts. The outcome includes a geometric layout of the system, functional specifications for each part, and a process flow diagram for the production and packaging lines.

4. Specification. The output of this phase is the *control documentation* for the entire packaging system, as approved by the respective areas (i.e., structural, graphics, scheduling, manufacturing, marketing, customer service, the filler, etc.). For the graphic elements of the system, this phase implies the preparation of the final art work. There are a multitude of possibilities, but it could include adequate color separation for the printing system chosen, photography at sufficient resolution, die lines, overprints, illustrations, fonts, code bars, final identification suppliers for components and substrates, specifications for spot ultraviolet coating (varnish or lacquer), embossing/debossing, foil stamping, matt/glossy finish, and so on. For the structural parts of the system, specifications include detailed descriptions of geometry, tolerances, materials, and manufacturing processes of all components as well as production tooling. It also identifies any standard parts to be acquired from suppliers.

5. Refinement. The refinement phase involves the evaluation of preproduction versions of all packaging system parts and the final assembly. Typically, two types of prototypes are used here: *alpha* and *beta*. *Alpha* prototypes are early versions of the packaging system; they have the same geometry and material properties as intended for the production version parts, but they may or may not be fabricated using the actual production process. *Alpha* prototypes are used to determine if the design will work as intended, fullfilling key stakeholder's needs and requirements. *Beta* prototypes are built with parts produced with the intended manufacturing processes, but their assembly might not be performed using the final assembling process. *Beta* prototypes are evaluated by the team and by different stakeholders to identify whether engineering changes are needed for the final packaging system.

6. Production. During this phase, the packaging system is produced on the final packaging line using actual packaging components and parts. Packaged products are evaluated using carefully constructed sampling plans to determine the process' ability to produce within specified tolerances and to adjust the parameters of manufacture. There is a gradual transition to full blown production. At some point during this phase the final packaged product is launched and distributed.

CONCLUSIONS

Seller and end-user trial, satisfaction, and repeat purchase may be a direct function of packaging for many consumer non-durables and perhaps for some durables as well. The three functions of packaging (protection, communication, and utility) play a key role in achieving success.

Packaging that fails to fully protect the product has the potential to result in excess damage and waste, diminished shelf life, and loss of flavor or efficacy. Problems associated with insufficient protection are likely to lead to customer dissatisfaction and negative word-of-mouth advertising. Likewise, packaging that fails to communicate its marketing positioning, to differentiate from its competitors, and to connect emotionally with consumers will result negatively on the bottom line. Packaging that does not provide the expected utility will put off consumers. The product/package system must generate satisfaction, and poorly designed packages have the potential fail to attract sales and discourage repeat purchase.

It is important that designers recognize the power of a comprehensive, deliberate approach to package design. This chapter presents a six-step approach that can be used to design packaging and the packaging matrix, a tool for prioritizing the myriad of considerations and perspectives that must be considered.

MAP DESIGN

MAP design requires the determination of intrinsic properties of the produce—that is, respiration rate, optimum O_2 and CO_2 gas concentrations, and film permeability characteristics as shown in Figure 1. The ultimate aim of this design process is to select suitable films for a given product, its area and thickness, filling weight, equilibrium time, and the equilibrium gas composition at constant and varying temperature conditions (1, 2). It is noted that the temperature is never constant in the distribution chain of fresh produce. Due to the temperature dependence of the respiration rate and the gas permeability of a packaging film, a film that produces a favorable atmosphere at the optimal storage temperature may cause excessive accumulation of CO_2 and/or depletion of O_2 at higher temperatures, a situation that could lead to metabolic disorders with concomitant safety and quality issues.

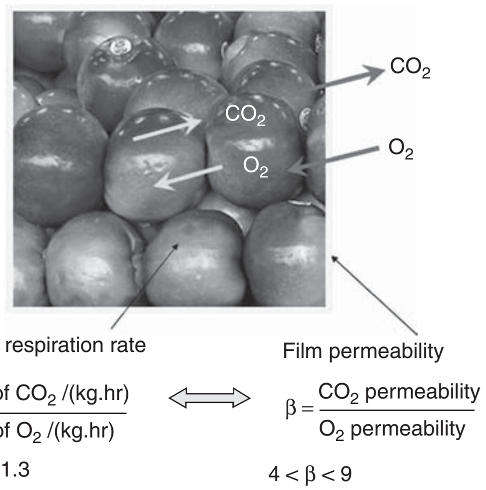

Figure 1. Basic principles of modified atmosphere packaging (MAP).

The "pack-and-pray" approach and in-house trial-and-error experiments are normally used to find a suitable packaging material, film area for gas/water vapor exchange, package size, and the quantity of product to be packaged. This is both time and labour intensive and a potential risk to health. It is noted that the existing commercial vegetable packages deviated from the optimum MAP conditions as measured by our research group (Figure 2) (3). A MAP system, if not designed correctly, may be ineffective or even shorten the storage life of a product. There is a wealth of published information on MAP, yet no systematic study has been conducted to establish which commercially available polymeric films would be most suitable for a particular produce under a given set of environmental conditions. Such analysis could provide an initial screening of films, point out their potential limitations, and allow a better package engineering design. Mathematical modelling and computer simulation is a valuable tool in this context.

AN ENGINEERING APPROACH TO THE PACKAGE DESIGN

Sound use of MAP entails consolidated knowledge of the food–package–environment interaction: When a product is packed, it is surrounded by a gaseous mixture, the composition of which depends on the interactions between the food product, the package material, and the environment. If the packed food is a fresh-cut product, such interactions concern the respiration metabolism of the product (Figure 1): The product exchanges gas with the

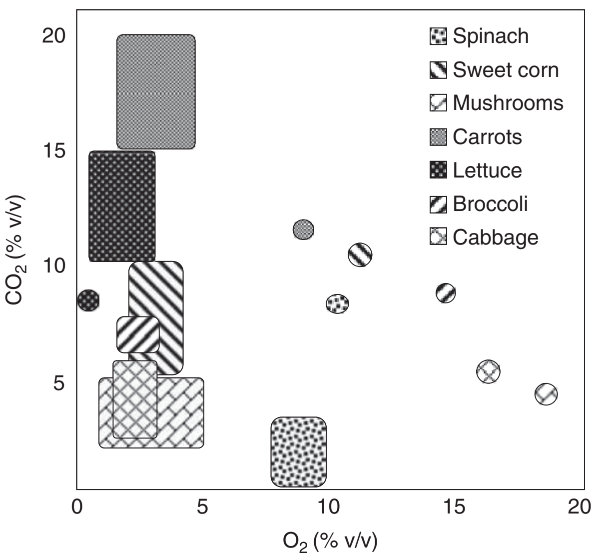

Figure 2. Recommended atmospheres for vegetables and average atmospheres of commercial packages. (Boxes show the recommended gas composition, and circles show the average gas composition of commercial packages.)

surrounding atmosphere, consuming O_2 and CO_2 carbon dioxide (4). The ratio between the CO_2 production rate (mL/(kg · h)) and O_2 consumption rate (mL/(kg · h)) is the respiration quotient (RQ). Due to the respiration process, an O_2 and CO_2 concentration gradient between the headspace and the environment is generated. Thus, a gas flow is activated through the packaging material due to film permeability to O_2 and CO_2. The ratio between the permeability to CO_2 and the permeability to O_2 is known as selectivity (β). From the above considerations, to design a package for a fresh-cut product, one clearly needs to deal with packaging system in dynamic conditions. Therefore, to ensure a suitable gas composition during the product's shelf life, a model should take into account the factors and steps shown in Figure 3. The first and most important factor is the respiration rate. The mathematical model for respiration rate is usually a function of O_2, CO_2, and temperature (5). The second important factor is the type of packaging material and its permeability in terms of O_2 and CO_2. Permeability changes with temperature; hence, a mathematical model is required to predict the permeability change in the packaging material, which is a function of temperature. Another factor is the best optimal atmosphere required to extend product shelf life which varies from product to product and is widely covered in the literature. A real challenge is how to achieve this atmosphere for a given type of product and packaging conditions. The answer is to go for either (a) a layman's approach of trial-and-error experiments or (b) an engineering approach where mathematical equations depicting product respiration rate and package permeability could be used to solve the mass balance equations of a packaging system using software tools.

INTEGRATION OF MATHEMATICAL MODELS FOR MAP DESIGN

For any packaging design, the product characteristics such as respiration rate, density, and the optimum range of O_2 and CO_2 for the best shelf life are needed for solving the mass balance equations. Such data are widely available in the literature and has been compiled in a ready-to-use format (2, 6). This database helps to choose the appropriate film for the given product. Another database has been created for packaging materials; this includes their permeability values, mathematical models to predict permeability at any temperature, film thickness, availability, and cost. When several films can be used to provide a protective atmosphere, their cost is a major selection factor. A packaging design protocol has been developed for selection of the best film for a given product. This requires knowledge of the optimum gas composition (O_2 and CO_2) and determination of the respiration rate of the selected product using the database on respiration rate mathematical models.

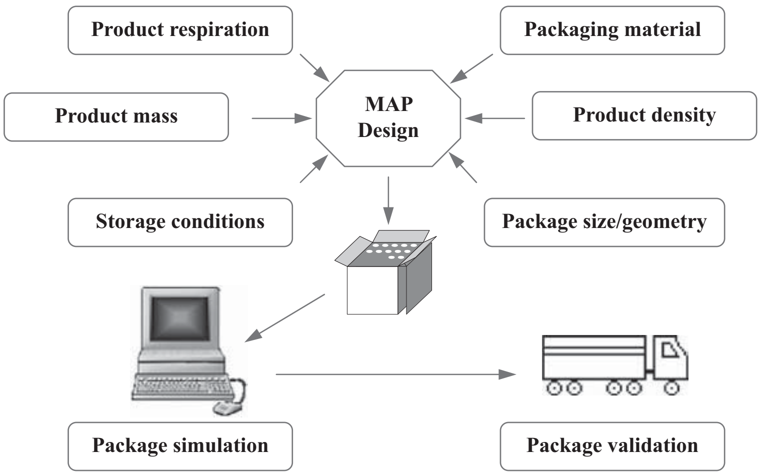

Figure 3. Factors affecting MAP design.

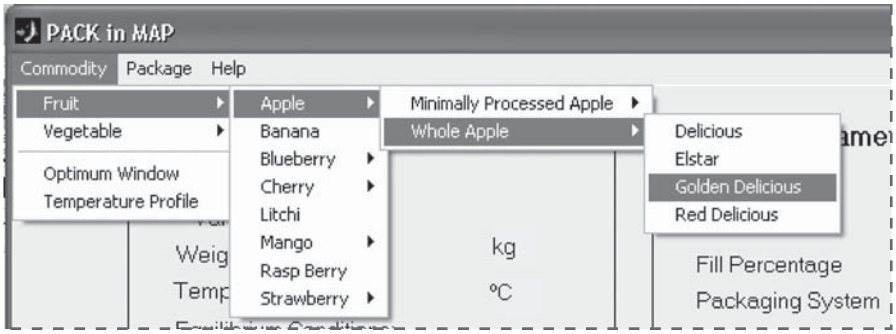

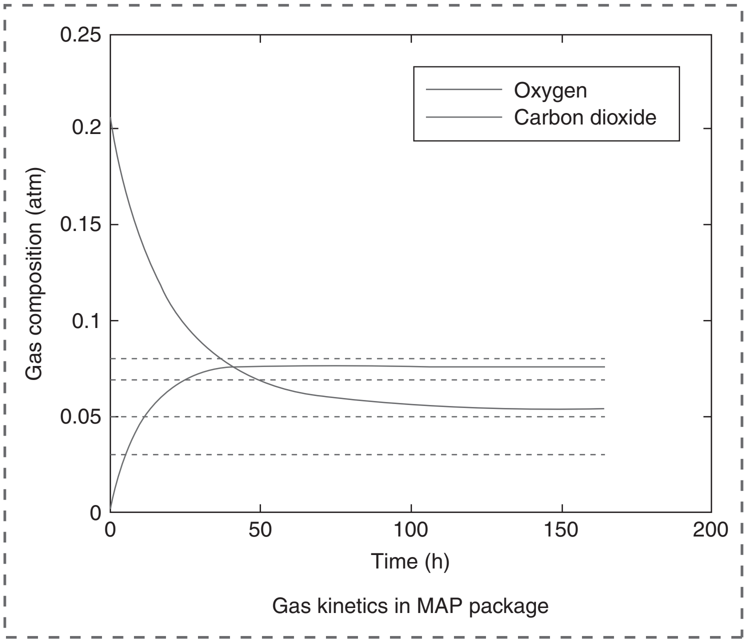

Figure 4. A graphical user interface of PACK-in-MAP software and kinetics of gas exchange in MAP.

PACK-IN-MAP SOFTWARE

The published information on MAP has been compiled, and software called PACK-in-MAP (7) has been developed to establish which commercially available polymeric films would be most suitable for a particular produce (1, 2). The user-friendly software, PACK-in-MAP, has been developed using the Matlab 6.0 program. It incorporates the database for respiration rate, optimum temperature, and optimum range of O_2 and CO_2 concentrations for different fruits and vegetables and permeability of different packaging materials, including micro-perforated films. This database is helpful in designing MAP for 38 fresh and fresh-cut products using 27 polymeric films and micro-perforated packages. Some of the database is made flexible so that users can configure it to their requirements.

In the Pack-in-MAP software, the user defines the type of product, storage conditions, amount of product to be packed, and size and geometry of the package. The software selects the optimum gas composition (O_2 and CO_2) and calculates the respiration rate for that product. The software then selects the best possible films in the given range of permeability ratio and calculates the area of each film required to achieve the desired gas exchange. Alternatively, the user may specify the area available for gas exchange, and the software calculates the amount of product that can be suitably packed. It avoids time-consuming trial-and-error experiments to determine the best packaging system for the given product (1, 2). Finally, the software simulates how the package atmosphere (O_2 and CO_2) changes over storage time (Figure 4) for the given time–temperature profile for the particular product. The simulated results have been successfully validated for mushrooms and cheese by conducting packaging experiments under known environmental conditions for each product.

FEATURES AND BENEFITS OF PACK-IN-MAP SOFTWARE

Features

- Stand-alone user-friendly software for packaging design

- Option for user-defined conditions for respiration and permeability
- Selects the optimal storage conditions for a given product (O_2 and CO_2)
- Calculates the specified product respiration rate at given storage conditions
- Selects the package geometry and calculates product volume
- Selects the suitable packaging film(s) for a given product
- Defines the amount of product to be packed
- Calculates the area of the film that should be available for gas exchange
- Simulates the package atmopshere with time in a graphical form
- Enlists other polymeric film(s) suitable for the given product
- Suggests different packaging options:
  - Polymeric films with micro-perforations,
  - Polymeric films with macro-perforation,
  - Perforation-mediated packaging systems
- Defines the optimum size and number of perforations for a given product

Benefits

- Reduces the cost by minimising the number of trials per optimal packaging design
- Suggests the best possible packaging film to achieve an optimal atmosphere for a given product
- Simulates the package atmosphere without knowledge of mathematical models, package design, and modified atmosphere packaging itself
- Capability of simulating the package at varying temperature set according to the real-life distribution chain
- Evaluates the impact of product and package variability on internal package atmosphere

PACKAGING FUNCTIONS AND ENVIRONMENTS

KIT L. YAM
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

When designing a package, it is useful consider that the functions of the package and environments the package will likely encounter during its manufacture, distribution, and end use. The concept discussed below is applicable to almost any products; however, food is used as an example since the concept is very useful to this product.

PACKAGING FUNCTIONS

A food package must serve one or more functions to justify its existence. Traditionally, food packaging has four basic functions: protection, convenience, communication, and containment. A package design may be evaluated based on how well the package performs the required functions in a cost-effective manner.

- *Protection*. Protecting the food from physical damage, physiochemical deterioration, microbial spoilage, and product tampering is probably the most important function of packaging. Without proper protection, the food may become unappetizing, less nutritious, and unsafe to consume.

  The required packaging protection depends on the stability and fragility of the food, the desired shelf life of the food package, and the distribution environment. Good package integrity is also required to protect against loss of hermetic condition and microbial penetration.

  Generally, the protection function of packaging is limited to foods whose shelf lives are controlled by environmental factors relating to physical damages, humidity, oxygen, light, and, to some extent, temperature. Packaging is usually not effective for protecting foods whose shelf lives are controlled by internal factors. For example, consider a tuna sandwich in which moisture may migrate internally, from the tuna to the bread, causing the bread to become soggy and unacceptable to the consumer. The internal moisture migration is driven by the difference in water activities between the tuna and the bread, not by the relative humidity outside the sandwich. Thus enclosing the sandwich with a package will not solve the problem; perhaps placing an edible coating between the tuna and the bread may provide an acceptable solution.
- *Convenience*. This is an important function to satisfy the busy consumer lifestyle. Examples of convenient food packages are ready-to-eat meals, heat-and-eat meals, and self-heating packages. Examples of convenient features are easy opening, resealability, and microwavability. Innovations are constantly sought

to provide more convenience without sacrificing quality or increasing cost.

- *Communication.* The function of communicating is important to create brand identity and influence consumer buying decisions. The package communicates with the consumer through written texts, brand logo, and graphics. In many countries, nutritional facts such as calories, fat, cholesterol, and carbohydrate are required on all food packages.

  The communication function is also important for facilitating distribution and retail checkouts. The bar code has virtually become an integral part of every commercial food package. Besides the bar code, there are other package devices, such as time-temperature indicator and radio-frequency identification (RFID), which enable the package to communicate more effectively for the purpose of ensuring food quality and safety. For example, intelligent packaging (1) is a new technology that pushes the communication function to a higher level.
- *Containment.* Containing the food product is the most basic function of packaging. The requirement for containment depends on the size, weight, form, and shape of the enclosed food; for example, a solid food has different requirements from a liquid food. The containment function is also closely related to the rigidity of the package.

PACKAGING ENVIRONMENTS

The package typically functions under three environments:

- *Physical Environment.* This environment is concerned with the physical conditions that a package may encounter during its life cycle. For example, the package may have to withstand the harsh temperature/pressure conditions during retorting, as well as shock and vibration, falls and bumps, crushing from stacking, and attack from insects and rodents during storage and distribution. To protect against this environment, the package must have adequate mechanical strength and thermal stability, as well as other properties depending on the situation.
- *Ambient Environment.* This environment is concerned with the oxygen, moisture, odors, molds, bacteria, light, and heat which are ubiquitous during storage and distribution. To protect against the negative impact of the ambient environment, the package must have an adequate level of barrier properties depending on the requirements of the food.
- *Human Environment.* This complex environment is concerned with the human aspects of packaging, such as the user-friendliness, liking/disliking, and safety of a package to the consumer. Many socioeconomic issues such as the impact of packaging on the environment, packaging related legislations and regulations, and packaging related litigations are largely influenced by humans. Human perception, vision, dexterity, and language are also included in this environment.

Understanding these three environments and the nature of the food product is important for specifying the packaging requirements.

Based on the above discussion, Table 1 may be constructed to provide an overview of the relationship between packaging functions and packaging environments. This table is particularly useful during the early stage of the package development process for facilitating brainstorming and identifying key areas for further consideration.

FUNCTIONS/ENVIRONMENTS TABLE

In Table 1, packaging functions and environments are arranged in columns and rows. This table is useful for identifying certain packaging features, operations, devices, or considerations that are important for the package to function under certain environments.

For many food packaging systems, it is possible to associate items to most of the cells in Table 1. Although the selection and interpretation of the cell items involve somewhat subjective choices, the functions/environments table helps the product development team to consider all aspects of the food packaging system in a systematic manner. Shown below are examples of items that may be associated with the cells. With some imagination, other helpful items may also be associated.

- *Containment / Physical.* The size and type of package determine how much and what kind of food can be contained and how much physical abuses the package can withstand.
- *Containment / Ambient.* The size and type of package determine how much and what kind of food can be contained and the ability of the package to protect

Table 1. Functions/Environments Table

		Packaging Functions			
		Containment	Protection	Convenience	Communication
ENVIRONMENTS	Physical				
	Ambient				
	Human				

against oxygen, moisture, or light from the ambient environment.

- *Containment/Human*. The size and type of package determine how much and what kind of food can be contained and ease of use of the package to humans.
- *Protection/Physical*. Mechanical strength and seal strength are important for protecting the product from physical abuses.
- *Protection/Ambient*. Barrier properties and seal integrity are important for protecting the food product from the adverse effects of oxygen, moisture, microbes, and light in the ambient environment.
- *Protection/Human*. Tamper-evident packaging is useful to protect the consumer from product tampering. Regulations are necessary to protect from unsafe packages harmful to the consumer.
- *Convenience/Physical*. Efficiently bundled packages offer convenience to the manufacturer during storage and distribution.
- *Convenience/Ambient*. Aseptic packages offer the convenience of storing food products at ambient environment instead of refrigerated conditions.
- *Convenience/Human*. Microwavable packages and easy-to-open packages offer convenience to the consumer.
- *Communication/Physical*. Bar codes can facilitate communication of information through the physical distribution of the product in the supply chain.
- *Communication/Ambient*. Time-temperature indicators and biosensors may be attached to the package to communicate the conditions of the ambient environment.
- *Communication/Human*. Nutrition labels, instructions, and graphics on the package can provide useful information to the consumer.

To take a step further, relative values (from 0 to 100) may be assigned to the cells in Figure 1 (2). A three-dimensional chart may then be generated using the functions, environments, and relative values as x, y, z coordinates. The determination of these relative values is a process that frequently requires subjective judgment. A hypothetical example of this chart is shown in Figure 1. The chart provides a bird's-eye view of the functions–environments relationships and is useful for prioritizing the cells and identifying areas of strength and weakness of the food packaging system.

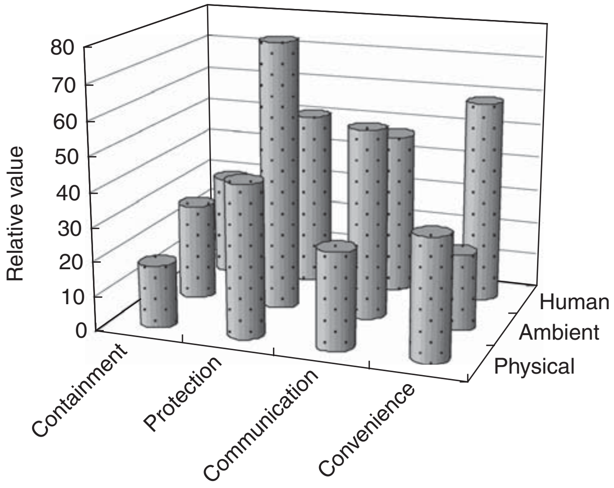

Figure 1. Three-dimensional plot of functions versus environments.

PACKAGING IN CHINA

Zhi-Wei Wang
Packaging Engineering
Institute, Jinan University,
Zhuhai, People's Republic of
China

PACKAGING INDUSTRY OF CHINA

The Chinese packaging industry is playing a more and more important role in the world. It has now maintained a good momentum of growth for the past 30 years due to the progress of reform and opening up of trade, the establishment of the socialist market economy system, and China joining the World Trade Organization (WTO). From 1980 to the present, the total output value of the Chinese packaging industry including packaging materials (paper, plastic, glass, metal, bamboo and wood, and others), packaging printing, and packaging machinery has increased from RMB 7.2 billion (US$ 0.89 billion) to RMB 500 billion (US$ 61.96 billion) at an average annual growth rate of over 18%. It ranks 14th among 42 main industries in China. In terms of packaging production, China has become the third largest packaging country after the United States and Japan.

The output of paper, plastic, metal, glass, and other packaging materials has increased largely. Paper and plastic packaging materials, which represent over 60% of the Chinese packaging industry's output, have become the two pillars. The output of some packaging products in China has taken the lead in the world, such as paper bags, plastic weave bags, plastic bags, compound soft package, and metal barrels. The packaging industry undertakes annual packaging for hundreds of billion US dollars domestic and overseas commodities, which has met the need of national economic development.

Take year 2005, for example (1). The total output value of the Chinese packaging industry has reached RMB 401.687 billion (US$ 49.774 billion), which is about 2.2%

of the gross domestic product (GDP) for the year. The total output value and growth rate of each kind of packaging are shown in Figures 1 and 2. The proportion of the output value of each packaging in the total output value of China's packaging industry is shown in Figure 3. In terms of packaging innovation, the new product output value is RMB16.261 billion (US$ 2.015 billion), which is about 4.05% of the total output value for the packaging industry. Although the innovation capability of the Chinese packaging industry is low, its development speed has exceeded the growth rate of total industrial output value. In each kind of packaging, the largest proportion of new product output value in total industrial output value is occupied by packaging machinery, which is about 11.4%. The contribution of new product output value of each kind of packaging to total new product output value of packaging industry is shown in Figure 4.

The economic structure of packaging enterprises changes with the sound development of the Chinese packaging industry. The number of public enterprises is decreasing, while that of stock enterprises and others types is increasing relatively fast, especially foreign-funded enterprises. On the other hand, there is a tendency of group development in the Chinese packaging industry.

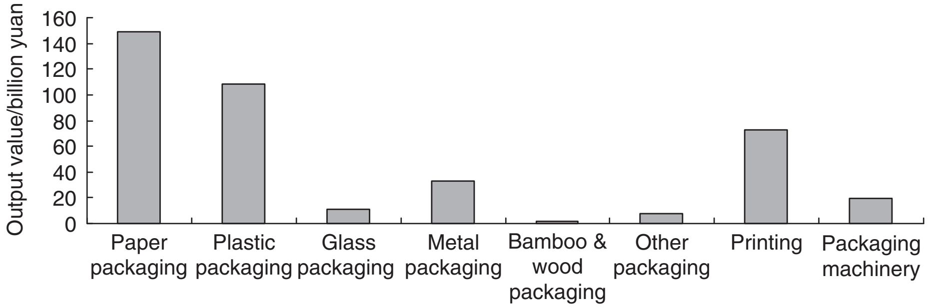

Figure 1. The total output value of each kind of packaging. [Data source: Information and Statistics Collections on China's Packaging Industry 2006 (1).]

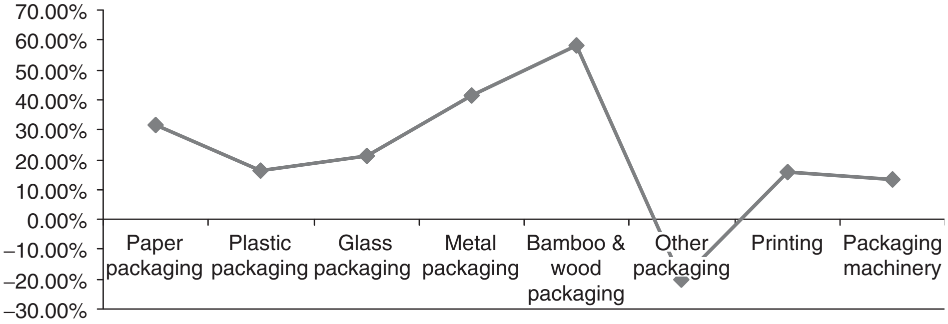

Figure 2. The growth rate of each kind of packaging. [Data source: Information and Statistics Collections on China's Packaging Industry 2006 (1).]

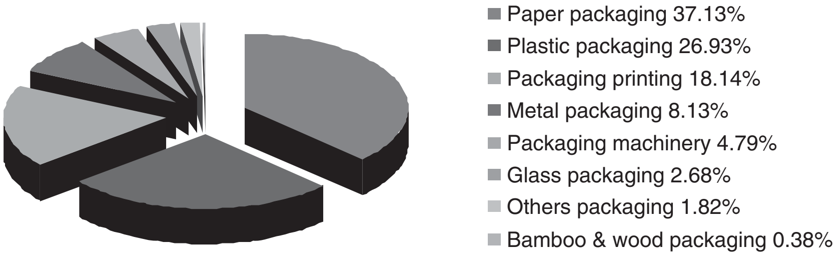

Figure 3. The proportion of the output value of each kind of packaging in the total output value of China's packaging industry. [Data source: Information and Statistics Collections on China's Packaging Industry 2006 (1).]

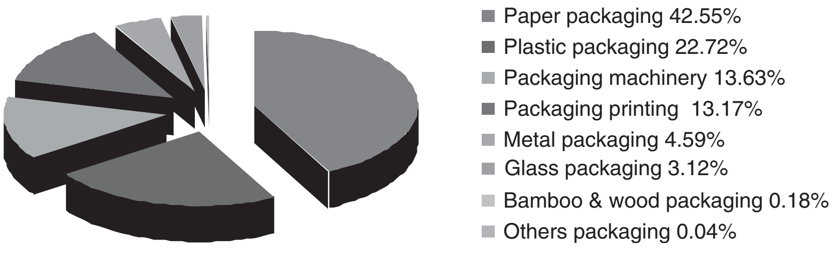

Figure 4. The contribution of new product output value of each kind of packaging to total new product output value of the packing industry. [Data source: Information and Statistics Collections on China's Packaging Industry 2006 (1).]

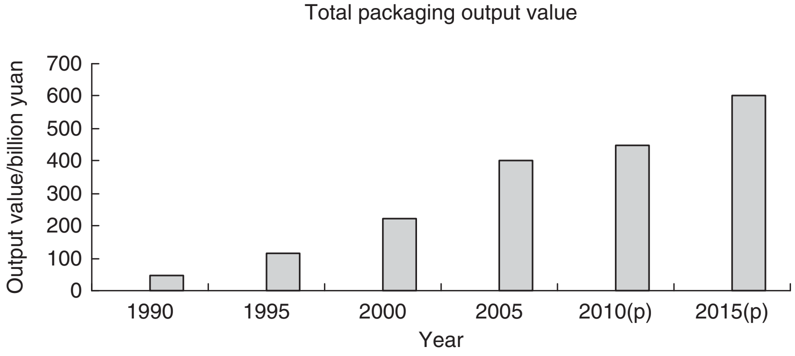

Figure 5. Total output value of China packaging from 1990 to 2015. [Data source: China Packaging Annual 2006 (2). Note: "p" means "plan".]

Many large packaging groups have emerged in some provinces and metropolitan regions of China, such as Guangdong, Zhejiang, Jiangsu, and Shanghai.

The development of the Chinese packaging industry is unbalanced due to the inconsistent development of the local economy. The packaging industry in Eastern China develops markedly faster than in Central and Western China. In terms of economic structure, state-owned packaging enterprises in Middle and West China surpass foreign-funded enterprises and other types, while in Eastern China the opposite situation is found. The further economic development in China brings the need for accelerating the development of the packaging industry in Central and Western China.

The Chinese packaging industry has formed an elementary modern industry system with the main constitutes of packaging materials and modern packaging technology and equipments. China is developing from a large packaging country to a powerful packaging country in the world. By the year 2010, it is projected that the Chinese packaging industry will be built into a modern packaging industry with higher comprehensive innovation ability, reasonable industry infrastructure, optimized industry distribution, remarkable technical progress, wholesome service system, perfect industry standard system, prominent brand, and resources with multipurpose use. The total output value of the Chinese packaging industry should reach about RMB600 billion (US$ 74.3 billion) in the year 2015. With the remarkable development of packaging technology, it is estimated that the output of paper packaging materials will reach 36 million tonnes, plastic packaging materials 9.46 million tonnes, metal packaging materials 4.91 million tonnes, glass packaging materials 15.5 million tonnes, and packaging machinery 1.2 million sets, as shown in Figures 5–11 (2). At same time, the high-quality packaging will strongly support the further development of export trade of China, particularly in those of higher-value products.

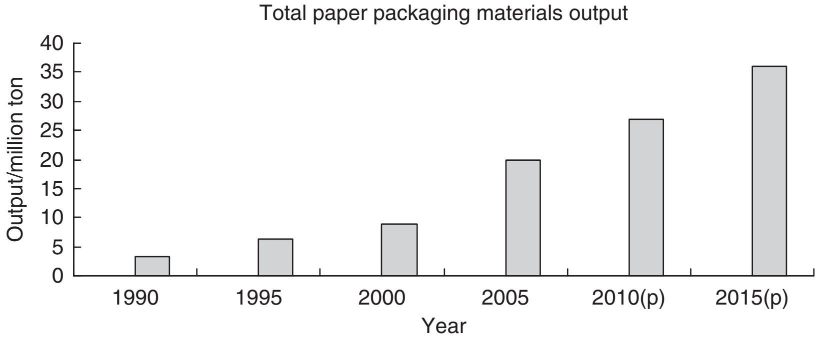

Figure 6. Output of paper packaging materials of China from 1990 to 2015. [Data source: China Packaging Annual 2006 (2).]

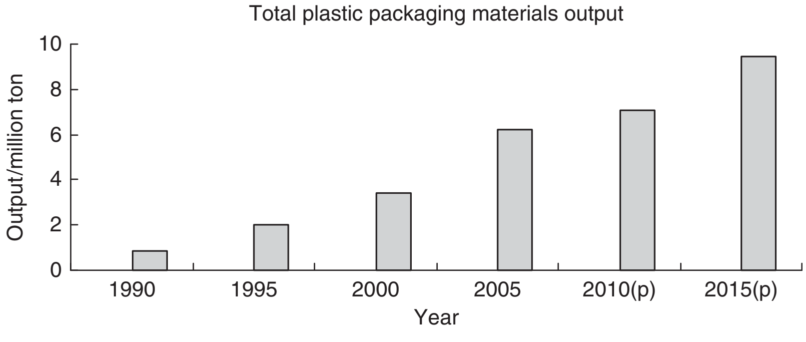

Figure 7. Output of plastic packaging materials of China from 1990 to 2015. [Data source: China Packaging Annual 2006 (2).]

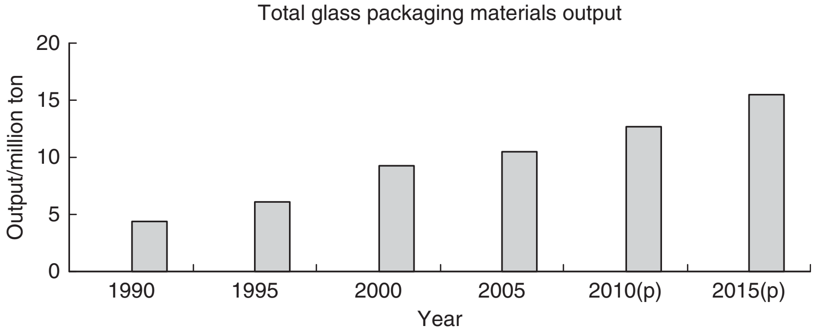

Figure 9. Output of glass packaging materials of China from 1990 to 2015. [Data source: China Packaging Annual 2006 (2).]

CHINESE PACKAGING STANDARDS

Since Packaging Standards are beneficial to national interest and world economic prosperity, it is very important to establish standards that meet international criteria and fit the national situation within China as well. Up to now, China has set up more than 500 national packaging standards, which can be divided into three levels: (1) fundamental packaging standards, such as packaging glossary, packaging label, packaging series dimension, fundamental test method of transport package, packaging technology, and packaging management standards; (2) specialized packaging standards, such as packaging material, packaging container, and packaging machine standards; and (3) product packaging standards, which specify the requirements for packaging of every product. On the whole, China has built a system of packaging standards which meets the needs of packaging industry. The existing problems are: (1) Some standards are unreasonable and imperfect; (2) the different packaging standards are unsystematic and not well-coordinated; and (3) some standards prefer form to content and have poor operability.

In order to solve the problem of time efficiency and low-level packaging standards, China has adopted many ISO standards (IDT, MOD, NEQ). The Standardization Administration of the People's Republic of China has made a vast revision to the packaging standards. In the food contact materials, the standards of materials and containers including paper, plastic, glass, aluminum, steel, pottery, plant fiber, and wood have been put into effect in recent years; these focus on the restrictions on the harmful substances in packaging materials and containers, but no one considers the overall and specific migration limits (OMLs & SMLs) compared with those of the EU and the United States. At present, the revised standard systems include: import and export food packaging, imported timber packaging adopting international quarantine standards, exported timber packaging adopting international standards, toy packaging keeping to the international standards, food packaging acceptance standards, prepackaging food marking standards, classification and quality standards for pharmaceutical packaging materials and container, and so on. These standards systems will regulate and boost the development of commodity packaging forcefully. For the need of resources economizing, the national standard "Requirements of Restricting Excessive Package for Foods and Cosmetics" is in discussion and will go into effect in 2008.

PACKAGING HIGHER EDUCATION IN CHINA (3)

Higher education in packaging within China has developed at a high speed in keeping with the development of the packaging industry. The courses for packaging technology were set up in 1960s, and the undergraduates of "Packaging Machinery" (as a subdiscipline of "Mechanical Engineering") were enrolled in *Jiangnan University* in the 1970s. The National Ministry of Education approved the establishment of "Packaging Engineering" as an academic discipline for undergraduates in the year 1984. Since

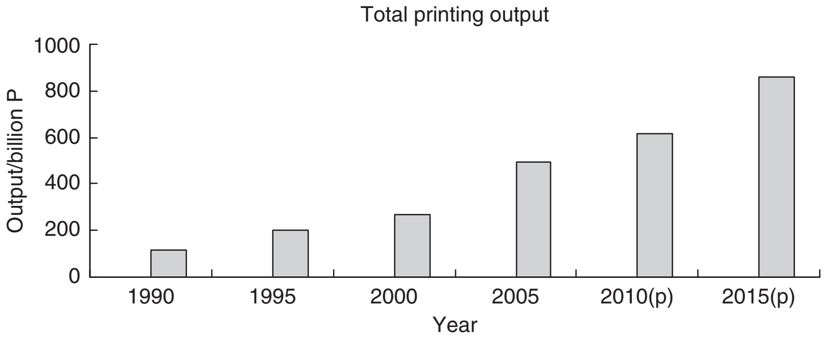

Figure 10. Output of printing of China from 1990 to 2015. [Data source: China Packaging Annual 2006 (2).]

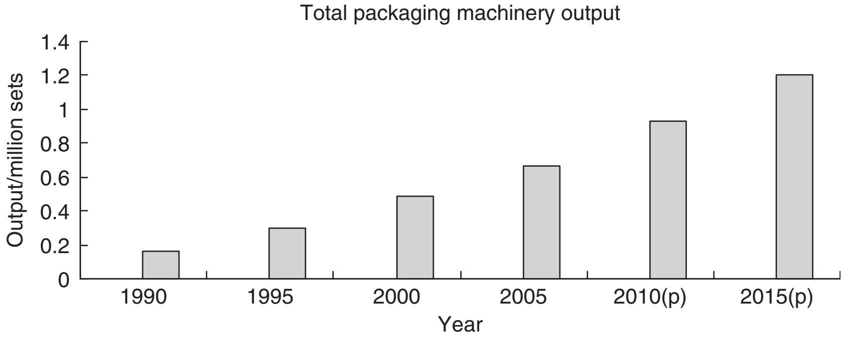

Figure 11. Output of packaging machinery in China from 1990 to 2015. [Data source: China Packaging Annual 2006 (2).]

then, the number of universities with a "Packaging Engineering" program has increased to about 60. Annually about 3000 students graduate in "Packaging Engineering" from the universities, and about 70% graduates are employed within the Chinese packaging industry. Some universities have set up Master's programs in "Packaging Engineering," "Packaging Materials," and "Packaging Mechanics and Engineering"; *Jinan University* and *Jiangnan University* were the first to enroll Ph.D. students in "Packaging Engineering." China has now established an integrated talents cultivation system for the "Packaging Engineering" discipline, which contains graduate education (M.S and Ph.D), undergraduate education and vocational education. The year 2007 has witnessed the successful graduation of the first four Ph.D students in "Packaging Engineering" in China (supervised by professor Zhi-Wei Wang of *Jinan University* and *Jiangnan University*). Compared with the higher education of packaging in some advanced countries, such as the United States, it could be argued that China has the following weak points: (1) The curriculum is not systematic; the coverage of the specialized subjects is narrow, and the core courses are not clear; (2) "Packaging Engineering" is an applied discipline, but the domestic universities usually pay more attention to theory than to practice; and (3) the domestic universities stress engineering but neglect the important disciplines of graphic art, economy, and management.

To solve these problems in packaging education in China, a reform has been conducted in the higher education of packaging undertaken by professor Zhi-Wei Wang (Program of 21st Century National Higher Education Reform (1282B12111): "Train and Practice of Modern Packaging Talents" supported by the Ministry of Education of China and World Bank Organization). Through reform, China has established a new platform for the "Packaging Engineering" discipline and has made new teaching plans and goals. The new teaching plan includes six core courses: "Packaging Materials," "Packaging Technology and Process," "Packaging Machinery," "Packaging Structure Design," "Packaging Decoration and Modelling Design," and "Transport Packaging." These courses have been acknowledged by domestic packaging universities. Until now, the Packaging Education Committee of the People's Republic of China has published two series of widely accepted textbooks and is publishing the third series. Meanwhile, the packaging universities in China are conducting an active academic exchange and cooperation with international packaging universities and institutes. The development of higher education in packaging in China supports and accelerates the development of the national packaging industry.

PACKAGING IN INDIA

P. V. Narayanan
Indian Institute of Packaging,
India

INTRODUCTION

The growth, expansion, and diversification witnessed in the packaging and the consumer sectors over the last five decades have compelled the industry in India to review and revamp its strategies. It is no longer a domestic issue. The opportunities supported by the technology capabilities and infrastructural facilities have caused the outlook for the packaging industry in India to be global and customer-oriented. The reach is aimed at new markets, state-of-the-art packaging, accessibility, and optimization of manufacturing with focus on logistics. The managerial acumen achieved has provided the leadership quality to enable economical production by adopting best practices, provided under one roof and brand, with the aim of becoming a category champion. Specialization is the key for development that drives innovation and closer customer relationship, with the goal of becoming a total and optimum packaging solution provider. The industry has indeed a daunting task to meet demands from an estimated 300 million consumers to at least 600 million consumers by 2010. The fact that 2010 is not that far away intensifies the demands.

The packaging industry with a consolidated average growth annually at 12% on a normal path should aim to produce over 20 million tons of packaging by 2010. This estimate could be higher if the growth estimate of the retail sector is any indication. This is not an exaggeration if one considers the many shopping malls being constructed in many locations. In simple mathematical terms, the industry sources of supply of converted packages are set to double, if not more. Interestingly, it is not the number, but instead new concepts and newer materials, that suits the changing taste of the dynamic market display and the product-package buyer. Industrialization can only grow with little chance of decline in demand. Industry will have to improve and specialize in niche areas. With the per capita consumption valued at only USD 10 as against the global average of USD 75, the rise in demand is a clear indication of what the packaging industry is heading toward.

The economic environment showing (a) a sustained growth, (b) demographics and skill base, and (c) a positive trend aided by liberalization and deregulation indicates a conducive development of the business environment. It is not "how you grow" but "how much will you grow." The country also has a positive advantage of a cross section of demographic population with 50% below the age of 20 years and 64% below the age of 34 years. In essence, the market movers and takers are a high percentage majority and will set the trend of packaging. India is also moving to attain the enviable position of the second strongest economy in the world, overtaking the United States. The per capita income is set to quadruple by the year 2020, thereby swelling the pocket of the consumers with higher personal disposable income and higher purchasing capacity. It seems that the moment is right for progress. Four key forces influence the shaping of the Indian economy: rapid sustained growth; demographics and skill base; liberalization and deregulation; and conducive atmosphere for business development. The key goals are exploring nontraditional partnerships earmarking global technology, markets, and the supply chain. Trade in goods and services now account for over 35% of the GDP (gross domestic product). The capital market is the most developed in emerging economies, and the liberal foreign investment policy has enabled rapid growth in foreign direct investment (FDI) and foreign institutional investor (FII). India enjoys the benefit of having the largest English-speaking graduate population with the third largest number of science and engineering graduates and will emerge to have the largest work force by the year 2020. All these have a direct positive impact toward obtaining technologically developed resources worldwide. The national GDP is estimated to reach one trillion USD in 2011 and is expected to be three trillion USD by 2025 and 27 trillion USD by 2050. With productivity set to grow at a minimum of 8% by 2050, India is set become the second largest economy in the world. Productivity in industry and services will engage 60% of the labor services and will grow four times that of agriculture. Also the India GDP per capita between 2007 and 2020 in U.S. terms will quadruple. During the period, crude oil consumption is set to increase threefold and car purchases will multiply fivefold.

India has 10 of the 30 fastest-growing cities in the world and is urbanizing at a rapid rate.

Development of infrastructural facilities—that is, road, rail, housing, townships, and dedicated freight corridors—is considered a priority. The unprecedented demand and actual purchase of high-end consumers goods such as two-wheelers, four-wheelers, cell phones, and color televisions, along with the use of credit cards, are clear indications of the upgraded lifestyle of the common masses and the increased availability of personal disposal income. More and more families are becoming smaller and their economic situation is becoming stronger with double incomes; also a clear shift is seen for consumer-value-added products and convenience features. Hence, there is a growing demand for brand name products packaged in various sizes and styles.

GLOBAL PERCEPTION

The extent to which packaging has reached the common public is indeed a matter of concern, particularly when one talks of the growing consumer awareness on one hand while mentioning the contribution of packaging to health and hygiene on the other hand. The concept seemingly gains ground in the context of the observation that 80% of the world population gets the benefit of only 20% of the global package production and availability. The essence probably lies herein as much the 80% of the population belongs to the developing third world. Most of these countries have a very low per capita with respect to packaged product consumption and hence the emerging markets. All these countries, no doubt India too, have a long way to go to reach the global average in terms of package consumption. What is more significant is that the trend has been set and is unlikely to reverse. The overall population is younger, and the lifestyle is now catalyzed by economic considerations and an independent nature. The new buyers are willing to experiment and spend. They are articulate and seek solutions to satisfy their needs even by paying the price. Quality and reliability are the buzzwords, yet costs would remain an important factor. The package conversion industry will find consumer demands for development of new concepts and systems. The challenge will be to evolve packages that would provide the optimum shelf life rather than long shelf life, considered uneconomical and costlier, while at the same time moving toward mechanization and semi- and fullautomation. The product manufacturers will shift their choice for packaging materials and packages that would suit such operations with minimal waste and the amenability to quicker changeover. The packages would need to be modular to facilitate distribution. The purpose of the package is to increase value, widen the marketplace, achieve desired performance and ensure compatibility, improve shelf life, and make a favorable impression.

RETAIL SECTOR

The retail market in India presently estimated at 350 billion USD is expected to grow at about 12% consolidated annual growth. The modern and sophisticated format stores (supermarkets and department stores) are envisaged to grow over 40% annually and will account for 12% of retail trade by value of 60 billion USD by 2012. The total of retail sales is estimated at USD 500 billion by 2012. This has been primarily facilitated by the increasing willingness of the Indian consumer to accept the modern system of shopping. The growing younger generation is found to be experimental and can think differently on how to spend their higher disposable personal income. Interestingly, this phenomenon is not restricted to the urban areas, but occurs equally in the rural areas as well. The urban consumer is fundamentally different from the conservative budget shopper of earlier decades. This is augmented equally by the increasing exposure to Western lifestyles and habits. The consumer demographics are evolving in smaller towns and rural areas where a shift in shopping patterns and buying habits is motivated by consumers' desire to emulate an urban lifestyle.

This adds to the spread of the markets and penetration of consumer-value-added packages and product range in width and depth of the markets. The product and package producers will have to rethink their package sizes in the context of the retail sectors with more emphasis on family-size and multidose packs. Product mix range and brands will have to be increased since this will be demanded by the growing cross section of interested buyers who will look for wider choices. Physical parameters and graphic design will have a greater role to play in display arrangements and will have to create a favorable impression for the impulse buyer. The physical design, display features, and graphics will have a hidden role to play—that is, to convert an onlooker into a buyer and unconsciously create a brand change. The retail market seems to be dominated by textiles and apparel at 36%, followed by jewelry and watches at 17%, food and grocery at 14%, and footwear at 13%. Other markets will be mainly durables, entertainment, health care, and home care. Besides display and graphics, a significant need in the physical design feature will be "carry home" facilities. With the retail sector being offered for foreign direct investment and all world leaders set to enter the Indian retail trade, the growth will be exponential. There will also be bulk movement of farm products to supermarkets, and packaging for consumer packs of fresh produce, poultry, meats, eggs, and so on, will be needed. The retail and distribution segments will have to address to two principal inventory management tools: bar coding and RFID. These both demand creators of labels and labelers, aided by automated produce handling, tighter tolerances, and quality standards for speed and efficiency of larger volume processing and packaging lines.

SHIFTS/TRENDS

The packaging industry began in India in the 1950s and became noticeable in the 1960s. The industry grew in dimensions in the 1970s with a larger cross section of packaging materials and packages produced domestically. In the early 1970s the machinery manufacturers for the packaging industry seized the opportunity and made a very successful impact. The industry assumed greater significance in the 1980s, probably getting excellent support and recognition due to the industrial and fiscal support extended to the food processing industry. The 1990s are considered the golden and growth years when the industry grew in leaps and bounds due to the liberalization policies adopted in the early 1990s and continued thereafter. From the CAG (consolidated average growth annually) of percent growth in the mid-1980s the industry recorded a CAG of 18% by the mid-1990s and stabilized thereafter at around 12%. The estimated packaging materials/package consumption in the mid-1990s was on the order of 5 million tons and rose to over 10 million tons by 2005 and is expected to be more than double by 2010. This takes into account the normal average growth with 5% of agriculture and 10% of horticultural produce that is to be processed and packed. An upward trend in this and the fast-growing retail market will have tremendous impact and probably will double the demand estimates. This also reflects the need to increase the basic material production and conversion industries. In simple terms, there is potential for a yet another packaging industry. The output value of the industry is over 2% of the GDP of the country. A large number of factors attributed to the growth, and principally they include: the shift from bulk distribution and packaging to more and more consumer packages; adopting newer systems in place of conventional packaging; optimizing the packaging needs instead of long-life packages; use of materials and packages conducive to ease in handling convenience; productivity; and distribution. Mechanization—that is, semi- and fully automated systems exhibiting favorable economic efficiency—is another factor. These shifts and trends are principally influenced by consistently increasing (a) consumer consciousness, (b) demand for convenience, (c) attention to health and hygiene, (d) willingness to pay, (e) brand association, (f) quality and value addition, and (g) exports in consumer-value-added packages, as well as by shrinking families.

The industry has witnessed an overall growth contributed by both the basic material manufacturers and package converters, including the printing and graphic design community. All across the industry, there is a favorable growth, some in single digits but others in healthy, double digits. Higher opportunity sectors and, hence, higher growth rates are seen in flexibles, paper, boards, and labels. The CAGs in these sectors are estimated at over 25%, around 18%, and over 20%. Flexible packages have made enviable in-roads in the markets for all forms of rigid packaging, principally due to cost factors, innovation, and cost to product sale value ratio. Laminated tubes have become the virtual choice for toothpaste and now provide solutions as alternatives in pharmaceutical packaging. The polyester-based bottle is probably the single largest packaging media recording spectacular entry and growth. It is equally true for jars and other containers. Metals and glass suffer because of the entry of blow-molded plastics. Typical uses would be to package lubricants and talcum powders. Folding cartons have attained recognition in major industry sectors and not just in food and pharmaceutical sectors. Availability of quality board, improved conversion technologies, multicolor prints (moving from the traditional four-color to eight-color), and modernization through holography have been added advantages. Efforts by both the metal and glass industry cannot be understated. Shaped cans and package modification as composites are significant efforts. The narrow web technology and even sheet-fed label conversion for pressure-sensitive labels have been earmarked with new and modern label presses. Shrink sleeves have gained considerable popularity and found ideal for contoured surfaces.

The bag-in-box and lined carton systems are other sectors that have found greater acceptance, particularly as refill packs. The growth of stand-up and spouted pouches is spurred by a global trend. The rate at which the flexible bottles have made their entry provides new-generation packs and a concept for different market segments. Material-process and technology developments have kept pace with the growing demand, but considerably more is needed to meet the new trends and differentiating marketing systems particularly in the era of retailing, which is now a fast-moving segment in the country.

The Indian market, country–consumer–product needs, need not follow the global situation because quite a few domestic demands could be peculiar to India and Indian consumers. Single-dose flexible packaging is a case by itself, which is known, opened the floodgate for the demand for flexible packaging in the country. Yet another is the introduction of tea in flexibles. The Tetra for edible oils is a typical example of a package that satisfies the need of the market with the technological back up. For a long time, one wished to reuse the 5-paise paper bag for tea (single-dose one-cup tea bag). Thus the evolution of refillable bags followed, cutting cost across the board. The market is indeed revolutionary. All these led to one major facet of the "cost-centric" nature of the consumer, but at the same time the sense of "willingness to experiment." The success of many of these products has obviously led to a chain reaction with more and more products coming into the realm of packaging, thereby widening the scope for packaging.

INDUSTRY SEGMENTS

Industry segments are estimated at INR 400 billion with a share of nearly 60% for consumer packaging with the following breakdown:

Flexible packaging, 21%
Rigid plastics, 18%
Printed cartons, 17%
Glass, 10%
Metals, 6%
Caps/closure, 5%
Labels, 4%
Others, 19%

The consumer packaging industry annual growth is placed at:

Processed food, over 20%
Pharmaceuticals, over 10%
Health/personal care, 15%
Home care, 8–10%
Engineering and electronics, over 10%
Software, over 20%
Textiles, 7%
Chemicals, 8%
Consumer durables, 8%
Toys, 7%
Incense sticks, 10%

Table 1 gives data on packaging consumption patterns.

Table 1. Packaging Consumption Patterns

Sector	Percent
Food	–40
Personal care/Cosmetics	–15
Pharmaceuticals	–8
Engineering and electronics	–10
Chemicals	–10
Others (toys, textiles/-garments/handicrafts, etc.)	–17
	100

PACKAGING MATERIALS

Flexible packaging has been the dominant area that has made considerable inroads into all rigid packaging. This is the single largest packaging media with the most innovation and most suited to the cost-centric Indian consumers. Laminated and coextruded tubes have virtually replaced the aluminum tubes. Aluminum tubes, however, continue to be the preferred medium for medicinal eye ointments. The PET bottle is yet a major packaging resource with over 20% annual growth. Bottles for drinking water, edible oils, and preserves are specific growth areas. Blow-molded polyolefins also have virtually dominated the edible oil, lube oil and greases, adhesives, pharmaceuticals, and talcum powders sectors.

The flexible packaging industry is valued at Indian Rupees 48,400 crores (USD 12,000 million) and has become the most economical form of packaging not only for consumer quantities, but also for institutional and family packages up to 5 kg. The manufacturing sector, however, is highly fragmented and spread throughout the country. They belong to small, medium, and organized sectors, and the output caters to various segment needs. Among the primary packaging conversion industries, flexible packaging could primarily take the lead with updated technologies, innovations, and development of various permutations and combinations. The latest technologies with complete automation process control are now installed within the industry. The conversion capabilities are built with both (a) proven technologies and machinery from around the world and (b) domestically produced equipment. The total number of converting units should be around 700, a few of which also have been established as excellent supply hubs for export markets.

The entry of coextruded film production was with a 2-layer structure demanded by the milk sector, but slowly and gradually a large number of 3-layer plants of both overseas and domestic origin were established. The country today has seven 5-layer plants and two 7-layer plants. The 2- and 3-layer plants are used as direct packaging media and as substrates in laminate structures. The common end-use applications are milk, edible oils, ghee, vanaspati, and sensitive food products. High-barrier structures also have extensive application in tubes for cosmetics and personal care products.

The printed folding-board cartons are closely on the heels of the flexibles, with an estimated growth of 17–18%. The industry consumes nearly 1 million tons of materials valued at INR 50 billion (USD 1250 million). Pharmaceuticals, food, cosmetics, personal care and toiletries, incense sticks, clothing, and liquor are the major use segments of folding-board cartons. The folding-board cartons also include lined cartons, and the major user sectors include malted foods, milk powder, and baby cereals. In aseptic packaging, good-quality board, now domestically available, is primarily used for fruit juices. New market areas are edible oils, motor oils, and buttermilk.

Among the plastics, HMHDPE has made considerable inroads into the metal container industry for packaging of a variety of liquids, semisolids, and solid products, including those that fall under the dangerous goods codes. These are available in capacities of 5–210 L. A very interesting shift is the 20-liter HDPE containers that now replace the traditional tinplate containers. Clarified polypropylene (PP) is a recent entrant that also has excellent applications. Trials are underway to introduce retail juice and beverage packs. Poly(ethylene terephthalate) (PET) is possibly the single most used plastic that has emerged as a most popular package in sizes of 200-mL to 5-L bottles/jars.

The 1-L/2-L widemouth jars have found their way into household kitchens as storage containers for sugar, salt, cereals, grains, and so on. An interesting application is gas flush container for “Basmati Rice.” PET bottles have recorded an annual growth of nearly 25%; and between 1995 and 2005, the consumption has grown from 11,000 tons to 140,000 tons. Bottled water and carbonated soft drink (CSD) are the major use sectors. Breakthroughs have been made in the pharmaceutical and liquor sectors.

Glass and metal (tinplate, tin-free steel, and aluminum), continued to show growth in single digits and constrained their growth by the competitive packaging media both for ease in availability and economic considerations. The recently formed Tinplate Promotion Council (TPC) working on the lines of appeal in Europe has been striving through various activities to promote and increase the use and consumption of tinplate in the country. At the annual international conference, TPC gives awards for excellence in design, development, innovation, and informative literature.

Composite containers continue to be packaging for traditional areas and earlier efforts to introduce leakproof composites have not been successful. Cellulosic films have virtually disappeared, but are still used for very restricted applications. Cost and yield are the major influencing factors.

The growth and consumption in primary packaging have a direct impact on the consumption and demand for various ancillary packaging materials. Development is immense and includes inks, adhesives, caps/closures/dispensing systems, and labels. Adhesives and inks are two specific areas that have witnessed leading global companies establishing production facilities either alone or with Indian partners. This has helped in bridging the gaps as well as improving export potential. High-tack and high-bond adhesives, as well as security inks, are already in vogue. Environmentally friendly water-based and alcohol-based inks are knocking at the doors. A phenomenal growth is witnessed in the label sector at a minimum CAG of 20%. The turnover during 2007–2008 is estimated to be worth USD 1 billion and will be 1.4 billion USD by 2010 corresponding to 3 million square meters. This trend will double its 3.2% world market size to 6.3% by 2009–2010 in terms of square meters. The major user sectors are apparel and textiles, food and beverage, tobacco and other fast moving consumer goods (FMCGs), automotive components, and electrical and electronics products. Others would be pharmaceuticals, personal care, industrial lubricants and paints, jewelry, watches and gift articles, computer/software, and so on. Although currently wet-glue labels are prominent, pressure-sensitive (self-adhesive) and shrink-sleeve labels are the growth areas with 25%

CAG. Some of the beer and liquor industries are already evaluating the use of pressure-sensitive (PS) labels. Bar-code technology is being used increasingly, so bar-code labels will find considerable demand. The new segment will be RFID labels, transparent and film labels and “no look” labels, and smart and intelligent and functional labels. They are clever labeling solutions.

Until recently the industry had been confined to some of the closure systems like RSNP (roll-seal non-pilfer-proof) (screw cap), ROPP (roll-on pilfer-proof), 4/6-lug cap (twist on, twist off), press lids, and lever lids. Both metals (tinplate and aluminum) and plastics are general materials in use. With demands shifting to convenience features, dispensing needs are growing faster. The caps/closure/dispensing mechanisms have entered the packaging sector and are penetrating the market at a faster rate. Spouted pouches/flexibles bottles are typical end uses.

Similarly, revolutionary changes also are seen in marking and coding systems. Online coding, with rubber stereos and inkjet printing technology, has helped the packaging line systems.

The Paper, Film, and Foil Converters Association (PFFCA) represents the interest of this industry group and undertakes various promotional programs besides sponsoring the national awards competition for excellence in packaging.

MACHINERY

The machinery required is generally and broadly delineated under the following categories:

- Packaging conversion machines, including printing machinery
- Machinery for packaging line operations
- Machinery for packaging systems
- Ancillary machinery (e.g., coding, marking, labeling, etc.)
- Testing and quality control equipment.

The engineering industry in India considered the viability of designing, development and production of machinery and equipment only in the early 1970s. Until then, most of the domestic needs were met through imports. However, with the encouraging growth of the packaging sector the opportunities also widened and catalyzed the interest of the domestic sector. In the three and half decades, achievements are indeed commendable. Most of the current requirements are met through domestic capabilities. Also, the machinery manufacturing sector also has become a global hub to meet international requirements. Essentially, they have progressed from being an import-dependent sector to becoming an export sector. The exports are even sent to developed countries. This manufacturing sector has geared itself to adopt newer and modern technologies such as PC controls, servo controls, and so on.

The majority of manufacturers are domestically oriented, and only a very few have overseas technical know-how or collaboration. It should, however, be observed that the technologies available are mostly to suit small and medium enterpreneus. The machinery manufacturers have established the Institute of Packaging Machinery Manufacturers of India (IPMMI) to support and encourage the industry and also to address industrial and fiscal issues.

ENVIRONMENTAL ASPECTS

With the per capita consumption of packaging pegged at about USD 10 by value and the global average at about USD 75, the figure for the country is indeed low. The statistics, however, need to be perceived differently for a country like India inasmuch as consumption pattern in urban areas will be different from rural areas. This will also, in turn, influence the post-consumer waste generation. All packaging-related associations are aware of this situation and are involved in activities to source reduction and promotion of the three golden “R’s” (reduce, reuse, recycle). Plastics are at the center of attraction and probably the center of controversy, and they demand greater attention. It is in this context that the Indian Centre for Plastics in Environment (ICPE) was set up by the plastics apex bodies at the behest of the Ministry of Forest and Environment. This center aims to disseminate information and help in all waste management issues, as well as promote and support technologies and methods for waste collection, recycling, and reuse values. The publications and project documents published by the ICPE are indeed excellent resources and provide a wealth of information. The efforts of the associations, institutions, and the concerned departments and agencies need to be augmented in the context of consistently increasing demand and consumption of packaging in the country.

EDUCATION AND HUMAN RESOURCES DEVELOPMENT

The growth in the packaging industry also has led to the recognition and need for trained and qualified packaging personnel to meet the requirements of every segment of the industry: conversion, packaging user, and machinery sector. The requirements are identified on the shop floor and in the laboratory, as well as in R&D (research and development), production, technical service, information, and marketing. Background support education for such personnel is science, technology, engineering, printing, graphics, computer, electronics, and related areas. Personnel with such background and a professional course of one or two years in packaging technology and sciences become ready for the industry. Aware of the need, the universities have included the subject of packaging as part of their syllabus. Exclusive institutions such as the SIES School of Packaging/Packaging Technology Centre offer both graduate and postgraduate programs to aspiring professionals. The Bachelor of Engineering in Printing and Packaging program is of four years duration and is a step toward bridging the gap of qualified printing and packaging people to serve the industry needs. As the demand is set to increase, HRD in packaging will be the need of the hour for a joint effort of institutions, universities, and industries.

GROWTH AREAS

With the branded products on the increase coupled with organized retailing gaining ground and steadily increasing consumerism, the product marketers look for newer and dynamic concepts. The trendsetters will be the large farm sectors, growing middle-class families with better personal disposable income, higher propensity to spend, smaller households, and health and hygiene consciousness resulting in depth in product mix and innovations as dynamic features. The opportunity and niche growth areas will be:

Flexible packaging
Stand-up pouches
Zipper pouches
Dispenser and pouring devices
Retortable pouches
Flexible bottles
PET and PET hot fill bottles
Folding board cartons
Lightweight and specialty glasses
Shaped cans
Co-ex bottles
Speciality lacquers
Environmentally friendly inks and adhesives
Irradiation
Tamper-evident systems
Cold storage and cool storage

High-barrier materials
Reclosable pouches
Spouted pouches
Laser cut pouches
Aseptic systems
Bag-in-box
Clarified PP bottles
Oven/microwavable tray/cartons
Two-Piece tinplate can
Easy-open devices
Thermoform disposals
PS and shrink labels
Smart and intelligent packaging
Bar-code /RFID technologies
Cap/map systems
Display and promotional packs

The Indian packaging industry until recently has been identified as a low-profile sector. It has now moved to a high-profile category. Paper and board and plastics are emerging as preferred packaging media. The often-asked question is, “Is the packaging industry ready to meet the onslaught arising out of the demands?” That probably sums up the positive future of the packaging in the country.

PACKAGING IN THE EUROPEAN UNION

LUCIANO PIERGIOVANNI
Department of Food Science
and Microbiology, Milan
University, Milan, Italy

INTRODUCTION

Following the last two entries in 2007 (Romania and Bulgaria), the European Union (EU) now embraces 27 democratic and independent European countries, gathering approximately 490 million citizens (as Table 1 shows) on a surface of almost 4 million square kilometers. In 2005 two more countries (Turkey and Croatia) asked to join the EU and it is foreseeable that within a span-time of about 8–10 years they will become Member States, provided that they pledge to share the values on which the EU is founded—that is, respect for human dignity, freedom, democracy, equality, the rule of law, and respect for human rights. (The European flag is in Figure 1.) They will have also to demonstrate a functioning market economy and a civil service capable of applying EU laws. The European Union is a family of independent countries, with many different traditions and languages, but also with shared values and rules. Among these, a number of EU directives, measures, and regulations apply both directly and indirectly to the packaging area. They refer to sustainable production, packaging waste, food contact reliability, supply chain regulations, environment protection, and consumer safety (1).

Packaging is a leading industrial activity in Europe, where about one-third of packaging worldwide is produced, for a value of almost 130 billion euros. Because European packaging industries are highly oriented toward export and are well known and appreciated in many parts of the world, European packaging materials and packaging technologies deal with a population that is much greater than the actual number of European citizens. The percentage of consumption of packaging materials is more or less the same all over the world; that is, more than 30% accounts for plastics, almost 40% for paper and board, 17.5% for metals, and 7% for glass.

The European packaging economy is estimated to grow further in the next few years, and the expected growth for the 2006–2010 period ranges in the main countries from 1.3% to 2.1%. This is in line with the expected increases in

Table 1. EU Members, the Increasing Population, and When They Joined

State Members	Total Population (2005 Values in Millions)	Year

Bulgaria, Romania	484.1	**2007**
Turkey (70.4[a]), Croatia (4.5[a])	559.0[b]	2013–15

[a] Population that can add when those Countries will become Member States

[b] Possible EU total population in 2013–2015

Figure 1. The European flag is the symbol of the European Union. The circle of gold stars on a blue field represents solidarity and harmony between the peoples of Europe. The number of stars has nothing to do with the number of Member States.

the Unites States (1.8%) and in Japan (1.5%) but very far from the forecasts for Russia (7.0%), China (8.5%), Turkey (19.0%) and India (13.0%).

RESEARCH AND TECHNOLOGICAL DEVELOPMENT

The EU allocates a very large amount of economical resources to R&D activities in packaging. Scientific research was one of the first and most important functions that the European community shared and harmonized. In 1984, the European Commission (the executive body of the EU) launched the first pluriannual Framework Programme (FP1) for research and technological development. Since then the FPs have played a leading role in multidisciplinary research and cooperative activities in Europe and beyond, and in each FP the themes of packaging, and food packaging in particular, have had much relevance, leading to important results and real and effective consequences in real life. For example, during FP4 (1999–2001) ACTIPACK, a project coordinated by the Dutch TNO, approached the topic of active and intelligent packaging and promoted a radical change in the European food packaging law that now admits the use of active materials and intelligent packages. MIGROSURE, in FP5, was coordinated by the Fraunhofer Institute (Germany) and demonstrated that diffusion in and migration from food contact materials (FCM) are foreseeable physical and mathematically describable processes. The project provided novel and economic tools for the estimation of consumer exposure to chemicals migrating from food contact plastic materials by establishing and testing a physicochemical migration model now recognized by the food packaging law. SUSTAINPACK, managed by the Norwegian Matforsk during FP6, coordinated 13 countries, including former eastern Europe states. The overall objective of the project was to develop and implement a sustainable packaging tool platform based on renewable resources. The year 2007 saw the start of the seventh programme, which is both larger and more comprehensive than earlier Framework Programs. It will run to 2013 with a budget of 53.2 billion euros, the largest funding allocation yet for such programs. Also in this latest project, the themes of safe and innovative packaging are well represented, attracting the attention of several research groups in research centers and universities in Europe, including those of eastern Europe which are invited to cooperate in the project.

European research and development strategies are under the responsibility of one of the several Directorates General into which the European Commission is organized. In carrying out its own activities, the Directorate General for Research works closely with the Joint Research Centre (JRC), the science and technology reference center for the Union (2). The JRC is organized into seven scientific institutes which carry out research activities of direct concern to EU citizens. One of these, the Institute for Health and Consumer Protection, located in Ispra (Italy), is a well-known and advanced laboratory that carries out fundamental research and testing activities in the field of packaging to improve, in particular, the understanding of potential health risk of food contact materials (3). The JRC in Ispra is the common reference EU Laboratory for FCM, and it assists Member States in carrying out official inspections to enforce compliance with the shared rules on FCM.

Table 2. The Main Packaging Exhibitions in EU and in the World

Exhibition	Exhibitors	Visitors	Surface of Exhibition (m^2)
Interpack 2005 Dusseldorf, Germany	2,654	176,964	164,199
Emballage 2006 Paris, France	2,200	108,054	66,927
Ipack-Ima 2006 Milan, Italy	1,558	47,761	63,172
Hispack 2006 Barcelona, Spain	2,194	40,405	53,669
Total 2007 Birmingham, UK	1,061	Not available	42,870
Pack Expo 2006 Chicago, USA	2,302	45,741	116,600
Upakovka 2007 Moscow, Russia	350	23,000	23,000

The European Food Safety Authority (EFSA), the keystone of EU risk assessment regarding food and feed safety, is also committed to this field. In close collaboration with national authorities and through its Scientific Panel on Food Additives, Flavourings, Processing Aids, and Materials in Contact with Food (AFC), the EFSA provides independent scientific advice on existing and emerging risks to the entire packaging community and their stakeholders (4).

EU PACKAGING STAKEHOLDERS

Besides the industrial organization that represents the small and large private enterprises, the various technical magazines, and the electronic newsletters dealing with the packaging business, almost every country in EU has its own national packaging institute. Their main activity is lobbying the fundamental interests of their members: a number of different bodies which include manufacturers of raw materials, retailers, end-users, packaging producers, schools of packaging, experts and technical consultants in the packaging area. In 2002, a Pan-European cooperation was set up with the constitution of the European Packaging Institutes Consortium (EPIC). EPIC is a consortium where European Packaging Institutes work together to identify areas where cooperation might best be initiated or concentrated for the future sustainable development of the entire packaging chain. EPIC was founded by 12 European Packaging Institutes, covering around 2200 associated companies and approximately 22,000 professional individuals in packaging throughout Europe. Educational programs, qualifications for packaging professionals, instruments for the promotion and facilitation of packaging innovation, methods for the optimal implementation, and enforcement of packaging-related legislation are the main areas in which EPIC is involved. Because EPIC works in a project-oriented manner, packaging education and information services were selected as the most urgent topics to deal with (5).

PACKAGING EXHIBITIONS AND CONFERENCES IN EU

Due to the high technological level of the European packaging industry and also to the proximity of the EU to areas of many developing countries like those in the Mediterranean basin and in eastern Europe, packaging exhibitions in the EU members states are very important trade events.

The biggest packaging event in the world by far is INTERPACK in Dusseldorf (Germany), which takes place every 3 years and hosts the highest number of exhibitors and visitors. The five most important EU countries for the packaging business are Germany, Italy, France, Great Britain, and Spain, and in all of them an international packaging exhibition is regularly organized, attracting globally almost 10,000 exhibitors and 400,000 visitors. In Table 2, the most recent data of these packaging events are presented together with the figures of PACK EXPO in Chicago, the second most important packaging event in the world as a comparison. Data concerning the Russian exhibition UPAKOVKA are also reported. This particular event deserves to be mentioned because it was promoted and organized along its 15 editions since 1982 by the Italian IPACK-IMA and is recognized as the leading and most important business connection between Western and Eastern Europe in the packaging area, the route by which technological innovations first moved to Russia and neighboring countries.

Another proof of dynamicity of the packaging context in the EU is witnessed by the high number and the high level of technical-scientific events which are regularly held in Europe, both on general and specific topics. These events are fundamental moments for sharing news regarding technical and scientific progress and achievements and are also valuable forums for spreading the progressively harmonized regulations on important packaging issues. It is almost impossible to enumerate all the Symposia, Congresses, Conferences, and Workshops organized in Europe each year, but some events and institutions certainly deserve to be mentioned and remembered. Pira International, for instance, which is recognized worldwide as one of the most important knowledge providers in different industry sectors, guarantees both the purposes of sharing harmonized regulations and updating scientific information in packaging; this is done mainly by means of its subsidiary Intertech-Pira (6) which offers events, training, online information, and much more. Alongside business-oriented organizations, there are several nonprofit and scientific associations that also deal with broad scientific topics in packaging. The European Federation of Food Science and Technology (EFFoST), for example, is an organization with 80 members affiliated in 21 European countries, deeply committed to stimulating innovations in novel food processing and packaging through its periodical events and activities (7). A further example of a nonprofit organization is ILSI Europe, which belongs to the International Life Sciences Institute (ILSI). This is a network of scientists which regularly provides publications and organizes meetings on packaging subjects, especially through the Packaging Materials Task Force, aimed at advancing the safety and quality of packaged foods (8). ILSI Europe meetings and symposia are often organized in close collaboration with the European Commission (EC) and the European Food Safety Authority (EFSA).

No less important and numerous are the events and the organizations that in Europe approach more specific packaging issues. Two representative examples in this direction may be chosen selecting an industrial-related topic and a prevailing scientific theme of interest. The field of bioplastics and biodegradable plastics, for instance, is covered by European Bioplastics (9), an industrial association supporting the market introduction of bioplastics but also very active in organizing conferences and exhibitions on the topic. The new achievements for shelf-life extending, shelf-life testing, and prediction are the subject of SLIM (Shelf Life International Meeting), a periodical symposium set up in 2003 that every two years brings together scientists from both industrial and public research institutions (10).

THE PACKAGING MEGA-TRENDS IN THE EU

Pinpointing the main trends and the targets of such a big and diversified world like the packaging world is always difficult and somewhat of a gamble. And it is even more so when a heterogeneous context like the EU is considered. Nevertheless, for the leading influence that the most advanced countries have on the entire European market and that often extend to extra-EU countries, it is worth trying to identify the hottest packaging trends. The pursuit of a correct balance between market and environment will very likely be a significant aspect of the future of packaging in Europe. “Sustainability” will still be one of the most pronounced and written words in packaging, even if the contexts might be different. At least three broad topics can be tentatively mentioned:

1. The prevention or reduction of the impact of packaging and packaging waste on the environment, ensuring the functioning of the internal market, will drive the development of new biodegradable and recycling packaging options.
2. The shaping of the role of outsourcing and workflow, as well as the limitation of the logistics and transport costs, will lead to industrial policies that will affect packaging production and usage.
3. The design of smart and safe packaging that can meet the consumer’s expectations and act on purchasing behavior will certainly engage creative designer and packaging scientists in the search for more sustainable, convenient, and attractive packages.

CONCLUSION

In the increasingly interdependent world of an almost completely globalized economy in the 21st century, it is more than ever necessary to have a common vision for every business, particularly for packaging, because of its tight link with human activities. The EU model of co-operation appears to be a good example of promoting unity while preserving diversity, ensuring that policies satisfy the requirements of all of the peoples of Europe. After the tragedy of the Second World War, European citizens slowly learned to work together in a spirit of curiosity, openness, and solidarity, which also seems to be the best strategy for a balanced development and progress of packaging worldwide.

PACKAGING LINE PERFORMANCE

Paul J. Zepf
Zarpac, Inc.—Engineering,
Oakville, Ontario, Canada

Performance in most production environments is a widely used term similar to efficiency, which means different things to many different people. Therefore the word *performance* can be relative and qualitative if it is not rigidly defined. The only understanding that may be common to all is that it is a reflection of productivity (value/time), output, or effectiveness of time. Unless it is rigorously defined and understood, the word *performance* has limited value to decision makers, other than projecting a sense of being or desire. Performance can be described as a measure of profitability based on the ability to produce the needed quantity of quality packages in the time required to fulfill customer needs at the lowest per unit cost over a sustained long period of time (>1 month). To many people, performance is the best return based on up-front costs or capital costs only. To successful companies, performance is also the best value that is based on capital and ongoing operating costs. If one buys a system based on up-front costs or lowest costs to just get into production without working out operational costs over one-year, three-year, and five-year periods (TCO or true cost of operating), then their anticipated profits (based on marketing targets) will rarely materialize. Too many people are hooked on this false sense of performance that will only contribute to the long-term uncompetitiveness of the company. Short-term or no planning leads to long-term disasters. Anyone can demonstrate excellent performance for an hour or even a day, but performance can only truly be judged quarter by quarter and better still year by year. The best performance translates into consistent steady-state production demonstrating control and quality at all times and under all conditions.

Terms such as output, capacity, efficiency, and reliability have always been key words used in production. They describe the pulse of the production line and play an important role in managerial decision-making.

Nevertheless, these terms are frequently confused, misunderstood, ill-defined, and improperly used. Also, proper mathematics and new tools such as "designed experiments" and computer simulations have not been understood and used effectively because of confusion and misunderstandings.

Efficiency, utility, capacity, and output, when maximized through the application of all available tools, are major contributors to the producers' economic viability.

Unfortunately, production is filled with confusing definitions and outmoded concepts concerning productivity and production line performance.

It is important that all levels of management, especially top management, understand these new or tired and true historical ideas in order to make timely and profitable decisions.

Although efficiency and utilization each tell a story about the performance of a production line, only proper OEE (overall equipment effectiveness) and their derivatives can give a true view of production performance.

OEE (OVERALL EQUIPMENT EFFECTIVENESS)

OEE is the best-recognized hard performance measure and methodology for packages or products that have a very dominant critical input or high-cost product component and few, if any, other input items (e.g., paper mills—rolls of newsprint or white paper, converting, blow molding, injection molding). Some companies use the term *process reliability* instead of OEE. It is usually a key metric that supports or directs TPM, lean, six-sigma, and other common performance-enhancing philosophies below.

$$\textbf{Definition of OEE} = \textbf{Availability} \times \textbf{Quality} \times \textbf{Performance}$$

Availability. *Availability* takes into account **downtime loss** and is calculated as

$$\boxed{\textbf{\textit{Availability}} = \textit{Operating time}/\textit{Planned production time}}$$

Performance. *Performance* takes into account **speed loss** and is calculated as

$$\boxed{\textbf{\textit{Performance}} = \textit{Ideal cycle time}/(\textit{Operating time}/\textit{Total pieces})}$$

Ideal cycle time is the minimum cycle time that your process can be expected to achieve in optimal circumstances. It is sometimes called *design cycle time*, *theoretical cycle time*, or *nameplate capacity.*

Since run rate is the reciprocal of cycle time, *performance* can also be calculated as

$$\boxed{\textbf{\textit{Performance}} = (\textit{Total pieces}/\textit{Operating time})/\textit{Ideal run rate}}$$

Performance is capped at 100%, to ensure that if an error is made in specifying the *ideal cycle time* or *ideal run rate*, the effect on OEE will be limited.

Quality. *Quality* takes into account **quality loss** and is calculated as

$$\boxed{\textbf{\textit{Quality}} = \textit{Good pieces} \ / \ \textit{Total pieces}}$$

More rigorous mathematical definitions of OEE for production processes are

$$\textbf{OEE = Availability} \times \textbf{Quality} \times \textbf{Performance}$$

$$\textbf{OEE} = \underset{\substack{\downarrow \\ \textbf{Main source of} \\ \textbf{time loss}}}{\textbf{Availability}} \times \underset{\substack{\downarrow \\ \textbf{Typically not large} \\ \textbf{(should not be)}}}{\textbf{(1}-\textbf{Scrap factor)}} \times \underset{\substack{\downarrow \\ \textbf{Typically low}}}{\textbf{(1}-\textbf{Rate factor)}}$$

$$\textbf{OEE} = \frac{\text{MTBF}}{\text{MTBF} + \text{MTTR}} \times \frac{\text{Net production}}{\text{Net production} + \text{product loss}} \times \frac{\text{Effective run rate}}{\text{Normal rate}}$$

$$\text{OEE} = \frac{\text{Output (Y)}}{\text{Scheduled time} \times \text{Normal rate}}$$

MTBF is the mean time between failure.

MTTR is the mean time to repair (similar to MTOF or mean time of failure, depending on how you define them).

Normal rate is the steady-state speed of the production process as designed, tested, and verified.

TEEP (TOTAL EFFECTIVE EQUIPMENT PRODUCTIVITY)

TEEP is a recognized overall hard performance measure for production processes. It is essentially what you actually produced over a given time period (usually a week) divided by the output the equipment could conceivably produce using all of the defined time period. The rate loss factor is determined from the specifications agreed to by the OEM and the user and is the normal rate of steady-state running divided by the maximum rate that can be sustained and still ensure quality products. TEEP is in a way the top view of how the plant utilizes all time and its assets, but it lacks the detail and understanding of planned and unplanned events.

TEEP is basically an equipment productivity/efficiency index that corresponds to the total productivity and efficiency of equipment in how much the equipment has served to produce the quality products by using the calendar time given in order to produce. This index indicates the operation environment and machine condition (Chand and Shirvani, 2000), and also indicates what the degree of total productivity/efficiency during the given calendar time is. This index can be calculated as in the equations below.

$$\mathrm{TEEP} = \frac{\text{Actual output}}{\text{Theoretical output}} \qquad \text{for the same time period}$$

$$\mathrm{TEEP} = \left(\frac{\text{Loading time}}{\text{Calendar time}}\right) \times \left(\frac{\text{Operating time}}{\text{Loading time}}\right) \times \left(\frac{\text{Net operating time}}{\text{Operating time}}\right) \times \left(\frac{\text{Valued operating time}}{\text{Net operating time}}\right)$$

$$\mathrm{TEEP} = \left(\frac{\text{Valued operating time}}{\text{Calendar time}}\right)$$

$$\mathrm{TEEP} = \frac{\text{Valued operating time}}{\text{Calendar time}}$$

Valued operating time is the equivalent time the production process has been continuously running at its ideal rate or OEM established possible rate for that machine and product.

$$\mathrm{TEEP} = \text{Schedule factor} \times \text{Rate loss factor} \times \mathrm{OEE}$$

$$\mathrm{TEEP} = \left(\frac{\text{Scheduled time}}{\text{Calendar time}}\right) \times \left(\frac{\text{Normal rate}}{\text{Maximum rate}}\right) \times (\mathrm{OEE})$$

The normal rate is that steady-state line speed that the line was designed to run at during the scheduled producing time period for that product.

The valued operating time is the equivalent time required to run the actual output at the capable rate. All suggested equipment performance indices such as productivity, reliability, efficiency, and maintainability in this model do not directly consider the manufacturing costs.

TEEP is the top view above OEE. OEE is the best metric to use at first because it gives better insight and direction for improving the production process directly.

OTHER COMMON PERFORMANCE-ENHANCING BUSINESS PHILOSOPHIES AND METHODOLOGIES

In this section we will briefly explain some common methodologies for optimizing plant operations and production throughput and thereby affecting performance. Regardless of the methodology used, hard data in the form that can be easily analyzed such as benchmarks and efficiency values are still required. The purpose of introducing these methodologies is to see how performance measurements fit as a requirement for all of them.

CBM—Condition-Based Maintenance (or monitoring)

The Applied Research Laboratory at Penn State University (www.arl.12su.edu/areas/soa/conditionmaint.htrnl) describes this term:

> The objective of condition-based maintenance (CBM) is to accurately detect the current state of mechanical systems and accurately predict systems' remaining useful lives. This enables organizations to perform maintenance only when needed to prevent operational deficiencies or failures, essentially eliminating costly periodic maintenance and greatly reducing the likelihood of machinery failures. CBM represents one of the most promising developments in the evolution of maintenance practices. As organizations are increasingly faced with demands to lower maintenance costs, increase product quality, and hasten organizational responsiveness/operational readiness, CBM has emerged as a viable alternative to traditional planned maintenance, run-to-failure operation, and the various maintenance approaches between those two extremes:

For an example see www.pwcglobal.com/parn/case-studies/case-study/html.

CMMS—Computerized Maintenance Management System

It's pretty well impossible to work in the plant engineering and maintenance area without coming across CMMS software programs. Most technical magazines contain entire columns and even devote whole issues to these software systems. In recent years, vendors have been making the software available on secure, remote internet sites as well. It's hard to come up with a set definition for CMMS, but, in general, software programs that capture data on plant purchasing, maintenance and repair scheduling, and equipment monitoring fall into the broad category of CMMS software.

Because of their role in tracking plant assets and work, CMMS packages are also often used in conjunction with specific, acronym-based maintenance initiatives like PdM and RCM. Finally, CMMS is also often used interchangeably with EAM (enterprise asset management) and ERP (enterprise resource planning) to comprise the wider field of plant software that ties in or attempts to tie in all aspects of plant and production operations from ordering to distribution. See http://controleng.com and search under CMMS.

FMECA—Failure Mode Effect and Criticality Analysis

In his article *Uptime: Strategies for Excellence in Maintenance Management* (Productivity Press, 1995), John D. Campbell defines FMECA as "a logical, progressive method used to understand the root causes of failures and their subsequent effect on production, safety, cost, quality, etc."

In general, FMECA is basically up-front negative thinking with a positive outcome—that is, thinking about what can go wrong and how to fix or deal with it before the fact. FMECA is usually a group activity to identify, prioritize, and identify corrective actions and document all the potential ways a product and/or production system can or could fail to perform its intended function. Prioritizing is done by scoring a severity (S), likelihood (L), and detection (D) (correction (C) if used) and multiplying them together to get an RPN (risk priority number) value, in order to sort and establish a hierarchy of risk and/or items needing further investigation. See Volume 8 of *How to Use Advanced Analysis Tools for Optimum Selection and Troubleshooting of Production Machinery.*

FMECA is a proactive key tool used to prevent problems from occurring and is a vital part of the up-front engineering disciplines. There should be a special focus on safety and environmental issues that must be corrected despite a lack of justification. It also aids in identifying key design or process characteristics that require special controls (those above normal process controls) for manufacturing, as well as highlighting areas for improvement in safety, functional control, or performance. FMECA is a cost-effective logical risk assessment tool for product development & evaluation, safety, environment conditions, quality, time reduction, and historical reference.

There is a web site completely devoted to the FMECA cause, at www.fmeca.com; it provides a functional definition of the term, which is usually used interchangeably with the acronym FMEA: FMEAs are intended to result in preventative actions, and they are not "after-the-fact" exercises done to satisfy a customer or obtain TS or QS 9000 status. Time and resources for a comprehensive FMEA must be allotted during design and process development, when design and process changes can most easily and inexpensively be implemented. Only after a product failure or financial crises arising from late changes in production is the cost of not performing an FMEA revealed.

Good Business Practice

Good business practice has always been and will always be the holistic effective endeavor or work guided by a main purpose or a goal (the focus). All work has to be coordinated in a proper hierarchical manner to yield results of quality and quantity to fulfill human needs in a timely manner with optimum value based on efficient efforts expended and needs required. Good business always focuses on arriving at the optimum combination of product design, assembly process, equipment design, and customer needs. (Some people would call this concurrent engineering, or cross-functional development, but in fact it is just common sense.) Good business practice never yields to wants, likes, or desires, which are false needs and contribute a negative value to the company and eventually to society. False needs are very deceptive but over time always display themselves as negative fruits or results that can be costly to the company; but most of the time, false needs are costly in human lives, money and/or a waste or misuse of the physical and mental resources that we never could nor will be able to waste in the future. See the book *The Art of Work* by Thomas J. Zepf for a more complete development of good business practice.

ISO—International Organization for Standardization

It's impossible to ignore the banners draped on the side of industrial facilities that proudly proclaim the company's compliance with one or another ISO standard, with ISO 9000 and ISO 14000 being the two most popular. As ISO says itself, it is a network of the national standards institutes of 157 countries, on the basis of one member per country, with a Central Secretariat in Geneva, Switzerland, that coordinates the system.

ISO is a nongovernmental organization: Its members are not, as is the case in the United Nations system, delegations of national governments. Nevertheless, ISO occupies a special position between the public and private sectors. This is because, on the one hand, many of its member institutes are part of the governmental structure of their countries, or are mandated by their government. On the other hand, other members have their roots uniquely in the private sector, having been set up by national partnerships of industry associations.

Therefore, ISO is able to act as a bridging organization in which a consensus can be reached on solutions that meet both the requirements of business and the broader needs of society, such as the needs of stakeholder groups like consumers and users.

For everything you'd ever want to know about ISO—including more about the organization's history, how you can start the certification process at your plant, and which standards should be applicable to your organization—visit their home page at http://www.iso.ch/ for detailed information.

Lean Manufacturing

Lean is a quality philosophy that strives to minimize consumption of resources that add no value to the finished product. Its focus is waste from all areas of production from labor, materials, energy, time, inventory, and so on, as well as reaching deep into the organization.

MRO—Maintenance, Repair, and Operations (or Overhaul)

MRO, the generic term for just about everything in the plant engineering and maintenance world, appears to have a product-based implication. That is, people talk about "MRO sourcing" and "MRO procurement" to mean searches for the kinds of products and supplies that help plant professionals do their jobs. An important sub-branch of this industry is e- MRO—that is, the buying and selling of these products online.

PdM—Predictive Maintenance

PdM, one of the most popular terms in the maintenance field, covers a wide range of practices, all of which try to refute the old adage, “If it ain’t broke, don’t fix it.” PdM practitioners follow a credo more like, “Don’t wait for it to actually break before you fix it—figure out when it is *going* to break and make sure you don’t have to fix it in the middle of production.”

From http://www.plant-maintenance.com/terminology.shtml, **predictive maintenance** can be said to be an equipment maintenance strategy based on measuring the condition of equipment in order to assess its present condition, predict its remaining useful life, and determine an expected failure time in the future and then taking ongoing appropriate action to avoid the failure and its consequences. The condition of equipment could be monitored using condition monitoring, statistical process control techniques, by monitoring equipment performance, or through the use of the human senses. The terms condition-based maintenance, on-condition maintenance, and predictive maintenance could be used interchangeably.

As the name implies, predictive maintenance anticipates equipment outages rather than reacting to them. Benefits include fuller useful life for equipment and lower backup inventory. It goes beyond preventive maintenance, which at least strives to shift plant downtime to noncritical periods. Initial cost of predictive monitoring systems tends to be high, but much less than forced reactive maintenance due to just one serious outage of a manufacturing line. In an era of intensive competition, where asset usage and plant operating efficiency must be maximized, it is predictive maintenance that should be a tool along with reliability centered maintenance.

Diagnostic equipment is central to the PdM methodology, and therefore it is no surprise that there are thousands of products that enable users to anticipate machine failure. Software—like CMMS, ERP, and EAM packages—is a big part of this.

PM—Preventive Maintenance

In his 1998 book, *Developing Performance Indicators for Managing Maintenance* (Industrial Press), Terry Wireman has this to say about PM:

> The preventive maintenance program is the key to any successful asset management process. The preventive maintenance program reduces the amount of reactive maintenance to a level low enough that the other initiatives in the asset management process can be effective. However, most companies in the United States have problems keeping their PM programs focused. In fact, surveys have shown that only 20 percent of the companies in the United States feel their PM programs are effective.

Historically; PM was introduced in the United States in the 1950s and then adopted into the Japanese philosophy of TPM (see below). PM is sometimes seen as an outmoded concept today, having been supplanted by more recently honed philosophies like RCM, TPM, and PdM, but its general foundation of what TPM guru Seiichi Nakajima calls “time-based maintenance featuring periodic inspection, servicing and overhaul” is still the basis for many maintenance initiatives today. Regarding overhauling equipment, it is now being more recognized by industry to overhaul equipment based on predictive analysis and inspection and overhaul as needed, not on a fixed cyclical time parameter.

QCP—Quick Change Process

Quick change process (Figure 1) can be defined as all those tasks that must be done quickly with accuracy and precision when changing from one product to another or one

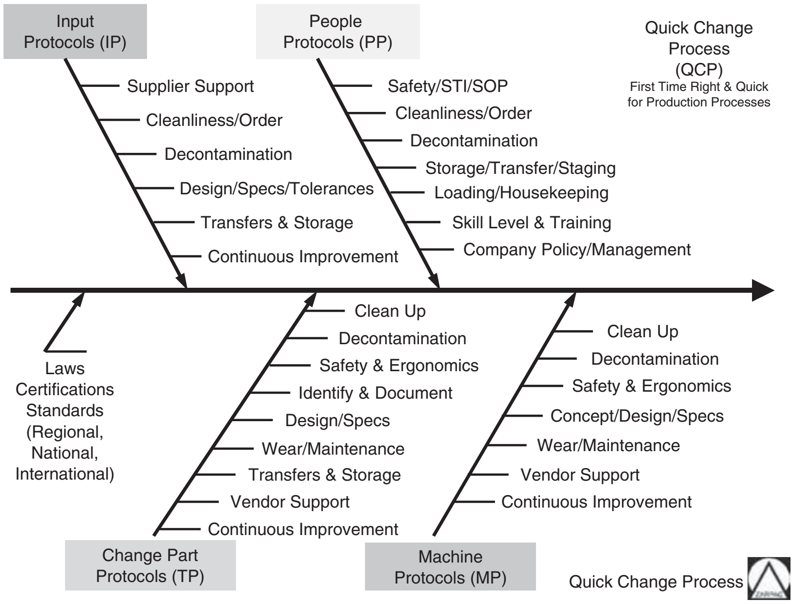

Figure 1. An overview of the quick change process.

SKU to another. To accomplish this requires the proper execution of associated tasks that are related to a given SKU. The main tasks are made up of:

1. Offline preparatory, documentation, and ready events.
2. Purge-out activities.
3. Change-out activities or changeover.
4. Run-up or start-up.

The interrelationship of all these tasks and their subtasks involved in the change process can be very complex. A review of this complexity will be done, along with discussion of why changing the packaging process to be quick change is a coordinated holistic effort.

Today the change-out process has to be taken seriously and integrated into company policy in order to:

- Develop a just-in-time or on-demand production philosophy.
- Increase their margins and profits.
- Run a large variety of different products on the same line.
- Demonstrate control to regulatory groups.
- Maintain and increase market share.

Quick change process is fundamentally a significantly modified version of single minute exchange of die (SMED) philosophy and techniques expanded and targeted to production facilities especially related to packaging, blow molding, and converting industries. SMED uses philosophical concepts and industrial engineering techniques to facilitate the quick exchange of die sets in stamping operations, as found in the automotive industry.

RCM—Reliability-Centered Maintenance

There is a whole sub-industry in the maintenance field centered on RCM and its offspring, RCM2. Reliability can be defined as “the process of managing the interval between failures. If availability is a measure of the equipment uptime or conversely the duration of downtime, reliability can be thought of as a measure of the frequency of downtime.

RCM thinking and practice began in the commercial airline industry—a field where “downtime” has some pretty unfortunate connotations—in the 1960s. In the following decades, two engineers, Stanley Nowlan and Howard Heap of United Airlines, published a study on the subject that established it as a standard maintenance practice.

There is likely nobody who has done as much to spread the cause of RCM and RCM2 as John Moubray, who, through his Aladon consulting firm (www.aladon.co.uk), has worked with plants worldwide on reliability-based initiatives. He defines RCM2 as “a process used to decide what must be done to ensure that any physical asset, system or process continues to do whatever its users want it to do.”

SCM—Supply Chain Management; or ISCM—Integrated Supply Chain Management

Always a tough one to define—there are several competing theories as to where the industrial chain of raw goods, manufacturing, and distribution actually starts and ends. Practitioners have, within the last few years, taken to referring to “integrated supply chain management” (ISCM) just to further confuse the issue, but basically they are the same.

> ISCM is a process-oriented, integrated approach to procuring, producing, and delivering products and services to customers. ISCM has a broad scope that includes sub-suppliers, suppliers, internal operations, trade customers, retail customers, and end users. ISCM covers the management of material, information, and funds flow:

You can find an excellent overview of the subject in the “Supply Chain Management Review” online magazine site at: http://www.manufacturing.net.

Six Sigma

It is a systematic quality program that strives to limit defects to three standard deviations on either side of the mean or a total of six sigma. Sigma is just a term for one standard deviation about the mean of a significant population of measurements of a process variable. One of the major focuses of Six Sigma is to reduce process variation. In most companies, quality loss will be by far the smallest of the OEE losses. A Six Sigma or equivalent program may be necessary to maintain focus on quality improvements.

SPC—Statistical Process Control and SQC Statistical Quality Control

Statistical process control (SPC) and statistical quality control (SQC) methodology is one of the most important analytical developments available to manufacturing in this century. SPC has come to be known as an online tool providing close-up views of what’s happening to a process at the moment. SQC provides offline tools to support analysis and decision-making to help determine if a process is stable and predictable from shift to shift, day in and day out, and from supplier to supplier. When SPC and SQC tools work together, users see the current and long-term picture about processing performance. SPC provides online tools that permit a close-up view of what’s currently happening to a process. SQC provides offline tools to support analysis and decision-making about process stability over time.

Before SPC, products were inspected after they were completed and defective products were discarded or reworked. The idea behind continuous improvement is to focus on designing, building, and controlling a process that makes the product correctly the first time at the point of manufacture.

How to Improve Using SPC and SQC

Key to improving a process is removing as much variation as possible. When products and services are delivered with minimal variation, customer requirements and expectations are met. Manufacturers applying SPC and SQC techniques rely on a variety of methods, charts, and graphs to measure, record, and analyze processes to reduce variations. In general, processes achieving the most benefit from SPC and SQC are products with:

1. Highly repetitive manufacturing processes.
2. High-volume production and low margins.
3. Narrow tolerances.

To make SPC and SQC work, key parameters indicating product variations are measured and recorded. For example, key parameters for a roll of cloth could include shrinkage, color, strength, and flaws per yard (meter). SQC methods are used to analyze recorded data and establish which variations are a natural part of the process and which unusual variations are caused by external factors, such as variations in raw materials.

SPC and SQC Tools

Control charts are a fundamental tool of SPC and SQC and provide visual representation of how a process varies over time or from unit to unit. Control limits statistically separate natural variations from unusual variations. Points falling outside the control limits are considered out-of-control and indicate an unusual source of variation.

Performance improvements of personal computer hardware and software permit real-time data collection, number crunching, and graphing. Providing SPC information in real-time allows operators to make adjustments or to schedule maintenance on an as-needed basis. SPC and SQC are an effective part of continuously improving a manufacturing process. When measurements are accurately collected and analyzed, improvements are identified and implemented, and controls established to ensure improvements are permanent and the process is well on its way to meeting quality requirements.

Process capability Cp or Cpk is a process that is used within the SPC environment. It is a process that is a unique combination of tools, materials, and methods, and people engaged are producing a measurable output; for example a manufacturing line for machine parts. All processes have inherent statistical variability that can be evaluated by statistical methods. The process capability is a measurable property of a process. It is usually reported in terms of the inherent variability of a process and its output.

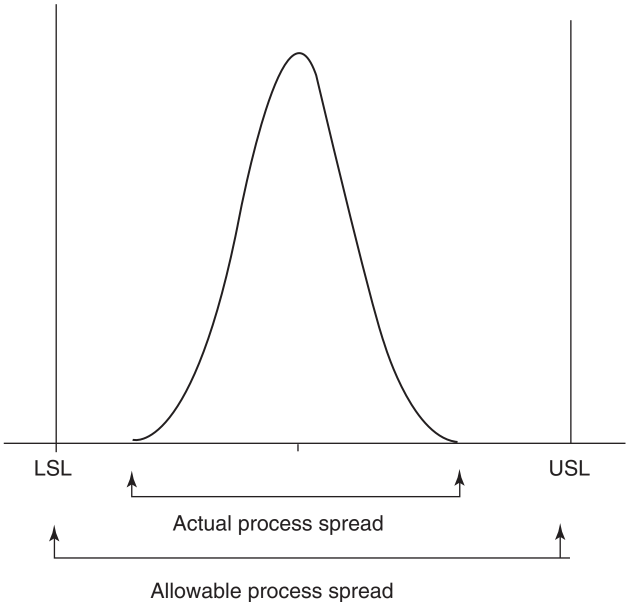
Two parts of process capability are: (1) Measure the variability of a process and (2) compare that variability with a proposed specification or product tolerance.

Process capability compares the output of an *in-control* process to the specification limits by using *capability indices*. The comparison is made by forming the ratio of the spread between the process specifications (the specification "width") to the spread of the process values, as measured by 6 process standard deviation units (the process "width").

The process capability index uses both the process variability and the process specifications to determine whether the process is "capable."

We are often required to compare the output of a stable process with the process specifications and make a statement about how well the process meets specification. To do this, we compare the natural variability of a stable process with the process specification limits.

A capable process is one where almost all the measurements fall inside the specification limits. This can be represented pictorially by the plot below:



There are several statistics that can be used to measure the capability of a process: C_p, C_{pk}, and C_{pm}.

Most capability indices estimates are valid only if the sample size used is "large enough." Large enough is generally thought to be about 50 independent data values. The Cp, Cpk, and Cpm statistics assume that the population of data values is normally distributed. This is displayed by the graph above in which there is a two-sided specification, $\bar{X}$ and σ are the mean and standard deviation, respectively, of the normal data and USL, LSL, and T are the upper and lower specification limits and the target value, respectively. TPM—Total Productive Maintenance

In the trendsetting 1982 book *TPM Tenkai* (which was translated into English as *TPM Development Program: Implementing Total Productive Maintenance* and published in 1989 by Productivity Press), editor Seiichi Nakajinia writes that in the years during and immediately following World War II, Japanese industrial managers sought to compete in the world marketplace by improving on the quality of their products. Building on the American PM model, the Japanese developed the field of TPM in the 1970s—most notably in the Toyota automotive plants, as a way of furthering refining their maintenance practice. The overall aim of TPM is "a double goal—zero breakdowns and zero defects."

Nakajinia says that TPM was defined in 1971 by the Japan Institute of Plant Engineers with these 5 goals in mind:

1. Maximize equipment effectiveness (in improving overall efficiency).
2. Develop a system of productive maintenance for the life of the equipment.
3. Involve all departments that plan, design, use, or maintain equipment in implementing TPM (engineering and design, production, and maintenance).
4. Actively involve all employees from top management to shop floor workers (Top down approach).
5. Promote TPM through motivation management: autonomous small-group activities.

For overviews of TPM, go to *NASA's* site at www.larc.nasa.gov/ or search for TPM.

Other Performance-Enhancing Methodologies

ABC/M	Activity-Based Costing/Management
BPI	Business Process Improvement
BPR	Business Process Reengineering
CI	Continuous Improvement
EAM	Enterprise Asset Management
ERP	Enterprise Resource Planning
JIT	Just-in-Time (manufacturing)
LCC	Life Cycle Costing
LEAN	Lean production or manufacturing
MES	Manufacturing Execution System
MP	Maintenance Prevention
MPI	Maintenance Performance Indicators
MRP	Material Requirements Planning (MPR-I and MPR-II)
MSDS	Material Safety Data Sheet
MTBF	Mean Time Between Failure
MTTR	Mean Time to Repair (MTOF—Mean Time of Failure)
RCAF	Root Cause Analysis of Failure
RCD	Reliability-Centered Design
SMED	Single Minute Exchange of Dies
TCO	Total Cost of Ownership
TMM	Total Maintenance Management
TQM	Total Quality Management
ZD	Zero Downtime

PACKAGING OF FOOD

GORDON L. ROBERTSON
Food•Packaging•Environment,
Brisbane, Australia

INTRODUCTION

Role of Food Packaging

Food packaging is essential and pervasive: It is essential because without packaging the safety and quality of food would be compromised, and it is pervasive because almost all food is packaged in some way. Food packaging performs a number of disparate tasks (1). It protects the food from contamination and spoilage; it makes it easier to transport and store foods; and it provides uniform measuring of contents. By allowing brands to be created and standardized, it makes advertising meaningful and makes large-scale distribution and mass merchandising possible. Food packages with dispensing caps, sprays, reclosable openings, and other features make products more usable and convenient.

Functions and Attributes of Food Packaging

Four primary and interconnected functions of packaging have been identified: containment, protection, convenience, and communication (1).

Containment. This function of packaging is so obvious as to be overlooked by many, but it is the most basic function of packaging. Food products must be contained before they can be moved from one place to another. The containment function of packaging makes a huge contribution to preventing losses from the myriad of foods that are moved from one place to another on numerous occasions each day.

Protection. This is often regarded as the primary function of the package: to protect its contents from outside environmental effects, be they water, water vapor, gases, odors, microorganisms, dust, shocks, vibrations, compressive forces, and so on, and to protect the environment from the product.

For the majority of food products, the protection afforded by the package is an essential part of the preservation process. For example, aseptically packaged milk in paperboard laminate cartons only remains aseptic for as long as the package provides protection; vacuum-packaged meat will not achieve its desired shelf life if the package permits oxygen to enter. In general, once the integrity of the package is breached, the product is no longer preserved.

Freedom from harmful microbial contaminants at the time of consumption can also be influenced by the package. Firstly, if the packaging material does not provide a suitable barrier around the food, microorganisms can contaminate the food and make it unsafe. Microbial contamination can also arise if the packaging material permits the transfer of, for example, moisture or oxygen from the atmosphere into the package. In this situation, microorganisms present in the food but presenting no risk because of the initial absence of moisture or oxygen may then be able to grow and present a risk to the consumer.

Packaging also protects or conserves much of the energy expended during the production and processing of the product. For example, to produce, transport, sell, and store 1 kg of bread requires 15.8 MJ (megajoules) of energy. This energy is required in the form of transport fuel, heat, power, and refrigeration in farming and milling the wheat, baking and retailing the bread, and distributing both the raw materials and the finished product. To produce the polyethylene bag to package a 1 kg loaf of bread requires 1.4 MJ of energy. This means that each unit of energy in the packaging protects 11 units of energy in the product. While eliminating the packaging might save 1.4 MJ of energy, it would also lead to spoilage of the bread and a consequent waste of 15.8 MJ of energy (1).

Convenience. Modern industrialized societies have brought about tremendous changes in lifestyles, and the packaging industry has had to respond to those changes that have created a demand for greater convenience in household products: foods that are pre-prepared and can be cooked or reheated in a very short time, preferably without removing them from the package; condiments that can be applied simply by pump-action packages; dispensers for sauces or dressings which minimize mess; reclosable openings on drink bottles to permit consumption on the go, and so on. Thus packaging plays an important role in allowing products to be used conveniently.

Two other aspects of convenience are important in package design. One of these can best be described as the apportionment function of packaging. In this context, the package functions by reducing the output from industrial production to a manageable, desirable "consumer" size. An associated aspect is the shape (relative proportions) of the primary package in relation to convenience in use by consumers (e.g., easy to hold, open, and pour as appropriate) and efficiency in building into secondary and tertiary packages. Packaging plays a very important role in permitting primary packages to be unitized into secondary packages (e.g., placed inside a corrugated case) and then for these secondary packages to be unitized into a tertiary package (e.g., a stretch-wrapped pallet). As a consequence of this unitizing function, materials handling is optimized since only a minimal number of discrete packages or loads need to be handled.

Communication. There is an old saying that "a package must protect what it sells and sell what it protects"; that is, the package functions as a "silent salesman." The modern methods of consumer marketing would fail were it not for the messages communicated by the package through distinctive branding and labeling, enabling supermarkets to function on a self-service basis. Consumers make purchasing decisions using the numerous clues provided by the graphics and the distinctive shapes of the packaging. Other communication functions of the package include (a) a UPC (Universal Product Code) that can be read accurately and rapidly using modern scanning equipment at retail checkouts and (b) nutritional information on the outside of food packages which has become mandatory in many countries.

Attributes. There are also several attributes of packaging that are important (2). One (related to the convenience function) is that it should be efficient from a production or commercial viewpoint—that is, in filling, closing, handling, transportation, and storage. Another is that the package should have, throughout its life cycle from raw material extraction to final disposal after use, minimal environmental impacts. A third attribute is that the package should not impart to the food any undesirable contaminants. Although this last attribute may seem self-evident, there has been a long history of so-called food contact substances migrating from the packaging material into the food (3). For many years the solder used in three-piece metal cans resulted in lead migrating into some foods; the switch to welded side seams eliminated this source of lead. Plasticizers have also migrated into foods—for example, phthalates (4), as well as monomers [e.g. styrene monomer (5)], catalysts [e.g., antimony from PET bottles (6)], and photoinitiators from printing inks [e.g., ITX (7)]. Not surprisingly, food packaging materials are highly regulated to ensure consumer safety.

DETERIORATIVE REACTIONS IN FOODS

Foods are frequently classified on the basis of their stability as nonperishable, semiperishable, and perishable. An example of the first classification is sugar; provided that it is kept dry, at ambient temperature and free from contamination, it should have a very long shelf life. However, few foods are truly nonperishable, and an important factor influencing their perishability is the packaging.

For example, hermetically sealed and heat processed (e.g., canned) foods are generally regarded as nonperishable. However, they may become perishable under certain circumstances—for example, if the can seams are faulty, or if there is excessive corrosion resulting in internal gas formation and eventual bursting of the can. Foods with low moisture content, such as dried fruits and vegetables and baked goods, are classified as semiperishable. Frozen foods, though basically perishable, may be classified as semiperishable, provided that they are properly stored at freezer temperatures. The majority of foods (e.g., flesh foods (such as meat and fish), milk, eggs, and most fruits and vegetables) are classified as perishable unless they have been processed in some way. Often, the only form of processing that such foods receive is to be packaged and kept under controlled temperature conditions.

Deteriorative reactions occur in foods during processing and storage, and they combine to affect food quality. These reactions can be biochemical (typically enzymic), chemical, physical (typically as a result of moisture gain or loss), and biological (both microbiological and macrobiological due to insect pests and rodents). Knowledge of the kinds of changes that influence food quality is an important first step in developing food packaging that will minimize undesirable changes in quality and maximize the development and maintenance of desirable properties. Once the nature of the reactions is understood, knowledge of the factors that control the rates of these reactions is necessary in order to fully control the changes occurring in foods during storage—that is, while packaged. The nature of the deteriorative reactions in foods, along with the factors that control the rates of these reactions, has been reviewed in detail elsewhere (1).

The rates of deteriorative reactions of particular foods are influenced by two factors: the nature of the foods and their surroundings. These factors are referred to as intrinsic and extrinsic parameters. Intrinsic parameters are an inherent part of the food and include water activity (a_w), pH, redox (oxidation–reduction) potential (E_h), oxygen content, and product formulation including the presence of any preservatives or antioxidants. The a_w of a particular food can affect the rates of deteriorative reactions in different ways; for example, the rate of nonenzymic browning peaks at around $0.65\,a_w$ while the rate of autoxidation of lipids decreases as a_w rises from zero to 0.3 and then increases with further rises in a_w. The destruction or inhibition of enzymes and microorganisms is necessary for shelf-stable, high moisture content ($a_w \sim 0.85$–1.0) foods, and this can be achieved through the selection of suitable packaging materials and the manipulation of extrinsic factors.

Extrinsic factors that control the rates of deteriorative reactions include temperature, relative humidity (RH), gas atmosphere, and light; packaging can influence the impact of these factors on the rates of deteriorative reactions to varying degrees, depending on the specific packaging material.

The RH of the ambient environment is important and can influence the a_w of the food unless the package provides a moisture barrier. Many flexible plastic packaging materials provide good moisture barriers but none are completely impermeable, thus limiting the shelf life of low-a_w foods. The presence and concentration of gases in the environment have a considerable influence on the growth of microorganisms, and modifying the atmosphere inside the package is widely used. Increased concentrations of gases such as CO_2 are used to retard microbial growth and thus extend the shelf life of foods. Furthermore, vacuum packaging (i.e., removal of air (and thus O_2) from a package prior to sealing) can also have a beneficial effect by preventing the growth of aerobic microorganisms.

The deterioration of packaged foods depends largely on transfers that may occur between the internal environment inside the package and the external environment that is exposed to the hazards of storage and distribution. For example, there may be transfer of water vapor from a humid atmosphere into a dried product, or transfer of an undesirable odor from the external atmosphere into a high fat product, or development of oxidative rancidity if the package is not an effective O_2 barrier. As well, flavor compounds can be absorbed by some types of plastic packaging materials, a phenomenon referred to as scalping (8).

INDICES OF FAILURE

In designing suitable packaging for foods, it is important to clearly define the indices of failure (IOF) of the food—that is, the quality attributes that will indicate that the food is no longer acceptable to the consumer. These might be development of rancid flavors in cereals due to oxidation; loss of red color (bloom) in chilled beef due to depletion of oxygen; reduction in carbonation in bottled soda due to permeation of CO_2 through the bottle wall; caking of instant coffee due to moisture ingress; development of microbial taint in chilled poultry; moisture loss in green vegetables, resulting in wilting; and loss of vacuum in canned berry fruits due to hydrogen gas production with consequent bulging of the can ends.

Once the IOFs for a particular food have been defined, the next step is to attempt to quantify the magnitude of the particular degradation—for example, how much moisture or O_2 can react with the food before it becomes unacceptable. The final step is to ascertain which (if any) of the IOFs might be influenced by the packaging material since packaging cannot prevent all deteriorative reactions in foods. If, for example, the IOF of a snack food was loss of crispness, then the packaging material could influence this, depending on the extent to which it permitted the ingress of moisture. Different plastic films, for example, have different WVTRs; thus the shelf life obtained will vary, depending on the particular plastic selected. Similar considerations apply to foods where the IOF is oxidation. However, it is not just the packaging material per se that can influence shelf life; the method of filling the product into the package is also important. For example, with roasted and ground coffee, vacuum filling into metal cans will remove 95% or more of the O_2 from the can compared with inert gas flush packing in plastic foil laminate pouches which will remove or displace 80–90% of the O_2 in the package. The residual O_2 in the package at the time of filling will have a major influence on shelf life regardless of the O_2 barrier properties of the package itself.

Data on the WVTR and OTR of various plastics are widely available. However, such data are often determined on flat samples of film rather than actual packages where creasing and sealing can adversely affect barrier properties. The dimensions of the package for a given weight of food can have a large influence on shelf life. While a spherical shape will minimize the surface area of the package (and thus the quantity of moisture or O_2 that will permeate into the package), it is not a practical shape for commercial use; in practice, most packages tend to be rectangular or cylindrical. Extremely thin packages have a much greater surface area:volume ratio and thus require a plastic with better barrier properties to get the same shelf life than if the same product were packaged in a thicker format. For the same product packaged in different sized packages using the same plastic material, the smallest package will have the shortest shelf life because the package surface area:volume ratio increases with decrease in package size.

PACKAGING OF MAJOR FOOD GROUPS

Space does not permit a detailed description of the IOFs and typical packaging materials used for the wide variety of foods available to consumers today; such detail can be found elsewhere (1). Instead the major food groups and their packaging will be briefly considered.

Flesh Foods

Flesh foods such as meats, poultry, and seafood are subject to rapid microbial spoilage due to their high pH and a_w. Oxidation of fat is also a problem, especially with pork and poultry; another problem is oxidation of pigments in red meats.

Beef. The importance of color as a marketing attribute of red meat is well established, especially for self-service retailing. Consumers, used to seeing bright red meat prepared for sale, associate this color with good eating quality, although there is little correlation between the two. This association of the color of red meat (both in the chilled and frozen form) with freshness has been the dominant factor underlying retail meat marketing. The loss of this bright red color, known as loss of "bloom" in the industry, is affected by many factors, although the consumer will usually relate the color loss to bacterial growth. Because of the importance of meat color, various methods of transportation, distribution, and packaging have evolved which optimize the maintenance of a desirable meat color.

The color of fresh meat depends chiefly on the relative amounts of the three pigment derivatives of myoglobin present at the surface: myoglobin (Mb), also referred to as deoxymyoglobin; oxymyoglobin (O_2Mb); and metmyoglobin (MetMb). Mb is purple in color and predominates in the absence of oxygen; O_2Mb is bright red in color and results when Mb is oxygenated or exposed to oxygen, producing the familiar "bloom" of fresh meat. MetMb is brown in color and exists when the oxygen concentration is between 0.5% and 1%, or when meat is exposed to air for extended periods of time. The color of meat as perceived by the consumer is primarily determined by factors such as the concentration and chemical form of the myoglobin, the morphology of the muscle structure, and the ability of the muscle to absorb or scatter incident light. To preserve red meat, the objective is to retard spoilage, permit some enzymic activity to improve tenderness, retard weight loss, and ensure an O_2Mb or bright red color at the consumer level.

In distribution, most red meat is packaged under vacuum in high O_2 and water vapor barrier flexible packaging materials to retard deterioration. Vacuum packaging achieves its preservative effect by maintaining the product in an O_2-deficient environment (nominally less than 500 ppm). Any residual O_2 is rapidly consumed by meat and muscle pigments, and CO_2 is produced as the end product of tissue and microbial respiration. At the retail level, highly oxygen-permeable flexible packaging permits restoration of the bright red O_2Mb color while retarding the passage of water vapor.

Vacuum packaging has the inherent disadvantage that both package and meat are subjected to mechanical strain. Mechanical pressure on the meat may increase drip loss; and if bone is present and not adequately covered with a suitable material, the pack may be ruptured. As an alternative to vacuum packaging, attempts have been made to store meat under various gaseous atmospheres, a process referred to as modified atmosphere packaging or MAP. The strain on the packaging material can be alleviated by introducing another gas or mixture of gases after evacuation and before sealing. The intention has generally been to preserve the fresh meat color (O_2Mb) and prevent anaerobic spoilage by using high concentrations of O_2 (50–100%) along with 15–50% CO_2 to restrict the growth of *Pseudomonas* and related bacteria; EVOH is commonly used as the barrier layer in coextruded films.

Poultry. Raw poultry meat is a perishable commodity of relatively high pH (5.6 for breast muscle and up to 6.4 for leg muscle) which readily supports the growth of microorganisms when stored under chill or ambient conditions. The shelf life of such meat depends on the combined effects of certain intrinsic and extrinsic factors, including the numbers and types of psychrotrophic spoilage organisms present initially, the storage temperature, muscle pH and type (red or white), as well as the kind of packaging material used and the gaseous environment of the product.

The vacuum packaging of poultry carcasses, cuts, and other manufactured products can extend shelf life, provided that the product is held under chill conditions. Vacuum packaging of poultry meat leads to the development of mainly lactic acid bacteria, sometimes accompanied by cold-tolerant coliforms. Although vacuum packaging may be used to encourage the development of an atmosphere around the product which delays microbial spoilage, other systems in use involve addition of at least 20% CO_2, to either individually packaged items or bulk packs of varying size in an O_2-impermeable plastic film.

Seafood. Flesh foods such as fish and shellfish are highly perishable due to their high a_w, relatively high pH, and the presence of autolytic enzymes which cause the rapid development of undesirable odors and flavors.

The effects of MAP on seafood are similar to those described above for meat and poultry. Vacuum and MAP (including flushing with N_2 and CO_2), which suppress the normal spoilage bacteria that cause off-odors and flavors, extend the shelf life of seafood.

Most studies of MAP of seafood indicate a shelf-life extension from a few days up to a week or more compared with air storage, depending on species and temperature. Differences in spoilage microflora and pH are mainly responsible for the observed differences in shelf life, provided that similar gas:product ratios are used. Although some claims have been made of a shelf life of up to 3–4 weeks for the refrigerated storage of MAP fish, this is generally considered to be unrealistic. Target shelf lives of these products are typically in the range of 10–14 days, but may reach 18–20 days if the temperature is controlled very closely just above freezing point.

High-temperature abuse (21–27°C) for periods of 12–24 h is a major concern since MAP fish generally do not become overtly spoiled under these conditions yet may be toxic, whereas fish held at the same temperatures under similar aerobic conditions start to become putrid before toxin production occurs. If MAP fish are held at temperatures greater than 10°C, strong spoilage signals may not develop in advance of *C. botulinum* toxin production.

The use of active packaging technologies such as O_2 scavengers and CO_2 emitters does not improve microbial safety above that obtained by traditional MAP, and it gives little or no additional shelf life to fresh seafood products compared to MAP and vacuum packaging (9).

Horticultural Products

Fruits and vegetables are perishable products with active metabolism during the postharvest period. Their shelf life can be extended by, in simple terms, retarding the physiological, pathological, and physical deteriorative processes (generally referred to as postharvest handling). Fruits may be divided into climacteric and nonclimacteric types. Climacteric fruits are those in which ripening is associated with a distinct increase in respiration and ethylene production, with low temperatures greatly reducing the magnitude of the climacteric. Typical climacteric fruits include apples, pears, peaches, nectarines, bananas, mangoes, plums, tomatoes, and avocados. Ethylene is a natural plant hormone and plays a central role in the initiation of ripening; it is physiologically active in trace amounts (less than 0.1 ppm).

Aerobic respiration involves the oxidation of starch, sugars, and organic acids to simpler molecules (CO_2 and H_2O) with the concurrent production of energy (ATP and heat). If hexose sugar is used as the substrate, the overall equation can be written as follows:

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O + \text{energy}$$

This equation suggests that if the CO_2 in the atmosphere were increased (or the O_2 decreased), the respiration rate would decrease and the storage life would be extended. Such is the case, and the application of this approach is the basis of MAP. The availability of absorbers of O_2, CO_2, C_2H_4, and water provide additional tools for the packaging technologist to use to maintain a desired atmosphere within a package. Fresh fruits and vegetables vary greatly in their relative tolerance to low O_2 concentrations and elevated CO_2 concentrations. Reduction of the O_2 concentration to less than 10% provides a tool for controlling the respiration rate and slowing down senescence, although an adequate O_2 concentration must be available to maintain aerobic respiration.

Minimally processed fruits and vegetables (MPFVs) are products that have the attributes of convenience and fresh-like quality, with their forms varying widely depending on the nature of the unprocessed commodity and how it is normally consumed. They are sometimes referred to as “fresh-cut” produce. Polymeric films are the most common materials used for the packaging of horticultural products including MPFVs; such films require a high permeability to gases to avoid the development of injurious atmospheres inside the package. This can typically be achieved by microperforation of the film to give holes with diameters ranging from 40 to 200 μm. In addition to enabling the creation of MA conditions, polymeric films provide other benefits including maintenance of high RH and reduction of water loss. In packages where it is not intended to create a MA, the main concern is to avoid anoxic conditions and condensation of water vapor inside the package. This is most easily achieved either by incomplete sealing or by perforation of the plastic packaging.

Dairy Products

Dairy products are derived from milk, which is usually not sterile. Pasteurization is a low-heat process to destroy disease microorganisms but not all microorganisms that could cause spoilage. Pasteurized dairy products must be maintained under refrigeration.

Milk is processed into a variety of products, all having different and varying packaging requirements. The simplest product is pasteurized milk where, after a mild heat treatment, the milk is filled into a variety of packaging media and distributed. Nonreturnable packages such as blow-molded HDPE bottles or LDPE-coated paperboard gabletop packages are most often used for packaging and distributing milk under refrigeration; the shelf life of such a product varies from 2 to 10 days. UHT milk is subjected to a more complex process and is aseptically packaged; the packaging is sophisticated (typically a paperboard laminate foil carton) and its shelf life can be up to 8 months at ambient temperatures. Cream is typically processed and packaged in a way similar to that of fluid milk and has a similar shelf life. Fermented dairy products, although being subjected to more complex processing operations, are also typically packaged in a manner analogous to that of fluid milk.

The other dairy products (butter, cheese, and powders) are quite different in nature when compared to fluid milk, and their packaging requirements are therefore also quite different. Butter is very susceptible to light-induced flavors, which results in off-flavors. Since butter is generally exposed to fluorescent light during storage in retail display cabinets, the packaging material has a marked effect on the amount of light transmitted and the related intensity of the oxidized flavor. Butter packaged in various types of conventional parchment papers develops objectionable levels of oxidized off-flavor after a few hours exposure in a supermarket display cabinet, while aluminum foil laminates are satisfactory even after 48 days of continuous exposure.

Cheese is the generic name for a group of fermented milk-based food products produced in at least 500 varieties throughout the world. With the exception of some soft cheeses, most cheese varieties are not ready for consumption at the end of manufacture but undergo a period of ripening (also referred to as curing or maturation) which varies from about 4 weeks to more than 2 years. The duration of ripening is generally inversely related to the moisture content of the cheese, although many varieties may be consumed at any of several stages of maturity depending on the flavor preferences of consumers (1).

The two key parameters contributing to the stability of cheeses are pH and a_w. However, neither of these parameters is low enough to ensure complete stabilization of the product, with the result that cheeses as a class lie between perishable foods on the one side and intermediate moisture foods on the other. While the packaging will have no influence on the pH of the cheese, the a_w of the surface (and ultimately the interior) of the cheese will be affected by the water vapor permeability of the packaging material. Two other key factors that must be considered in the packaging of cheese are the effect of light and O_2. Light initiates the oxidation of fats, even at temperatures found in refrigerated display cabinets, giving rise to off-flavors. In addition, the ingress of molecular O_2 through the packaging film is undesirable because it will contribute to the oxidation of fats and the growth of undesirable microorganisms. Thus packaging films for cheese must be sufficiently impermeable to O_2 to prevent fat oxidation and mold growth. The introduction of pure CO_2 into the package often produces the appearance of vacuum packaging after a certain period of storage as a result of absorption of CO_2 by the cheese as well as some loss by diffusion through the packaging material.

Cereals, Bakery Products, Snack Foods, and Candy

Cereals. Cereals are the fruits of cultivated grasses, with the principal cereal crops being wheat, barley, oats, rye, rice, maize, sorghum, and the millets. The presence of water and air renders grains susceptible to biochemical deterioration; grains are also subject to infestation from insects and rodents. It is essential that grain be dried to a moisture content corresponding to $0.70\,a_w$ or less prior to packaging and storage. Consumer packages for grain commonly consist of heat-sealed pouches made from LDPE film; these provide a satisfactory moisture barrier and result in the required shelf lives for the grains.

Breakfast cereals contain most of the whole grain in cooked or toasted form plus flavorings, vitamins, and minerals. There are five modes of deterioration to be considered when selecting suitable packaging materials for breakfast cereals. They are moisture gain resulting in loss of crispness; lipid oxidation resulting in rancidity and off-flavors; loss of vitamins; breakage resulting in an aesthetically undesirable product; and loss of aroma from flavored products. The shelf life of breakfast cereals depends to a large extent on the content and quality of the oil contained in them. Breakfast cereals are packaged in glassine, waxed glassine, or, mostly, polyolefin coextrusions in the form of pouches or bags within paperboard cartons. Sugared cereals are often packaged in aluminum-foil laminations to retard water vapor transmission.

Bakery Products. A wide variety of bakery products can be found on supermarket shelves, including breads, unsweetened rolls and buns, doughnuts, sweet and savory pies, pizza, quiche, cakes, pastries, biscuits, crackers, and cookies. It is useful to classify bakery products on the basis of their a_w and pH since these parameters are a good indication of the spoilage problems likely to be encountered. Microbial growth—in particular, mold growth—is the major factor limiting the shelf life of bakery products; chemical preservatives are used by the bakery industry to prevent or retard microbiological spoilage. Staling is the common description of the decreasing consumer acceptance of bakery products as they age, caused by changes in crumb other than those resulting from the action of spoilage organisms; it is the major mode of deterioration.

The objective in packaging bread is to maintain the bread in a fresh condition by preventing too rapid drying out without providing too good a moisture barrier, which would promote mold growth on a soggy crust. Vacuum packaging is not a suitable technology to extend the mold-free shelf life of most soft bakery products since the product is crushed under a vacuum. However, it has been used to prevent mold problems in flat breads and pizza crusts. An alternative to vacuum packaging is to modify the atmosphere inside the package. A range of gas mixtures has been used to extend the shelf life of bakery products, from 100% CO_2 to 50% CO_2 and 50% N_2.

Extensions of 3 weeks to 3 months at room temperature are achievable using appropriate mixtures of CO_2 and N_2.

Hard baked goods such as cookies and crackers generally have moisture contents within the range 1–5%, a_w values of about 0.1, and often a high fat content. Loss of crispness and development of rancidity are the two major IOFs. The typical material used for the packaging of cookies and crackers is OPP, either as plain or pearlized OPP film. If a superior O_2 barrier is required, acrylic-coated OPP is used, and sometimes one side is coated with PVC/PVdC copolymer rather than acrylic. Soft cookies are packaged in low WVTR laminations containing aluminum foil or metallized plastic film.

Snack Foods. Snacks foods comprise a very wide range of products including potato and corn chips, pretzels, popcorn, extruder puffed and baked/fried products, and rice-based snacks. Fried snack foods can consist of many different ingredients; but common to them all is fat, which is used as a processing agent to dehydrate the product or puff it and develop characteristic flavors. There are two major IOFs of fried snack foods: development of fat rancidity and loss of crispness. Thus a satisfactory package for fried snack foods would need to provide a good barrier to O_2, light and moisture.

Fried snacks foods are typically packaged in multilayer structures, although spiral-wound, paperboard cans lined with aluminum foil or a barrier polymer and sealed under vacuum with an LDPE/foil end are used for some specialty products that also require mechanical protection. The major mode of deterioration for extruded and puffed snacks is loss of crispness; for example, the critical a_w for puffed corn curl is 0.36. Many extruded and puffed snack foods are packaged in material identical to that for fried snack foods. However, since the major mode of deterioration is loss of crispness, a package that provides a good barrier to water vapor is the primary requirement.

Candy. The three basic types of candies are chocolate and hard and soft sugar. Chocolate is a suspension of finely ground roasted cocoa beans or cocoa mass and sugar particles in cocoa butter (the lipid fraction of the cocoa mass). Chocolates may be either solid, solid with inclusions such as nuts, or molded with centers. The chocolate acts as a water vapor barrier that helps protect the inclusions and fillings such as nuts, crisped rice, or liquid cherry, which are susceptible to water gain or loss. Oxidative and lipolytic rancidity are flavor defects, with the former coming from oxidation of unsaturated fats and the latter coming from enzymic hydrolysis of short-and medium-chain triglycerides. Cocoa butter contains tocopherols, which act as antioxidants and therefore confer a natural protection against oxidation during storage. Being high in fat, chocolate is very likely to absorb any foreign odors from the surrounding atmosphere. Thus suitable packaging materials must provide a good barrier to light, O_2, water vapor, and foreign odors. The most common material used to package blocks of chocolate is a laminate consisting of aluminum foil and LDPE, making it possible to heat seal the package; chocolate products are also packaged in pearlized OPP.

Hard candies consist almost entirely of sugar with added flavors and are heated under vacuum to reduce the moisture content to about 1%. They are extremely hygroscopic, hard, and fragile. Soft candies include jellies, marshmallows, and other crystallized products; they contain a matrix of water that can be lost as a consequence of evaporation, and so these products must be protected against water loss. An important difference in the mode of deterioration between the various candies is that crystallized products tend to dry out under normal storage conditions, while uncrystallized products tend to pick up moisture from the atmosphere. Sugar candies are sealed in packaging with a low WVTR such as cast polypropylene; individual twist wraps are also common for many candies.

Beverages

Beverages may be still or carbonated, alcoholic or nonalcoholic. The major categories are water, juices, carbonated soft drinks, and beer.

Water. The major deteriorative reaction in bottled water is microbial growth. To avoid this, the water is usually treated prior to bottling with chlorine or ozone. Glass bottles were long considered the container of choice for sparkling waters and carbonated soft drinks; but in recent years, PET bottles have gained an increasing share of this sector. The majority of still waters are now packaged in plastic containers, with five principal resin alternatives: PET, PVC, PP, HDPE, and PC.

Juices. The quality of a juice depends essentially on the species and maturity of the fresh fruit, the main factors influencing the quality being the sugar:acid ratio, the aroma volatiles, the phenolic components, and the ascorbic acid content. The four key deteriorative reactions in juices are microbiological spoilage, nonenzymic browning, oxidation resulting in loss or degradation of flavor components and nutrients (essentially ascorbic acid), and absorption of flavor compounds by the package. The rate of browning and nutrient degradation is largely a function of storage temperature.

For many years, juices were packed in metal cans using the hot-fill/hold/cool process to ensure that the juice was commercially sterile. The use of glass bottles is also widespread, with glass being the preferred packaging medium for high-quality juices. However, over recent years an increasing proportion of juices has been packaged aseptically, generally into laminates of plastic film/aluminum foil/paperboard. These products are then held at ambient temperatures and the shelf life and nutrient composition are greatly influenced by the barrier properties of the carton, the interactions of the juice with the carton, and the storage environment. The end of shelf life is related to the extent of nonenzymic browning and the sorption of key aroma and flavor compounds by the plastic in contact with the juice, with the latter process being referred to as “scalping.”

Flexible packaging is also used for juices; a variety of laminate constructions are available, the most common being LDPE-PET-alufoil-PET. For specific applications, EVOH, OPA, or PP can be included in the structure. Recent developments in barrier coatings for PET have led to increasing use of PET bottles for fruit juices and drinks, and this trend is likely to accelerate as production ramps up and costs come down. Frozen concentrated orange juice (42°Brix) is usually held at −12°C, at which temperature it is still liquid; typical packaging materials consist of a spiral wound paperboard tube with aluminum ends, or an aluminum can.

Carbonated Soft Drinks. Soft drinks are prepared almost exclusively using the pre-mix system whereby the blended syrup, after flash pasteurization if necessary, is mixed with carbonated, treated water prior to delivery to the filler. The degree of carbonation ranges from 1.5 to 5 volumes, each volume producing about one atmosphere of internal pressure. The two major deteriorative reactions in carbonated beverages are (a) loss of carbonation and (b) oxidation and/or acid hydrolysis of the essential flavor oils. The first is largely a function of the effectiveness of the package in providing a barrier to gas permeation, while the latter can be prevented to a large extent by the use of high-quality flavorings and antioxidants and by deaerating the mix prior to carbonation (1). Typical packaging for soft drinks are aluminum cans and PET bottles.

Beer. Beer is an alcoholic beverage made by brewing and fermentation from cereals (usually malted barley) and flavored with hops to give a bitter flavor. Owing to its low pH (about 4.0), microbial degradation is not usually a problem, and the use of pasteurization and aseptic cold filtration excludes wild yeasts which could thrive. However, during storage, beer can undergo irreversible changes leading to the appearance of haze, the development of off-flavors, and increased color. Flavor loss is accelerated in the presence of light and certain metal ions. Beer is particularly vulnerable to O_2, which causes significant flavor deterioration; ideally the O_2 level in beer should be less than 50 ppb immediately after packaging.

The traditional packaging media for beer was the glass bottle sealed with a crown closure; but today in many countries, two-piece DWI aluminum cans with a stay-on tab now outnumber bottles. A small but increasing quantity of beer is packaged in PET bottles containing an O_2 barrier to provide acceptable shelf life.

PACKAGING OF FOOD FOR HIGH PRESSURE TREATMENTS

Rafael Gavara

Food Technology, IATA-CSIC,
Packaging Laboratory,
Burjassot, Spain

High hydrostatic pressure processing (HPP) is a novel food preservation technology that is gaining commercial importance as a consequence of current consumption trends toward high-quality products with natural flavor and taste, fresh-like characteristics, and no preservatives. HPP presents unique advantages over conventional thermal treatments due to low-temperature processes that improve retention of food quality. Moreover, it is independent of product size and geometry, and the pressure effect is uniform and almost instantaneous; and although the HPP has been reported to affect the texture of the food product, other characteristics such as flavor, color, and nutritional value are largely maintained (1).

Food preservation through HPP basically consists on the application of hydrostatic pressures between 100 and 1000 MPa, with holding times typically between 0 and 3 min, at refrigeration and ambient temperature. Current HPP research is exploring future applications at subzero temperatures to more than 100°C and holding times up to 30 min. The simplest process consists of (a) heating (cooling) to the treatment temperature (b) pressurization, which produces an inherent adiabatic heating (c) pressure holding time, which can include heat transfer between the food, pressurizing fluid, pressure equipment, and the environment, and (d) depressurization, which results in an adiabatic cooling and final cooling (or heating) to product storage temperature (2). However, to attain the desired extent of the shelflife of foodstuffs by means of the inactivation of microorganisms and enzymes in a short treatment process, the HPP process can be very complex with successive changes of pressure, as occurs in pulsed high-pressure treatments (3).

Most HPP equipments work through batch processes, although a few commercial semicontinuous units for the treatment of liquid foods and sauces that may contain solids under 5 mm are under operation. In this latter case, the food product flows and fills the treatment vessel, which is then closed and pressurized. The treated product is then driven to an aseptic (or clean) packaging step. The food is not sterilized during the HPP treatment; therefore, HP treatment can be classified as a nonthermal pasteurization and can be used commercially for refrigerated, lowacid ($pH < 4.5$) or low-water-activity products (e.g., jams). Since the food is processed prior to packaging, no special requirements need to be fulfilled. Therefore, packaging solutions for the packaging of HPP-treated food in a semicontinuous unit are similar to those of aseptic packaging. Refer to the aseptic packaging section for packaging solutions.

The HPP treatments by batch processing present several differences with respect to the semicontinuous one, the most relevant being that the product is packaged before the treatment. Figure 1 presents a batch HPP scheme. The packaged product is introduced in the vessel, which is then filled with a pressure-transmitting fluid; this can be water or aqueous solutions of ethylene glycol, propylene glycol, or other soluble oils. Then the vessel is closed, and pressurization (100–1000 MPa) takes place by pumping additional pressure-transmitting fluid. After the treatment, pressure is released in a few seconds, the vessel is opened, the fluid may be removed, and the packages are removed, cleaned, and sent to the next packaging step.

Except for the case of foods processed by semicontinuous units, packaging is a key factor to the feasibility of high-pressure processing, because it must preserve the intrinsic qualities of the food products without losing integrity, barrier performance and mechanical characteristics. This section highlights the requirements that a food package has to fulfill to be used in high-pressure treatments, lists the effects of such preservation technology over packaging materials, and presents some of the most conventional solutions.

PACKAGING REQUIREMENTS

During the HPP process, the food packages are immersed in water or in aqueous solutions and exposed to high pressures. Therefore, besides typical requirements of food packaging such as airtightness, minimal food-packaging interactions, and adequate optical and barrier properties, the package must transmit the hydrostatic pressure to the packaged product, withstand the action of the pressurizing liquid, and resist the action of pressure without relevant changes. To transmit the hydrostatic pressure to the packaged product, flexible packaging is more convenient than rigid packaging. Rigid packages such as metal cans or glass bottles tend to fracture or become distorted as a result of the high pressure applied (4). The use of packaging structures designed with cellulosic or other hydrophilic materials at the outermost layer should be reconsidered since it could present signs of deterioration caused by the direct exposure to water.

It is then crucial to understand the effects of high pressure on relevant properties of plastic materials to ensure the safety of the foodstuffs along their shelflife. Isostatic pressure causes the food product to compress three-dimensionally up to approx 12% at 600 MPa.The package should follow this volume change without alterations. Rigid containers do not compress to this extent, and therefore they usually get distorted. On the other end of the spectrum, expanded polymeric materials such as expanded polystyrene or expanded polypropylene can be compressed a minimum of 80% due to the large percentage of air occluded in the package walls, and their use should be avoided.

PACKAGING SOLUTIONS

Many flexible packaging materials have been shown to withstand HPP without visible signs of integrity loss. One of the most important factors that have contributed to the success of plastic films and sheets is the availability of

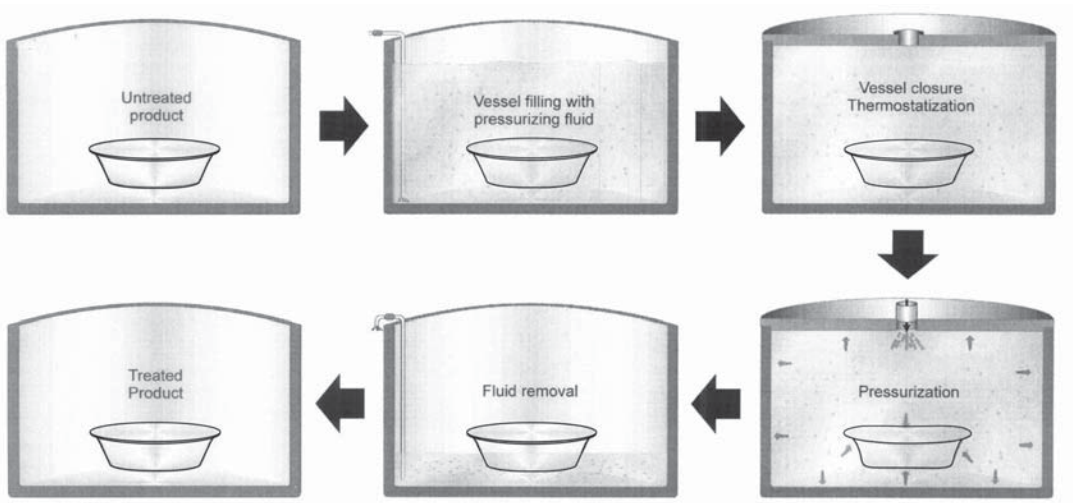

Figure 1. Scheme of a batch high hydrostatic pressure process.

multilayer structures. A suitable multilayer structure used to pre-package foods must have sufficient flexibility, resilience, and resistance to delamination during the compression process, because a loss of packaging integrity would result in major food safety and quality deterioration (5). Initially, the innermost layer of the structure should be selected to limit food–package interactions (unless the substance exchange is desired and beneficial; see Active Packaging) and to provide hermetic a seal. Heat-sealable materials such as polyolefins could be a good option, although other sealing process can widen the materials spectra (see the sealing section). The outermost layer of the structure should resist the action of the pressurizing fluid. With the exception of highly hydrophilic materials such as polyvinyl alcohol, most polymeric materials could be suitable. Reversed printed oriented polypropylene, polyester, or polyamide films can be good choices.

Finally, the barrier properties to oxygen can be tailored to the product requirement by varying the materials and the number of layers in the structure (see the barrier section). Many structures have been tested using PA, EVOH, PVOH, aluminum foil, or polymer films coated with aluminum, silicon oxide (SiOx), or aluminum oxide (AlOx). Most of these packaging structures have been tested with no relevant changes caused by the HPP treatment. The packages showed sufficient degree of flexibility and resilience to compensate for the reduction in volume, no significant changes in tensile strength being observed between controls and HPP treated samples.

Heat seal strength is a critical point in packages, because if any void is present or generated by the treatment along the seal of the package, the safety of the packaged food will be seriously compromised. In general, thermoplastic materials have been proven to withstand HPP without significant losses in sealability. In other technologies, such as in retortable food packages, the seal is exposed to high temperatures and pressure changes in both directions, which can affect and even break the sealing. However, the sealing is not exposed to such critical conditions in HPP treatment, since the package always receives the pressure from the outside and the temperature rarely reaches 70°C.

High-pressure-induced delamination has been observed in flexible packages made of composite materials and having relatively large headspace volumes. Gases reduce their volume during the HPP treatment much more than food and packaging materials, promoting tensions and failures. Headspace volumes should be minimized to reduce the chances of having seal damages, delaminations, and large deformations. The presence of large headspace volumes increases largely the time to obtain the required pressure since more pressurizing fluid has to be pumped in the vessel. Also the packaging design with materials of diverse nature can produce changes in packaging properties. Thus, aluminum and metal oxides present lower compressibilities than do polymeric materials. This difference can be responsible for the delamination and blistering observed in barrier structures containing aluminum layer or coatings which increase in delamination with exposure time and temperature (5, 6).

BARRIER PROPERTIES

The barrier properties are often the most relevant characteristic to be considered in the design of functional polymeric packages for food. Therefore, HPP-induced barrier changes can have a very negative impact concerning packaged food quality. In general, the permeability to oxygen, carbon dioxide, and water vapor do not change relevantly after the HPP treatment. Nevertheless, a large decrease of barrier has been observed in metalized films apparently due to the damage caused in the aluminum layer (4). It is also relevant to mention that HPP treatments produce much less damage than do conventional thermal treatments in the barrier properties of hydrophilic materials such as EVOH. The concurrence of low temperatures of treatment, shorter treatment period, and the presence of high pressure produces a much lower water sorption in those polymers, which results in the reduction of package plasticization and of the subsequent loss of barrier. The volume reduction of the voids present in the polymer (free volume) which takes place during the high-pressure treatment could be responsible for a decrease in solubility and a much slower molecular diffusion though the polymer matrix. These two parameters contribute to reduce the extent of mass transport through packages and food–package interactions. In agreement with this statement, migration studies showed that HPP treatment do not alter the migration values of flexible packaging structures (7).

Tests should be carried out to confirm the validity of a package for HPP treatments keeping in mind that, although most polymeric materials are suitable since their main properties are not modified, good sealing properties, design of the package structure with materials of similar compressibility, and the reduction of the package headspace volume will lead to a successful packaging solution.

PALLETIZING

A pallet is a low platform used to stack or accumulate several smaller units of product so that they may be conveyed by mechanical means. Pallets may be made of wood (see Pallets, wood), plastic (see Pallets, plastic), or corrugated kraft board (see Pallets, expendable corrugated), and they are usually rectangular rather than square. The arrangement of product on the pallet (pallet pattern) is critical to an orderly, compact loading, and distribution system. Patterns correspond to the pallet shape and are designed to afford the maximum load in the minimum space without forfeiting structural strength. Pattern design may be restricted by the primary and secondary product packages, the shipping method and size of conveyance, as well as warehouse space.

The quantities of pallets and tiers also are determined by the shipping container, shipping method, and distributor space allotment. The second layer, or tier, may be exactly like the first, or rotated 180°, or it may be an entirely different pattern. Unless the cases are heavy and/or large, the pattern of the second layer is changed to form a load that will not break apart. Rotation by 180° is a common solution. The stacking strength of the load must be judged against the space limitations of the pattern. A column stack (each layer identical) with corners one above the other is strongest, but it is most likely to topple because the tiers are not interlocked. Many different pallet patterns are shown in Figure 1.

PALLETIZING

Once the pattern and number of tiers have been designed, the method of product-to-pallet transfer is determined. Hand palletizing is the most versatile method and is effective when loading is slow. Single-product, single-pattern, high-level palletization developed from hand palletization. Recent technological advances permit automated palletization of almost every product, but this process may not always be economical. The selection of a palletizer demands consideration of performance requirements and space limitations. The palletizer is an element in the total packaging/distribution system, and it should never be a limiting factor. The palletizer should be capable of speeds exceeding normal line speed by 5–10%, and change over time from product to product should be minimal. A fully automatic palletizer does not require an operator in attendance full time.

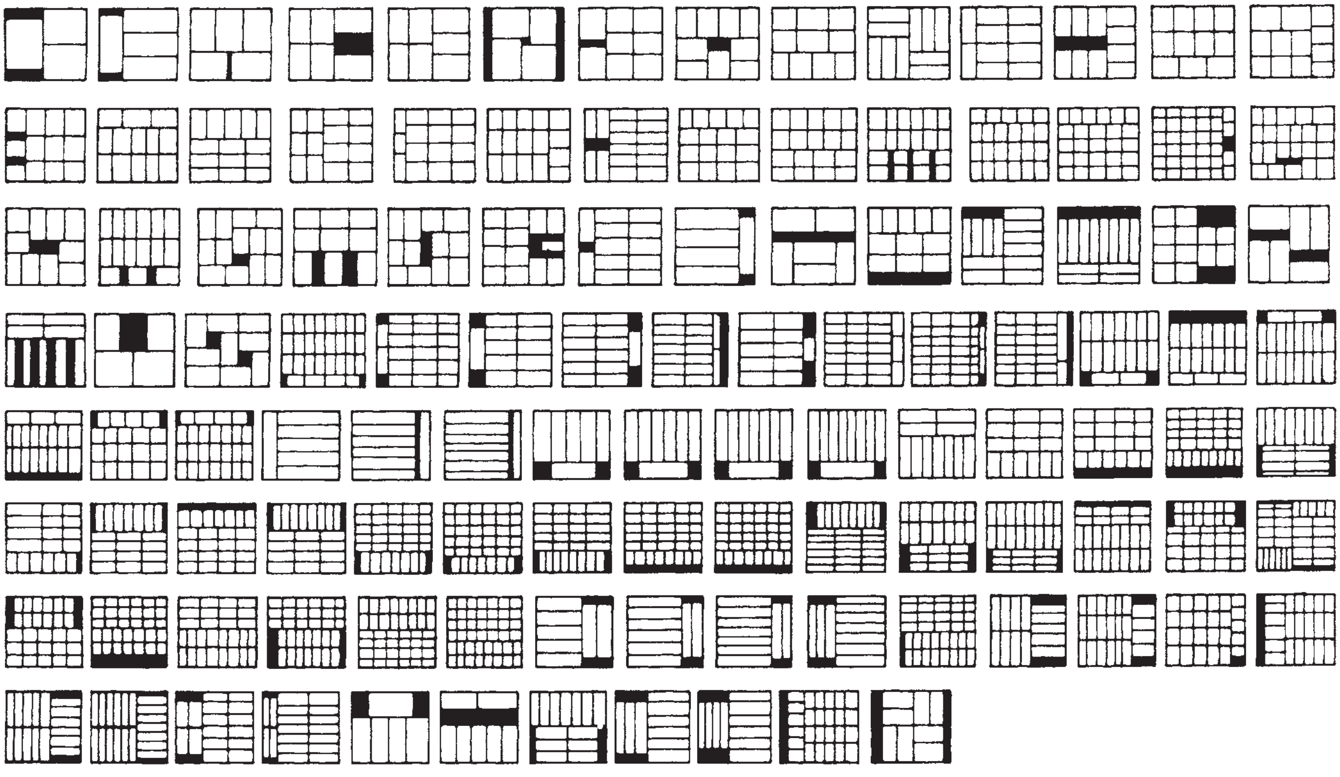

Figure 1. Pallet patterns.

High-Level Palletizers. High-level palletizers (also called moving-pallet palletizers) pick up the product at a level above the height of a full pallet and form the tier pattern on a bed. The pallet is raised to the bed level, and the product is transferred (by a sweep or rake off system) to the pallet. Then, the pallet is lowered one layer, and the next tier is formed in the same manner and placed atop the first. This process continues until the pallet reaches the prescribed height. It is then transferred out to be replaced by an empty pallet that is raised to the bed for a repetition of the process. Numerically controlled tape programs provide simple multipattern capability and are adaptable for a variety of users.

Low-Level Palletizers. Low-level palletizers (also called "fixed-pallet" palletizers) were developed more slowly than high-level palletizers, but with the introduction of programmable logic controllers, they have become highly competitive with high-level units in cost and speed. The low-level palletizer operates at floor level (see Figure 2). The pallet is neither raised nor lowered, and the tier is formed at low level. The transfer bed or apron is raised or lowered to the appropriate level, and the tier is transferred to the pallet. The bed returns to the tier-forming position, and the next layer is formed. This pattern is repeated until the pallet is full. After the full pallet is discharged, an empty one is transferred into the load station, and the process is repeated.

Robotic Palletizers. In the past, "pick-and place" systems picked up a product at one point and placed it at a second point repeatedly. At present, robotic palletizers may be thought of as intelligent, discriminating systems capable of picking up several different products and placing them at several different points. These units are usually capable of movement in two or three planes, often on rotational coordinates that operate from a fixed point at the center of a circle. They are capable of picking up a variety of products from one point on the circumference of the circle and placing it on one of several pallets located at other points around the circumference. Robotic palletizers are most applicable when a variety of products require different pallet patterns and relatively slow speeds are acceptable.

Bulk Palletizers. The shift to bulk handling has reduced the demand for case depalletization of empty containers. Numerous applications exist for palletizing without benefit of a case, for example, the transfer of empty cans from the can manufacturer to the filler. Cans are bulk palletized successfully because they are strong enough to withstand relatively rough treatment. Improved handling methods permit bulk palletization of glass containers, and many plastic containers now are being bulk palletized as they gain a greater place in the market.

Nested container-to-container bulk pallets can save up to 15% space for the same number of containers compared with column-stacked cases. That means 15% more containers can be shipped in the same truckload to the user, which cuts time and expense. The compact loads also reduce warehouse requirements. In addition, bulk palletizing eliminates the labor and expense associated with uncasing equipment and additional conveyors for empty cases.

Bulk palletization is essentially an adaptation of high- or low-level palletization. The product is accumulated on a table or bed, then transferred by lifting a tier or clamping the perimeter and sweeping the tier onto a pallet. A corrugated sheet the size of the pallet, called a tier sheet, is generally used between layers to provide stability to the load. Increased stability can be gained by use of an inverted tray instead of a tier sheet.

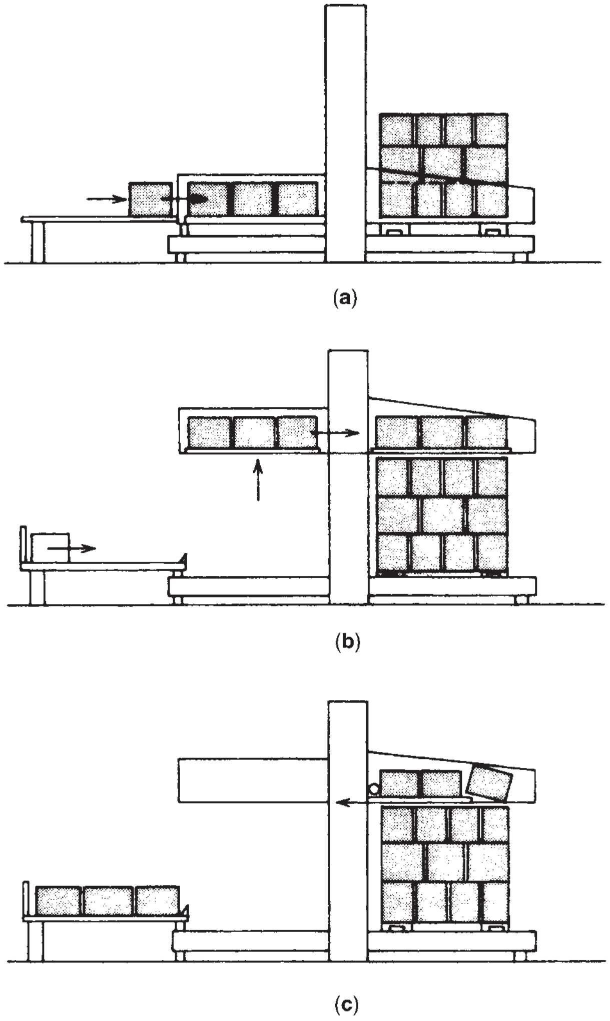

Figure 2. Operation of a low-level palletizer. (**a**) Operation 1. Sealed shipping cases feed in and are oriented to the preprogrammed pattern. When one row is formed, the cases move forward. The next row forms and moves forward, which continues until the layer is complete and the loading plate is filled. (**b**) Operation 2. The layer is lifted to the height of the existing pallet stack. The filled loading plate moves into position just above the pallet stack. (**c**) Operation 3. The loading plate retracts allowing the cases to settle, row by row onto the top of the pallet stack. The pallet is squared by a squaring bar, which also assures complete unloading. The loading plate returns to starting position where another accumulated load is ready.

Miscellaneous Palletizers. Other types of palletizers include drum palletizers, keg palletizers, and bag palletizers. In most cases, these machines address a particular end-use and are concerned only with a narrow portion of the market place.

DEPALLETIZING

The removal of product from pallet depends on the conformation of the product. Bulk depalletizers remove tiers of product from the pallet in much the same manner as bulk palletizers in reverse. In one approach, the tops of the containers are gripped mechanically, pneumatically, or with a vacuum, and the tier is lifted onto a discharge table. In another, the tier is swept onto the discharge table. Removal of the tier sheet or inverted tray is as critical here as in bulk palletization. Product stability is a key factor in all bulk handling operations and the primary determinant of method.

Depalletization of plastic cases or crates may require modified bulk depalletizers or specialized robotic depalletizers. Plastic crates usually have an interlocking feature that requires a tier to be lifted clear of the one below before transfer to the discharge table, thus precluding a sweep system. Most pail depalletizers must handle the products individually in addition to lifting clear of the pail below.

Depalletization of corrugated cases is more difficult than palletization. The flaps on the cases get caught on one another, which prevents consistent sweepoff. Corrugated cases do not interlock, so clamping the perimeter causes the center cases in the tier to slip down. The most reliable way to remove a whole tier of corrugated cases is to use tier sheets, but the additional cost discourages wide acceptance. The next-best method is a combination clamping and vacuum system. Some automated warehousing systems remove cases from pallets one at a time in a type of “order-picking” operation. Little effort is being expended today on finding better case-depalletization methods because the shift to bulk handling has shifted research and development work in that direction as well.

PALLETS, PLASTIC

L. T. Luft
Menasha Corporation
Neenah, Wisconsin

Plastic pallet construction began during the late 1960s when the low cost of commodity resins such as polystyrene (PS) and polyethylene encouraged scores of molders to enter this promising market. In the early 1970s, high-density polyethylene (HDPE) was priced at about $0.16/lb ($0.35/kg). Still in its infancy, the plastic pallet market was severely curtailed when prices of commodity resins more than doubled at the time of the 1973 oil embargo. A 2:1 price differential between wood and plastic pallets quickly became a 4:1 price disadvantage.

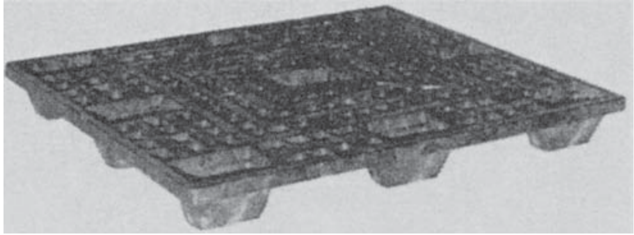

Figure 1. Typical single-faced plastic pallet.

Several changes that took place in the 1980s have encouraged and use of plastic pallets as follows:

Packaging is now often considered part of direct production cost instead of fixed overhead. This highlights the savings generated by reusable pallets (1).

Adoption of the just-in-time inventory concept (2) including reusable packaging, inventory reduction, and higher quality.

Greater use of robots and automated palletizers that require uniform size/weight pallets.

Increased awareness and regulation of plant sanitation.

Typical single- and double-faced pallets are shown in Figures 1 and 2.

Materials. Most plastic pallets are manufactured from HDPE (see the Polyethylene, high-density article). Materials such as polystyrene, fiberglass-reinforced plastics (FRP), and polypropylene are used occasionally. Heavy pallet loads and unsupported pallet racking may dictate the use of stiffer polystyrene (see the Polystyrene article).

FRP (see the Thermosets article) are used for low-volume custom pallet requirements or prototype pallets. In this situation, low-cost wooden tooling is used with the hand-layup fiberglass technique. Polypropylene (see the Polypropylene article) has been used to construct structural foam plastic pallets by companies with excess virgin or regrind polypropylene. Polypropylene is not normally used in pallet construction because it requires relatively expensive impact modifiers for cold-weather performance.

Polyethylene is favored for a many reasons, such as commodity status (i.e., low cost, uniform performance, readily available, and wide acceptance); excellent resistance to impact; good performance under a wide range of operating conditions (i.e., temperatures of –30 to 150°F (−34 to 66°C), indoor or outdoor applications; light- to heavy-weight loading; outstanding chemical resistance to most acids and bases; U.S. Department of Agriculture (USDA) and U.S. Food and Drug Administration

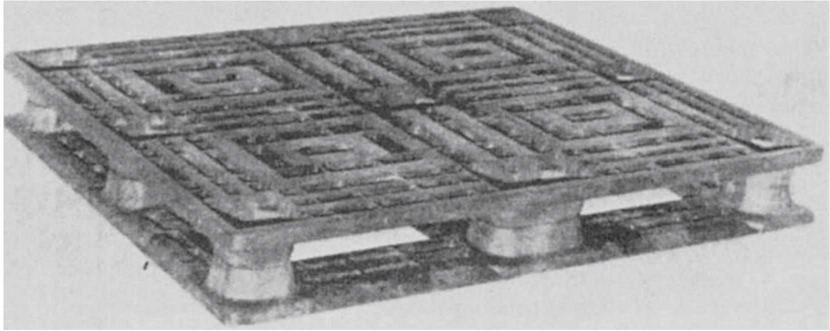

Figure 2. Typical double-faced plastic pallet.

(FDA) clearance for use in food and pharmaceutical plants; easy cleaning; and outstanding molding and design flexibility.

Polyethylene's one glaring weakness is its inability to resist deflection (bending) under load. This deflection problem is especially serious in pallet-racking applications. Unsupported racks do not have center supports or decking. In these racks, the pallet must span an open space while maintaining the load. With loads of over 2000 lb (907 kg), plastic pallets are prone to bending (deflection). In addition to the initial deflection, the plastic pallet will continue to bend or creep for up to 2 weeks. Over time, it may become difficult to reenter the pallet with the forks of a lift. Most standard pallet rack, drive-through rack, and gravity-flow rack are "unsupported."

In situations where heavyweight racking is a must, steel-reinforced plastic or stiffer PS are frequently used. Steel reinforcements add expense, and compared to HDPE, PS costs more and offers less chemical and impact resistance. One solution to the racking problem is in the design of rackable pallets. Two-way-entry pallets can rack over 3000 lb (1360 kg) in an unsupported rack (see Figure 3). Experimental plastic resins are also being tried in an attempt to solve the racking dilemma.

Design and Construction. Pallet design and the method of construction greatly influence pallet performance, price, and acceptance. Today plastic pallets are designed and built using several different processing techniques (see Table 1).

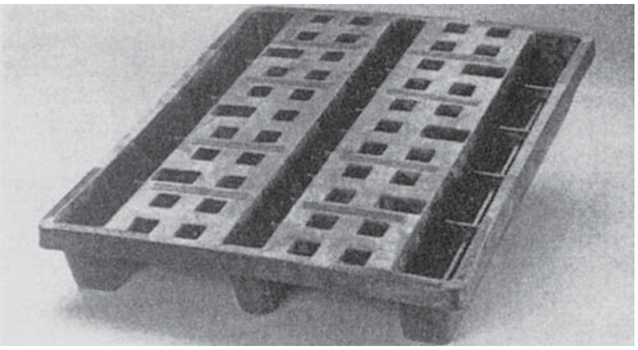

Figure 3. Two-way entry racking pallet.

Structural Foam Molding. Most plastic pallets made today are made by structural foam molding (3, 4). This low pressure injection molding process produces parts with a solid skin surrounding a foamed core. Compared to high-pressure injection molding, structural foam molding allows the economic production of heavy wall sections and helps reduce stress points throughout the pallet. The structural foam process provides outstanding design flexibility. Wall thickness of $\frac{3}{16}$–$\frac{3}{4}$ in. can be molded to produce pallets ranging from lightweight single-faced units to super-duty racking pallets. Another benefit is high-speed production, with cycle times as low as 2–3 min. Good resistance to impact, high strength per pound (kilogram), and good deflection strength are all positive characteristics that make structural foam a good choice for large-scale production of both custom and proprietary pallets. The chief limitation of structural foam is that relatively high volume (3000 total units minimum) is required to amortize the relatively high tooling cost. When compared with high-pressure injection molding, the tooling for structural foam may be less costly. Most low-pressure foam tools may be built from machined aluminum or Kirksite, which reduces tooling costs by up to 50%. When structural foam tools are built from steel, the cost savings are negligible.

Injection Molding. High-pressure injection molding (see the Injection molding article) also offers design flexibility. It is used for the production of pallets that range from light weight disposables to heavy-duty 60-lb (27-kg) reusables. Injection molded parts generally have narrower wall sections than structural foam, ≤ 0.300 in. (≤ 7.62 mm), and rely on their rib design for structural integrity (5). Injection molding excels in light weight, large-volume production. Cycle times for $\frac{1}{8}$ -in. (3.2 mm) injection-molded pallets can be under one minute. Heavy-duty parts with wall section $\frac{1}{8}$in (3.2 mm) offer high strength and excellent durability. Because high molding pressures require expensive equipment and hardened-steel tooling, high-volume production runs $\geq 10{,}000$) are generally required to amortize tooling and press costs.

Table 1. Plastic Pallets, Production Methods

Molding Process	Plastic Pellets Advantages	Plastic Pallets Disadvantages	Ideal Pallet Application	Secondary Applications	Tooling Options	Average Cycle	Wall Thickness
Structural-foam molding	Economic production of heavy-wall sections Short cycle times Good impact resistance Good deflection strength High strength per pound (kilogram) Good weight and dimensional tolerance allows complex shapes	High-cost tooling and processing equipment	Large-volume custom or proprietary pallets with runs of 1000 pallets or more Minimum custom order quantity 3000 units	Manufacture of heavy-duty racking pallets is possible by using filled polyethylene pallets or polystyrene Wall thicknesses of up to 1 in. (2.54 cm) can be used when necessary	Kirksite aluminum steel	2–4 min	$\frac{3}{16}$–1.0 in (4.8–25.4 mm)
Injection molding	Flexible process allows production of light-weight disposable as well as heavy-duty returnable pallets; allows complex geometry	Highest tooling cost Highest equipment costs High energy costs	Largest-volume custom and proprietary pallets	Lightweight disposable pallets can be inexpensively produced by keeping wall sections narrow and cycle times short; heavy-duty racking pallets can be manufactured by using heavier wall sections and a well integrated rib design	Hardened steel	30 s–3 min	$\frac{1}{32}$–$\frac{3}{8}$ in. (0.8–9.5 mm)
Rotational molding	Low equipment cost Low tooling cost Production of double walled parts	Relatively long cycle times Limited weight and dimensional stability Limited to simpler design (geometry)	Low-volume production of large pallets Custom pallet projects of 1000 units or more are feasible	Manufacture of heavy-duty racking pallet is possible by ecapsulating steel reinforcements into the pallets	Cast- aluminum fabricated metal-plated nickel	3–6 min	$\frac{1}{8}$–$\frac{1}{4}$ in. (3.2–6.4 mm)

(*Continued*)

Table 1. Continued

Molding Process	Plastic Pellets Advantages	Plastic Pallets Disadvantages	Ideal Pallet Application	Secondary Applications	Tooling Options	Average Cycle	Wall Thickness
Vacuum forming	Low equipment cost Low tooling cost	Relatively long cycle times Limited wall thickness Limited depth of draw Limited design complexity	Lower-volume, low cost, lightweight pallets Pallets projects of 500 units and above are feasible	Heavier loads up to 3000 lb (1361 kg) can be accomodated by using twin-sheet vacuum forming Vacuum-formed pallets are not generally used for heavy-duty racking applications	Metal Plaster Epoxy Wood	3–6 min	$\frac{1}{8}$–$\frac{1}{4}$ in. (3.2–6.4 mm)
Reaction-injection molding	Lighter weight tooling and equipment costs less than injection molding processes	Limited deflection strength	Lighter duty custom and proprietary pallets	Fiberglass-reinforced reaction injection molding is used to increase deflection strength for heavier applications	Lightweight steel Aluminum Kirksite Sprayed metal	2–4 min	$\frac{1}{8}$–2.0 in. (3.2–51 mm)
	Allows complex designs Lower pressures and temperatures afford significant savings (70%) over injection-molding processes	Slightly longer cycle times than injection-molding processes Limited dimensional stability	Pallet projects of 1000 units and above should be justifiable	Steel reinforcements can be encapsulated for additional strength			

Rotational Molding. Rotational molding (3) (see the Rotational molding article) uses a heated tool into which solid or liquid polymer is placed. This process offers the most economical tooling costs. Myriad sizes and designs of a relatively low quantity (1000–2000 units) can be economically justified. Design innovation, including the molding of steel-encapsulated, smooth-skinned pallets is a feature of rotational molding. Rotationally molded parts offer good resistance to blunt impact and the repair of small puncture damage is possible. Its drawbacks include relatively long cycle times (as high as five min) and relatively narrow $\frac{3}{16}$-in. (4.8-mm) wall thickness (6), which limits rotationally molded pallets to medium-duty applications. Some rotationally molded designs can accommodate the addition of steel reinforcement for heavier loads and pallet racking operations.

Thermoforming. Thermoformed plastic pallets (see the Thermoforming article) are offered in dozens of low-cost lightweight designs. Inexpensive tooling allows faster amortization of low-volume custom pallets. For example, custom reusable dunnage trays are often thermoformed. Thermoforming, too, has its disadvantages. With cycle times averaging 5-min (5), high-volume projects are sometimes impractical. In addition, relatively narrow wall thicknesses limit these pallets to lighter loads, usually under 3000 lb (1360 kg). They are not often found in heavy-duty racking applications. Twinsheet vacuum forming allows heavier loads with reduced deflection, but it lengthens cycle times and adds cost.

Reaction Injection Molding (RIM). RIM polyurethane pallets have entered the market. RIM uses two or more liquid components (polyol and isocyanate) that are mixed, then injected into a closed mold. These two components react to form a finished polymer, which takes on the shape of the tool. The chief advantages of RIM are lower cost equipment and tooling, especially in building large parts such as pallets. The chief disadvantage of RIM pallets is the lower resistance to deflection. For this reason, many large RIM parts are steel reinforced or manufactured with fiberglass or mineral fillers. These stiffening techniques add cost.

Advantages. Plastic pallets are used primarily in the food, pharmaceutical, textile, high-technology, and automotive industries. Because of the higher cost of plastic pallets, most purchasers use their pallets in-plant, or in closed-loop shipping system. Plastic pallets are almost always found in applications where the user can retrieve most of the pallets after each trip.

Plastic pallets of all types offer certain generic advantages which make them attractive alternatives to other pallet materials. Listed below are some of the plastic pallet's chief benefits.

Long Pallet Life. The relatively expensive plastic pallet must offer a long service life. Many customers experience plastic pallet life of 5–9 years and more (7).

Reduced Load Damage. Smooth molded plastic helps eliminate product damage. There are no broken boards or protruding nails to damage-sensitive loads (7).

Easy Cleanup. Plastic pallets are easy to clean and keep clean (8).

USDA and FDA Clearance. Both polyethylene and polystyrene are acceptable in food and pharmaceutical plants. Pallets made from these materials can be approved on a case by case basis by the on-site inspectors.

Reduced Worker Injury. Smooth construction and consistent weights help to eliminate minor cuts and back strain (7).

Chemically Inert. Polyethylene plastic pallets are highly resistant to acids and bases, and at ambient temperatures, hydrocarbon solvents.

Moistureproof. Plastic pallets will not absorb moisture and soak loads. Plastic pallets will not rust or break down in wet conditions (8).

No Harbor for Pests. Plastic pallets will not harbor or support the growth of worms, eggs, molds, or mildew.

The design advantages of plastic pallets can include the following:

Nestability (single-faced pallets can nest with each other when unloaded). This feature can save over 50% of valuable truck or dock space.

Interstacking (the ability to positively locate one loaded pallet on top of another loaded pallet).

PAPER

Updated by Staff

INTRODUCTION

There is no strict distinction between paper and paperboard, particularly in view of the tremendous variation in density possible with current technology. Generally, structures less than 0.012 in. thick (12 “points” or 305 μm) are considered paper regardless of weight per unit area. Except for the use of paper as an overwrap for folding cartons, most packaging papers are used in flexible applications.

A large number of grades of paper and board are available for packaging and are employed for many different purposes. Packaging paper grades range from simple wrapping paper (made from mixed recovered paper) to kraft paper and are predominately supplied in rolls. They are made from virign pulps (sulfite/kraft pulp), from recycled fibers, or from mixtures of chemical pulp and recycled fibers. These grades are used in the production of bags, beer mats, carrier bags, and gift wrapping paper for example.

For the foodstuff sector, special types of paper and board are produced which must fulfill the requirements of the food laws. These papers are used in the nonfood sector—for example, as coating papers. The possibilities of combination with each other and with other materials, such as plastics, are numerous. In this way, special packing materials can be produced for most packaging purposes (1).

The primary intermediate product used to make paper is wood pulp. The properties of an individual paper or paperboard are extremely dependent on the properties of the pulps used. Pulp preparation from deciduous (hardwood) or conifer (softwood) species may be done by mechanical, chemical, or hybrid processes (2, 3). These hardwood or softwood pulps may be used unbleached, or they can be bleached to varying degrees by a diversity of techniques.

Mechanical pulps produce papers that are characterized by relatively high bulk, low strength, and moderate to low cost (4). Their use in packaging is very limited.

The kraft (sulfate) pulping process, introduced about 100 years ago, dominates the chemical pulping industry: Yields are higher, pulps are stronger, and process chemicals more completely and economically recovered than with any other process. Although the sulfite processes were extremely prominent 75–125 years ago, their chemicals are difficult to recover, the resultant pulps are significantly weaker than those produced by the kraft process, and they produce no unique paper properties. Unbleached pulps are generally stronger, stiffer, and more coarse than their bleached counterparts, but papers made of white, comfortable fibers are used in many more applications. General treatments of pulping and bleaching are provided in references (5–8).

The standard ream basis for packaging papers in the United States is 500 sheets cut to a size of 24×36 in. (61×91.5 cm) (3000 ft^2 or 279 m^2). On this basis, packaging papers normally weigh 18–90 lb/ream (8.2–40.8 kg/ream), but some specialty applications require weights as low as 10 lb (4.5 kg) or as high as 200 lb (90.7 kg)/ream. At any given basis weight, density may typically be 0.08–0.16 lb/in.^{3} (2.2–4.4 g/cm^3), providing a very wide range of thickness and strength properties.

The two most general classifications of packaging papers are coarse and fine. Coarse (kraft) packaging papers are almost always made of unbleached kraft softwood pulps. Fine papers, generally made of bleached pulp, are typically used in applications demanding printing, writing, and special functional properties such as barriers to liquid and/or gaseous penetrates.

KRAFT PAPERS

In order to meet the high strength requirements, kraft papers consist of primary or a mixture of primary and secondary fibers of kraft pulp. They are used mainly for packaging purposes.

Kraft papers, produced by the kraft process, derive their name from the German word for “strong.” Kraft paper is made from at least 80% sulfate wood pulp. It is typically a coarse paper with exceptional strength. Sometimes made with a rough finish to keep bags from sliding off piles, these papers are often made on a fourdrinier machine and then either machine-finished with a calendar stack or machine-glazed by using a Yankee dryer (5, 6). The surface of these papers is acceptable for printing by letterpress, flexography, and offset processes (see Printing). In addition to wrapping applications, kraft papers are used for multiwall bags and shipping sacks (see Bags, multiwall), grocers’ sacks, envelopes, gummed sealing tape (see Tape, gummed), butcher wraps, freezer wraps, tire wraps, and specialty bags and wrappings that require economy and strength. Paper for grocery bags and fast food bags must have a high resistance to tearing. The fiber of choice is softwood kraft, which may be bleached or unbleached (9). Many papers formerly manufactured from sulfite pulps, especially those of tissue weight, are now manufactured with kraft pulps. Unbleached “sulfite” papers are used for products such as oil cans (intermediate liner) and single-service food packages.

Extensible kraft papers have satisfied a special niche in the packaging industry. Although creped papers have long served both decorative and functional roles, other papers capable of absorbing energy at sudden rates of strain have become increasingly important in uses such as shipping sacks. Conventional creping is performed either at the wet press section of a paper machine (wet crepe) or on a Yankee dryer (dry crepe). Dry creping is most commonly used to generate qualities such as softness and absorbency; wet creping is a technique for making tough, flexible papers capable of absorbing tensile energy. A secondary creping operation rewets a dry sheet, and it may be done in-line on the paper machine or as an independent manufacturing process. Whereas a standard kraft paper might have a stretch (before breaking) of 3–6%, creped papers generally may be stretched 35–200% of their original length before breaking. Manufacturers of creped, extensible, and other coarse (kraft) papers may be found in reference (10).

BLEACHED PAPER

Packaging applications that place a higher priority on printing, writing, and special functional properties than on economy and strength generally utilize bleached papers. The pulps used to manufacture bleached papers are relatively white, bright, and soft, and they are also receptive to special chemicals necessary to develop many functional properties. Although generically not as strong as unbleached kraft papers, bleached papers can be manufactured to meet simultaneous requirements of both strength and printability. Their whiteness enhances print quality and generates a perception of cleanliness and quality. The aesthetic appeal of bleached packaging papers may be augmented by clay coating one side (C1S) or both sides (C2S). The increasing demand for a combination of functional performance and top-quality graphics favors the C1S manufacturer who can satisfy the variety of challenges of this market.

VEGETABLE PARCHMENT

Vegetable parchment is a highly waterproof, greaseproof, boilproof paper of high purity. It is used in the packaging of fats in combination with aluminum foil or a plastic coating. Silicon-coated parchment paper has a wide range of applications—for example, in antiadhesive papers (1).

The process for producing parchment paper was developed in the 1850s, making it one of the grandfathers of special packaging papers. By soaking an absorbent paper in concentrated sulfuric acid, the cellulosic fibers are swollen tremendously and partially dissolved. In this state the plasticized fibers close their pores, fill in voids in the fiber network, and thus produce intimate contact for extensive hydrogen bonding. Rinsing with water causes reprecipitation and network consolidation, resulting in a paper that is stronger wet than dry, lint-free, odor-free, taste-free, and resistant to grease and oils. By combining parchment's natural tensile toughness with extensibility imparted by wet creping, paper with great shock-absorbing capability can be produced. Special finishing processes provide qualities ranging from rough to smooth, brittle to soft, and sticky to releasable. Parchment was first used for wrapping fatty substances like butter; but this versatile paper is now also used whenever food is prepared, frozen, packaged, or displayed, as well as when tough, lint-free, chemically pure surfaces are needed for special packages.

GREASEPROOF AND GLASSINE

Because cellulose is hydrophilic, it is a good substrate to use for resisting penetration of hydrophobic liquids. As noted above, vegetable parchment performs well as a greaseproof paper because it is essentially pore-free and composed of a hydrophilic material. "Greaseproof" paper is a substrate manufactured to also have an essentially pore-free consolidation; but mechanical refining ("buffing" or cutting) is used in its production instead of swelling with concentrated sulfuric acid. Refining fibrillates, breaks, and swells the cellulose fibers to permit consolidation of a web with many interstitial spaces filled in. Glassine paper is produced by further treating "greaseproof" paper with a supercalendar operation. The supercalendar step involves moist high temperatures (steam), pressure (several hundred pounds per lineal inch or ~100 kg/cm), and differential hardness (one roll typically cotton or soft rubber, the other roll hard rubber or metal) to polish the surface. Supercalendering a greaseproof paper generates such intimate interfiber hydrogen bonding that the refractive index of the glassine paper approaches the 1.02 value of amorphous cellulose. This indicates that very few pores or other fiber–air interfaces exist for scattering light or allowing liquid penetration. High transparency is achieved by intensive supercalendering. The paper is frequently colored. This paper is used, for example, for wrapping chocolates or for packing high-quality preserves.

Greaseproof and glassine papers are frequently plasticized to further increase their toughness. They have a reputation of running well on high-speed packaging lines, and they have served well for odor and aroma barriers. Like other flexible-packaging papers, they can be chemically modified to enhance functional properties (e.g., wet strength, adhesion, release). When waxed, they are standard materials for primary food pouches used to package dry cereals, potato chips, dehydrated soups, cake and frosting mixes, bakery goods, candy and ice cream confections, coffee, sugar, pet food, and so on. In addition to their protective functions, these papers heat-seal easily when waxed and reclose well. Greaseproof paper is neither waterproof nor boilproof.

WATER-, GREASE-, AND OIL-RESISTANT PAPERS

The distinction between greaseproof papers and grease-resistant papers is a fairly subtle one, involving an understanding of the methods of penetration of liquids into surfaces. Because the primary mechanisms involve capillary penetration and/or wetting, it is appropriate to consider the severity of the packaging requirement. The requirement may be for minimal staining by grease, oil, or water under negligible pressure; or it may be for absolute resistance to any penetration of the liquid over long periods of time and/or under substantial pressure; or it may lie between these extremes. Parchment, glassine, and greaseproof papers offer decreasing protection from grease and oil at the more restrictive end of the spectrum. As noted above, their resistance is generated by the lack of capillaries and the oleophobic nature of cellulose. Greaseproof paper can be made resistant to grease primarily by a beating process and by the addition of auxiliary agents (1).

A consideration in designing primary packages is the economics of using the various barriers available for the job. A bag for a single-service consumable (e.g., French-fried potatoes) may require resistance to staining for only several minutes. A lubricating oil package, on the other hand, may require a stain-free barrier for several months. Imparting sufficient resistance to liquid penetration to meet the requirements of the less demanding applications can be done very economically with chemical treatments. If grease and/or oil penetration is the only concern, moderate resistance (package life of minutes to days) can be developed using waxes (see Waxes) and other low-surface-energy materials such as fluorocarbons. Fluorocarbon technology in papermaking has expanded from multiwall and consumer bags to labels, coupons, and carryout food packaging, perishable bakery goods packaging, candy and confection packages, and form-and-fill packages where edge wicking may be an important consideration.

In many applications (e.g., carryout food packaging), resistance to both water and oils must be developed for adequate performance. The use of rosin-based chemicals for developing water repellency in paper requires the use of alum ($Al_2(SO_4)_3$) or other multivalent cations that destroy the grease-resisting properties of fluorocarbons. The simultaneous development of both water and oil resistance requires (a) the use of oleophobic chemicals that react with hydroxyl and carboxyl groups on the cellulose fibers and (b) the use of hydrophobic chemicals such as fluorocarbons, which have also been modified to react with the same cellulose functional groups. Typical oleopholic chemicals currently in widespread use are alkylsuccinic anhydrides and alkylketene dimers. The most successful economic choices are made through close consultation between the paper manufacturer and the user, which allows the careful selection of designs for meeting specific performance requirements. Grease- and oil-resistant papers can be made to run well in most any converting and printing processes.

WAXED PAPERS

Waxed papers are age-old papers that have served the packaging industry well in applications requiring direct contact with food for barrier against penetration of liquids and vapors, as well as heat sealability, lamination, and even printing. Waxing can be performed in-line with the paper-manufacturing process, in-line with printing, converting or lamination processes, or as a discrete process. A great many base papers are suitable for waxing processes, including (a) greaseproof and glassine papers and (b) water-resistant papers. Supercalendered base paper is designed for waxing and frequently contains titanium dioxidea as filler. This type of paper is used for wrapping candy. There are two fundamentally different waxing processes, generating different characteristics for the finished sheet (see Waxes). Wet waxing is an operation in which the wax coating is applied to the surface of the sheet. Surface wax is desirable for heat sealing and lamination and is essential for vapor-barrier development. Dry waxing is performed to absorb wax into the sheet, leaving a surface that often does not look or feel waxy. Penetration of wax allows additional surface treatments for special release applications, or for further lamination. Absence of the continuous film of wax on the surface characteristic of wet waxed paper also allows the dry waxed paper to “breathe” moisture, carbon dioxide, and oxygen.

Waxed papers provide an economical choice for primary food packaging not only because of their versatility but also because of their safety as tasteless, odorless, nontoxic, and relatively inert materials. Their widespread use in conventional packaging applications includes: delicatessen pickup sheets; box liners; cover, scale, and utility sheets; patty papers; sandwich wraps; and bags, laminations to other papers and paperboard for food trays, locker papers, carryout cartons, food pails, baking cups, folding cartons, cereal liners, and folding carton overwrap.

SPECIALTY-TREATED PAPERS

Many packaging applications require barrier to substances other than water, grease, or oil. Most food-packaging applications are well-served with water- and/or oil-penetration resistance, but a number of products require more elaborate barriers. Meat-wrapping paper demands exceptional strength; resistance to grease, moisture, and blood; easy release with no residual taste or odor; plus “bloom” retention. Freezer paper must remain pliable at low temperatures and must offer puncture resistance, moisture-vapor barrier, exceptional seal integrity, and easy release from frozen or thawed meats. Other products such as chemicals, drugs, cosmetics, personal-care items, and industrial products require package functions such as acid resistance, alkali resistance, alkali solubility, mold resistance, flame retardation, solvent resistance, organic polymer adsorption/absorption resistance or affinity, adhesion, release, tarnish or rust inhibition, heat stability, sterilizability, specific-ion adsorption, conductivity, resistivity, stiffness, or flexibility. Photographic protective wrapping paper is a black-dyed chemically neurtral paper that can be folded without breaking and is suitable for wrapping photographic film. To address the general manufacturing techniques or even the functional property classification of such a variety is beyond the scope of this publication. Reference (11) provides a general treatment of some of these products that have transcended proprietary technology.

WET-STRENGTH PAPERS

Conventional papers are not strong when wet. The most predominant fraction of paper's strength is the result of hydrogen bonding between hydroxyl and carboxyl groups of adjacent fibers. The removal of water during the papermaking process generates these bonds, and the process is reversible. The two strategies for manufacturing strong-when-wet papers are (a) keep the water out of the paper and (b) introduce additional chemical bonds between fibers which are not influenced by the introduction of water.

As mentioned above, paper that has been parchmentized is actually stronger wet than dry, principally because of the loss of individual fiber identity during the gelatinized stage of the process. Through advances in chemical technology, several more economical alternatives exist for generating wet-strength papers. In general, the chemicals used to augment the natural hydrogen bonding are crosslinked during the manufacturing process. Common chemicals for producing wet-strength papers include protein, urea, melamine, resorcinol, and other phenolic or amino resins crosslinked with formaldehyde, and condensation products of polyalkylene polyamines with dicarboxylic acids crosslinked with epichlorohydrin (12).

The conventional tests of wet-strength papers are for tensile, tear, and burst strength, because these are the most useful indicators of use requirements. The degree of wet strength is expressed as a percentage of original dry strength, and is referred to as the percent of strength retention. The typical range for sack or pouch papers is 15–30%. Wet strength may also be generated in a variety of permanence levels, so that the product will either remain tough-when-wet, or eventually disintegrate with soaking time or application of force.

ABSORBENT PAPERS

Papers designed for absorption of specific fluids are an important part of the packaging industry. Although they are a member of the class of "specialty-treated papers," they are distinctive enough to warrant separate discussion. Typically at the low end of the strength spectrum, absorbent papers must not only be exceptionally porous, they must also have surface modifications to render affinity to the target liquid. When that liquid is aqueous, they must generally also have a definitive level of wet strength. Providing the special affinity to a given liquid is often a proprietary technology involving chemicals that are substantive to cellulose and to the target liquid. This special class of papers currently services industries ranging from fresh-food packaging to industrial-products packaging.

TISSUE PAPERS

Tissues form a special group of fine packaging papers because of their versatile performance. Tissue is made of either virgin or recycled fiber. Always fairly thin, tissues range from semitransparent to totally opaque. They can be waxed or treated with any of the specialty treatments (e.g., edible oils, for fruit wrapping, antitarnish metal protection), or they can be used "as is" for applications ranging from intermediate lamination steps in composite-container construction (see Cans, composite) to gift wrapping. They may be made exceptionally weak for softness, or surprisingly tough in all directions. Tissue papers are generally either machine-finished (MF) or machine-glazed (MG). Machine finishing involves calendering between rolls that are usually constructed of highly polished steel that are hydraulically loaded to squeeze and polish both sides of the paper to similar levels of smoothness. Machine glazing of papers produces a smooth glazed side and a rough back side. The special finish is the result of drying the paper with 60–70% moisture on a Yankee dryer [diameter 6–18 ft (1.8–5.5 m)] with a mirrorlike surface. This glazing process produces a very smooth surface for printing, adhesion, release, or wet waxing. A physical fusion takes place with the surface fibers, producing a physical barrier similar to a cast film. MG papers may also be machine-finished to improve the smoothness on both sides or to produce intermediate rolls which process better through subsequent converting steps. A great many applications for tissue paper today utilize special treatments for adhesion or release in an intermediate package-manufacturing process where the paper's light weight and thinness make it an economical carrier for more costly substances (see Multilayer-flexible packaging).

COATED PAPERS

Coated papers is a term generally reserved for papers acting as a base for aqueous mixtures of clay and/or other mineral pigments with natural and/or synthetic polymers as pigment binders. The term does not typically refer to papers that have been extrusion- or solvent-coated with organics or plastics, or surface-treated with specialty treatments listed above for functional improvements. Aqueous coatings of paper are performed primarily for market appeal where graphics are important. Coated papers are consumed not only for labels and multiwall bags, but also for lamination or combination with other functional materials in composite structures. Coated papers are often coated on one side. Coated papers can be designed for printing by any process from letterpress to ink jet (see Code marking and imprinting). They can also be painted, bronzed, and punched. They are waterpoof and alkali-resistant to prevent the detachment of labels in washing machines. They are used, for example, as wrapping paper for chocolates, cigarettes, and soap. Coated packaging papers are bleached kraft papers having a one-sided matt or glossy coat and are suited for the production of bags and carrier bags. Packaging laminates based on cardboard and paper have been reported (13, 14). The most-valued grades are typically produced in discrete manufacturing processes that vary widely (5, 6, 8). Detail of coating technology state of the art are contained in annual *TAPPI Coating Conference Proceedings* (15).

NONWOVENS

Nonwovens are materials used as cloth substitutes, made entirely or partially from cellulosic fibers. As an industry, nonwovens is dynamic and growing in medical, health-care, industrial, food-processing, and consumer- and household-products areas. Differentiated from classical paper, which is formed in water and consolidated with interfiber hydrogen bonds, nonwoven-manufacturing technologies include resin and thermally bonded carded web process, melt-blown process, and an air-laid process (16) (see Nonwovens).

PAPER, SYNTHETIC

Tamerica Products
Chino, California
Updated by Staff

INTRODUCTION

Synthetic plastic paper is a calendered plastic sheet that is a unique mixture of clay (calcium carbonate) and polypropylene resin. This formulation makes it feel, look, print, and fabricate like paper, but with the durability and tear resistance of plastic. White opaque with a fine matte finish, it is a single-layered substrate that offers superior ink adhesion and has excellent bonding characteristics. It is easily printable (no pretreatment). Hop-Syn G2 synthetic paper is designed for printing high-quality heavy-gauge polypropylene and designated for packaging applications. Hop Industries, the maker of the Hop-Syn line, has reported an increase in sales of its products from its initial sales in 1997 of $\$22.9 \times 10^6$ to $\$45.2 \times 10^6$ in 2006 (1).

PROPERTIES

Temperature, Abrasion, Moisture, and Tear Resistance

Synthetic paper is dimensionally stable and can withstand temperatures ranging from −60°F to +200°F. Under any of the above conditions, it is resistant to cracking, abrasion, shrinking, or any distortion in color or sheet size. It is scuff-resistant and weather-resistant and has high opacity for two-sided printing.

It is 100% waterproof and will not be affected by moisture or humidity and offers superior tear resistance over paper.

Printability

Hop-Syn brand synthetic paper (trademark of HIC Industries Corporation, formerly Tamerica) is formulated with antistatic agents and offers a porous printing surface good layflat and a very close gauge tolerance suitable for high-speed printing. Its antistatic surface eliminates double-fed sheets when printing, folding, and stacking. Suitable commerical printing methods include flexography, rotary gravure, offset lithography, thermal transfer, rotary letterpress, and screen (1).

Its porous surface allows ink to be absorbed underneath its surface, preventing the printed image from being damaged by scuffing or scratching; this makes it easily washable with a damp cloth when removing stains such as grease, oil, foods, soft drinks, soaps, and/or detergents.

USES

Since synthetic paper is manufactured in a variety of gauge thicknesses from 0.0031 to 0.020 in both sheet and roll form, it has many new uses. Popular applications include displays, boxes, tags, labels, maps, charts, licenses, credit cards, menus, posters, signs, banners, calenders, greeting cards, and shopping bags. However, this is only a small sample of applications.

ENVIRONMENTAL CONSIDERATIONS

Synthetic paper (in this case Hop-Syn) is made from polypropylene resin and clay (calcium carbonate). These are nontoxic materials that contain no chlorine or other halogens, producing neither dioxins, hydrochloric acids, or other highly toxic materials. It recycles as a plastic, does not drip when burned, emits no toxic fumes, and leaves a clean ash when incinerated and can be easily recycled in the manufacturing process.

PAPERBOARD

B. W. Attwood
St. Annes Paper and
Paperboard Developments Ltd.
Updated by Staff

INTRODUCTION

Paperboard, often called simply "board," is one of the major raw materials used in packaging. The term includes boxboard, chipboard, containerboard, and solid fiber. Its application covers a wide range of uses from simple cartons (see Cartons, folding) to complex containers used for liquids. It can also be converted into drums for bulk packaging of chemicals or combined with other materials to produce containers large and strong enough for the protection of large, heavy, and often fragile items during transport. In addition to product-protection requirements, paperboard must often have at least one smooth surface capable of accepting high-quality print (see Printing). Paperboard is widely used because it meets the following criteria for successful packaging, namely to: contain the product; protect goods from mechanical damage; preserve products from deterioration; inform the consumer; and provide visual impact through graphical and structural design (1).

TERMINOLOGY

"Paper" is the general term for a wide range of matted or felted webs of vegetable fiber (mostly wood) that have been formed on a screen from a water suspension. The general term can be subdivided into paper (see Paper) and paperboard. There is no rigid line of demarcation between paper and board, and board is often defined as a stiff and thick paper. ISO standards state that paper with a basis weight (grammage) generally above $250\,g/m^2$ ($\sim 51\,lb/1000\,ft^2$) shall be known as paperboard, or "board." The definition becomes less clear because in some parts of the world, board is classed as such when its caliper (thickness) exceeds $300\,\mu m$ ($\sim$12 mil) [in the United Kingdom, $250\,\mu m$ ($\sim$10 mil)]. There are exceptions to the above: Blotting papers and drawing papers thicker than $300\,\mu m$ are classified as paper; and corrugating medium, linerboard, and chipboard less than $300\,\mu m$ are classified as paperboard.

It is also not possible to strictly define paperboard by its structure or by the type of machine used to produce it. For example, paperboard can have either a single- or multi-ply structure and can be formed on a fourdrinier-wire part, a single or a series of cylinder molds, or a series of modern formers, or sometimes by means of a combination of one or more of the above (see diagrams and related text). For a small part of the market, paperboard is produced by laminating sheets of paper together. In that case, the product is solid fiber (see Boxes, solid fiber).

The following terms are in general use in paperboard manufacturing and associated converting industries:

Basis Weight. This is the weight of a known area—for example, g/m^2 (grammage) or (lb/1000 ft^2), the weight in pounds of a ream (usually 500 sheets) of paperboard cut to its "basic size."

Caliper (Thickness). The thickness of the sheet expressed in micrometers (μm), or thousandths of an inch (mil or points) (mil = 25.4 μm).

Size of a Sheet. The width and length of a sheet of paperboard. The width, always expressed first, is the dimension cut at right angles to the direction of the sheet. Length is the dimension cut in the machine direction. For example, 20 × 30 in. means 20 in. (50.8 cm) cut across the machine by 30 in. (76.2 cm) cut in the direction of the machine. The first dimension is often termed the cross-direction and the second dimension the machine direction.

Structure. The composition of the web (see Figure 1).

Ply. A fibrous layer of homogeneous composition.

Topside. The side of the web opposite to the wire side is the normal paper definition for this term. In the case of paperboard, topside can also mean liner side, generally the better-quality face of the web. Some grades of paperboard are known as double-lined, in which case the two faces of the web are both of high quality.

Liner. A ply of good-quality fiber (usually white), on the topside.

Underliner. The layer (ply) of fiber between the external layer (topside/liner) and the middle.

Middle. The layer (ply) of fiber between the two external layers or between the underliner and an external layer.

Backs. The outside layer (ply) of fiber directly opposite to the liner layer.

Duplex (or Biplex). This is a board consisting essentially of two layers of different furnish.

Triplex. This is a board consisting essentially of three different furnish layers (external furnish layers may have the same composition).

Multiplex. This is a board with more than three furnish layers. Two or more of the layers can have the same composition. Also known as a multilayer board.

Furnish. The constitution of the various materials that are blended in the stock suspension from which the paperboard plies are made. The main constituents are the fibrous material (pulp or secondary fiber), sizing agent, fillers, and dyes.

STRUCTURE AND PROPERTIES

The structure of a typical multiply paperboard (see Figure 1) consists mainly of cellulose fibers. The most common source is mechanical and chemical pulps derived from wood. Secondary fibers are used widely in the cheaper grades. Other sources of cellulose fiber are occasionally used such as straw and esparto.

Examination of the structure shows that it consists of a compact network of the fibers bonded together by mechanical entanglement and chemical links. This structure can be a thick single homogeneous ply or, as is more often the case, of two to eight thinner plies. The multiply construction allows different types of fibers to be used for the different plies. Improved fiber economy is achieved by selected distribution of the fiber types through the web (e.g., by using cheaper fibers for the inner layers). Improved characteristics are obtained by using the correct selection of fiber for the individual layers (e.g., stronger fibers for the outer plies). A typical example of a multi-ply construction is a type of paperboard known as whitelined chip. The top ply (liner) is made of bleached chemical wood pulp, which provides surface strength, good appearance, and printing properties. For the other plies, secondary fiber is used.

It is of extreme importance that the individual plies of multilayer paperboard are bonded together. If the bonding is poor, the structure can break up, with resultant deterioration in strength during subsequent processing and use. The level of bonding achieved, which must meet certain requirements, is dependent on having the right balance of mechanical entanglement and chemical bonding. If, for example, a paperboard sheet is subjected to continuous folding (e.g., the hinged lid of a cigarette carton) and the bonding level is too high, cracking at the hinge will occur.

PHYSICAL CHARACTERISTICS

Mechanical Properties

Because paperboard has the same type of fibrous structure as paper, the strength-to-weight relationship is of the same order as that for paper. Because of its extra thickness and the bonding between the plies, it normally has considerably greater flexural rigidity (stiffness). The choice of furnish for the individual plies influences the

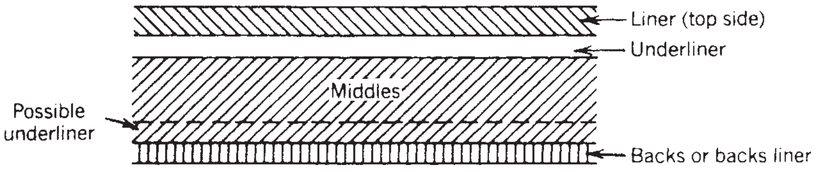

Figure 1. Structure of a typical multi-ply paperboard.

stiffness characteristics: Increased stiffness is obtained by increasing the strength of the outer plies by using a stronger pulp. During the converting of paperboard, it is often necessary to fold the sheet, and because of the thickness of the paperboard, large internal forces are generated. These can cause structural damage to the outer layers (cracking). In order to carry out the folding operation with minimum damage to the outer layers, the ply bonding is broken down locally by a creasing operation before the paperboard is folded. A paperboard sheet has grain characteristics similar to those of paper, with the sheet being strongest in the machine direction.

Optical Properties

Paperboard is normally opaque by virtue of its thickness, and only the color (whiteness, etc.) and occasionally the gloss of its outside plies are important. For a multi-ply paperboard with a white liner on darker underplies (e.g., when wastepaper is used), liner-ply opacity is important in order to maintain the white appearance of the liner surface. If a dark waste paper is used, an underply (underliner), consisting either of a lighter colored waste paper or a mechanical pulp furnish, is applied. This reduces the showthrough of the dark waste layer and improves the whiteness of the liner surface.

Absorptive Properties

The surface of paperboard is often required to have characteristics suitable for printing. To obtain these characteristics the surface layers are sized in ways similar to those used for paper. Paperboard, however, must often be glued during the manufacture of cartons, and for this the surfaces must be absorbent. In a typical case, the back surface has higher absorption characteristics than the liner ply, thus allowing the back ply to absorb some moisture during the gluing operation. Like paper, paperboard changes dimensions if it absorbs moisture. The degree of change depends on many factors such as type of fiber, condition of fiber, and structure of the fibrous network. This effect of dimensional change with change of moisture content presents many problems during converting operations such as printing. For example, in lithography and laminating (see Laminating), serious dimensional change can cause print misregister or curling of the paperboard web.

PAPERBOARD MANUFACTURE

The methods of fiber treatment (beating, refining, cleaning, etc.) are essentially the same as those used in manufacturing paper grades. After the sheet has been formed, the methods used for removing excess water and finishing the web (pressing, drying, calendering, etc.) are also essentially the same as those in the manufacture of paper. The main difference is found at the forming section of the machine, where the web is formed.

Sources of Fiber

The choice is between virgin, or primary, fiber derived from logs of wood, and recovered, or secondary fiber derived from waste paper and paperboard. About 55% of fiber used is virgin fiber and the remainder is from recovered fiber. It must be noted that fibers from all sources are not universally interchangeable with respect to the paperboard products that can be made from them. Some fibers are not not recoverable and some that are recovered are not suitable for recycling. Fiber cannot e recyled indefinitely.

Forming Methods

The following are the main forming methods used in the manufacture of paperboard:

- *Single-ply paperboard:* mainly Fourdrinier.
- *Multi-ply paperboard:*
  1. Fourdrinier with secondary head boxes.
  2. Rotary formers (multiples and using multilayer formers).
  3. Twin wire formers (multiples and using multilayer flow boxes).
  4. Combination of the above.

Fourdrinier Machine

The forming section of a Fourdrinier machine is made up of two essential parts: the flow box and the drainage table. The operation of both parts can influence the structure of the resulting paperboard web. It is normally the aim to deliver the fiber suspension, well-dispersed, to the moving screen at approximately the same velocity as the screen. The concentration going to the screen for paperboard generally ranges within 0.4–1.2%, depending on the furnish and product requirements (Figure 2).

On early machines and some still used today, preliminary dewatering takes place at the table rolls. The action of each table roll can be considered as a pump, with drainage being induced by the suction on the downstream side of each table roll, so that the drainage flow is intermittent. A positive-pressure pulse exists on the upstream side of each table roll, so water is forced up through the screen and the deposited mat. This mechanism has considerable influence on web structure. The magnitude of the positive and negative pulses depends on table roll diameter and screen speed.

Modern practice is to replace the table rolls by stationary foils. These units generate less intense suction pulses than table rolls, and the length of the drainage zone can be considerably extended. These foils are often closely spaced along the Fourdrinier forming table so that there is a gain in available drainage. Further down the Fourdrinier table, when concentration is 3–4%, suction flat boxes are used to continue the drainage at a rate controlled by the level of vacuum in the box. It should be noted that flat vacuum boxes can be used at the initial drainage zone, and today a unit is often used that in effect is a combination of foil sections in a vacuum enclosure

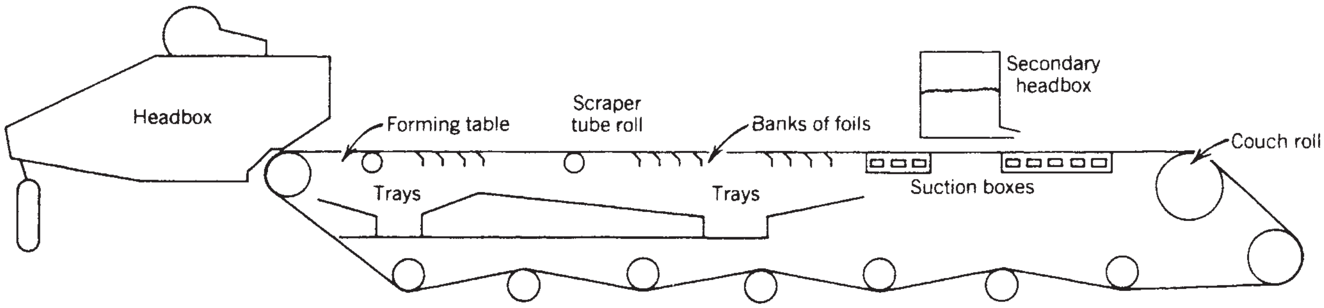

Figure 2. Fourdrinier forming.

(wet-suction box). When producing heavyweight papers and boards, because drainage is more difficult, it is usual to use additional vacuum boxes. This can lead to excessive drag on the screen, resulting in higher power requirements and excessive wear of suction box tops and screen, and may even lead to screen stalling. For the production of multi-ply paperboard, such as linerboard, a secondary flow box is often used. A base ply is formed first and after sufficient dewatering has taken place a second ply is applied by means of the secondary flow box. The associated fibrous suspension is then drained through the base ply, and dewatering is carried out essentially by flat vacuum boxes with thickening as the main mechanism.

Rotary Forming Devices

In these units the forming screen is in the form of a drum and the fibrous suspension is fed to the screen by various methods ranging from (a) simply immersing the rotating screen in a chamber (vat) containing the fibrous suspension to (b) the use of a type of flow box.

Cylinder Mold Machines. There are two basic types: Uniflow and Contra Flow. In the Uniflow machine, the fibrous suspension is fed into the vat at the ingoing face of the cylinder mold (forming screen); in the Contra Flow, the suspension enters at the emerging face (see Figure 3).

The draining forces are low, typically 1–5 in. of water static head difference. The mechanism of forming is complex; and because of the low-drainage forces, considerable washoff of the fragile newly formed web followed by redeposition takes place in the forming area. The forming zone is obviously too long with continual washing off and redepositioning taking place so that the overall mat deposition is inefficient. Various modifications have taken place in attempts to overcome this problem. Further development has led to a variation known as the rotary former.

Roll Formers. Figure 4 shows a typical rotary former. It is easy to see that it consists essentially of a cylinder-forming screen with an associated type of flox box. The forming length has been considerably decreased, and the drainage forces can be far higher than is the case with the previously described cylinder mold units (Figure 4).

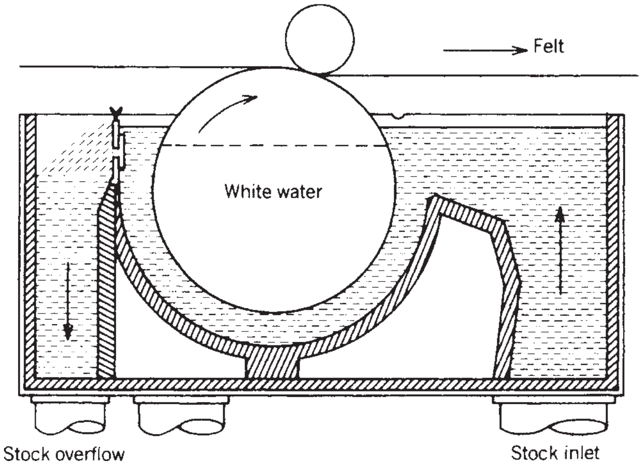

Figure 3. Cylinder-mold forming.

The cylindrical screen can be of relatively simple construction relying on a pressure force in the forming zone to assist drainage or it can be in the form of a suction roll using a series of vacuum boxes to further assist dewatering. Compared to cylinder molds, roll formers have several advantages:

1. They can develop and tolerate higher levels of turbulence in the initial forming zone because the drainage zone is enclosed, whereas the initial forming zone in a cylinder-mold machine starts at a free surface.
2. High pressure in the free suspension and the possibility of using suction on the underside of the forming screen permit a much higher rate of drainage.
3. The rotary former has a more uniform metering of the fibrous suspension onto the forming screen.

Although both types of rotary forming devices can be used to produce paper, the greatest application by far is the manufacture of multi-ply board. A number of the units are operated in series, progressively building up a multi-ply web.

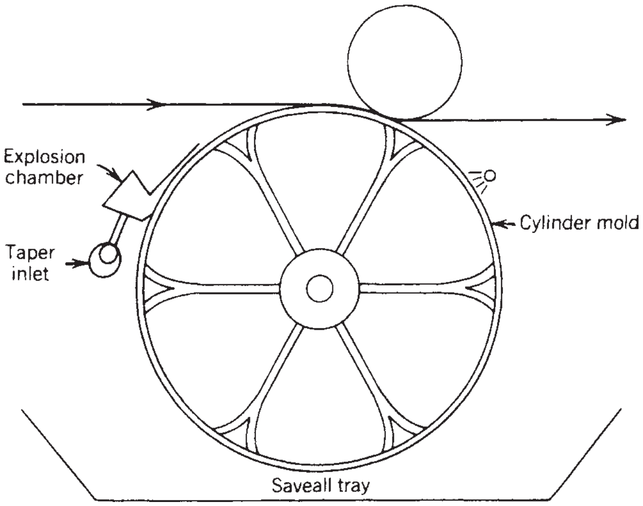

Figure 4. A cylinder former.

Twin-wire Formers

The third basic method used for paper and paperboard forming is a relative newcomer, invented in the 1950s and called the twin-wire method. In this technique the paper web is formed between two forming screens. The idea dates back to the nineteenth century, but it was only in the 1950s that serious development took place, taking advantage of improved ancillary equipment. The process became a commercial reality and a viable contender in some applications. Figure 5 shows a typical twin-wire forming unit, in this case the basic Inverform concept, a UK invention and the first commercial twin-wire system.

In all twin-wire formers, the fibrous suspension is fed into the gap between two converging forming screens by means of a flow box where dewatering and associated web forming takes place. The action related to web structuring in the forming zone is still not fully understood but with regard to dewatering, the twin-wire concept offers the opportunity to carry out symmetrical drainage of the fibrous suspension from both sides. This allows a symmetrically structured web to be formed and provides the opportunity to greatly increase the dewatering potential. Dewatering is assisted by the use of deflectors, which press into the forming screens, and/or vacuum boxes operating on one or both forming screens. A further benefit of the twin wire concept is the absence of a free surface in the forming zone. Wire hs been repalced by plastic netting.

In general terms, multi-ply webs are produced by (a) separately forming the individual plies and then combining them together; (b) forming onto an existing ply or plies, to form more plies; (c) using multilayer (stratified) flow boxes; or (d) a combination of a–c.

Examples of multi-ply arrangements in use today are shown in Figures 6 and 7.

Machine Finishing

The surface of the paperboard web can be treated during the manufacturing process by various means according to the characteristics required of the finished product. It is not unusual to use as part of the drying process an M.G. (Yankee) cylinder, which imparts a smooth surface to one side of the web without too much densification of the web taking place. In the drier section, there is often a size press where chemicals can be added to the surfaces of the web in order to impart certain characteristics (e.g., hard sizing or barrier properties). Paperboard machines often have coaters "in line" with the operation at which one or more layers of coating medium can be applied. At the end of the manufacturing process, right before the windup, one or more stacks of calenders are installed. A stack of calenders consists of a number of horizontal cast iron rolls set one above each other. As the web of paperboard passes through the nips, the calenders increase the smoothness and gloss of the surface of the web.

TYPES OF PAPERBOARD

The simplest types of paperboard are single-ply thick papers used for many nonpackaging purposes (e.g., index board for card-filing systems and display mounting). They have a degree of stiffness and an acceptable appearance (e.g., a uniform surface). This type of paperboard can also

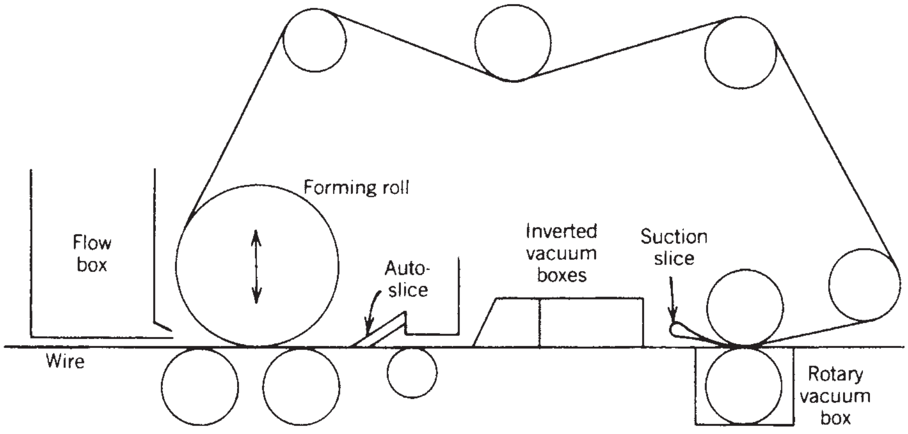

Figure 5. An Inverform (Beloit) twin-wire forming section.

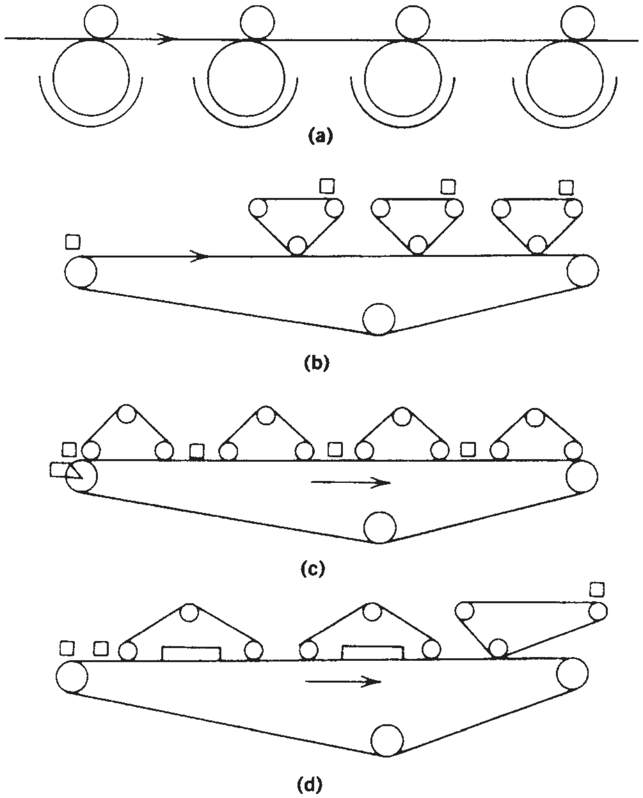

Figure 6. Typical multi-ply forming arrangements. (**a**) Typical cylinder M/C. Common throughout the world. Can be Uniflow, Contra Flow, and so on, including mixtures. (**b**) Fourdrinier with "on top" mini-Fourdriniers. Examples in Europe and the United States. (**c**) Suction breast roll with Inverform units. Example in the United States. (**d**) Fourdrinier with bel bond units and mini-Fourdrinier. Examples in United Kingdom and Europe.

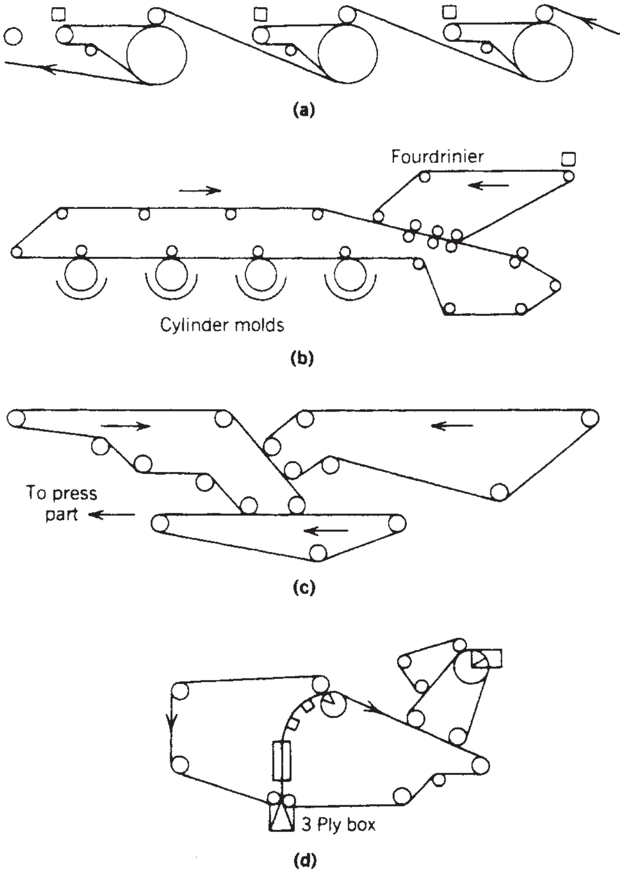

Figure 7. Examples of multi-ply formers. (**a**) Super ultra former. Examples include Japan, the United States, Canada, and so on. (**b**) Typical combination M/C. Examples are mainly in Europe. (**c**) Typical multiwire M/C. An example is Finland. (**d**) Commercial application of contro flow former. An example, is Finland. Contra Flow former combined with an arcu (rotary) former.

be made from waste paper. The product will have good stiffness characteristics, but not necessarily good appearance. Its main use is as package inserts and envelopes. Paperboard with similar structure, but with improved printing surfaces, has a wide range of uses (e.g., high-quality display). The greatest volume of paperboard is used, however, in packaging.

Single-ply paperboard made from 100% bleached-chemical wood pulp is used for food packaging where purity and clean appearance is required together with a degree of strength and a surface of sufficient quality to accept good-quality print. Materials of this type are often coated or laminated with a plastic film to improve barrier properties. Compared to single-ply structures, multiply paperboard can be used over a much wider range of applications because virgin-pulp outer layers with good appearance, strength, and printing properties can be combined with lower-grade middle plies. These paperboards are often combined with other materials such as plastic film or high-quality paper in order to extend the range of application. The general term for this range of paperboard is folding box-board.

Another type of paperboard, known as fiberboard, is used to produce large and strong cases. The materials used for the construction of these containers are made from several layers of paperboard. There are two main types: solid board (two or more boards are laminated together) and corrugated board. In the production of corrugated board, two facings are glued to both sides of the corrugating medium to produce a single-wall corrugated board. For stronger and larger boxes, three facings and two media are used (double-wall corrugated). Triple-wall corrugated uses four facings and three media (see Boxes, corrugated).

The types of paperboard mentioned have, in general, a basis weight range from 200 to 600 g/m^2 ($\sim$41 to 123 lb/1000 ft^2). Thicker and heavier paperboards are used in many applications ranging from building materials to suitcases. They are often produced by laminating many layers of thinner paperboards.

Table 1. Examples of Typical Paperboard Grades

Board Grade	Grammage Range g/m^2 ($lb/1000\,ft^2$)[a]	Typical Furnish	Special Requirements (Physical)	Typical Usage
White-lined folding-box board	200–800 (40–160)	Liner, virgin pulp Underliner, mechanical pulp Middles, waste Backs, mixture (mechanical and chemical pulp)	Bending Printing Plybond Stiffness	General packaging cartons
Chipboard	200–800 (40–160)	100% waste	Bending Plybond	Packaging cartons, tubes, and stiffeners
Gypsum board	300–800 (60–160)	100% waste	Plybond	Outer component of plasterboard
Test liner	150–300 (30–60)	Liner, virgin pulp (kraft): rest, waste	Bending Bursting strength Plybond Crush resistance	Outer components of corrugated containerboard
Linerboard	150–300 (30–60)	100% virgin pulp	Bursting strength	Outer components of corrugated board
Foodboard	200–600 (40–120)	100% virgin pulp (single- or multi-ply)	Bending Printing Plybond Stiffness	All foods, especially frozen foods (high-quality containers)
Liquid packaging	200–400 (40–80)	100% virgin pulp (single- or multi-ply) with barrier (coating and/or laminate)	Bending Printing Plybond Stiffness	Containers for wide range of liquids including milk
Fluting medium	90–200 (18–40)	Typical—100% waste or semichemical hardwood pulp	Crush resistance	Inner components of corrugated containerboard

[a] $g/m^2 = 0.2\,lb/1000\,ft^2$.

Table 1 shows a typical range of paperboard grades with comments on their furnish, requirements, and end usage. The following definitions describe the most common types of paperboard used in packaging.

Body or Baseboard. This is a board that is ultimately treated by, for example, a coating or a surface application.

Lined Board. A multi-ply board with a liner ply, usually of high-grade material (e.g., white-lined chipboard).

White-Lined Board (Duplex). A board with a bleached pulp liner and the remainder of the board made up of, for example, a mixture of chemical pulp and mechanical pulp. Often used for food packaging (2).

Kraft-Lined Chipboard. An unbleached kraft liner on a wastepaper base used for packaging products such as electrical and mechanical components.

Test Jute Liner. This is a type of kraft-lined chipboard. Sometimes the liner is made from a strong kraft waste furnish. This material is combined with fluting medium to produce corrugated board.

Double-Lined Board. A board lined on both sides. For example, the outer surfaces (liner) can consist of bleached pulp and the middle mechanical pulp. It is used for high-quality packaging of foods and cosmetics.

Carton Board (Folding-Box Board). Paperboard of various compositions used for the manufacture of folding cartons and set up boxes.

Foodboard. Single- or multi-ply paperboard used for food packaging. It is hard-sized for water resistance.

Liquid Packaging Board. Also called special-food board, or milk-carton board, this strong board is usually 100% chemical pulp, often plastic-coated. It is formed into containers for a wide range of liquids (e.g., milk, other beverages).

Frozen-Food Board. Single- or multi-ply paperboard with high moisture- and water-vapor resistance. It is often single-ply, made from bleached wood pulp with a surface coating for high-quality print.

Kraft Linerboard. A strong packaging paperboard with a two-ply construction made essentially from virgin kraft pulp and produced on a Fourdrinier machine. The top ply is added by means of a secondary flow box. It is used in the manufacture of large containers, combined with fluting medium to form corrugated board.

Fluting Medium (Corrugating Medium). A board usually with a basis weight of 100–125 g/m^2 (20–25 lb/1000 ft^2) and a caliper of 225 μm (9 mil) made from semichemical hardwood pulp or waste paper. The material is fluted in a corrugating machine and combined with linerboard to produce corrugated board.

Chipboard. A paperboard made from waste paper, used in low-grade packaging, solid fiber, and bookboard. Chipboard is not usually used in contact with food, but is used as an outer carton (2).

Machine-glazed Board. Paperboard that in its manufacture has had one face made smooth and glossy by drying on a large polished steam-heated drying cylinder (Yankee cylinder).

Tube Board. A paperboard generally unsized and smooth finished. It is slit into narrow widths for winding and pasting into spiral or convoluted mailing tubes, cores, etc.

Can Board. Paperboard used for the manufacture of composite cans and fiber drums. The cans are used for packaging a wide range of materials including liquids and powders.

Coated Boards. Paperboards of various grades that have been coated on one or both faces in order to make the surfaces suitable for high-quality printing.

ENVIRONMENTAL CONCERNS

Environmental and waste issues are current major issues (1). Paperboard's advantages are as follows:

1. The main raw material (wood) is based on a naturally renewable resource, the growth of which removes carbon dioxide from the atmosphere, thereby reducing the greenhouse effect.
2. When the packaging is completed, many types of paperboard packaging can be recovered and recycled. If these are not options, it is biodegradable in a landfill.

INTRODUCTION TO THE UNITED STATES PATENT SYSTEM

The Role of Patents

Patents have economic and business implications. For example, in 2006, on the eve of a patent infringement trial involving semiconductor packaging, the parties entered into an $80 million settlement (1). While such multi-million dollar disputes do not occur every day, patents are regularly used to generate licensing revenues, to block competitors from a market, and as negotiating tools. The packaging industry has been active in building patent portfolios in diverse packaging-related technologies such as packaging machines, systems and materials, methods of manufacture, closure systems, and so on. Universities have also become more active in patenting inventions to generate licensing revenues. For example, U.S. Patent 7,213,967, entitled "Method and System for Conservative Evaluation, Validation and Monitoring of Thermal Processing," was issued to researchers from the University of North Carolina (2).

To function most effectively in a world where patents play an ever larger role, scientists and engineers should have at least a basic understanding of patents and what they can and cannot do. Lack of such knowledge can be costly. For example, learning about a competitor's patent too late could prevent a product launch even though plant and equipment have been built and purchased and employees have been hired and trained.

The Foundations of U.S. Patent Laws

The U.S. Constitution. The U.S. Constitution explicitly authorizes Congress to provide a system to encourage innovation by providing inventors with exclusive rights to their discoveries for a limited amount of time. This is the foundation of U.S. patent laws, which grant inventors the right to exclude others, for a limited time, from making, using, selling, or offering for sale in the United States, or importing into the United States, a patented invention. George Washington signed the first patent statute in 1790 (3). Since then, U.S. patent laws have undergone various revisions. Currently, the patent statute is codified in Title 35 of the United States Code. The associated rules and regulations are in Title 37 of

the Code of Federal Regulations. More recently, Congress has been considering revisions to harmonize U.S. patent law with that of the rest of the world.

The United States Patent and Trademark Office ("USPTO"). The USPTO interprets and applies U.S. patent laws to determine whether inventions are patentable. This chapter focuses predominantly on "utility patents." Utility patents protect the way an article is used and works. To receive a utility patent, an invention must have a utility and it must be novel and nonobvious. These requirements are described below.

Utility: A patentable invention must have a practical use (4). This standard is easy to meet, but there are some restrictions (5). For example, inventions that only have harmful uses are not patentable, nor is the impossible (such as a perpetual motion machine) patentable.

Novelty: A patentable invention must be new (6). It cannot already exist in the public domain, also known as the prior art. For example, an inventor cannot patent what someone else has already done or published. Furthermore, if an inventor publishes his own invention, a patent must be sought within a time period set forth in the U.S. patent laws, or the invention will not be considered new. Therefore, to avoid inadvertently losing the right to obtain a patent, one should speak with a patent attorney before disclosing an invention to the public, through publication, commercial use, or any other means. For example, the courts invalidated a design patent directed to an ornamental juice container design because the patentee had offered for sale containers of an indistinguishably similar design more than one year before applying for the design patent (7). The prior offer for sale rendered the container design non-novel.

Obviousness: Even novel inventions cannot be patented if they are obvious (8). An invention is obvious if it is a straightforward combination or application of prior art information and does not require doing something inventive. For example, two patents directed to meat packing technology were invalidated as obvious in view of prior art patents that, taken together, disclosed features similar to those in the invalidated patents. This was so even though the invalidated patents were the first to have combined the prior art features (9).

In addition to utility patents, one can seek design patents. Design patents cover ornamental features of an object. To receive a design patent, an ornamental feature must be novel and nonobvious. The utility requirement does not apply to design patents.

The Federal Courts. The federal court system interprets and applies the patent laws to resolve disputes between patentees and potential infringers. Patent disputes begin in one of the United States District Courts ("District Courts"). All patent appeals from District Courts are heard by a single court, the Court of Appeals for the Federal Circuit ("the Federal Circuit"). The District Courts must abide by Federal Circuit rulings. Having the Federal Circuit handle all patent appeals promotes uniformity in interpretation and application of patent laws, thereby strengthening the patent system. Appeals from the Federal Circuit go to the U.S. Supreme Court. The Federal Circuit (and all U.S. courts) must abide by Supreme Court rulings.

The Terminology of Patent Enforcement: Infringement, Validity and Enforceability

Patent disputes typically concern the infringement, validity, and/or enforceability of a patent. These terms are explained below.

Infringement: Patents give patent holders the right to prevent others from making, using, selling, or offering for sale in the United States, or importing into the United States, the patented inventions (10). Infringement occurs when one violates such patent rights without authorization (for example, without a license) from the patent holder. The relief for infringement can be damages and/or an injunction (11). Damages are payments of money. Injunctions involve a Court ordering an infringer to stop all infringing activity, even if it means closing plants, recalling products, and eliminating jobs.

Validity: An issued patent is presumed to be valid (12). This means that it can be used to exclude others from infringing unless someone proves that the patent is invalid or unenforceable. Invalidity is a defense to patent infringement and requires proof that a patent, even though it issued, does not satisfy the requirements of patentability, such as utility, novelty, or nonobviousness. Proof of invalidity precludes the patentee from recovering damages or obtaining an injunction even if there is infringement.

Enforceability: Patent applicants have a "duty to disclose" (13) to the USPTO all information that the applicants believe could be material to determining whether a patent should issue. The USPTO Examiner relies on the applicant for such disclosure. In contrast, an accused infringer, through the litigation process, can review the patent holder's internal documents, including notebooks, e-mails, reports, memoranda, and the like. If these documents show that the patentee violated the duty of disclosure (by intentionally failing to disclose information to the USPTO or misleading the USPTO), a court can find the patent unenforceable. An unenforceable patent cannot be enforced, even if it meets the requirements of patentability and is infringed. For example, in a case concerning a patent to nonhydrogenated canola oil having superior oxidative and fry stability, the inventor obtained the patent by telling the examiner that the new oil had superior stability compared to similar oils. The alleged infringer, however, proved that the applicant withheld contradictory data from the patent examiner. As a result, the Court found the patent unenforceable (14).

The Players

The following entities are involved in obtaining and enforcing patents.

The USPTO is the administrative agency empowered to issue patents in accordance with the patent statute and rules. Patent examiners work with applicants to determine whether inventions are patentable.

The Federal Courts are the arbiters of patent disputes. Litigation in the federal courts is an adversarial process in which patent holders attempt to enforce their patent rights and alleged infringers defend themselves. The written decisions of the federal courts set precedent for interpreting and applying patent laws. Federal Circuit patent decisions are available at http://www.cafc.uscourts.gov/dailylog.html.

Inventors are the creators of intellectual property.

Society is the ultimate beneficiary of intellectual property. Intellectual property laws strive to balance the goals of spurring innovation for the benefit of society while preventing removal of common technology, ideas, and business tools from the public domain.

Persons of skill in the art are the contemporaries to whom patent teachings are addressed, and through whose eyes patents are interpreted.

Businesses frequently invest in and own intellectual property, and set strategies regarding what intellectual property to pursue and how to protect and leverage it.

Patent Counsel are company and law firm attorneys involved in planning and implementing patent-related activities, including:

Developing and implementing patent strategies, budgets and priorities;
Drafting and filing patent applications and working with the USPTO to obtain patents;
Managing and maintaining patent portfolios;
Licensing patents;
Monitoring competitor patent activity;
Providing legal opinions regarding patent infringement, validity and enforceability;
Evaluating patent portfolio value and strength prior to mergers or acquisitions, and;
Litigating patent disputes.

A Changing World for Innovation and Its Laws

The value of a patent depends on its scope and strength. Evaluating the scope and strength of a patent requires staying abreast of changes in U.S. patent laws and their interpretation by the Federal Courts. For example, the U.S. Supreme Court has shown a renewed interest in patent cases, recently deciding cases relating to the standard of obviousness (15), the standard for awarding a permanent injunction in patent cases (16), the propriety of a licensee (i.e., the party taking a license from the patent owner) suing a licensor (i.e., the patent owner) to invalidate a licensed patent (17), and application of patent exhaustion doctrine, under which the initial authorized sale of a patented item or process terminates all patent rights to that specific item or process (18). Thus, although U.S. patent laws have existed for over 200 years, they are constantly evolving.

THE INTERPLAY BETWEEN PATENTS AND OTHER FORMS OF INTELLECTUAL PROPERTY

Intellectual property has been defined as "[a] category of intangible rights protecting commercially valuable products of the human intellect" (19). In practical terms, intellectual property relates to patent, trademark, copyright, and trade secret rights. Utility patents and trade secrets protect functionally useful technologies (i.e., the useful arts), but in different ways. Design patents protect ornamental features of an article of manufacture. Trademarks, which include trade dress and servicemarks, protect brand reputation and are extremely important with respect to consumer products packaging. Copyrights protect works of authorship, including computer software programs, and are available for registration of packaging designs. Table 1, at the end of this section, compares the forms of intellectual property discussed in this section.

Patents

Patentable Subject Matter. There are three types of patents: utility and design patents, which relate to packaging, and plant patents. The discussion below focuses primarily on utility patents.

Utility patents cover new and useful processes, machines, articles of manufacture, or compositions of matter (4). These subcategories are broad and cover most inventions, including packaging machinery and systems, chemical compounds, formulations, methods of synthesizing compounds, and more. Abstract ideas, principles of nature, and purely mathematical formulas without a practical application are not patentable.

The USPTO has issued over seven million patents, and it posts thousands of newly issued patents every Tuesday. One can use the USPTO to learn about a field of interest by searching and reading patents and published patent applications as follows:

1. Go to: http://www.uspto.gov/patft/index.html;
2. On the left side of the page, under issued patents, select "Advanced Search";
3. In the Query box, type a search term;
4. Click on the "Search" button.

The result will be a list of issued patents. Utility patents are numbered without prefix, design patents have the prefix "D," and plant patents have the prefix "PP."

Table 1. A Comparison of Patents, Trademarks, Copyrights, and Trade Secrets

	Utility Patent	Design Patent	Trademark	Copyright	Trade Secret
How created	Invented	Invented	Used in commerce	Independent creation once fixed in tangible form	Expended efforts
Governing Law	Federal (35 U.S.C.)	Federal (35 U.S.C.)	Federal (15 U.S.C.: Lanham Act) & State	Federal (17 U.S.C.: post 1-1-1978)	State Federal: Economic Espionage Act
Federal system for conferring rights	USPTO assess patentability	USPTO assess patentability	USPTO ensures criteria are met	No substantive examination Registration with Copyright Office suggested but not required	n/a
Subject Matter	Useful arts	Ornamental features	Words, symbols, sounds, trade dress, etc., used to associate a product or service with its source	Forms of expression, not underlying ideas or functional features	Secret information that provides a competitive advantage
Criteria	Utility Novelty Nonobviousness Other	Novelty Nonobviousnesss Other	No prior user Distinctive mark Other	Original, but not necessarily novel	Secret
Duration	20 years from earliest filing date	14 years from issuance.	As long as trademark is in use	Individual 70 years after the author's death Works for hire, anonymous, pseudonym Earlier of: 95 years from publication or 120 years from creation	As long as kept secret
Nature of exclusive rights	Preclude others from making, using, selling, offering for sale in the United States, or importing into the United States	Preclude others from making, using, selling, offering for sale in the United States, or importing into the United States	Preclude use of confusingly similar mark with similar goods or services	Control over reproduction, derivative works, distribution, performance, display, and digital transmission	Preclude misappropriation

The Nature of Patent Rights.

Patent Rights Are Governed By Federal Law. Each country has its own patent laws. The U.S. Patent Statute is codified in Title 35 of the United States Code. U.S. patents provide rights only in the United States and its territories. Therefore, a patent application must be filed in each country in which patent rights are sought. Furthermore, one does not have to live in or do business in the United States to obtain or enforce a U.S. patent.

The Goal Is Disclosure, Not Secrecy. A patent, and the concomitant right to exclude others, is granted in exchange for disclosing to the public the details of how to make and use an invention, including disclosure of the inventor's understanding of the best way to make and use the invention when the patent application was filed (20). Such disclosure enriches the public knowledge, provides a foundation for future innovation, and gives competitors notice of what a patent covers, so that the competitor can try to avoid infringement. Failure to disclose such information may render a patent invalid if the adequacy of disclosure is challenged during a patent dispute.

An Application Is Examined Before Patent Rights Are Granted. The USPTO grants patents only after a USPTO examiner has reviewed an application and found that it complies with all statutory criteria. To be patentable, an invention must have utility and be novel and nonobvious, and the patent application must satisfy the disclosure requirements mentioned above (21).

A Right to Exclude. A U.S. patent confers upon the patent owner a *time limited* right to *exclude* others from making, using, selling, or offering the invention for sale in the United States, or importing the invention into the United States. A patent does not, however, grant the patentee any right to make, use or sell anything. For example, assume that Company A has patented a novel polymer A and that Company B has patented an improved method of synthesizing the polymer. Company A can use its patent to preclude Company B from using polymer A in any way. Likewise, Company B can use its patent to preclude Company A from synthesizing polymer A using the improved method. Due to the exclusive nature of patent rights, companies in patent-active industries often obtain freedom-to-operate or noninfringement opinions before investing too much on developing or launching a new product.

Duration. The right to exclude others from practicing a patented invention starts on the date that the patent is issued by the USPTO and ends on the patent's "expiration date." Although a patent suit cannot be initiated until a patent is issued, under certain circumstances, damages may be recoverable for infringement that occurred before issuance (22). The right to exclude others from practicing a patented invention ends on the patent's expiration date. The expiration date of U.S. utility patents (and U.S. "plant patents," which are not discussed in this chapter) is typically calculated as 20 years from the date that the application was filed, while design patents expire 14 years from the date the patent is granted. However, the expiration date of a utility patent in force on June 8, 1995 (or that issued on an application that was filed before June 8, 1995) is the greater of 20-years from the earliest applicable filing date or 17 years from the patent grant. In addition, a patent term extension may be granted when specific types of delays occurred during PTO examination of the patent application. Ultimately, determining the expiration date of a patent can be complex. Therefore, it is best to consult an attorney when trying to determine the expiration date of a patent of interest.

Enforcing Patents. Obtaining a patent does not guarantee that a competitor will not attempt to practice the patented invention. This is because the competitor (1) may not know about the patent or (2) may know about the patent but think it is not infringed or that it is invalid or unenforceable (and may have a legal opinion supporting this position). Therefore, a patent holder should vigilantly identify potential infringers, analyze suspected products, and enforce patents as appropriate. This could involve either (a) contacting the potential infringer to discuss licensing or some other arrangement or (b) initiating a law suit seeking damages and an injunction.

Design Patents. Design patents are granted on ornamental designs of articles of manufacture (23). A design patent protects only the appearance of the article and not structural or utilitarian features. In the packaging field, protectable designs include the overall configuration or shape of the package. For example, The Coca Cola Company received a design patent for its contour bottle in the 1930s (24). Ornamentation on the surface of the package may also be patentable. Like utility patent applications, design patent applications are reviewed for novelty and nonobviousness, among other criteria. Inventions with both a utility and a novel appearance may be eligible for both utility and design patent protection.

Trademarks

Subject Matter of Trademarks. Trademarks are any "word, name, symbol or device, or any combination thereof," used by providers of goods and services to distinguish their goods and services from others in the minds of consumers (25). Features such as color, shape, smell, sound, and configuration may also serve as a mark (26, 27). A loyal consumer will often associate a trademark with certain characteristics of a brand, such as quality or durability. This phenomenon is often referred to as "brand recognition." Trademarks, therefore, encourage companies to invest in the goodwill associated with their trademarks by producing products with desirable qualities. Trademark disputes arise when marks on similar goods lead to consumer confusion or deception.

Trademarks Cannot Contribute Functionality to the Product. The purpose of a trademark is to associate a good with its source. A trademark should not provide functionality to the product. For example, a trademark was granted for a unique scent applied to embroidery yarn, because the scent was not a natural or inherent feature of the yarn and provided no utilitarian advantage other than to identify the manufacturer (26). If the scent had utility, patent protection would have been more appropriate.

Trademarks Should Not Be Descriptive of the Product or Service. One should be allowed to accurately describe his products or services without fear of infringing a trademark. Therefore, trademark law is loathe to remove descriptive words from the public domain. In contrast, distinctive words make strong trademarks. Trademarks are, as a result, classified on a spectrum of increasing distinctiveness as generic, descriptive, suggestive, or arbitrary/fanciful (28).

Generic words lack distinctiveness and are ineligible for protection because it would be unfair to deny competitors the right to refer to their products by name. Thus no one can claim the exclusive right to use the phrase "Barrier Bag" as a trademark for bags made from "barrier materials" possessing "barrier characteristics" (29).

Descriptive words describe the product, its attributes, or its claims. Descriptive words have little distinctiveness and are protectable only after developing "secondary meaning" wherein the public associates the mark with the products of a single source. For example, "Squeeze 'n Serve" as applied to a ketchup container was denied trademark registration because it is merely descriptive of a feature of the product and had not developed secondary meaning (30).

Suggestive marks do not name or describe the product, but still suggest qualities or claims of that product. Suggestive words are given trademark rights without demonstrating secondary meaning. "Loc-Top" as applied to bottle closure caps is an example of a suggestive mark (31).

Arbitrary or **fanciful** marks are the strongest. Such marks bear no logical relationship to the product on which they are used. "Apple" as applied to computers is an arbitrary mark. "Exxon" and "Kodak" are made-up terms and are fanciful marks (28).

The Nature of Trademark Rights. Trademarks do not exist on their own. Trademarks must be associated with a product or service. Actual use of a mark (or intended use followed by evidence of actual use) is necessary to establish and maintain a trademark. A valid trademark gives the owner the right to prevent others from using a confusingly similar mark with related goods or services.

Trademarks Are Governed by State and Federal Law. Federal and state laws provide for trademark registration, but the systems differ. State registrations are typically administered by the Secretary of State. Each state has its own requirements. The federal system involves USPTO examination to ensure that there are no conflicting marks and that the mark is proper. Furthermore, to obtain federal protection, a mark must be used in interstate commerce. The "®" symbol denotes a federally registered trademark and may only be used with registered marks. Federal registration lasts 10 years and is renewable indefinitely as long as the mark is in use (32).

Trademark registration is not required, but it offers enforcement advantages if litigation arises. The "TM" or "SM" symbols are available for state registered and unregistered marks. They denote a common law or state registered trademark or servicemark and are not governed by federal statute. Using the appropriate symbol is important because it impacts the defenses alleged infringers can raise in litigation.

Duration. Unlike patents, trademarks can last indefinitely. However, trademarks can be lost through non-use or if the mark becomes "generic." A mark becomes generic when the public starts using the mark as a noun rather than an adjective to describe the product's source of origin. For example, the former trademark "cellophane" became generic (28). While companies invest heavily in promoting trademarks, they also take pains to prevent the trademarks from becoming generic.

Copyrights

Subject Matter of Copyrights. Copyrights protect original works of authorship, including literary, musical, dramatic, choreographic, sculptural, audiovisual, and architectural works (33). These categories are interpreted broadly. For example, a computer program can be considered a literary work, and the decorative features of a belt buckle can be considered a sculptural work.

Novelty is not required to receive copyright protection, provided that the work is original to the author. Thus, independent creation is a defense to copyright infringement. In contrast, independent (but later) invention is not a defense to patent infringement (although it may be a defense to a charge of "willful" infringement, where a patentee seeks "enhanced" damages from an alleged infringer).

Copyrights Protect Form of Expression. Copyrights protect *forms* of expression, not underlying ideas or information conveyed. For example, an engineer could write a manual on how to build a new reaction vessel and obtain copyright protection for the manual. Copying the manual, word for word, without permission would be copyright infringement because the manual, as written, embodies the *form* of expression. However, following the manual's instructions to build the reaction vessel would not violate the copyright. Protecting the vessel itself would require a patent.

Additionally, copyrights do not protect functional features of a device. For example, a copyright might protect ornamental aspects of a belt buckle as a sculptural work, but will not protect the functional features themselves (34). Design patents and trade dress might also protect such nonfunctional features.

Computer Software. Copyright and patent protection overlap when it comes to computer software. A computer program, as a written expression of language, is eligible for a copyright for the program code. The functional aspects of the program as executed—what it *does*—are not copyrightable, but may be patentable.

The Nature of Copyright Protection. The copyright owner has the right to control reproduction of the copyrighted work, preparation of derivative works, distribution of copies, public performances, public displays, and public digital audio transmissions.

Copyright Is Protected by Federal Law. Copyright protection is afforded by federal statute, set forth in Title 17 of the United States Code. Congress adopted the first copyright statute in 1790, and since then it has made substantial changes to the copyright laws in 1831, 1870, 1909, and 1976 (33). For most purposes, the provisions of the 1976 Copyright Act went into effect on January 1, 1978. The 1909 Act continues to be important for protected works that were originally governed by the 1909 Act (33).

Registration Is Available. A work receives copyright protection under the 1976 Copyright Act as soon as it has been "fixed in a tangible form of expression" (33). This is a relatively easy standard to meet. If a work can be perceived and copied, it is in a tangible form of expression. For example, notes on a blackboard can have copyright protection. Registration with the U.S. Copyright Office is not required to get copyright protection, but registration provides benefits. A work can be registered at any time during the life of a copyright (35). For works authored prior to January 1, 1978, the Copyright Act required certain formalities to receive protection and to maintain protection.

Duration. Copyright duration depends on when the work was created. A typical lifespan for a work under the current law can be 70 years from the author's death. However, for "works made for hire," anonymous, and pseudonymous works, it is the earlier of 95 years from publication or 120 years from creation (35). Works under the prior act (i.e., works authored prior to January 1, 1978) could last for a maximum of 95 years.

Overlap Between Copyright, Patent, and Trademark Law

The nonfunctional features of a package may be protectable as trademarks/trade dress, by design patent, and by copyright. For example, a company sued its competitor for allegedly infringing its design patent and copyrights to packaging for a food product. Based on the design patent infringement claim, the court granted preliminary injunctive relief, enjoining the defendant from selling its product in its infringing packaging (36). Because the nature of the protection provided by trademarks, design patents, and copyrights differ, an intellectual property attorney should be consulted when deciding how best to protect nonfunctional features of a package.

Trade Secrets

Subject Matter of Trade Secrets. A trade secret is virtually any type of confidential information that provides its owner a competitive advantage because the information is not generally known or readily ascertainable. Trade secrets can encompass patentable information, such as product formulations, or nonpatentable information, such as customer lists. The "formula" for Coca-Cola® is an example of a trade secret.

The Nature of Trade Secret Rights.

Trade Secrets Are Governed by State Law. Trade secrets are governed by state law, not federal law (except for the Federal Economic Espionage Act of 1996, 18 U.S.C. §§ 1831–39, which is beyond the scope of this chapter). Therefore, the definition of a trade secret can vary from state to state, with important implications. For example, in a case involving a technical executive moving from a first company to a competitor, the court recognized three theories of trade secret misappropriation: actual, threatened, and inevitable disclosure. The first company's position was that the executive would inevitably communicate its trade secrets to the competitor. The court indicated that under an inevitable disclosure theory, misappropriation would exist. But, the case was decided under state laws that did not recognize "inevitable disclosure," and no misappropriation was found (37). Such cases highlight how important it is for companies to have protocols that address expectations and obligations of newly hired employees and employees that leave to find work elsewhere.

Trade Secrets Do Not Involve a Registration or Review Process. As explained above, the goal of patent law is disclosure, not secrecy. In contrast, the value of a trade secret is its secrecy. One does not "apply" for a trade secret. Instead, trade secrets simply exist if kept secret. Indeed, failure to adequately protect the secrecy of the trade secret can result in its loss.

Duration of a Trade Secret. While patent rights expire when a patent expires, trade secret rights last as long as secrecy is maintained. Therefore, maintaining trade secrets requires reasonable measures to prevent careless disclosure by employees or easy access by outsiders. Such measures include establishing and enforcing company policies regarding trade secrets, educating employees about maintaining trade secrets, limiting employee and visitor access to sensitive information and areas, maintaining nondisclosure agreements with employees and third parties, screening information in marketing and sales materials to prevent disclosure of trade secrets, controlling communications with vendors and co-manufacturers, and using noncompete agreements where appropriate. One can sue if a trade secret is misappropriated. Reverse engineering a product to learn a trade secret is not misappropriation.

To Patent or Maintain As A Trade Secret

Companies often must decide whether to seek patent protection or maintain information as a trade secret. In making the decision, one might consider the following factors:

Period of an Invention's Utility: Is the field of invention fast moving? If so, is it worth spending the time, potentially years, to obtain a patent – or is trade secret protection preferable?

Plans to License or Sell the Invention: Will the invention be licensed or sold? If so, patent protection may be preferable.

Ability to Reverse Engineer: Is the invention easy to reverse engineer? If so, patent protection may be preferred. Typically, products are easier to reverse engineer than processes.

Ability to Design Around: Will the invention obtain broad or narrow patent protection? If the invention is narrow and the same result can easily be achieved without using the invention, does the invention merit patent protection?

Combining Patent And Trade Secret Protection: An applicant, after having filed a patent application for an invention, may develop patentable improvements that can be protected by patent or as trade secrets.

Summary Comparison of Patents, Trademarks, Copyrights, and Trade Secrets

Table 1 provides a summary comparison of the different forms of intellectual property discussed above.

OBTAINING A PATENT

This section introduces the concepts and terminology involved in obtaining patents and the strategic purposes for doing so. As explained below, the procedure for obtaining a patent is very rule oriented.

How Patents Fit into Business Plans

Before seeking a patent, a company should understand what role patents can or will play in its business plan. For example, companies obtain patents for different reasons, including:

Excluding others and protecting a competitive advantage
Maintaining customer confidence (e.g., for ingredient suppliers)
Generating licensing revenue
Creating negotiating leverage when dealing with competitors
Attracting potential acquirers

The Value of a Patent

Once a company decides to obtain a patent, it makes sense to obtain the most valuable patent possible. Patent value depends on many factors, including:

Usefulness:. Value increases with increasing usefulness/necessity of the patented technology to the patent holder and/or its competition.

Unassailability:. Valuable patents can withstand challenges to their validity and enforceability during a lawsuit.

Breadth:. Value increases with increasing breadth of the patent, making it harder for competitors to achieve a similar result without infringing the patent.

The Patent Process

There are three primary phases in obtaining a patent: (1) the invention, (2) drafting and filing the patent application, and (3) prosecuting the patent application before the USPTO. Each phase requires a commitment of resources and money. Additionally, phases 2 and 3 involve attorney time and USPTO fees. A schedule of such fees, including reduced fees for "small entities," is available at the USPTO website (38). An overview of each phase is provided below.

The Invention. Many companies have procedures for employees to submit inventions for review and potential patenting. Such procedures often employ an invention disclosure form which:

Identifies the potential inventors and their contribution(s) to the invention
Describes the invention, how to make and use it, and how and when it was developed
Identifies materials (notebook(s), memoranda, etc.) that record the work underlying the invention
Identifies prior art
Identifies past and planned marketing activities
Identifies past and planned publications or presentations regarding the subject matter of the invention

Typically, a committee comprising members from technical, business, and legal departments meet and review invention disclosures to assess commercial viability and determine whether to seek patent protection, rely on trade secret protection, or take no action at all.

The United States has a *first-to-invent* patent system. This means that if two inventors file separate patent applications on the same invention, the patent goes to the first inventor, regardless of who filed the first patent application. Laboratory notebooks and internal memoranda are often used to establish the invention date.

Most of the rest of the world uses a *first-to-file* system, rather than a first-to-invent system. In a first-to-file system, the patent goes to the first individual to file an application—the invention date is irrelevant. Congress is considering changing the U.S. to a first-to-file system to harmonize U.S. patent law with the rest of the world.

Drafting and Filing a Patent Application.

Conducting a Literature Search. If a patent is desired, the invention disclosure and other technical information are forwarded to a patent attorney. The patent attorney may conduct a search of related patents and publications to assist in understanding the potentially patentable aspects of the invention—the aspects not already known in the field. This search may also reveal competitors' patents in the same field that may impact the ability to launch a product based on the invention.

Drafting the Patent Application. The next step is to draft the patent application. This step depends on whether the patent attorney is filing a *provisional* application or a *non-provisional* application. The patent attorney could also file a U.S. application that is a counterpart to a previously filed international application. Such counterparts are beyond the scope of this article.

Provisional applications serve as a temporary placeholder to establish a filing date. They are not reviewed by the USPTO and do not result in issued patents. Provisional applications require a thorough description of the technical details of the invention, but the description can be informal. For example, a technical report, memorandum, or set of data tables may suffice. Provisional applications, unlike nonprovisional applications, do not require claims (described below). Thus, filing a provisional application is convenient when there is no time to draft a more formal nonprovisional application before publicly disclosing the invention. Additionally, filing a provisional application buys an applicant some time to assess whether the invention merits the costs associated with filing a nonprovisional application, which can be significantly more than the cost of filing a provisional application. A non-provisional application must be filed within a year of the filing of the provisional application.

A nonprovisional patent application is the formal application that the USPTO examines for patentability. Nonprovisional applications must include a written description of the invention and at least one claim. The requirements for filing a nonprovisional application are available at the USPTO website (38). An applicant can file a nonprovisional application without filing a provisional application. Only a nonprovisional application can issue as a patent. Attorney time and filing fees can make filing a nonprovisional application expensive.

The Claims Define the Invention. Patent claims, which appear at the end of each patent, define the invention. They are the legal boundaries of the patentee's right to exclude. Drafting claims typically involves discussing the invention with the inventors and probing whether and how the invention can be applied beyond the immediate uses envisioned by the inventor. In drafting patent claims, the patent attorney balances the conflicting goals of obtaining the broadest possible protection for the novel aspects of the invention without encompassing subject matter that was already known in the field. Patent attorneys often achieve this balance by drafting a series of claims of varying breadth.

Other Statutory Requirements of the Application. In drafting the application, the patent attorney considers criteria the patent examiner will use to assess patentability, including utility, novelty, and nonobviousness, and satisfying the *definiteness, written description, enablement*, and *best mode* requirements described below (20).

Definiteness: The claims of a patent must clearly set forth the patented subject matter, such that one can determine whether or not they infringe the patent.

Written Description: The patent specification must describe the invention in a way that demonstrates that the inventor actually possessed the claimed invention. For example, when during prosecution (i.e., the back-and-forth communication with the examiner to obtain a patent, described below), an applicant amended a claim to cover packaging configurations that lacked "an annular reinforcing bead," while everything in the patent (i.e., the abstract, specification, and drawings) described that feature as mandatory to the invention, a court found the amended claim invalid for failure to comply with the written description requirement of the patent statute (39).

Enablement: The patent specification must enable those skilled in the art to make and use the invention without undue experimentation. This entails providing information that is necessary to make and use the invention and that would not otherwise be known. It does not require providing basic information that would be know to people working in the field.

Best Mode: The patent specification must disclose the best way of practicing the invention known to the inventors at the time of filing the application. For example, if the inventors believe that a particular grade of plastic works best in the invention, they must disclose that grade in the application.

Determining Inventorship. In the United States, only inventors can apply for patent applications. The inventors can assign ownership of the invention to a company, but the application must be filed by the inventors. Consequently, the patent attorney must determine the identity of the true inventors. Although inventorship can be corrected, improper inventorship is also a basis for invalidating a patent.

Each claim of a patent can have one or more inventors, and different claims can have different inventors. Each inventor should be included in the patent application. Therefore, joint inventorship is common. Joint inventorship may cause issues for inventions created with outside consultants, comanufacturers, or research institutes. Therefore, when working on joint projects, it is important to consider up front who will own inventions resulting from such projects. Issues may also arise when an inventor has left a company and is needed to participate in filing a patent application.

Accuracy of the Application. Before filing an application with the USPTO, the inventors must carefully review the application for accuracy. The inventors then sign a *Declaration* stating that they are the original inventors and that the contents of the application are accurate. In the

Declaration, the inventors also acknowledge their *duty of candor* to the USPTO. This duty is described below.

The Duty of Candor. Under U.S. patent law, the patent applicants (including each named inventor) have a duty to provide to the patent examiner any information that could be material to the patentability of their invention. Such information could be prior art, public presentations, or data relating to the invention. This is known as the "duty of candor." This duty begins with the filing of the application and continues until the patent issues. This duty may be satisfied by identifying such information in the application itself, or by separately submitting materials to the USPTO in what is called an *Information Disclosure Statement*. Failure to comply with the duty of candor can render an issued patent unenforceable.

The Filing Date and Its Implications. Once the USPTO receives an application, it assigns a filing date. This date is the presumptive date of invention and is used by the patent examiner when searching for prior art to assess novelty and nonobviousness. Furthermore, in the United States, an inventor has a one-year grace period to file a patent application after a public disclosure or public use of the invention by the inventor (or anyone else). The filing date marks the end of the one-year grace period. This grace period distinguishes U.S. patent law from that of most of the rest of the world, where patent rights are not available after an invention has been disclosed to the public. Therefore, before publicly disclosing or publicly using an invention, it is important for the inventor (or intellectual property management) to discuss such potential disclosures with a patent attorney to (1) ensure that the U.S. patent application is filed within one year of such events and (2) consider how such disclosures might impact patentability in other countries.

Prosecuting the Patent Application. The USPTO publishes its *Manual of Patent Examining Procedure* ("the MPEP") to provide patent examiners, applicants, and attorneys a reference on practices and procedures relating to prosecution of patent applications before the USPTO. The MPEP is available on the USPTO website at http://www.uspto.gov/web/offices/pac/mpep/mpep.htm.

The USPTO assigns patent applications to examiners who specialize in the relevant technology. The examiner reviews the application to ensure that it complies with the statutory requirements described above. The examiner then communicates with the applicants regarding whether the application meets such requirements. This process of communication between applicant and examiner is referred to as *patent prosecution*. The USPTO maintains a written record of these communications known as the *prosecution history* of the application/patent. The public and competitors may rely on the prosecution history to aid in understanding the scope of the patent claims. The applicant and examiner may speak with each other, but only written communications become part of the prosecution history on which the applicant, public, and competitors may rely. Such written communications can include summaries of oral communications.

Office Actions. If an application does not meet the requirements for patentability, the examiner issues an *Office Action*. An Office Action is a written communication from the examiner containing a claim-by-claim analysis of the invention. The examiner separately either *allows* or *rejects* each claim, providing the basis for each rejection. Office Actions become part of the prosecution history.

Office Action Responses. Applicants have a set period of time, typically two to three months, to respond to an Office Action. This time can be extended through payment of extension fees. A response can address a rejected claim by canceling the claim, amending the claim to attempt to overcome the rejection, or explaining why the rejection is wrong and arguing for allowance of the unamended claim.

A response can include a submission of data or other information in support of the applicant's arguments. Office Action responses become part of the prosecution history.

Examiner Interviews. In addition to or in lieu of submitting an Office Action response, an applicant can request an *Examiner Interview* to discuss the invention, discuss the examiner's bases for rejection, and explain the applicant's counterarguments. Interviews can be telephonic or face-to-face. After an examiner interview, the examiner typically issues an *Examiner Interview Summary*, summarizing what was discussed in the examiner interview. Examiner Interview Summaries become part of the prosecution history.

The Prosecution History. As explained above, all written communications between applicant and examiner go into the prosecution history. Thus, any admissions or explanations in the prosecution history can be used by accused infringers during litigation, or by competitors trying to interpret the scope of a patent. This prevents applicants from (a) adopting a narrow view of the invention with the examiner for purposes of patentability and (b) later arguing for a broad interpretation when asserting the patent in litigation. Therefore, the ability to amend claims and debate claim scope with the examiner is not a substitute for drafting a well-thought-out application.

Publication of the Application. Patent applications are generally published by the USPTO about 18 months after filing, even if the application is still being prosecuted and even though the application may never issue as a patent. Applicants who file a patent application only in the United States may request that the application not be published. This enables an applicant to maintain the information in the patent application as a trade secret until the patent issues, if it issues. If such a request was made and a patent never issues, the USPTO will not make the information of the patent application available to the public.

Monitoring published applications can provide insight into competitor activities. The USPTO posts newly published patent applications every Thursday(38). Once a patent application is published, its prosecution history becomes publicly available and is accessible at the USPTO website at http://portal.uspto.gov/external/portal/pair.

Final Rejection or Allowance. Eventually, a patent application is either allowed or the examiner issues a final rejection of one or more claims. If at least one claim is allowed, the applicant can obtain a patent on that claim, and file a continuation application (see below) to continue prosecution of the other claims. The applicant can also appeal the Examiner's rejections.

Upon issuance, the patent owner's rights and the presumption of validity attach. The USPTO issues new patents every Tuesday.

The Patent Family. During prosecution, before a patent application is abandoned or matures into an issued patent, an applicant may file related applications, which may include *divisional applications*, *continuation applications*, and *continuation-in-part applications*, each of which is briefly described below. The original application is called the *parent* application.

Divisional Applications: If a parent application contains claims directed to more than one invention, the examiner may require that the applicant prosecute the claims to the different inventions in different applications. For example, if an application contains claims to both a new compound and a new package, the examiner might require the applicant to prosecute the compound claims in one application and the package claims in another. The applicant must then choose which type of claim to prosecute in the original parent application and cancel the unchosen claims. The applicant can then file a *divisional application* to prosecute the unchosen claims. The divisional application is limited to subject matter disclosed but not pursued in the original application.

Continuation Applications: A *continuation* can be filed to continue prosecution of finally rejected claims with new arguments or amendments. A continuation may also be useful where only some claims in the original application have been allowed and some have been rejected. In such circumstances, the applicant can choose to have a patent issue on the allowed claims and pursue the rejected claims in the continuation application.

Continuation-in-Part Applications: A *continuation-in-part ("CIP")* is an application filed during the pendancy of a parent application that contains some *new matter*—that is, information that was not in the original application. The original matter in the CIP is entitled to the filing date of the original application, but the new matter is not. New matter may be added for any reason, including providing support for claim amendments necessary to overcome an examiner's rejection or to pursue improvements made to an invention during prosecution of the application.

Divisional, continuation, and CIP applications must be filed during the pendancy of the parent application.

Maintenance Fees. The USPTO requires patent holders to pay significant maintenance fees at 3.5, 7.5, and 11.5 years after issuance, respectively, to keep a patent alive. Companies often reevaluate the value of a patent when maintenance fees are due because paying maintenance fees on patents claiming unused or outdated technology may not make business sense.

Reissue and Reexamination. After a patent issues, applicants and third parties can have the USPTO reconsider the issued patent through *reissue* and/or *reexamination* procedures.

Reissue: A patent holder can seek reissue to correct mistakes in a patent, such as claiming too much, or claiming too little. A reissue that narrows the claim scope can be pursued any time before patent expiry, but a reissue that broadens the claim scope must be requested within two years after issuance.

Reexamination: Reexamination allows the patentee or a third party to request that the USPTO reexamine a patent's claims in light of specific pieces of prior art. The USPTO will only conduct a reexamination upon presentation of a substantial new question of patentability. A patentee may seek reexamination to bolster the strength of a patent—that is, reinforce the presumption of validity in light of newly discovered prior art. A competitor may seek reexamination as a relatively inexpensive alternative to litigation to invalidate a patent. However, such an approach can backfire where, because the competitor's rights are limited during reexamination, the patent makes it through reexamination and is actually strengthened by the procedure.

THE ANATOMY OF AN ISSUED PATENT

Below we familiarize the reader with the structure of patents to facilitate reading, navigating, understanding, and using patents.

Sections of a Patent—Overview

Reproduced below, as Figure 1, is the cover page of U.S. Patent No. 6,639,004, entitled "Method For Making Odor Sorbing Packaging Material."

In addition to the cover, a patent also contains drawings (where necessary), a specification, and at least one claim. Below we provide a brief overview of the content and function of these parts.

The Cover. The cover of a patent includes the patent number and issue date, its title, the names of the inventors and patent owner or assignee, information regarding the filing of the application, information regarding related references, and an abstract. These parts of the cover are described below.

(57) **ABSTRACT**

An odor sorbing packaging material is prepared by applying to at least one surface of a flexible substrate an odor absorbing coating containing an effective concentration of activated carbon. The packaging material may be converted into packages, bags, pouches, liner members, wrappers or the like for packaging products and other materials that generate objectionable odors.

5 Claims, No Drawings

Figure 1. Cover of U.S. Patent 6,639,004.

Patent Number: The patent number is at the top right-hand corner of the cover. Here, the patent number is 6,639,004. Patents are frequently referred to by the last three digits of the patent number. Thus, we refer to U.S. Patent No. 6,639,004 as "the '004 patent."

Issue Date: The issue date is just below the patent number. The '004 patent issued on October 28, 2003. A patent owner's rights and the patent's presumption of validity begin on the issue date.

Title: The title of a patent appears in the upper-left-hand column of the cover. The '004 patent is entitled: "Method for Making Odor Sorbing Packaging Material." This provides some guidance regarding the subject matter of the patent. However, what a patent protects is defined by its claims, not its title. Indeed, due to changes in claims during prosecution, the title may not completely or accurately reflect the subject matter claimed. Therefore, any review of a patent should go far beyond the title. For example, the title of the '004 patent recites a "method" of making materials, but the claims are directed to materials, not methods of making them.

Inventors: Beneath the title is a listing of the inventors, Ladislav Falat, James R. Miller, Mark E. Shiek, and David R. Walker.

Assignee: Beneath the listing of inventors is identification of the assignee of the '004 patent, Mead Westvaco Corporation. A patent is personal property and therefore can be sold, mortgaged, transferred, and so on. Under U.S. patent laws, such transfers are made by using a written instrument known as an assignment. The person transferring the patent, often the inventor, is the assignor, while the recipient is the assignee. Employment contracts often require that an employee assign to the employer/company rights to any invention made during employment. Patents can be assigned multiple times. The USPTO maintains an assignment database within its website (40). The cover may not have the most current assignment information. For the most current assignment information, one should check the assignment database and check with the USPTO assignment office.

Filing Date: Beneath the assignee information is filing date information. The cover of the ’004 patent indicates that the application for the ’004 patent was filed on July 12, 2001.

Notice Regarding Patent Term: The determination of the expiration date of a patent can be complex and is beyond the scope of this article. One fact to consider in such a determination is whether any portion of the patent term has been disclaimed or extended. The cover indicates that the term of the ’004 patent has been extended by 162 days.

Prior Publication Data: U.S. patent *applications* are typically published about 18 months after they are filed. The publication date is provided beneath the filing date. The cover indicates that the application for the ’004 patent was published on October 3, 2002 as publication number 2002/0149161 A1.

Related U.S. Application Data: Beneath the filing date is the heading “Related U.S. Application Data.” This part of the patent provides information regarding related applications, such as divisionals, continuations, and continuations-in-part. This section indicates that the application that matured into the ’004 patent was a divisional application filed off of an earlier application having serial number 09/388,071 (“the ’071 application”). The ’071 application was filed on September 1, 1999 and is now abandoned.

U.S. Cl.: The USPTO classifies patents into classes and subclasses based on subject matter. All issued patents are classified according to this system. The class is identified by the heading “U.S. Cl.”, found beneath the related U.S. application data. The classifications provide information about the subject matter of the patent.

Field of Classification Search: This section lists the classes and subclasses that the patent examiner searched when assessing the novelty and obviousness of the ’004 patent. One can search the USPTO patents database by class and subclass to uncover patents in a field of interest. The USPTO website provides an index of classes (41). For example, the following are some classes relevant to packaging:

053	Package making
065	4Glass manufacturing
106	Compositions: coating or plastic
156	Adhesive bonding and miscellaneous chemical manufacture
206	Special receptacle or package
215	Bottles and jars
224	Package and article carriers
229	Envelopes, wrappers, and paperboard boxes
264	Plastic and nonmetallic article shaping or treating: processes
413	Sheet metal container making

References Cited: The cover lists the U.S. patents, foreign patents, and other materials the examiner considered when assessing patentability. Such materials often provide a starting point for learning more about the subject matter of an invention, or for an alleged infringer trying to attack the validity of a patent.

Abstract: The cover includes an abstract of the invention at the bottom of the right-hand column. The abstract provides an overview of the invention. Like the title, due to changes during prosecution, the abstract may not completely or accurately reflect the subject matter ultimately claimed.

Drawings. After the cover come drawings, if there are any. Drawings are required, if necessary, to understand the invention. Therefore, the USPTO may deem an application incomplete if drawings are absent. Drawings are typically explained in the specification (described below). The cover of the ’004 patent indicates that it has no drawings.

Specification. The specification is the text of the patent. It comes after the cover and drawings and before the claims. In essence, the specification is a “user manual” that should provide enough description and detail to enable persons skilled in the art to make and use the full scope of the claimed invention. It defines terms used in the claims and often provides examples of the invention. It is the specification that must satisfy the *written description*, *enablement*, and *best mode* requirements of patentability. Therefore, the specification must be drafted as broadly as necessary to support broad claims, and with as much specificity as necessary to support narrow claims. Understanding the claims of a patent often requires careful review of the specification.

A specification typically has the following sections: background of the invention; summary of the invention; brief description of the figures; detailed description of the invention; examples, and claims (which are technically part of the specification).

The background of the invention describes the general field of the invention, notes insufficiencies in existing technology, and explains generally how the invention solves such problems. The summary of the invention usually provides additional information about how the invention solves the problem addressed by the invention. The brief description of the drawings briefly explains what the drawings show. The detailed description of the invention typically explains the invention and how to make and use it. Finally, the examples demonstrate how the invention works, either by describing actual experiments and results or by setting forth methods that could be used and indicating expected (but not actual) results (known as “prophetic” examples). A proper specification should make clear whether an example is actual or prophetic.

Claims. The claims are found at the end of the patent and follow the statement “I Claim” or “What is claimed is.” The claims include “limitations” that define the boundaries of a patent owner’s right to exclude. Such limitations are (a) the elements against which patentability is tested and (b) the elements that a product or process must contain to infringe. Thus, any review of a patent must include careful consideration of the claims.

Claims are numbered. By statute, each claim must be written as a single sentence. As a consequence, claims often are less readable than typical English sentences. Claims usually have three parts: a preamble, a transition, and a body. For example, consider the following hypothetical claim in which the parts are denoted.

$$1.\quad \underbrace{\text{A composition}}_{\textit{Preamble}}\ \underbrace{\text{consisting of}}_{\textit{Transitional Phrase}}$$

$$\underbrace{\text{ingredient A, ingredient B, and also ingredient C.}}_{\textit{Body}}$$

Below we provide some basic information about these three claim parts. Books have been written about claim drafting and how to determine the meaning of claims. Such detail is beyond the scope of this article (42).

The Preamble. A preamble is an introductory statement that names the thing that is claimed or defines the field of invention. The preamble may or may not serve as a claim limitation. If a preamble serves as a claim limitation, it narrows the claim. In other words, it provides an additional requirement a product or process must possess to infringe the claim.

The Transition. The transition comes between the preamble and the body. One of the following two transitional phrases, or a variation thereof, is used in most claims: (1) *consisting of*, as used in the hypothetical above, or (2) *comprising*. The transitional phrase used affects how a claim is construed.

Consisting Of: The term “consisting of” is referred to as a “closed” transitional phrase. This means that the claim covers products and process that include only the limitations that follow the transition. For example, in the hypothetical above, the claim covers only compositions that contain ingredients A, B, and C; compositions with only A, B, and C would infringe claim 1. The claim would not cover compositions that also contain ingredient D; a composition containing A, B, C, and D would not infringe claim 1.

Comprising: The term “comprising” is known as an “open” transitional phrase. This means that the claim covers products and processes that include each limitation that follows this phrase but that infringing products can also include additional elements. For example, had the hypothetical above used “comprising” as the transitional phrase, the claim would cover compositions that contain ingredients A, B, and C, whether or not they also contain ingredient D; a composition containing A, B, C, and D would infringe the claim if it were written with “comprising” as the transitional phrase.

The Body. The body of the claim is everything that follows the transition phrase. The body contains the *limitations* of the claim. As noted previously, limitations are (a) the elements against which patentability is tested and (b) the elements that a product or process must contain to infringe. In claim 1, above, A, B, and C are limitations.

There are two primary claim types: independent and dependent. *Independent* claims stand on their own. *Dependent* claims relate back to or “depend from” a previous claim. A dependent claim is construed to contain each limitation of the claim from which it depends, as well as the additional limitations added in the dependent claim itself. Consider the following hypothetical claim set:

1. A packaging film comprising laminate A, laminate B, and an adhesive.
2. The packaging film of claim 2 further comprising a coating.
3. The packaging film of claim 3, wherein the coating is impermeable to moisture.

Claim 2 is an independent claim that has three limitations: laminate A, laminate B, and an adhesive. Claim 3 is a dependent claim that depends from claim 2. Therefore, claim 3 contains all three limitations of claim 2 (laminate A, laminate B, and an adhesive), as well as the additional limitation of a coating (whether impermeable to moisture or not). Claim 4 depends from claim 3 (which depends from claim 2). Therefore, claim 4 contains the laminate A, laminate B, and the adhesive limitations of claim 2 and the coating limitation of claim 3, with the additional limitation that the coating must be impermeable to moisture. A competitor need only infringe one patent claim to be liable for infringement and face an injunction and/or infringement damages.

Claim Construction. Claim construction is a very complicated process by which the claims are interpreted to understand what they do and do not cover. It requires consideration of the language of the claims themselves, the specification, and the prosecution history of the patent (e.g., representations made to the examiner to obtain the patent). Claim construction begins with the language of the claim. Typically, the words and phrases in the claims are given their ordinary meaning as used and understood by people in the field of the invention. However, a patentee can be his or her own “lexicographer,” meaning that the patentee may use claim terms in a way that is markedly differently from their ordinary meaning, provided that the patentee’s definition is clearly set forth in the patent specification. Even seemingly simple terms may lead to claim construction disputes during litigation. Resolution of such disputes often requires a court hearing that can last hours or even days. For example, in one patent dispute, the parties fought about the meaning of the claim term "generally convex" (43). Resolution of such claim construction issues is often determinative of whether a patent is valid and/or infringed.

Legal Opinions

Understanding what a claim covers is crucial to assessing issues of infringement and validity. For example, if a business wants to determine if a proposed new product may infringe an existing patent, it must (1) construe the claims and (2) compare the construed claims to its new product. Infringement is not determined by comparing a proposed product to the patent holder's product. Infringement is tested against what is claimed in the patent. Similarly, to assess the validity of a patent, one must (1) construe the claims and (2) consider the construed claims in view of the prior art and other patentability requirements to determine if the claimed invention meets the requirements of patentability. Federal courts strictly adhere to these two-step processes.

Due to the complexity of the claim construction process, a patent attorney is typically consulted. For example, companies often seek *freedom-to-operate opinions* or *non infringement opinions* from patent attorneys before launching a new product. Such opinions entail searching the patent landscape to identify patents of interest, analyzing the patents (claims, specification, and prosecution histories), construing the claims, and comparing the claims to the proposed product to assess the potential for infringement liability. If potentially troublesome patents are identified, the patent attorney may be asked to assess the validity and/or enforceability of the patent. The patent attorney may also be asked for advice regarding design around options—that is, ways to achieve the same result without infringing any potentially problematic patent claims.

ENFORCING PATENTS

The rights that accompany an issued patent are not self-executing. Although the patent holder has the right to exclude competitors from making, using, selling, or offering for sale in the United States, or importing into the United States, the patented invention, the mere existence of a patent does not ensure that infringing competitors will not enter the market. For example, a competitor might sell a potentially infringing product because the competitor (1) did not know about the patent, (2) believed that the product would not infringe the patent, (3) believed that the patent was invalid, (4) believed the patent was unenforceable, and/or (5) believed that infringement would not or could not be detected.

This section addresses the identification of potential infringers, the interaction between business goals and appropriate enforcement action, and the litigation process.

The Several Phases of Patent Enforcement

Pre-Enforcement. Before attempting to enforce a patent, a patentee must first determine whether there are potential infringers. This typically involves monitoring the market to identify potentially infringing activity, obtaining potentially infringing products, and assessing whether such products infringe. The scientists and engineers working within a field, reading related literature, and attending trade conferences are often a source of such competitive information. Monitoring published patent applications and issued patents can also provide insight regarding competitor activities and where infringement might arise.

Once a potentially infringing product or process is identified, one must construe the claims and compare them to the potentially infringing product or process to determine whether there is infringement (see section entitled "The Anatomy of an Issued Patent," above). Patent counsel can be very helpful construing claim terms. Again, whether the patentee has a product of its own, and how that product compares to the potentially infringing product, is not relevant to the infringement analysis.

Deciding What to Do About Potential Infringer. Upon identifying a potential infringer, and concluding that a product or process likely infringes, the patent holder must decide what to do. For example, the patent holder could contact the potential infringer with the goal of negotiating a license for royalties or a cross-license. Alternatively, the patent holder could provide the potential infringer with notice of the patent and ask the potential infringer to remove a potentially infringing product from the market. The patent holder may instead decide that the ultimate goal is a license or cross-license, but choose to initiate a litigation to signal the patent holder's belief in the strength of the patent, hoping that this will result in better license terms. Or, the patent holder might decide not to assert the patent for business or other reasons.

Ultimately, how a patent holder proceeds will depend on the specific facts. However, the decision making process often includes considering and weighing the answers to at least the following questions:

1. What role does the patent play in the patent holder's business strategy? For example, does the patent protect a market that is important to the patent holder and in which the patent holder competes? If so, the patent holder has increased incentive to sue to exclude competitors as opposed to providing a license that would likely increase competition.
2. What is the relationship, if any, between the patent holder and the potential infringer? For example, are they fierce competitors or have they worked out patent licenses and other business agreements in the past? What relationship does the patent holder desire? If a friendly relationship is desired, litigation may not be the best approach.
3. How strong is the patent at issue? For example, are there documents created during prosecution of the patent that might provide a basis for alleging

inequitable conduct? Through discovery (discussed below), alleged infringers will often find weaknesses in the patent—some previously known to the patent holder and some previously unknown. Weaknesses in a patent provide a motivation for a nonlitigation resolution.

4. How much time would a patent infringement lawsuit require from important scientists or executives, and would such time commitments disrupt important R&D or business functions? The level of disruption must be weighed when determining whether to bring suit.
5. Does the potential infringer have any patents that could be used against the patentee? If so, a cross-license may be an appropriate goal, because a lawsuit (and countersuit by the competitor) might result in neither party being able to market their respective products.
6. Is the relevant market large enough, or important enough, to merit a lawsuit that could cost millions of dollars? Litigation can result in large damage awards that justify the costs involved. It can also result in excluding a competitor from an important market, whereas a license might result in less of a revenue stream.
7. What are the potential damages that could be recovered from the potential infringer?

Enforcement Through Litigation

If a patentee decides to sue, the lawsuit will typically progress through the following phases, each of which is discussed below: (1) filing of the lawsuit, (2) fact and expert discovery, (3) claim construction; and (4) trial. Patent lawsuits rarely go to trial in under a year, and they often take several years to reach that point. The following sections go into more detail on the phases of litigation.

Filing of the Lawsuit.

The Patent Holder Files a Complaint. If a patent owner has a good faith belief that a competitor is infringing, the patent owner can enforce its patent rights in court. As explained in the section entitled "Introduction to the United States Patent System," patent suits are handled in the federal court system. To initiate a lawsuit in the federal court system, the patentee must file what is called a *Complaint*. The Complaint names the alleged infringer, identifies the patent(s) that are allegedly infringed, recites the allegedly infringing activity, and specifies the remedies that the patent holder seeks. Typically, the patent holder seeks payment of money damages and/or an injunction ordering the infringer to stop the infringing activity.

The patent holder may bring suit on one patent or several patents. For example, assume that the patent holder has a first patent covering a packaging material and a second patent covering packages made with the material. If a competitor is selling a product in a package made with the claimed packaging material, the patent holder could sue on both the material and the packaging patent. Furthermore, a patent holder can assert a patent even if it suspects that only some, but not all, of the claims are infringed; that is, a patent is infringed if there is infringement of a single claim.

The party filing suit is known as the *Plaintiff*, and the party being sued is known as the *Defendant*. Typically, but not always, the Plaintiff is the patent holder and the Defendant is the potential infringer.

The Alleged Infringer Files an Answer to the Complaint. After the Complaint is filed, the competitor files an *Answer*, which additionally includes *defenses*. These defenses usually include one or more of the following: noninfringement, invalidity, and/or unenforceability. The alleged infringer can assert as many defenses as applicable.

Evidence And Burdens. Discovery is the process through which the parties obtain information, known as *Evidence*, relevant to the case. The patent holder uses discovery to uncover details about the accused product or process to prove that infringement exists. Conversely, the alleged infringer uses discovery to uncover information relevant to invalidity or unenforceability defenses, such as information regarding how an invention was conceived or whether the inventors withheld material information from the USPTO during prosecution of the patent.

Such evidence, in the form of documents, testimony, and often expert opinion, is presented to the court to try to meet a party's burden of proof in the case. In patent litigation, the patent holder has the burden to prove infringement by a *preponderance of evidence*—that is, that there is more than a 50% likelihood that the allegedly infringing product uses the patented subject matter. This means that if neither the patent holder nor the alleged infringer provide any proof of infringement or non-infringement, there will be no infringement because the patent owner has not met its burden.

Similarly, the alleged infringer has the burden of proving defenses against infringement but, as explained above, does not have to prove noninfringement. With regard to proving invalidity and/or unenforceability, the alleged infringer must do so by *clear and convincing evidence*. This is a more difficult standard to satisfy than the preponderance of the evidence standard, because once a patent is issued by the USPTO, it is presumed valid.

Fact Discovery. During fact discovery, the parties request and exchange factual information related to the case. The *Federal Rules of Civil Procedure* ("the Rules"), which govern litigation in federal court, provide the following mechanisms for obtaining such factual information: document requests, interrogatories, requests for admission, and depositions. Fact discovery usually involves disclosing to the opposing party, a competitor, information that one would consider confidential. Typically the parties have the court enter a *Protective Order* that protects such information by governing who of the opposing party can see such confidential information, as well as what the receiving party can do with the information. In other words, the protective order is negotiated so that even though information is exchanged, the dissemination and use of confidential information can be restricted.

Document Requests. Each party is permitted to request documents from the opposing party to obtain evidence relevant to their allegations or defenses. These requests are called *Document Requests*. Each party is obligated to preserve and hand over documents that might prove relevant to the lawsuit. These include laboratory notebooks, meeting minutes, memoranda, financial data, advertising and marketing documents, flow diagrams, forecasts, organizational charts, invoices, consulting agreements, e-mails, and the like. The Rules require exchanging information maintained in paper form as well as in electronic form, and even electronic information that has been erased, where traces are accessible. Ultimately, the parties can exchange tens of thousands, hundreds of thousands, or even millions of pages of such documents. These documents are then reviewed by the respective parties to identify evidence to present to the court to prove infringement, invalidity, and so on.

Interrogatories and Requests for Admission. An *Interrogatory* is a question to the opposing party that the opposing party must answer. For example, an alleged infringer might propound interrogatories regarding how and when the inventors of a patent conceived their invention, or when the patent holder first showed prototypes of the invention to a customer. The patent holder must then make a good faith effort to obtain and provide an answer to the interrogatory. Likewise, the patent holder may present interrogatories to the alleged infringer asking for details about its process or products.

Requests for Admission are statements that the opposing party is asked to admit. Such admissions can reduce the issues for trial. For example, based on the review of documents produced in response to a document request, an alleged infringer might ask the patent holder to admit that its inventors had not conceived their invention by a given date. Once admitted, the alleged infringer would no longer have to prove (or present evidence regarding) the admitted fact at trial. Likewise, if the alleged infringer admits that its process uses a specific step(s), the patent holder will not need to separately prove this at trial when attempting to prove infringement.

Depositions. Typically after documents have been exchanged and reviewed, each side identifies individuals (i.e., witnesses) from the opponent's company for deposition. These often include the inventors, people with knowledge of the patent prosecution, people with knowledge of the accused products or processes, people knowledgeable about product costs and profit margins, and so on. During a deposition, the witness is required to answer questions from the opposing attorney. The attorney's questions and the deponent's answers are recorded by a stenographer and may also be videotaped. All questions are answered under oath, and the answers (subject to objections) can be used at trial for different purposes, including to impeach a witness' testimony if the witness' trial testimony differs from the witness' deposition testimony.

Fact depositions are used to gather fact evidence related to the issues in the case (infringement, validity, etc.). Fact depositions therefore address what actually happened with regard to the invention at issue, the allegedly infringing product, and other issues in the case. Questioning of the patent holder's witnesses often relates to how the patented process or product was developed, communications with the USPTO, and the content of relevant memoranda, reports, correspondence, e-mails, and so on. Questioning of the accused infringer often relates to (a) the details of accused products or processes and (b) the accused infringer's knowledge of the patents in suit.

Many scientists and engineers dread the idea of being deposed. Depositions represent an unfamiliar environment to most scientists and engineers, and many are anxious about how their performance will impact their company. To alleviate such anxiety and to prepare for the deposition, the witness will usually have a meeting with an attorney that will represent the witness at the deposition, also known as the attorney who defends the witness. During this meeting, the attorney can answer questions the witness has regarding depositions. In addition, the attorney will usually:

1. Explain the mechanics and rules of a deposition, such as the role of the witness, questioning attorney and defending attorney, the presence of a court reporter, and so on.
2. Review the issues in the litigation.
3. Discuss the witness' knowledge regarding the issues in the litigation.
4. Explain how the witness fits into the case.
5. Discuss questions and/or issues that will likely arise during the deposition.
6. Provide guidelines regarding how to answer questions, including telling the witness to listen to questions carefully, to answer only the question asked, and to tell the truth.

Adequacy of preparation for a deposition often correlates with how well a witness does do at deposition. Therefore, it is important to allow an appropriate amount of time for preparation. Often such preparation will last a day or more, depending on the anxiety level of the witness, how important the witness is to the case, and the amount of material to review.

Impact of Fact Discovery. As discovery proceeds, each party typically refines its litigation positions based on the discovery it obtains. For example, the alleged infringer might refine its defenses to include an unenforceability defense if it learned during discovery that one of the patent holder's inventors had information material to patentability that was not provided to the USPTO. Refinement can be based on uncovered documents, interrogatory responses, request for admission responses, and deposition answers.

In some cases, fact discovery can drain a company's resources. For example, key employees may have to spend days, or weeks, helping attorneys collect documents for production, helping attorneys respond to interrogatories and requests for admission, preparing for depositions, and being questioned as witnesses at depositions. Through the discovery process, opposing counsel will often find any "skeletons" that exist in relation to the litigation. The disruptive nature of litigation must therefore be weighed against the potential value of litigation before a patent owner asserts a patent.

Expert Discovery. Expert discovery follows fact discovery. During expert discovery, the parties work with experts in the field of the invention covered by the asserted patent(s). Experts can be university professors with expertise in the technology at issue, outside consultants, financial experts (to address, for example, damages issues), and the like.

Experts are retained to provide expert opinions regarding issues in the case. Unlike fact witnesses whose testimony is limited to what actually happened, experts can provide opinions and consider what would happen in various hypothetical circumstances. Experts typically rely on documents and other information exchanged by the parties during fact discovery. They may also conduct tests or find relevant scientific materials on their own. Thus, for example, a patent holder may hire an expert to submit a report providing opinions as to how the alleged infringer's product meets all of the limitations in its patent claims, supported by testing that the expert conducted. The alleged infringer may retain an expert to submit a report giving opinions regarding why the asserted patent claims are invalid.

After an expert submits an expert report on behalf of a party, the opposing party will usually take the expert's deposition. Such depositions are used to more fully understand the expert's opinions and to probe the bases for the opinions.

Claim Construction. At some point during litigation, the parties may have a hearing before the court to establish the meaning of the asserted claims, or, more particularly, specific terms within the asserted claims. This is known as a *claim construction hearing*. The claim construction hearing can happen during or after fact or expert discovery, or even as part of the trial. The result of a claim construction hearing often has a large impact on the litigation. For example, if a claim is construed narrowly, it might make it difficult for a patent owner to prove infringement. However, that same narrow construction might help the patent owner defend against an allegation of invalidity.

Trial. Many patent cases do not go to trial. One reason is that many patent cases settle before trial because of weaknesses in the parties' positions revealed during fact and/or expert discovery. Another reason is that cases may be resolved before trial if a party has proven to the judge that there are no issues of fact that have to be resolved at trial, thereby allowing the judge to rule without the need for a trial. However, if a case does not settle or end for some other reason, it will go to trial.

The trial is an opportunity for a judge and/or jury to see fact and expert witnesses testify and to assess their credibility. Indeed, many cases are won or lost based on whether the judge and/or jury believe a witness.

During trial, and even after the trial but before a decision has been rendered by the judge or jury, the parties can still settle the case. Again, such settlements occur because presentation of evidence at trial, or the performance of a witness at trial, may highlight a weakness in a party's position. If a case does not settle, a decision will be rendered. As explained in the section entitled "Introduction to the United States Patent System," such decisions can be appealed to the Federal Circuit and ultimately to the U.S. Supreme Court.

PERMEATION OF AROMAS AND SOLVENTS THROUGH POLYMERIC PACKAGING MATERIALS

DONGHWA CHUNG
Department of Marine Food
Science and Technology,
Kangnung-Wonju National
University, Gangneung,
Gangwong,
Republic of Korea

Mass transport in food and pharmaceutical package systems encompasses a number of phenomena referred to as either *permeation, adsorption*, or *migration*. Permeation includes the transfer of molecules from the product to the external environment through the package, or from the storage environment through the package to the product. Adsorption involves the takeup of molecules contained by the product into, but not through, the package, while migration is the passage of molecules originally contained by the package itself into the product. These mass transfer processes also provide the basis of further physiochemical activities within the package system. Such activities may induce physiochemical changes in the product, as well as physical damage of the package, or both (1). In a package/product system, the mass-transfer processes between product, package, and storage environment as well as the physiochemical activities associated with them are referred to as *product / package interactions* (2) (see Pharmaceutical packaging; Packaging, food).

The permeation of water vapor and gases, such as oxygen and carbon dioxide, has been extensively investigated for food and pharmaceutical package systems due to its significant effects on product shelf life. In the last decade, the overall concern on the mass transport in package systems has shifted a little more toward the transfer of volatile organic compounds of low molecular mass, such as aromas and solvents, due both to shelf-life reasons and to an incresing interest in safe and healthy food packaging. Aromas or flavors are one of the key attributes affecting the consumer acceptance of a packaged food. Their permeation through the package as well as their adsorption on the package, called flavor scalping, causes the loss of original sensorial characteristics of the product during storage, resulting in the reduction of product shelf life. Solvents, such as toluene, ethyl acetate, hexane, and abietic acid, are often contained in package materials, printing inks, or adhesive systems. Their migration into the packaged product not only changes the original sensorial properties of the product but also in some cases causes the generation of off-flavors that negatively alterate the consumer perception. In addition, the migrating solvents raise significant concerns about the toxicological safety of the product. Obviously, all these concerns are related to the product/package interactions. In this chapter, the permeation, rather than sorption or migration, of aromas and solvents has been discussed because the theory and experimental data on permeation can be expanded to understant the other processes.

The permeation process occurs in five consecutive steps, as schematically illustrated in Figure 1: (1) mass transfer from the bulk of phase 1 to the adjacent surface of package film, (2) sorption from the adjacent surface into package film, (3) molecular diffusion, (4) desorption from package film into the adjacent surface in contact with phase 2, and (5) mass transfer from the adjacent surface to the bulk of phase 2.

Since the molecular diffusion within package film is the rate-limiting step of the whole process, the rate of permeation can be described by Fick's law of diffusion. Under steady-state conditions, the flux (J) of permeant through the film is given by the following Fick's first law:

$$J = -D\,\frac{dc}{dx} \tag{1}$$

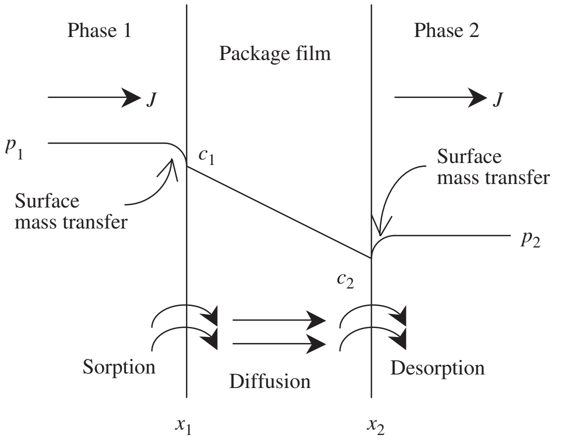

Figure 1. Schematic diagram of gas or vapor permeation through a package film.

where D is the diffusion coefficient of permenat in the film, c is the concentration of permeant in the film, and x is the distance in the film. Integration of equation (1) yields the following expression of J:

$$J = \frac{D}{l}\,\Delta c \tag{2}$$

where $l(=x_2-x_1)$ is the thickness of the film and $\Delta c(=c_1-c_2)$ is the difference in permeant concentration between the two surfaces of the film. Experimental determination of these surface concentrations is very difficult. Therefore, the surface concentration is necessary to be converted to the partial pressure (p) in bulk phase, which is easily measurable, using Henry's law of solubility:

$$c = Sp \tag{3}$$

where S is the solubility coefficient of permeant in the film. By substituting equation (3), equation (2) is rewritten as

$$J = \frac{DS}{l}\,\Delta p \tag{4}$$

where $\Delta p(=p_1-p_2)$ is the drop of partial pressure across the film. The product of D and S is often called permeability P, which is the most widely used coefficient for expressing the rate of packaging permeation:

$$P = DS \tag{5}$$

Another coefficient that has been frequently used is permeance R, which has a physical meaning similar to that of mass transfer coefficient:

$$R = \frac{DS}{l} \tag{6}$$

Substitution of equation (5) into equation (4) gives the following well-known packaging permeation equation:

$$J = \frac{P}{l}\,\Delta p \tag{7}$$

The gas flux J is often called the *permeant transmission rate*; and in the case of water vapor, the *water-vapor transmission rate* (WVTR) is commonly used.

The above equations are applicable only for situations where D is independent of permeant concentration and S follows Henry's law. However, when the permeation process involves highly interactive organic permeants such as aroma, flavor, or solvent molecules, the diffusion process is more complex than the diffusion of simple gases, and the diffusion coefficient may vary as a function of permeant concentration and time (3–6). Where D varies with time, the diffusion is often called *non-Fickian*. Mears (7) proposed the following expressions for cases where the diffusion coefficient is concentration-dependent:

$$D = D_0(1 + ac) \tag{8}$$

or

$$D = D_0 \exp(bc) \tag{9}$$

Equation (9) is more suitable in cases where the diffusion coefficient is strongly concentration-dependent. Here D is the differential diffusion coefficient, D_0 is the limiting diffusion coefficient, and a and b are constants.

The variables affecting permeation and diffusion processes in a package can be grouped as follows:

1. Compositional variables:
   a. Chemical composition of the polymer and permeant
   b. Morphology of the polymer
   c. Permeant characterstics
   d. Concentration of the permeant
   e. Presence of copermeant
2. Environmental and geometric factors
   a. Temperature
   b. Relative humidity
   c. Packaging geometry

While an in-depth treatment of each of the above factors is beyond the scope of this article, selected examples are discussed to illustrate their role in the transport of organic permeants in barrier polymers. For a more in-depth treatment, the reader is referred to the references listed in the Bibliography and references cited therein.

CHEMICAL COMPOSITION OF THE PACKAGING MATERIAL

The relationship between permeant transfer characteristics and the basic molecular structure and chemical composition of a polymer is rather complex, and a number of factors contribute to the permeation and diffusion processes; the most important are as follows:

- Cohesive-energy density, which produces strong intermolecular bonds, van der Waals or hydrogen bonds, and regular, periodic arrangement of such bonding groups.

- The glass-transition temperature (T_g) of the polymer, above which free vibrational motion and rotational motion of polymer chains occur, so that different chain conformations can be assumed.

With respect to the glass-transition temperature of barrier polymer structures, DeLassus (8) reported that glassy polymers have very low diffusion coefficients for flavor, aroma, and solvent molecules at low concentrations. Typically, these values are too low to measure by standard analytical procedures. The diffusion coefficient determines the dynamics of the permeation process and thus the time to reach steady state, which accounts for glassy polymers exhibiting high-barrier characteristics to organic permeants. Polyolefins, being well above their glass-transition temperature, are non-glassy polymers and have high diffusion coefficients for organic permeants, and steady-state permeation is established quickly in such structures.

Polymer-free volume is also a function of structural regularity, orientation, and cohesive-energy density. The aforementioned structure–property relationships all contribute to a decrease in solubility and diffusivity and thus permeability.

Salame (2) has proposed a relationship between polymer molecular structure and permeability based on an empirical constant (π), or “Permachor” constant, which, when substituted into the Permachor equation, predicts the gas permeability of polymer structures. The correlation parameter or the “Permachor” constant is based on the cohesive-energy density and free volume of the polymer, two major properties of the polymer. Agreement between the Permachor constant and film permeability has been shown to be quite good for oxygen, CO_2, and nitrogen, but not for water vapor and organic vapors.

The equation for relating gas permeability to the Permachor constant is as follows:

$$P = A\,\exp(-s\pi) \tag{10}$$

where A and s are constants for any given gas at temperature T and π is the Permachor constant of the polymer.

POLYMER MORPHOLOGY

Solid-state polymer chains can be found in a random arrangement to yield an amorphous structure or a highly ordered crystalline phase. Most polymers used in packaging are semicrystalline or amorphous materials (see Polymer properties).

Morphology refers to the physical state by which amorphous and semicrystalline regions coexist and relate to each other in a polymer, and it depends not only on its stereochemistry but also on whether the polymer has been oriented, on the conditions of temperature, strain rate, and cooling temperature, and on the melt cooling rate.

Fundamental properties that are associated with polymer morphology and will therefore influence the permeability and diffusivity characteristics of the polymer include:

- Structural regularity or chain symmetry, which can readily lead to a three-dimensional order or crystallinity. This is determined by the type of monomer(s) and the conditions of the polymerization reaction.
- Chain alignment or orientation, which allows laterally bonding groups to approach each other to the distance of the best interaction, enhancing the tendency to form crystalline materials.

Morphology is thus important in determining the barrier properties of semicrystalline polymers. This is illustrated by the results of permeation studies carried out on biaxially oriented polyethylene terephthalate (PET) films of varying thermomechanical history (9).

Film samples were biaxially stretched at a strain of 350%/s, based on the initial dimensions of 4 in. × 4 in., which corresponded to an orientation rate of 14 in./s biaxially.

The degree of orientation was 400% based on the initial dimensions. The orientation temperature was 90°C, 100°C, and 115°C, respectively.

Table 1 summarizes the results of permeation studies carried out with ethyl acetate in PET film biaxially oriented at 90°C and 115°C, respectively, and serves to illustrate the effect of thermomechanical history (stretching-temperature values) on the relative barrier properties of PET, for the permeation of ethyl acetate. The percent crystallinity of PET film oriented at 90°C was 22%, while the percent crystallinity of the film sample oriented at

Table 1. Permeability of Ethyl Acetate through PET Film Biaxially Oriented at 90°C and 115°C

Orientation Temperature (°C)	Vapor Activity (a_v)	Run Temperature (°C)	Permeability[a], $P \times 10^{20}$	Lag Diffusion Coefficient[b], $D \times 10^{12}$
90	0.59	30	2.6	1.8
	0.43	37	4.8	2.9
	0.21	54	15.4	11.0
115	0.59	30	0.014[c]	—
	0.21	54	3.6	5.3

[a] Permeability units are (kg · m) ($m^{-2} \cdot s^{-1} \cdot Pa^{-1}$).
[b] Diffusion coefficient units are $cm^2 \cdot s^{-1}$.
[c] No permeation after 550 h. Value of P reported represents an upper bound.

115°C was 31%. As shown, ethyl acetate permeability values decreased by approximately four times by increasing the film orientation temperature from 90°C to 115°C.

PERMEANT CHARACTERISTICS

The most important characteristics of the permeant affecting its transfer in and through a film include:

- Carbon chain length or boiling point
- Functional groups and polarity

With respect to the carbon chain length, different studies have been carried out to evaluate the influence of this characteristic on permeation phenomenon, particularly influencing the aforementioned second step of this process, that is, sorption. In particular, homologous series of hydrocarbons, esters, aldehydes, alcohols, and benzoates in the vapor phase were taken into consideration (10, 11). The obtained results showed that, in compounds below 10 carbon atoms, both the solubility and the permeability coefficients (*S* and *P*, respectively) of the volatiles increased two- to five-fold with each additional methylene group, depending on the types of packaging films. Obviously, diffusivity (*D*) decreased due to the steric hindrance. On the contrary, for molecules with 11 or more carbon atoms, the increments were less or negative, as in the case of aldehydes. Different experiments on the permeation of alkyl esters (C_5–C_{10}), methyl ketones (C_7–C_{10}), aldehydes (C_7–C_{10}), and sulfur compounds through different plastic films (PP, PE, PVDC, EVOH) led to similar results (12–16). Sorption into plastic films can take place also in the case of longer molecules as, for instance, fatty acids. A specific study (17) showed that these kinds of compounds with 16–18 carbon atoms moved through the LDPE film, with the final result of delaminating the composite (multilayer) flexible packaging film. Finally, carbon chain length and boiling point are strictly linked each other. For instance, within sorbates, there is a proportional relationship between boiling point and solubility. Moreover, a further relationship exists between the logarithm of the solubility coefficient and the boiling point of linear esters, alkanes, and ketones (e.g., hexyl butyrate, *n*-decane, or 3-octanone) through PVDC polymers (12–16).

The effect of functional groups on the transfer properties of aroma compounds through a film is much larger than the boiling point in the liquid phase rather than in the vapor phase, due to close interactions between molecules (10). Hydrocarbons and oxygenated terpenes, for example, did not over PP nor LDPE by permeation when put in aqueous model solutions (11). The polarity of the solutes can be effectively considered as the most important controlling factor to explain the tendency to permeation. Researchers pointed out that carvone ($C_{10}H_{14}O$) and limonene ($C_{10}H_{16}O$), even if similar terpenes, show different sorption and diffusion properties. In general, permeation of limonene (less polar than carvone), through plastic films, takes place quickly, because of lesser cohesive forces (11). In another study on the permeation of citrus oil compounds through polyolefins, it was found that terpenes (C_{10} carbon length) exhibited the highest affinity for the polymers, followed by sesquiterpenes (C_{15}) (18). In addition, the permeation of esters and aldehydes was more intense than alcohols due to polarity. Within aldehydes, those saturated showed a greater permeation compared to the unsaturated ones. For orange juice aromas, the following ranking was established in terms of affinity to LDPE: hydrocarbons > chetones > esters > aldehydes > alcohols (15, 16, 19). The same ranking can be extended to apple juice aromas associated with LDPE, LLDPE, PET, PA, and PP films (20). Another important factor influencing the permeation of flavor components into plastic films (in particular concerning the sorption step) is the pH of the system, which can modify the polarity of the permeant. The sorption of 2-hexanal into PE was found to be increased by a factor of 40 between pH 3.0 and pH 5.0 (21). Analogously, sorption of alcohols into LDPE was increased by lowering the pH up to 3.0 (19). Finally, sorption of limonene into LDPE at 22°C was higher at pH 5.2 than at pH 2.6 (1.3 times more; results significant at 95% level) (22).

CONCENTRATION DEPENDENCE OF THE TRANSPORT PROCESS

Permeance of limonene vapor through (1) oriented polypropylene, (2) saran-coated oriented polypropylene, (3) two-sided acrylic (heat-seal)-coated biaxially oriented polypropylene, and (4) one-side saran-coated, one-side acrylic-coated polypropylene film samples, as a function of permeant concentration, is presented graphically in Figure 2, where permeance (*R*) is plotted as a function of permeant concentration (23). The observed concentration dependency of the permeance values may be attributed to the permeant/polymer interaction, resulting in configurational changes and alteration of polymer-chain conformational mobility. Zobel (24) reported similar findings for the transport of the permeant benzyl acetate through coextruded oriented polypropylene and saran-coated oriented polypropylene, at various permeant concentrations.

PRESENCE OF COPERMEANT

As shown above, organic vapors are capable of exhibiting concentration-dependent mass transport processes. Therefore, the type and/or mixture of organic vapors permeating will determine the magnitude of sorption and permeation, as well as the effect of a copermeant on permeant permeability. The synergistic effect of a copermeant is illustrated by the results of permeation studies carried out on a biaxially oriented polypropylene film. The degree of film orientation was 430% (machine direction) and 800% (cross-machine direction), based on the initial dimensions. Binary mixtures of ethyl acetate and limonene of varying concentration were evaluated as the organic permeants (25).

Results of permeation studies for selected ethyl acetate/limonene binary vapor mixtures are presented in Figures 3 and 4, respectively. As shown in Figure 3 (ethyl

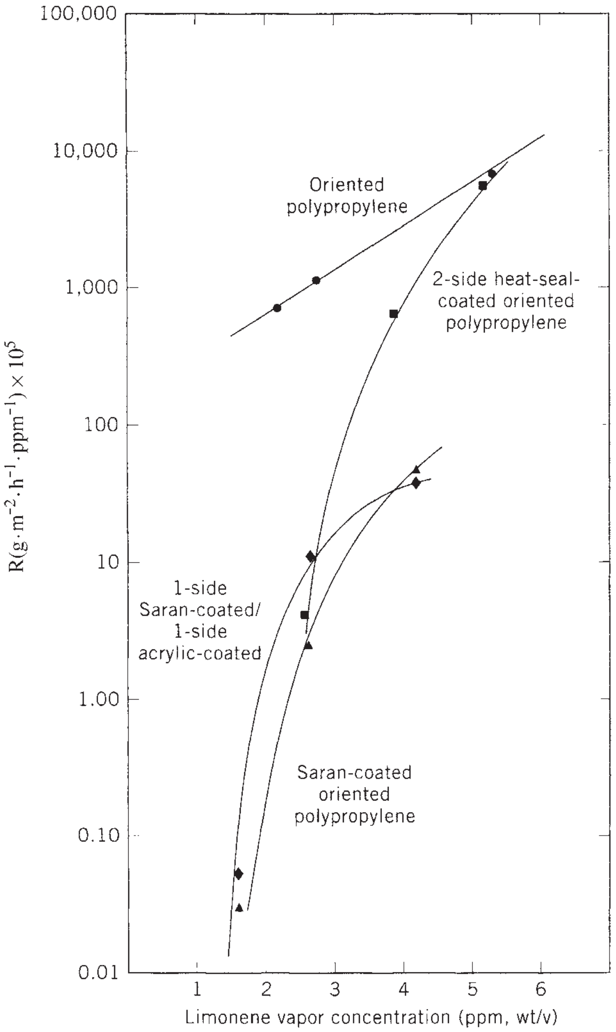

Figure 2. The effect of limonene-vapor concentration on log R for oriented polypropylene and coated oriented polypropylene structures (22° ± 1°C).

acetate $a_v = 0.10$ and limonene $a_v = 0.18$), limonene vapor had a significant effect on the transport properties of the copermeant. A 500% increase in the permeability constant of ethyl acetate was obtained, when compared to ethyl acetate vapor permeability alone, at similar test conditions. However, at this concentration level, ethyl acetate did not appear to influence the permeation of the limonene vapor. The transmission-rate profile curve for limonene vapor in the binary mixture is superimposed in Figure 3, to provide a complete description of the transmission characteristics of the mixed-vapor system.

For the ethyl acetate ($a_v = 0.1$)/limonene ($a_v = 0.29$) binary mixture, a permeation rate 40 times greater than the transmission rate of pure ethyl acetate vapor, of an equivalent concentration, was obtained. This is illustrated in Figure 4, where the transmission–profile plot of the binary mixture is presented, and compared to the transmission-rate profile curve for ethyl acetate vapor alone. Again, at this concentration level, ethyl acetate did not appear to affect the permeation characteristics of limonene vapor.

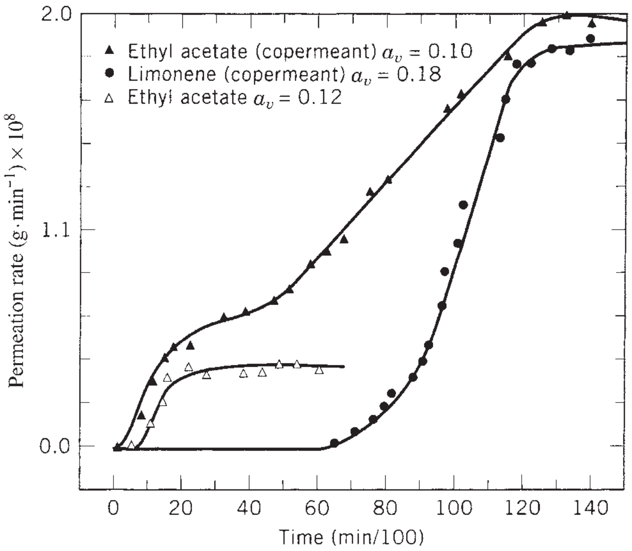

Figure 3. Comparison of the transmission profile of the binary mixture, ethyl acetate ($a_v = 0.1$)/limonene ($a_v = 0.18$), with the transmission profile of ethyl acetate ($a_v = 0.12$) through oriented polypropylene.

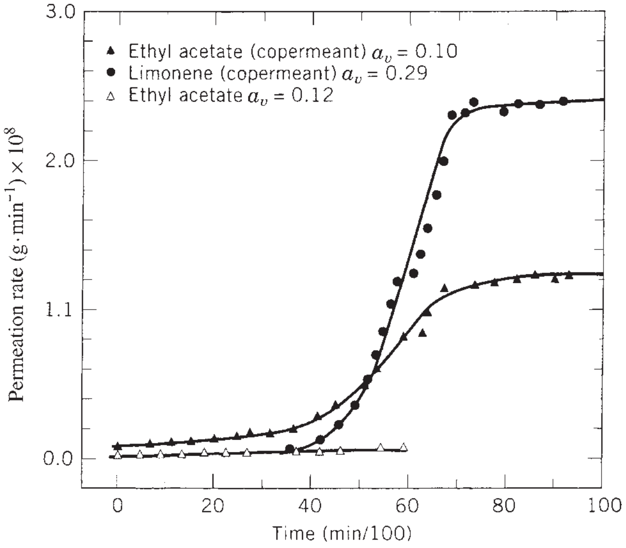

Figure 4. Comparison of the transmission profile of the binary mixture, ethyl acetate ($a_v = 0.1$)/limonene ($a_v = 0.29$), with the transmission profile of ethyl acetate ($a_v = 0.12$).

For studies carried out with the binary mixture of ethyl acetate $a_v = 0.48$ and limonene $a_v = 0.18$, the individual components of the mixture were found to have a significant effect on the permeation rates of the copermeant.

Since the permeability is drastically affected in the sorbate/polymer systems studied, the diffusion coefficient and/or the solubility coefficient must also vary in the presence of a copermeant to account for the observed increases in the transmission rates for the components of ethyl acetate/limonene binary mixtures. By direct measurement of the equilibrium solubility, Nielsen and Giacin

(26) found that the solubility coefficient values were independent of sorbate vapor activity, over the range of activity levels studied, and were not affected by the presence of a copermeant.

For the ethylacetate ($a_v = 0.10$)/limonene ($a_v = 0.21$) binary mixture, Hensley (25) reported a permeation rate of ethyl acetate 40 times greater than the transmission rate for pure ethyl acetate vapor of an equivalent concentration, while sorption studies showed the solubility coefficient of ethyl acetate to be constant and did not deviate from Henry's law in the presence of a copermeant. A possible explanation for the dramatic increase in the permeability coefficients for ethyl acetate in the presence of limonene as a copermeant lies with the high copermeant dependence of the diffusion coefficient.

For ethyl acetate/limonene binary mixtures, limonene as a copermeant appears to have little or no effect on the solubility of ethyl acetate in oriented polypropylene film, while significantly changing the inherent mobility of ethyl acetate within the polymer bulk phase. This accounts for the observed increase in the transmission rates for ethyl acetate through the OPP (oriented polypropylene) film in the presence of limonene.

While not fully understood, the proposed copermeant dependence of the diffusion coefficient may be due in part to copermeant-induced relaxation effects occurring within the polymer matrix. The absorption of organic vapors can result in polymer swelling and thus change the conformation of the polymer chains. These conformational changes are controlled by the retardation times of polymer chains. If these times are long, stresses may be set up that relax slowly. Thus, the absorption and diffusion of organic vapors can be accompanied by concentration as well as time-dependent processes within the polymer bulk phase, which are slower than the micro-Brownian motion of polymer chain segments that promote diffusion (7).

There is precedence in the literature in support of such long-time-period relaxation effects occurring in polymer films above their glass-transition temperature (27, 28). Thus, there may be copermeant-induced relaxation effects occurring during the diffusion of ethyl acetate/limonene binary mixtures in the oriented polypropylene film investigated. Such relaxation processes, which occur over a longer time scale than diffusion, may be related to a structural reordering of the free-volume elements in the polymer, thus providing additional sites of appropriate size and frequency of formation, which promote diffusion and account for the observed increase in the permeation rate of ethyl acetate in the presence of limonene as a copermeant.

EFFECT OF RELATIVE HUMIDITY

Table 2. Summary of Permeability Values of Acetone through Nylon 6I/6 T[a]

Temperature (°C)	$P \times 10^{19}$ (Dry Condition)[a]	$P \times 10^{19}$ (Humidified Conditions)[a]
60	3.7	4.9
75	6.5	11.2
85	9.8	17.6
95	11.8	—

[a] Permeability units are expressed in $(\mathrm{kg \cdot m})\ (\mathrm{m^{-2} \cdot s^{-1} \cdot Pa^{-1}})$.

The permeation of acetone vapor through amorphous polyamide (nylon 6I/6 T) under dry conditions and in the presence of a humid environment serves to illustrate the effect of water activity or moisture content on the barrier properties of hydrophilic polymer films. Studies were conducted at 60°C, 75°C, 85°C, and 95°C, at a constant permeant partial pressure value of 92 mm Hg (0.29 g/L). Water activity (a_w) of the permeant steam was maintained at 0.7 (70% RH), when measured at 23°C. Different film samples were used for dry- and humid-condition experiments. For an experiment, each run was maintained for a period of 8–14 days after attaining steady state, to ensure that the system was at equilibrium (29).

The respective permeability values are summarized in Table 2. As shown, sorption of water vapor resulted in an increase in permeability, as compared to dry conditions, with an increase of approximately 1.5 times being observed.

A further illustration of the effect of water activity on the barrier properties of polymer films is presented in Figure 5, where the total quantity of ethyl acetate permeated is plotted as a function of time, for the permeation of ethyl acetate through SiOx PET and EVAL-F films (30). The test conditions were as follows: temperature 22°C, 190 ppm (wt/v) concentration of ethyl acetate vapor, at 56% and 87% RH, respectively. Fluctuation of relative humidity was ±2%, and fluctuation of organic vapor concentration was ±5%.

For time, >500 h of continuous testing, there was no measurable permeation at 56% RH. The results indicate that both test films were excellent ethyl acetate vapor barriers at 56% RH and ambient temperature. However,

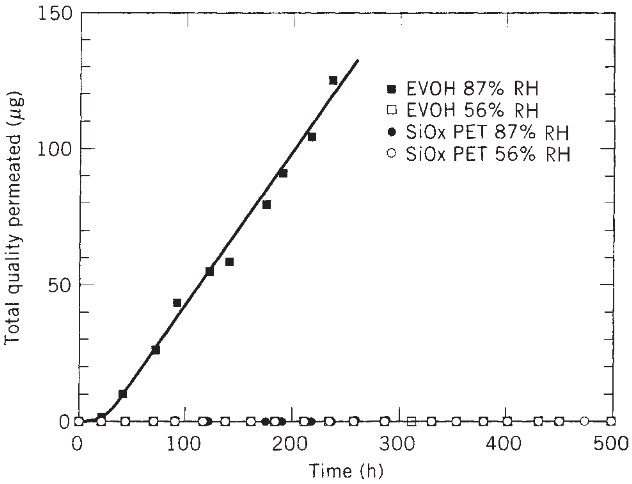

Figure 5. Transmission-rate profile curves of ethyl acetate vapor through SiO_x PET and EVAL-F films at 22°C, 190 ppm (wt/v), and 56% and 87% RH.

Table 3. The Effect of Relative Humidity on the Permeation of Ethyl Acetate Vapor through SiO_x PET and EVAL-F Films

Relative Humidity (%)	Sample	Permeance[a] $R \times 10^{17}$
56	SiO_x PET	<1.1
	EVAL-F	<2.2
87	SiO_x PET	<2.2
	EVAL-F	840±40

[a] Permeance units are expressed in $kg \cdot m^{-2} \cdot s^{-1} \cdot Pa^{-1}$.

as shown, at 87% RH the EVAL-F film had a significant increase in the permeation rate of ethyl acetate vapor, while the SiO_x PET film still showed no measurable increase in the rate of permeation. Table 3 summarizes the permeance values. Also presented in Table 3 are upper-limit-value estimations for film permeance.

Liu et al. (31) studied the effect of both water activity and permeant vapor concentration on the permeation of toluene vapor through a saran (PVDC)-coated OPP film. Studies were conducted at $22 \pm 1°C$. Since the film investigated in the present study is a multilayer structure, permeance values are presented to describe the barrier properties of the total structure.

The permeability parameters determined are summarized in Table 4.

A comparison of the permeance values for toluene, determined as a function of toluene vapor concentration and water activity, showed that the permeance values are highly dependent on both water-activity levels and toluene-vapor concentration. The findings suggested that the sorption of water vapor and/or toluene vapor leads to relaxation in the molecular structure of the saran barrier coating, resulting in a high concentration dependency of the permeance values. Toluene appears to be much more effective than water vapor in promoting relaxation of the saran coatings, since at the highest toluene-vapor concentration level studied (81 ppm), the permeance rate is independent of water-activity or sorbed-water levels. However, at the lower permeant concentration levels studied, the effect of sorbed water is quite significant, making this polymer structure very vulnerable to the permeation of low concentrations of toluene in the presence of sorbed water.

The results of this study also serve to illustrate the complex interrelationship of the barrier characteristics of the polymer film, permeant vapor activity, and sorbed-water concentration.

EFFECT OF TEMPERATURE ON PERMEATION PARAMETERS

Permeability, diffusion, and solubility coefficients follow a van't Hoff–Arrhenius relationship as given in equations (11–13):

$$P = P_0 \exp\left(\frac{-E_p}{R_c T}\right) \tag{11}$$

$$D = D_0 \exp\left(\frac{-E_D}{R_c T}\right) \tag{12}$$

$$S = S_0 \exp\left(\frac{\Delta H_s}{R_c T}\right) \tag{13}$$

where E_p = activation energy for permeation
E_D = activation energy for diffusion
ΔH_s = molar enthalpy of sorption
P_0, D_0, S_0 = constants
R_c = universal gas constant
T = absolute temperature

Lin (32) determined the permeability of ethyl acetate and toluene for the following commodity films: (*a*) oriented polypropylene, (*b*) high-density polyethylene, (*c*) glassine, (*d*) saran-coated oriented polypropylene, (*e*) acrylic-coated oriented polypropylene, and (*f*) metallized polyethylene terephthalate/OPP laminate.

Permeation studies were carried out at three temperatures to allow evaluation of the activation energies. For each temperature, three vapor activity levels were

terephthalate/OPP laminate structure following continuous testing for 44 h at 70°C and a vapor activity of 0.44.

From equation (11) the temperature dependency of the transport process associated with the respective barrier membranes, over the temperature range studied, was found to follow the Arrhenius relationship. From the slopes of the Arrhenius plots, the activation energy for the permeation process (E_p) was determined for the respective film samples, as a function of vapor activity. The determined activation energy values for both ethyl acetate and toluene are summarized in Tables 15, 16, respectively.

[a] N/A, data not available.

the permeation data will affect the values of both the diffusion coefficient and the permeability and would indicate any variations of the system parameters, such as temperature, or permeant concentration changes during the course of the permeation experiment. Gavara and Hernandez (33) have described a simple procedure for determining the diffusion coefficient and for performing a consistency analysis on a set of experimental permeation data from a continuous-flow permeation study. This procedure was applied to the continuous-flow permeation data obtained, to provide a better understanding of the mechanism of the diffusion and sorption processes associated with the permeation process. The consistency test for continuous-flow permeation experimental data has been described in detail by Gavara and Hernandez (33) and is summarized briefly below.

The value of the permeation rate at any time J_t, during the unsteady-state portion of the permeation experiment varies from zero, at time equal to zero, up to the transmission rate value (J_∞) reached at the steady state. This is described by the following expression (34):

$$\frac{J_t}{J_\infty} = \frac{4}{\pi^{1/2}}\left(\frac{\ell^2}{4Dt}\right)^{1/2} \sum_{n=1,3,5}^{\infty} \exp\left(\frac{-n^2\ell^2}{4Dt}\right) \tag{14}$$

Equation (14) is simplified to the following form:

$$\gamma = \left(\frac{4}{\pi^{1/2}}\right)(X)^{1/2}\exp(-X) \tag{15}$$

where γ is equal to the transmission rate ratio J_t/J_∞ and $X = \ell^2/4Dt$. In equation (14), D is assumed to be independent of permeant concentration and time. For each value of γ, a value of X can be calculated, and from a plot of $1/X$ versus t, the diffusion coefficient (D) can be determined. The authors further described two dimensionless constants, k_1 and k_2;

$$k_1 = \frac{t_{1/4}}{t_{3/4}} = \frac{X_{1/4}}{X_{3/4}} = 0.4405 \tag{16}$$

$$k_2 = \frac{t_{1/4}}{t_{1/2}} = \frac{X_{1/4}}{X_{1/2}} = 0.6681 \tag{17}$$

where $X_{1/4}$, $X_{1/2}$, and $X_{3/4}$ denote the numerical values of X when the permeation experiment has reached values of 0.25, 0.5 and 0.75, respectively, for γ, the transmission rate ratio.

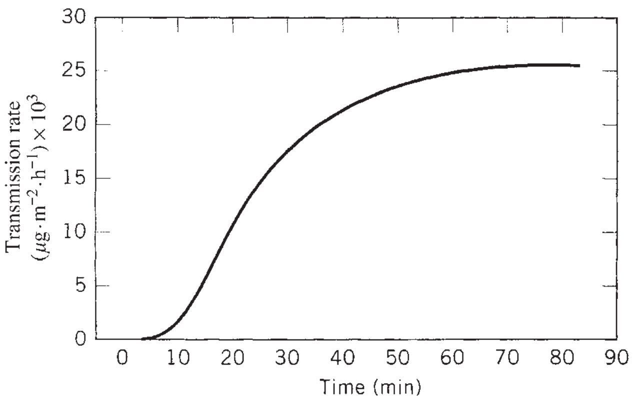
The numerical values of the constants k_1 and k_2 as given in Equations (16) and (17), together with the linear relationship of $1/X$ versus t, will provide values of the diffusion coefficient and a criteria to evaluate the consistency of the experimental data.

The results of a series of permeation studies carried out with limonene vapor are presented graphically in Figures 6, 7, where the transmission rate is plotted as a function of time, and serves to illustrate the applicability of the consistency test to permeation data obtained for polyethylene and polypropylene (35). The values of k_1 and k_2 calculated from the experimental data and the associated diffusion coefficients, $D_{1/4}$, $D_{1/2}$, and $D_{3/4}$, obtained by substitution into the expressions

$$D_{1/4} = \frac{\ell^2}{4X_{1/4}t_{1/4}} \tag{18}$$

$$D_{1/2} = \frac{\ell^2}{4X_{1/2}t_{1/2}} \tag{19}$$

$$D_{3/4} = \frac{\ell^2}{4X_{3/4}t_{3/4}} \tag{20}$$



$t_{1/4}$ = 839 (s)
$t_{1/2}$ = 1260 (s)
$t_{3/4}$ = 1936 (s)
$k_1 = t_{1/4}/t_{3/4} = 0.4333$
$k_2 = t_{1/4}/t_{1/2} = 0.6659$
$D_{1/4} = \ell^2/(4\,X_{1/4}t_{1/4}) = 1.62 \times 10^{-13}\ m^2 \cdot s^{-1}$
$D_{1/2} = \ell^2/(4\,X_{1/4}t_{1/4}) = 1.62 \times 10^{-13}\ m^2 \cdot s^{-1}$
$D_{3/4} = \ell^2/(4\,X_{1/4}t_{1/4}) = 1.58 \times 10^{-13}\ m^2 \cdot s^{-1}$
average $D = 1.61 \times 10^{-13}\ m^2 \cdot s^{-1}$

Figure 6. Transmission-rate profile and consistency test for the permeation of limonene ($a_v = 0.4$) through high-density polyethylene at 50°C.

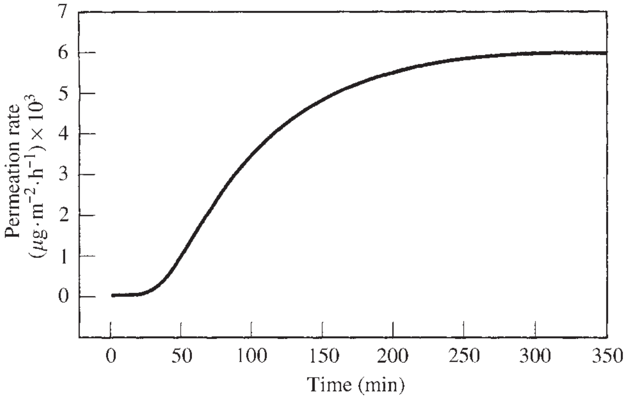


Figure 7. Transmission-rate profile and consistency test for the permeation of limonene ($a_v = 0.2$) through oriented polypropylene.

are also summarized in the respective transmission-rate profile plots. The values k_1 and k_2 calculated from the experimental data ranged within 4–14% of the theoretical values given by Gavara and Hernandez (33).

PERMEABILITY MEASUREMENT METHODS OF AROMAS AND SOLVENTS

The permeabilities of the permanent gases through different packaging materials are well known and deeply described elsewhere (36). They can be summarized by the following four major methods:

- Pressure increase method, a detailed description of which is given in the ASTM standard method D 1434 (37).
- Concentration increase method (also known as the isostatic method), related to the ASTM standard method D 3985 (38).
- Volume increase method. This technique is also described in the ASTM standard method D 1434 (39).
- Detector film method. This is a more recent method which requires little equipment and is both rapid and accurate (40).

Concerning aromas and organic vapors, unfortunately, not many data are available. Moreover, there are not accepted standard tests for the measurement and evaluation of aromas and organic vapors permeability. However, different methods and procedures related to the vapor permeability measurements can be recovered, including the isostatic and quasi-isostatic methods as seen before for the permeability studies of the permanent gases.

It is worth citing the sophisticated device developed by Niebergall et al. (41), able to provide accurate permeability values also at very low vapor levels. Zobel (24) built a simple equipment characterized by a higher sensitivity over vapor sampling methods due to the fact that the entire permeant is supplied to a specific detector, making it possible the measurements of permeation also at low vapor concentration gradients (in the low parts per million range). DeLaussus et al. (42) built an apparatus based on the use of a spectrometer to study the permeation phenomenon of aromas in polymer films, with the possibility to set the temperatures up to 150°C and relative humidities from 0% to 100%, allowing to achieve data on the aroma and odor permeation of materials used in retortable pouches. Finally, a procedure able to provide quantitative results on the aroma barrier property of different packaging materials has been developed (43). In this case, a permeation cell similar to that used for the concentration increase method is employed.

In recent years, several studies had been performed to develop new apparatuses for more effective and cheaper permeation test for aromas and organic vapors, with a wider application range than the previous ones. Al-Ati et al (44) developed an equipment based on a commercial TCD. The innovation involved in this new device is that it is able to detect permeants by measuring their thermal characteristics different with those of helium. Because helium is characterized by a low thermal capacity, nearly all volatile gases and vapors can be detected with this instrument. Moreover, this instrument provides not only permeability but also solubility and diffusion coefficients. Finally, it is claimed that this kind of apparatus can be built with an investment 10% less than a commercial instrument. Zhou et al. (45) constructed a system by combining dynamic vapor sorption (DVS) with purge-and-trap/fast gas chromatography (P&T-fGC). In particular, this apparatus can be used for simultaneous measurement of permeability of multiple aroma compounds. Simplicity, speed, and accuracy are some of the most interesting features of this new measurement system. Finally, a new quasi-isostatic permeation test method has been developed for aroma barrier testing by Vähä-Nissi et al. (46). In this case, aroma concentrations accumulated in the receiving cell as a function of time are measured during permeation from the source cell containing the model aroma solution through the tested polymer. This system uses automatic gas sampling from the test cells to the gas chromatography. It was successfully used to test different materials such as paper and paperboard (coated and uncoated) and polymer films. The main advantage linked to this new solution is represented by the absence of interfering carrier gas flows in the test cells. In fact, these flows could affect the final results, because the carrier gas can penetrate partly to porous materials such as fiber-based samples.

PHARMACEUTICAL PACKAGING

M. I. R. M. Santoro
A. K. Singh
Department of Pharmacy,
Faculty of Pharmaceutical
Sciences, University of São
Paulo, São Paulo, Brazil

INTRODUCTION

The packaging of a pharmaceutical product fulfills assorted roles, such as product presentation, identification, convenience, and protection until administration or use. Selection of packaging requires a basic knowledge of packaging materials, the environmental conditions to which the product will be exposed, and the characteristics of the drug formulation. Several types of packaging are used to contain and protect the drug product, such as the primary packaging around the product and secondary packaging such as subsequent transit cases (1).

Packaging system development, including primary and secondary packaging components, is as important as drug product itself. Basically, the packaging material is used as a barrier to protect the drug product against external factors that can degrade them and consequently decrease their efficacy and even provoke toxic effects. The material should be selected based on the characteristics of drug product and type of dosage form. After the production phase, packaging must be planned according to regulatory requirements and its quality should be controlled according to predefined specifications.

Once the type of packaging material is selected based on factors such as size, shape, capacity, and physicochemical properties, all these data, including quality control (QC) tests, should be included in the specification of the products in order to ensure the therapeutic effectiveness during its shelf life.

Several types of materials are being used in the manufacture of containers and closure systems: glass, plastics, metals, and combinations of these materials. However, care should be taken in the selection of appropriate material. These materials should not present any physical or chemical reactivity that could modify drug activity, quality, purity, or physical characteristics of the drug substance and drug product. Any minor modification in the pharmacopeial specification is acceptable if it does not present a threat to patient's health.

The role of packaging in the pharmaceutical industry has grown substantially over the past decade. The total packaging operation is part of any drug development program. Drug product require a standard of packaging which is superior to that of most other products (nonpharmaceutical) in order to support and comply with their main requirements, such as efficacy, integrity, purity, safety, and stability. For these reasons, packaging technology should be based on detailed information on drug substance and drug product, including their physical and chemical properties.

In the past, packaging concerns often arose only during the later steps of product development. Today, packaging is integral part of drug product development and is among the earliest considerations of new drug product being studied. Few examples of packaging concerns for common classes of drug products are presented in Table 1. However, the challenge is to maintain low packaging cost that is always integrated into the cost of the product itself.

Packaging in the post-World War II period benefited immensely from the commercialization of plastics, which were little known or used in prior years. Since then, the packaging industry has openly adopted plastics as a powerful new tool in the development of new packaging forms and functions.

Quality control of a packaging component starts at the design stage. All aspects of package development that may generate quality problems must be identified and minimized by good design. Identifying and correcting in packaging will avoid product recall and rejection of drug product (2–4).

The aim of this article is to discuss the importance of the packaging in the development of drug products and pharmaceuticals.

IMPORTANCE OF PROPER PACKAGING AND LABELING

The United States' Poison Prevention Packaging Act enacted in 1970 (www.cpsc.gov/businfo/pppa.html) requires special packaging of most human oral prescription drugs, oral controlled drugs, certain normal prescription drugs, certain dietary supplements, and many over-the-counter (OTC) drug preparations in order to protect the public from personal injury or illness from misuse of these preparations.

In many countries there are very strict regulations for packaging of many drug substances. Various types of child-resistant packages are covered in ASTM International Standard D-3475. Medication errors linked to poor labeling and packaging can be controlled through the use of error potential analysis. The recognition that a drug name, label, or package may constitute a hazard to safety typically occurs after the drug has been approved for use and is being marketed. Numerous reports of medication errors are being reported, some of which have resulted in patient injury or death. In a number of these reports, a medication was mistakenly administered either because the drug container (bag, ampoule, prefilled syringe, and bottle) was similar in appearance to the intended medication's container or because the packages had similar labeling. Obviously, the severity of such errors depends largely on the medication administered. The problem of medical errors associated with the naming, labeling, and packaging of pharmaceuticals is being very much discussed.

PACKAGING MATERIALS

General Considerations

Packaging refers to all the operations, including filing and labeling, through which a bulk product should pass to become a finished product. Usually, sterile filing is not considered part of the packaging process, although the bulk product is still in the primary container.

Table 1. Examples of Packaging Concerns for Common Classes of Drug Products (2, 4)

Degree of Concern Associated with the Route of Administration	Likelihood of Packaging Component–Drug Product Interaction		
	High	Medium	Low
Highest	Inhalation aerosols and solutions; injection; injectable suspensions	Sterile powders and powders for injections and inhalation powders	
High	Ophthalmic solutions and suspensions; transdermal ointments and patches; nasal aerosols and sprays		
Low	Topical solutions and suspensions; topical and lingual aerosols; oral solutions and suspensions	Topical powders; oral powders	Oral tablets and oral (hard and soft gelatin) capsules

A packaging component means any single part of a container closure system. Typical components are containers (e.g., ampoules, vials, bottles), container liners (e.g., tube liners), closures (e.g., screw caps, stoppers), closure liners, stopper over seals, container inner seals, administration ports [e.g., on large-volume parenterals (LVPs)], overwraps, administration accessories, and container labels (4).

A primary packaging component is one that is or may be in direct contact with the drug product. A secondary packaging component is one that is not and will not be in direct contact with the drug product (4).

A container closure system refers to the sum of packaging components that together contain and protect the drug product. This includes primary packaging components and secondary packaging components, if the latter are intended to provide additional protection to the drug product. A packaging system is equivalent to a container closure system (4).

The role of packaging material on the overall perceived and actual stability of the drug product is well established. Packaging plays an important role in quality maintenance, and the resistance of packaging materials to moisture and light can significantly affect the stability of drugs and their drug products. It is crucial that stability testing of drug products in their final packaging be performed. The primary role of packaging, other than its esthetic one, is to protect the drug products from moisture and oxygen present in the atmosphere, light, and other types of exposure, especially if these factors affect the overall quality of the product on long-term storage (5).

Compliance packaging such as for fixed-dose-combination pills and unit-of-use packaging is a therapy-related interventions that is designed so as to simplify medication regimens and thus potentially improve adherence. Compliance packaging can be defined as a prepackaged unit and provides one treatment cycle of the medication to both the pharmacist and the patient in a ready-to-use package. This innovation type of packaging is usually based on blister packaging using unit-of-one dosing. The separate dosage units and separate days are usually indicated on the dosage cards to help remind the patient when and how much of the medication to take, for example, blister-packed oral dosage forms with drug information leaflets, specifically the contraceptive pills (3, 6, 7).

The selection of packaging material for any pharmaceutical product is as important as proper drug product. To guarantee the safe and adequate delivery of drug product to the patient and improve patient compliance, the manufacturer should consider the following factors:

1. Compatibility and safety concerns raised by the route of administration of the drug product and the nature of the dosage form (e.g., solid or liquid based)
2. Kinds of protection the container closure system should provide to the drug product (e.g., photosensitive, hygroscopic, easily oxidized drug products)
3. Potential effect of any treatment or handling that may be unique to the drug product in the packaging system
4. Patient compliance to the treatment and ease of drug administration
5. Safety, efficacy, and quality of drug product throughout its shelf life

Glass as Packaging Material

A packaging system found acceptable for one drug product is not automatically assumed to be appropriate for another. Each application should contain enough information to show that each proposed container closure system and its components are suitable for its intended use.

Non Sterile Products.

Solids. Some topical drug products such as powders may be considered for marketing in glass bottles with appropriate dispenser. These topical drug products may be sterile and could be subject to microbial limits.

The most common glass-packed solid oral dosage forms is oral powders and granules for reconstitution. A typical solid oral dosage forms container closure system is a glass bottle (although plastic bottles are also used) with a screw-on or snap-off closure. A typical closure consists of a metal cap, often with a liner, and frequently with an inner seal.

Powders for oral administration that are reconstituted in their market container, need not be sterile; however, they have an additional possibility of an interaction between the packaging components and the reconstituting fluid. Although the contact time will be relatively short when compared to the component/dosage form contact time for liquid-based oral dosage forms, it should still be taken into consideration when the compatibility and safety of the container closure system is being evaluated.

Nonsolids. For nonsterile products the preservative provides some protection, but continual microbial challenge will diminish the efficacy of the preservative, and spoilage or disease transmission may occur (8).

Antimicrobial preservatives such as phenylmercuric acetate are known to partition into rubbers during storage, thus reducing the formulation concentration below effective antimicrobial levels (9). A complication of modern packaging is the need for the application of security seals to protect against deliberate adulteration and maintain consumer confidence.

Sterile Products. The sterile dosage forms share the common attributes that they are generally solutions, emulsions, or suspensions and are all required to be sterile. Injectable dosage forms represent one of the highest-risk drug products (Table 1). Any contaminants present (as a result of contact with a packaging component or due to the packaging system's failure to provide adequate protection) can be rapidly and completely introduced into the patient's general circulation. Injectable drug products may be liquids in the form of solutions, emulsions, suspensions, or dry solids that are to be combined with an appropriate vehicle to yield a solution or suspension.

Although ophthalmic drug products can be considered topical products, they have been grouped here with injectables because they are required to be sterile and the descriptive, suitability, and quality control information is typically the same as that for an injectable drug product.

The potential effects of packaging component/dosage form interactions are numerous. Hemolytic effects may result from a decrease in tonicity, and pyrogenic effects may result from the presence of impurities. The potency of the drug product or concentration of the antimicrobial preservatives may decrease due to adsorption or absorption.

A cosolvent system essential to the solubilization of a poorly soluble drug can also serve as a potent extractant of plastic additives.

A disposable syringe may be made of plastic, glass, rubber, and metal components, and such multicomponent construction provides a potential for interaction that is greater than when a container consists of a single material.

Injectable drug products require protection from microbial contamination (loss of sterility or added bioburden) and may also need to be protected from light or exposure to gases (e.g., oxygen).

Performance of a syringe is usually addressed by establishing (a) the force to initiate and maintain plunger movement down the barrel and (b) the capability of the syringe to deliver the labeled amount of the drug product.

Solids. For solids that must be dissolved or dispersed in an appropriate diluent before being injected, the diluent may be in the same container closure system (e.g., a two-part vial) or be part of the same market package (e.g., a kit containing a vial of diluent).

Sterile powders or powders for injection may need to be protected from exposure to water vapor. For elastomeric components, data showing that a component meets the requirements of USP Elastomeric Closures for Injections will typically be considered sufficient evidence of safety.

Nonsolids. The package must prevent the entry of organisms; for example, packaging of sterile products must be absolutely microorganism-proof, hence the continued use of glass ampules. Liquid injections are classified as small-volume parenterals (SVPs), if they have a solution volume of 100 mL or less, or as large-volume parenterals (LVPs), if the solution volume exceeds 100 mL (8). Liquid-based injectables may need to be protected from solvent loss.

A SVP may be packaged in a vial or an ampule. A LVP may be packaged in a vial, in a glass bottle, or, in some cases, as a disposable syringe. Packaging material for vials and ampules are usually composed of Type I or II glass. Stoppers and septa in cartridges and vials are typically composed of elastomeric materials.

Pharmaceuticals may interact with packaging and containers, resulting in the loss of drug substances by adsorption onto and absorption into container components and the incorporation of container components into pharmaceuticals. Diazepam in intravenous fluid containers and administration sets exhibited a loss during storage due to adsorption onto glass (3).

Glass surfaces are also known to adsorb drug substances. Chloroquine solutions in glass containers decreased in concentration owing to adsorption of the drug onto the glass (3).

Rubber closures are also known to absorb materials, including drugs. Absorption of preservatives such as chlorocresol into the rubber closures of injectable formulations has been studied extensively (3).

Water permeability of rubber closures used in injection vials is considered an important parameter in assessing the closures, but quantitative prediction of water permeability through rubber closures is difficult because the diffusion coefficient of water is dependent on relative humidity (3).

Liquid-based oral drug products are usually dispensed in glass bottle (sometimes in plastic), often with a screw cap with a liner, and possibly with a tamper-resistant seal or an overcap that is welded to the bottle. The same cap liners and inner seals are sometimes used with solid oral dosage forms. A laminated material could be used to overwrap glass bottles for extra safety.

The USP grade glass packaging components are chemical-resistant and could be considered sufficient evidence of safety and compatibility. In some cases (e.g., for some chelating agents), a glass packaging component may need to meet additional criteria to ensure the absence of significant interactions between the packaging component and the dosage form.

Several ophthalmic preparations are commercialized in glass containers. Although the risk factors associated with ophthalmic preparations are generally considered to be lower than for injectables, any potential for causing harm to the eyes demands caution.

A large-volume intraocular solution (for irrigation) may be packaged in a polyolefin (polyethylene and/or polypropylene) container.

The liquid-based oral dosage forms may be marketed in multiple-unit bottles. The dosage form may be used as is or admixed first with a compatible diluent or dispersant. Liquid-based oral drug products in glass containers must meet the requirements of USP containers. Glass containers are accepted as sufficient evidence of safety and compatibility. Performance is typically not a factor for liquid-based oral drug products but should be considered while treating pressurized liquid-based oral drug products (e.g., elixir spray).

Topical dosage forms such as unpressurized sprays, lotions, ointments, solutions, and suspensions may be considered for marketing in glass bottles with appropriate dispensers. Some topical drug products, especially ophthalmic, are sterile or may be subject to microbial limits. In these cases, packaging material and its handling should be done in the same manner as those for injectables.

Plastic as Packaging Material

For plastic components, data from USP biological reactivity tests will typically be considered sufficient evidence of safety. Whenever possible, the extraction studies should be performed using the drug product. If the extraction properties of the drug product vehicle may reasonably be expected to differ from that of water (e.g., due to high or

Table 2. Plastic Additives (6)

Type	Purpose	Examples
Lubricants	Improves processibility	Stearic acid paraffin waxes, PE waxes
Stablizers	Retard degradation	Epoxy compounds, organotins, mixed metals
Plasticizers	Enhance flexibility, resiliency, melt flow	Phthalates
Antioxidants	Prevent oxidative degradation	Hindered phenolics (BHT), aromatic amines, thioesters, phosphites
Antistatic agents	Minimize surface static charge	Quaternary ammonium compounds
Slip agents	Minimize coefficient of friction, especially polyolefins	
Dyes, pigments	Color additives	

low pH or due to a solubilizing excipient), then drug product should be used as the extracting medium. If the drug substance significantly affects extraction characteristics, it may be necessary to perform the extractions using the drug product vehicle. If the total of extracts significantly exceeds the amount obtained from water extraction, then an extraction profile should be obtained. It may be advisable to obtain a quantitative extraction profile of an elastomeric or plastic packaging component and to compare this periodically to the profile from a new batch of the packaging component. Extractables should be identified whenever possible (Table 2 and 3).

Nonsterile Products.

Solids. The most common solid oral dosage forms are capsules and tablets. A typical solid oral dosage forms container closure system is a plastic, usually high-density polyethylene (HDPE) bottle with a screw-on or snap-off closure and a flexible packaging system, such as a pouch or a blister package. A typical closure consists of a cap, often with a liner and frequently with an inner seal. If used, fillers, desiccants, and other absorbent materials are considered primary packaging components.

A change in the selection of packaging materials combined with a change in storage conditions or conditions during administration of the drug products may provoke stability problems.

Many studies have been conducted on predicting the role of packaging in moisture adsorption by drug products. Adsorption of moisture by tablets contained in polypropylene films was successfully modeled from storage temperature and the difference in water vapor pressure between the inside and outside of the packaging (3).

Chemical and physical degradation of packaged drug products caused by moisture adsorption has been predicted from the moisture permeability of the packaging. For example, strength changes of lactose-corn starch tablets in strip packaging and discoloration of sugar-coated tablets of ascorbic acid were predicted using the moisture permeability coefficient of the packaging.

Typical flexible forms of packaging containing solid oral dosage forms are the blister package and the pouch. A blister package usually consists of a lidding material and a forming film. The lidding material is usually a laminate that includes a barrier layer (e.g., aluminum foil) with a print primer on one side and a sealing agent (e.g., a heat-sealing lacquer) on the other side.

The sealing agent contacts the dosage form and the forming film. The forming film may be a single film, a coated film, or a laminate. A pouch typically consists of film or laminate that is sealed at the edges by heat or adhesive.

Solid oral dosage forms generally need to be protected from the potential adverse affects of following:

1. Water vapor (e.g., moisture may affect the decomposition rate of the active drug substance or the dissolution rate of the drug product)
2. Incident light (e.g., in case of photosensitive products)
3. Reactive gases (e.g., oxygen could provoke oxidative reactions)

The packaging material should be carefully studied and tailor-made to help protect the drug product. For example, photosensitive drug product may be blister-packed in dark polymeric film, and the covering lid on

Table 3. Parenteral Drug Administration Devices (6)

Sterile Device	Plastic Material
Containers for blood products	Polyvinyl chloride
Disposable syringes	Polycarbonate, polyethylene, polypropylene
Irrigating solution containers	Polyethylene, polypropylene, polyvinyl chloride
I.V. infusion fluid containers	Polyethylene, polypropylene, polyvinyl chloride
Administration sets	Nylon (spike), polyvinyl chloride (tubing), polymethylmethacrylate (needle adapter), polypropylene (clamp)
Catheter	Teflon, polypropylene, thermoplastic elastomers

the opposite side may be made of aluminum to give protection against incident light.. A blister packaging using multilayered HDPE packaging material and selection of adequate sealing technique may help prevent moisture access into the blister system. However, adequacy of plastics and glass for packaging of solid oral dosage forms and for powders for reconstitution should meet the requirements of the USP containers test.

Incorporating oxygen adsorbents such as iron powder in packaging units can reduce the effect of oxygen. Protection from light can be achieved using primary packaging (packaging that is in direct contact with the dosage forms) and secondary packaging made of light-resistant materials.

The photochemical reaction is a very complex process; many variables may be involved in the photolytic degradation kinetics. The velocity of the photochemical reaction may be affected not only by the light source, intensity, and wavelength of the light, but also by the size, shape, composition, and color of the container.

Great effort is taken to stabilize a formulation in such a way that the shelf life becomes independent on the storage conditions. Photostability of drugs and excipients should be evaluated at the formulation development stage in order to assess the effects of packaging on the stability of the final product. Molsidomine tablet preparations in inadequate primary container (blister) without secondary when exposed to irradiations may produce morpholine. These results illustrate the importance of packaging for the stability of molsidomine (3).

Three standard tests for water vapor permeation have been established by the USP for use with solid oral dosage forms.

1. Polyethylene containers (USP <661>) (8)
2. Single-unit containers and unit-dose containers for capsules and tablets (USP <671>)
3. Multiple-unit containers for capsules and tablets (USP <671>) (8)

The cotton and rayon used as filler in solid oral dosage forms containers may not meet pharmacopeial standards, but through appropriate tests and acceptance criteria for identification and for moisture content, their adequacy should be shown; for example, rayon has been found to be a potential source of dissolution problems for gelatin capsules and gelatin-coated tablets.

Desiccants are often used to eliminate moisture in packaging when the moisture resistance of the packaging itself is not sufficient to prevent exposure. The utility of desiccants has been assessed based on a sorption–desorption moisture transfer model (3).

The desiccant or other absorbent materials are primary packaging components. The component should differ in shape and/or size from the tablets or capsules with which it is packaged. Their composition should be provided, their inertness should be proved through appropriate tests, and acceptance criteria should be established.

A topical powder product may be marketed in a sifter-top container made of flexible plastic tubes or as a part of a sterile dressing (e.g., antibacterial product). The topical formulations in a collapsible tube can be constructed from low-density polyethylene (LDPE), with or without a laminated material. Normally, there is no product contact with the cap on storage. Thus usually there is no cap liner, especially in collapsible polypropylene screw caps. Normally, separate applicator devices are made from LDPE. Product contact is possible if the applicator is part of the closure, and therefore an applicator's compatibility with the drug product should be established, as appropriate (e.g., vaginal applicators).

Nonsolids. Typical liquid-based oral dosage forms are elixirs, emulsions, extracts, fluid extracts, solutions, gels, syrups, spirits, tinctures, aromatic waters, and suspensions. These products are usually nonsterile but typically need to be protected from solvent loss, microbial contamination, and, sometimes, exposure to light or reactive gases (e.g., oxygen).

The presence of a liquid phase implies a significant potential for the transfer of materials from a packaging component into the dosage form.

The higher viscosity of semisolid dosage forms and transdermal systems may cause the rate of migration of leachable substances into these drug products to be slower than for aqueous solutions. Due to extended contact, the amount of leachables in these drug products may depend more on a leachable material's affinity for the liquid–semisolid phase than on the rate of migration.

In addition to adsorption onto and absorption into containers, transfer of container components into pharmaceuticals may affect the perceived stability/quality of drug products. Adsorption of volatile components from rubber closures onto freeze-dried parenterals during both dosage form processing and storage brought about haze formation upon reconstitution. Leaching of dioctyl phthalate, a plasticizer used especially in PVC plastics, into intravenous solutions containing surfactants was observed. Plastics contain additives to enhance polymer performance. PVC may contain phthalate diester plasticizer, which can leach into infusion fluids from packaging (3).

The liquid-based oral dosage forms may be marketed in multiple-unit bottles or in unit-dose or single-use pouches or cups. The dosage form may be used as is or admixed first with a compatible diluent or dispersant. A liquid-based oral drug pouch may be a single-layer plastic or a laminated material. The pouches may use an overwrap, which is usually a laminated material.

For LDPE components, data from USP container tests are typically considered sufficient evidence of compatibility. The USP general chapters do not specifically address safety for polyethylene (HDPE or LDPE), polypropylene (PP), or laminate components.

For liquid-based oral drug products that the patient will continue to take for an extended period (i.e., months or years), during which time he or she is expected to extract greater amounts of substances from plastic packaging components than water (presence of cosolvents), additional extractable information may be needed to address safety issues.

Topical dosage forms such as creams, emulsions, gels, lotions, ointments, pastes, and powders may be marketed in plastic materials. Topical dosage formulations are for local (not systemic) effect and are generally applied to the skin or oral mucosal surfaces. Some vaginal and rectal creams, as well as nasal and ophthalmic solutions, may be considered for topical drug products.

A rigid bottle, a collapsible tube, or a flexible pouch made of plastic material may be used for liquid-based topical product. These preparations are marketed in a single- or multiple-unit container. Dissolved drug (or any substance, e.g., benzocaine) may diffuse in the suppository base, and can, for instance, partition into polyethylene linings of the suppository wrap.

Topical delivery systems are self-contained, discrete dosage forms that are designed to deliver drug for an extended period via intact skin or body surface (e.g., transdermal, ocular, and intrauterine).

These systems may be constructed of a plastic or polymeric material loaded with active ingredients or a coated metal. Each of these systems is generally marketed in a single-unit soft blister pack or a preformed tray with a preformed cover or overwrap.

Compatibility and safety for topical delivery systems are addressed in the same manner as for topical drug products. Performance and quality control should be addressed for the rate-controlling membrane (Table 2 and 3).

Sterile Products.

Nonsolids. An SVP may be packaged in a disposable cartridge, a disposable syringe, or a flexible bag made of polymeric plastic. Flexible bags are typically constructed with multilayered plastic.

An LVP may be packaged in a vial, a flexible bag, or, in some cases, a disposable syringe. Packaging material for cartridges, syringes, vials, and ampules are usually composed of polypropylene.

Stoppers and septa in cartridges, as well as syringes, are typically composed of elastomeric materials. An overwrap may be used with flexible bags to retard solvent loss and to protect the flexible packaging system from rough handling.

Diazepam in intravenous fluid containers and administration sets exhibited a loss during storage due to adsorption onto and absorption into plastics. Absorption of clomethiazole edisylate and thiopental sodium into PVC infusion bags was observed (3).

The pH dependence of adsorption/absorption of acidic drug substances such as warfarin and thiopental and basic drug substances such as chlorpromazine and diltiazem indicates that only the un-ionized form of the drug substance is adsorbed onto or absorbed into PVC infusion bags (3).

The absorption was correlated to the octanol–water partition coefficients of the drugs, suggesting that prediction of absorption from partition data is possible. Polymers such as Nylon-6 (polycaprolactam) are known to adsorb drug substances such as benzocaine (3).

The ophthalmic drug products are usually solutions marketed in a low-density polyethylene bottle with a dropper built into the neck. A few solution products use a glass container due to stability concerns regarding plastic packaging components.

Metal as Packaging Material

Metal tubes constructed of single material are packaging material of choice for topical dosage forms and may be tested readily for stability with a product. Tubes with a coating, however, present additional problems. The inertness of coating material must be established through adequate tests and guarantee that it completely covers underlying material. The coating material must be resistant to creaking, leaking, leaching and solvent erosion; for example, frequently used aluminum tubes have demonstrated reactivity with fatty alcohol emulsions, mercurial compounds, and preparations with pH below 6.5 and above 8.0. Nonreactive epoxy linings have been found to make aluminum tubes resistant to attack (6).

The ophthalmic ointments are marketed in a metal tube with an ophthalmic tip. Ophthalmic ointments that are reactive toward metal may be packaged in a tube lined with an epoxy or vinyl plastic coating.

Metal containers, pressurized or not, may also be used for topical drug products. topical dosage forms such as aerosols, emulsions, gels, powders, and solutions may be marketed in metallic flasks, pressurized or not. Topical dosage formulations are for local (not systemic) effect and are generally applied to the skin or oral mucosal surfaces. Some preparations for topical use, such as vaginal and rectal creams, as well as nasal and otic sprays, may be considered for marketing in metallic containers.

A number of topical products marketed as a pressurized aerosol may be dispensed in a metallic bottle with a screw cap. Topical dosage forms in aluminum tubes usually include a liner. A tube liner is frequently a lacquer or shellac whose composition should be stated. A metallic pressurized packaging system for a liquid-based topical product may deter solvent loss and may provide protection from light when appropriate.

The droplet size of topical aerosols spray does not need to be carefully controlled, nor is the dose usually metered as in case of inhalers. The spray may be used to apply dosage form to the skin (topical aerosol) or mouth (lingual aerosol), and functionality of the sprayer should be addressed. The drug product has no contact with cap and short-term contact with nozzle. A topical aerosol may be sterile or may conform to acceptance criteria for microbial limits. However, physical stability of aerosols can lead to changes in total drug delivered per dose and total number of doses that may be obtained from the container.

QUALITY CONTROL OF PACKAGING MATERIAL

The acquisition, handling, and QC of primary and secondary packaging materials and of printed materials should be accomplished in the same way as that for the raw materials. The printed materials should be stocked in a reserved place so the possibility of unauthorized access is avoided. The labels and other rejected printed materials should be stored and transported with proper identification and before adequate destruction procedure.

The identification affixed on the containers, on the equipment, in the facilities, and on the product containers should be clear, without ambiguity, and in a format approved by the company and contain the necessary data. Besides the text, differentiated colors indicating its condition could be used (e.g., in quarantine, approved, rejected, and cleaned).

The packaging materials should attend to the specifications, giving emphasis to the compatibility of the same with the drug product that it contains. The material should be examined with relation to visible physical and critical defects as well as the required specifications.

Several regulatory agencies as well as private agencies [Food and Drug Administration (FDA), United States Pharmacopeia (USP), World Health Organization (WHO), British Pharmacopoeia (BP)] (4, 8–10) have issued guidelines on the safety evaluation of materials and container closure systems. However, the ultimate proof of safety and suitability of a container closure system and the packaging process is established by full shelf life stability studies. An important step in such evaluations is characterization of the packaging materials and the chemicals that can migrate or extract from container closure system components to the drug product. This extractable material belongs to diverse chemical classes that can migrate from polymeric materials, such as antioxidants, contaminants, lubricants, monomers, plasticizers, and preservatives. Such basic information is critical to understanding the biological safety and suitability of a container.

Establishing the safety of container closure systems is of key importance to the medical and pharmaceutical industries (Table 1). It is no less important than the contents themselves. The FDA's document "Guidance on Container Closure Systems for Packaging Human Drugs and Biologics" makes this point clear (4).

While the tests and methods described in Table 4 allow one to provide data that the container closure system is suitable for its intended use, an application must also describe the QC measures that will be used to ensure consistency in the packaging components (11).

UPDATING ON PACKAGING MATERIALS: FUTURE DEVELOPMENTS

Within the last 20 years, computer simulations of materials have evolved from an academic curiosity to a predictive tool for addressing structure–property–processing–performance relations that are critical to the design of new products and processes.

The computational prediction of physical properties is particularly challenging for polymeric material, because of the extremely broad spectra of length and time scales governing structure and molecular motion in these materials. In a recent paper, Theodoro (12) discuss the fundamental underpinnings and presents applications of new methods and algorithms for the hierarchical modeling of polymers. It was discussed that quantitative relations can be established between structure, properties, processing, and performance of materials.

New packaging materials are being developed. A translucent PVC alloy having a satin look and soft touch was designed for use in the cosmetic industry (13). Meneghetti and Qutubuddin (14) studied and presented the synthesis, thermal properties, and applications of polymer–clay nanocomposites, with potential applications in film packaging and gas storage.

In every aseptic filling application, the sterile transfer of goods into the aseptic area is a challenge, and there are many different ways to do it. Thus, different types of sterilization of packaging materials are being studied and published (15–17).

Photostabilization of drugs substance in drug products without protection from packaging materials was studied by Thoma and Klimek (18), proving that when enwrapped by the packaging material, the drug product is normally well protected from the influence of photodegradation. Tveit et al. (19) presented a study in which they evaluated

Table 4. Properties of Suitability Concerns and Interactions (3, 11)

Attributes	Concerns and Interactions	Proposed Methods
Protection	Exposure to light, moisture, microbial ingress, and oxidation from presence of oxygen	USP<661> Light transmission and water vapor permeation, container integrity (microbial ingress, dye penetration, helium leak)
Compatibility	Leachable induced degradation; absorption or adsorption of drug, precipitation, change in pH, discoloration, brittleness of packaging materials	Leachability study (migration of chemicals into drug product) using LC/MS, GC/MS, ICP/AA, pH, appearance of drug and container, thermal analysis (DSC, TGA), and IR
Safety	No leached harmful or undesirable amounts of substances to expose patients treated with drug	Extraction study (USP physicochemical test—plastics), USP elastomeric closures for injections, Toxicological Evaluation, USP Biological Reactivity and complies with CFR, additives and purity
Performance	Container closure system functionality, drug delivery	Functionality (improved patient compliance or use), delivery (transfer dose in right amount or rate)

Abbreviations: DSC, differencial scanning calorimetry; TGA, thermal gravimetric analysis; AA, atomic absorption.

general patient tolerance to Omnipaque® 350 mgI/mL supplied in polypropylene containers compared to that of same product supplied in routinely used glass vials, with emphasis on allergy-like adverse events. This kind of research proves the importance of packaging material used to protect the pharmaceutical preparations.

A simple and rapid HPLC method for determination of di-2-ethylhexyl- phthalate (DEHP) the major plasticizer of most PVC materials was proposed by Aignasse *et al*. (20). Some practical pharmaceutical applications are presented in order to demonstrate the reliability of the proposed method for this determination of DEHP in PVC packaging, as well as for traces of DEHP leached on infusion bags.

During the past 20 years, research interest in the use of natural biopolymers for the manufacture of "green" biodegradable materials, such as films and coatings, has greatly increased. This is to overcome environmental problems associated with the use of synthetic petroleum polymers (21). As new biodegradable polymers and their packaging applications are emerging, there is a need to address their environmental performance. In particular, there is a need to understand the time required for their complete degradation, before these materials are deployed in commercial composting processes (22). For this reason, in some countries the substitution of plastic products with paper products is being suggested (23).

The recycling of either model polymers or waste products based on low-density polyethylene (LDPE), high-density polyethylene (HDPE), or polypropylene (PP), as well as pyrolysis, was studied by Achilias et al. (24) using the dissolution/reprecipitation method.

In demand for "green" packaging and consumer goods applications, chemical and pharmaceutical industries are introducing new families of all-natural colorants and additives for use in these environmental friendly polymers (25).

Biomimetics is a field of science that investigates biological structures and processes for their use as models for the development of artificial systems. Biomimetic approaches have considerable potential in the development on new high-performance materials with low environmental impact. The cell walls of different plant species represent complex and highly sophisticated composite materials that can provide inspiration on how to design and fabricate lightweight materials with unique properties. Such materials can provide environmentally compatible solutions in advanced packaging, electronic devices, vehicles, and sports equipment (26).

POINT OF PURCHASE PACKAGING

Jennifer Griffin
Polaroid Corp., Cambridge,
Massachusetts

Point-of-purchase (POP) packaging materials play an important role in marketing efforts of consumer product companies. Displays, fixtures, signs, and related materials at the retail store represent POP, packaging. Food, drug, specialty, and convenience stores, as well as mass merchandisers and warehouse clubs, all make use of POP packaging. The medium is used in almost every category of product from health and beauty aids to household appliances. POP materials are used to increase sales, obtain positioning on the retail floor, and carry the brand name and strategy along with related advertising efforts.

HIGH VISIBILITY VERSUS POP PACKAGING

A distinction can be made between the primary package that is considered highly visible and the packaging that is considered POP. Both forms of packaging are an important promotional medium, especially in self-service stores. However, POP packaging is different from high-visibility packaging, because in most cases, it consists of the promotional materials that surround the primary package. For most consumers, POP packaging implies that the product is new to the market, is offered at a sale price, or comes with another promotional tie-in (1). High-visibility packaging includes blister, clamshell, and skin packaging, as well as packages with windows (see Blister packaging; Carded packaging). These forms of primary packaging display the product's benefits, and they promote impulse purchases. Often, retailers request product manufacturers to replace the standard primary package with a high-visibility package for two reasons: (*1*) sales assistance is not available to help with customer purchase decisions so the package needs to sell itself, and (*2*) they request the high-visibility package to have better pilfer resistance than the standard package. Despite the distinction between the two types of packaging, the lines between primary packaging and POP packaging have blurred, and the diversity of POP allows for exceptions. Primary packaging can also function as a point-of-purchase device as observed in Figure 1. These two camera boxes function as the primary package and also as an informational sales tool. Retailers leave these boxes in the open position on a countertop for the customer to read about product features of the professional cameras. The bleached-white, laminated, E-flute, die-cut, corrugated box is designed in the style of a counter display (see Board, corrugated; Diecutting). Extra lithographic printing surfaces are available for the selling message as a result of the double wall hinge cover, double sidewalls, double front wall, and the interior shelf-style panel for a clean, finished appearance (see Lithography; Offset printing).

MATERIALS

Because POP packaging is so varied, material selection is based on the intended duration of the promotion. POP is commonly defined as either temporary or permanent. In general, temporary displays are used until the product is depleted, or for less than 6 months. Permanent displays have an intended length of use for more than 6 months. A third category called *semipermanent* often marries packaging materials used in both of the categories to give the display an extended shelf life over temporary displays. The most widely used material in temporary exhibits is corrugated board. Paperboard is also popular (see Paperboard). Permanent display construction makes use of extruded plastic sheet fabrications, plastic profile and tubing, plastic molding, wire, metal extrusions, foamboard, or wood. To create semipermanent displays, corrugated board can be used with more durable materials such as wood, plastic, or metal. Solid fibreboard (see Boxes, solid-fiber) or corrugated board of heavy construction could also be used alone. Figure 2 shows a temporary counter display made of bleached-white, corrugated board on the left. The permanent counter display on the right is an extruded plastic sheet fabrication.

Figure 1. A primary package functions as a point-of-purchase device.

Figure 2. A temporary corrugated-board counter display (*left*) and a permanent counter display made of extruded plastic sheet (*right*).

TEMPORARY POP CATEGORIES

Common Elements of Counter and Floor Stands. The most widely used display styles for temporary promotions are counter and floor-stand displays. Both styles share commonly used structural design elements. The most visual element that these two styles share is the header portion (also called the riser panel) of the display. The header is a display panel that protrudes up from the open side of the display box to advertise the contained product. The header often comes attached to the body of the display as a hinged-cover panel with a front tuck flap. The header folds back for setup. It may also arrive as a separate piece that slides into a slot on the body. The most popular manufacturing technique for header cards is to preprint a lithographic sheet and glue it to a sheet of paperboard or corrugated board. This technique allows for high-quality printing for the sales message, where as the other parts of the display can be printed at lower cost using flexography or can be left unprinted (see Flexography). The temporary display in Figure 2 has a flexo printed body with a litho sheet header card that is laminated to corrugated board.

The body of counter and floor-stand displays is designed in either an easel style or a tray style. Easels often have cells to partition the product. Figure 3 shows a corrugated-board, floor-stand display that uses an easel-style body with cells. This display ships as a prepackaged multipack so that the loading of the product is not required by the retailer. The tray style often uses a tiered tray as shown in Figure 4. The tiered-tray floor stand ships on a custom-sized wood skid. This display is intended as an end cap that will be placed at the end of an aisle. Some tiered trays are offset so that all of the product is displayed at once. The pallet-unit style shown in Figure 4 is commonly referred to as a “stacker.” This display is intended for a wholesale or warehouse club store. The large amount of product contained in the display would not be suitable for traditional retailers.

Floor-stand displays sometimes require a base to support the display. Figure 3 shows a typical base design. A popular industry practice is to use modular stock display designs from POP manufacturers. Then, the display is customized with special structural features on the header and the client’s graphics. The client incurs a lower cost, because no tooling charge for die-cutting exists for the stock elements.

Other Counter and Floor-Stand Displays. Counter displays have several unique categories, including contest boxes, counter cards, and literature holders. Figure 5 shows a counter card with an interactive feature. The camera’s audio unit is a talking voice chip with three prerecorded messages. Floor stands include several unique categories, as well. The standee is a standup person or object that is usually two-dimensional with an easel backing for support. Standees are often used when a

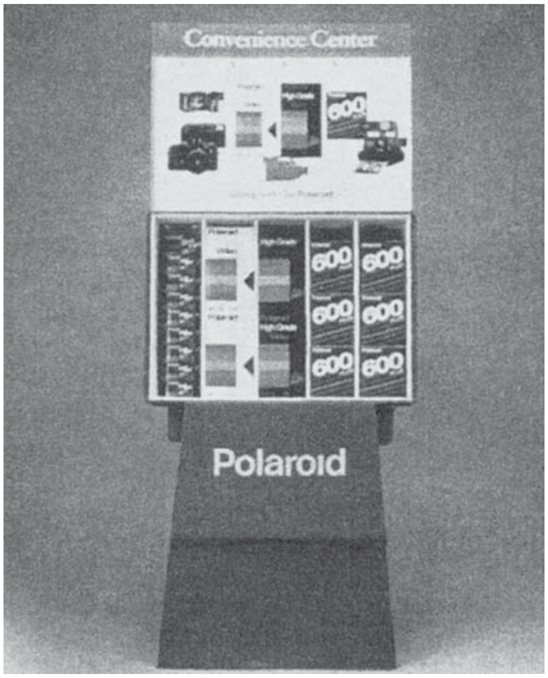

Figure 3. A corrugated-board floor-stand display that uses an easelstyle body with cells. The header and base are stock display designs.

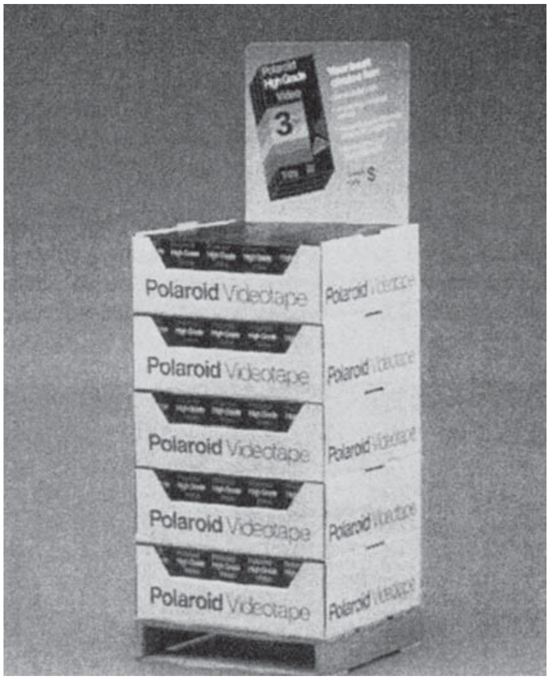

Figure 4. A palletized-unit display called a stacker uses a tiered tray design. A removable header tops the display.

public figure joins a company's advertising campaign. This visual element triggers recognition and reinforces a positive impression, which leads to consumer loyalty. Lastly, the dump bin style is also a category used in floor stands.

Figure 5. A counter card displays the product by mounting it in the card's panel. Customers can hear three prerecorded messages by pushing the RELEASE button.

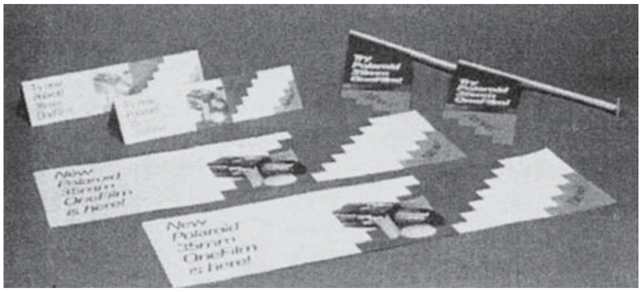

Figure 6. The photo includes banners, signs, and "shelf talker" flags on standout poles that clip onto a shelf edge.

Miscellaneous Temporary POP. Several miscellaneous categories fit under the temporary POP umbrella. Pole displays, overheads, banners, flags, posters, and mobiles are common. Figure 6 includes several examples of POP promotions that are used to complement a display system. The small flags in the photograph are used as "shelf talkers," with plastic clips to secure to the shelf edge. Along with hooks and clips, merchandising strips are popular, especially for use on power-wing or end-cap metal racks. A power wing is the side of an end cap where impulse merchandise is hung, often on hooks. Figure 7 shows two merchandising strips loaded with instant film packs.

The last area that falls under temporary POP is incentive items such as game cards, sweepstakes cards, rebate offers, on-pack coupons, and bottle neck toppers. The $5 mail-in rebate offer shown in Figure 8 has a counter card with a pad of rebate cards that explains the

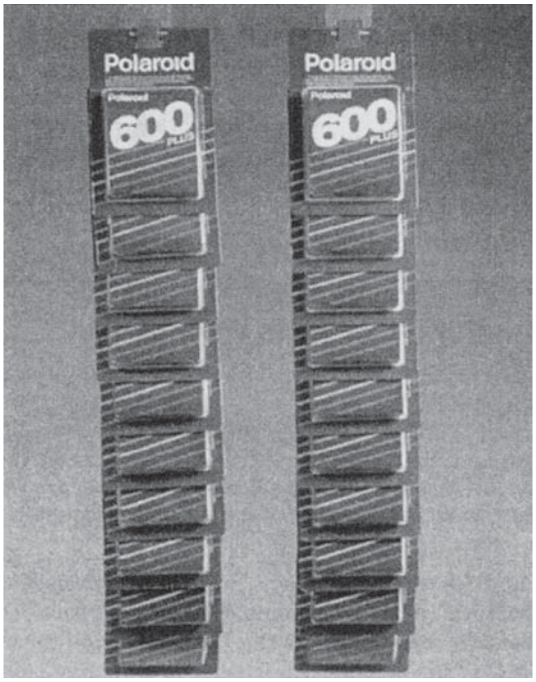

Figure 7. Two merchandising strips hold the instant film packs in a vertical display.

Figure 8. A pad of rebate offers on a counter card. Note the packaging graphics redesign to unify the look of the instant film product line.

rules of the promotion. Of special note to graphic artists is the packaging graphics redesign of the whole line of instant film shown on the center card. Earlier versions of the film box did not have a unified look for the product line's corporate and brand identity.

PERMANENT POP CATEGORIES

Permanent POP includes many of the categories that have been detailed for temporary displays such as any of the counter and floor stands. Much of permanent POP includes fixtures, which are not actually "packaging." However, it is the packaging engineer's job to specify the fixture and design shipping packaging to transport the promotion's fixture and the enclosed product to the retail store. A category called the spinner or spinner rack is most often intended for permanent display. It comes in counter or floor-stand designs. Figure 9 shows a floor-stand spinner rack with wire display pockets. Spinner racks that have hooks or pegs are also popular, and they are for products with hang tabs. Another form of permanent POP is product sampler or tester unit displays for industries such as cosmetics. Other categories usually associated with permanent POP are items such as dangling inflatables and motion displays that are heavily used in the competitive field of beverage and liquor packaging.

The next category of permanent POP is full-line merchandisers, which are category or shelf management systems. They are used to organize a company's offerings for a product line in any department of a retail store. It ensures facings are easily identifiable. Examples are seen in panty hose, wrapping paper and bows, and other product lines with many choices. For a product manufacturer, a full-line merchandiser ensures that the product will not be subject to the whim of a retailer's planogram. Retail stores use planograms—written diagrams with instructions—to lay out departments. The retail store finds planograms useful for cutting in new products, positioning higher-margin products in more visible locations, and periodic cleaning of fixtures. The last permanent category worth mentioning is computerized kiosks with interactive touchpad displays and printers. The kiosks are used in various applications such as multimedia questionnaires or self-service tools in which customers use the kiosk to help identify correct replacement parts for a product.

TRENDS

Trends in the industry include cross-merchandising in which two marketers join together in a promotion program. It is also called cobranding. For instance, a soft-drink manufacturer teams up with a candy company to do a joint temporary display. With changing channels of distribution due to increased competition from wholesale clubs and superstores, manufacturers are feeling a greater retailer influence. Promotions have become more account-specific, because retailers are demanding the customizing of displays for their use only. Another trend is co-marketing. Co-marketing teams up a retailer and a marketer who have developed a promotion together to leverage store and brand-name equity in order to build sales for both. A distinction is made between co-marketing and "prepackaged" promotions that a manufacturer has thoroughly thought out and then tailored to a specific retail account (2). For more specific data on trends in POP, *P/O/P Times* magazine published a second annual report on trends and growth patterns in its November/December 1994 issue.

FOR FURTHER INFORMATION

The Point-of-Purchase Advertising Institute offers many reference materials for sale through its information center in Washington, DC [phone (202) 530-3000]. These materials include written surveys, brochures, books, monographs, yearbooks, and audio cassettes. A helpful handbook is the *POPAI P-O-P Desktop Reference*, which provides 1200 POP industry terms. The General References list in the Bibliography (below) includes the only two books in print on the subject. Periodicals are the industry's major communication tool. Trade magazines that cater to the industry include *P/O/P Times*, a publication of point-of-purchase advertising and display; *P.O.P. & Sign Design*, for high-volume producers of displays, sign, and fixtures; *Creative*, which is published for sales promotion and marketing professionals who manage point-of-purchase display, trade-show-exhibit, and sales-promotion programs; and *Promo*, a magazine about promotional marketing. *Creative* publishes a yearly illustrated supplier directory arranged by category that includes company listings. In addition, several marketing management and packaging periodicals occasionally carry related journal articles. A *Marketing Science* article details a mathematical model for managing shelf space at retail (3). Research published by Percy and Rossiter shows how to apply successful message construction in POP to encourage a consumer purchase decision on the basis of an interplay of customer involvement and motivation (4).

Several trade shows catering to the POP market are held each year. Merchandising and design innovations

Figure 9. A permanent floor-stand spinner rack displays personalized greeting cards. The customer inserts the instant photo she has just taken into the card.

in POP packaging are promoted yearly in industry achievement award contests. The Point-of-Purchase Advertising Institute, POPAI, has sponsored a competition each year since 1960. Another contest is held at the annual Display, Sign and Fixture Design show.

POLY(VINYL CHLORIDE)

Dennis A. Cocco
PolyOne Corporation, Avon
Lake, Ohio

Poly(vinyl chloride) (PVC) is, in terms of sales volume, the largest member of a group of polymers commonly referred to as "vinyls." These polymers are all based on either the vinyl radical ($CH_2{=}CH-$) or the vinylidene radical ($CH_2{=}CR-$). Included in this unique and versatile group of polymers are poly(vinyl acetate), poly(vinylidene chloride) (PVDC), poly(vinyl alcohol), poly(vinyl fluoride), poly(vinylidene difluoride) (PVDF), and poly(vinyl butyral). However, homopolymer PVC has the greatest applicability to packaging applications.

PVC packaging represented about 6% of total annual North American sales of PVC of 16.0 billion pounds in 2006 (see Figure 1). Growth has remained fairly steady over the past 10 years at approximately 1–2% per year. However, PVC is still a relatively minor material in the overall packaging market and is about 4% of all plastics used.

When first developed in the 1930s, PVC found little applicability or marketplace acceptance because of its tendency to thermally degrade or dehydrochlorinate (1) when heated. However, scientists soon discovered that additives such as stabilizers and plasticizers could easily be compounded into PVC to make it processable without thermal degradation. More importantly, they found they could also modify PVC's physical properties across a broad spectrum.

As a result, PVC has evolved into one of the world's most versatile polymers and the second-largest volume-produced plastics because of its toughness, relatively low cost, and the ability to modify its physical properties. A wide range of applications today includes pipe and pipe fittings, house siding, windows, electrical and telecommunication wire coatings, credit cards, and medical intravenous bags and tubing, as well as packaging applications such as bottles, food films, and blister packs.

HOW VINYL IS PRODUCED

Poly(vinyl chloride) (PVC), more commonly referred to as *vinyl,* consists of three primary elements: chlorine, carbon, and hydrogen. Chlorine is derived from a chloralkali production process; carbon and hydrogen are derived from ethylene through either a petroleum or natural gas cracking process (see Figure 2).

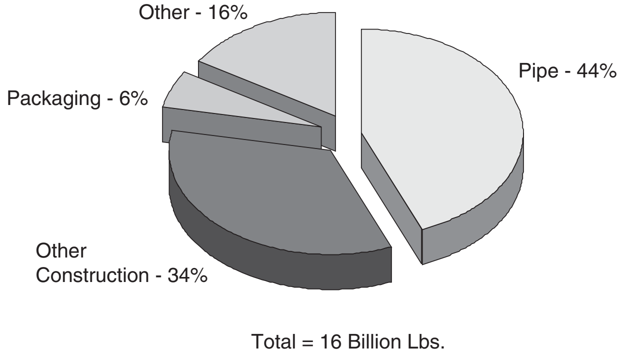

Figure 1. North American PVC end-market 2006.

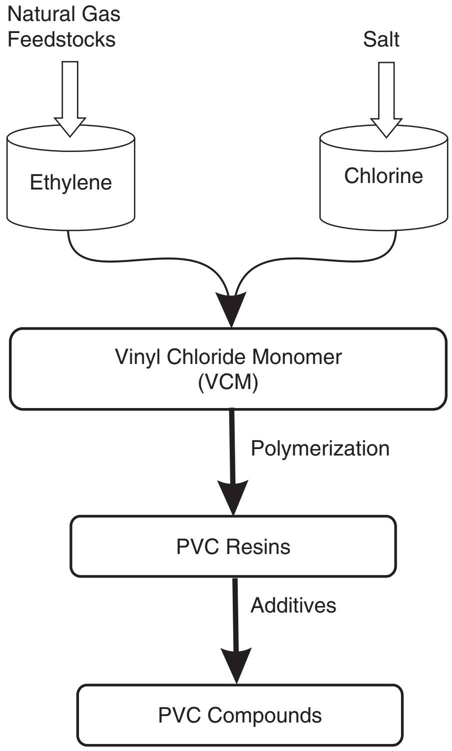

Figure 2. PVC production process.

In the chloralkali process, salt is combined with water to form a brine solution. This saltwater ($NaCl + H_2O$) solution is passed through an electric current in a process where chlorine atoms are attracted to the anode and where the sodium ions in the solution are attracted to the cathode electrode. This electrolysis process produces an electrochemical unit (ECU). The ECU is made up of 1.0 parts of chlorine and 1.1 parts of caustic soda (sodium hydroxide).

Ethylene is derived from the cracking of either petroleum or natural gas. In this process the feedstock is put through a catalyst bed at high temperature and pressure to produce ethylene and a number of other co-products such as propylene and butadiene. The ethylene is further processed to separate it from the coproducts.

Ethylene and chlorine are combined to first make 1,2-dichloroethane, then ethylene dichloride (EDC), and finally vinyl chloride monomer (VCM or $CH_2{=}CHCl$).

PVC is normally polymerized from VCM by one of four processes (suspension, mass, emulsion, and solution) into the following polymer structure:

$$(-CH_2CHCl-)_n$$

Each process uses peroxide-type initiations to produce free radicals, and the exothermic reaction is normally carried out at 95–167°F (35–75°C) (2). Under different reactor configurations, agitation, and reaction media, these four processes produce PVC resins with uniquely different physical characteristics. These characteristics play important roles in subsequent application processes such as extrusion and calendering.

The most commonly used process, which accounts for more than 90% of the PVC produced in North America, is called suspension polymerization. The remaining 10% is made up of mass polymerization and emulsion or solution polymerization processes. Each process creates a PVC resin that has a unique structure that plays a role in the type of end-use application that best fits the resin type. For example, suspension and mass polymerization-type PVC is used in pipe and house siding applications, while emulsion would be used coatings, toys, and flooring. Packaging applications generally use suspension and emulsion polymerized PVC resins.

There are presently six major manufacturers of PVC resins in the United States: OxyVinyls LP, Westlake Chemical Corporation, PolyOne Corporation, Shintech Inc., Georgia Gulf Corporation, and Formosa Plastics Corporation.

VINYL INDUSTRY CHANNELS

About 74% of all North American PVC resin is sold to fabricated products manufacturers, which convert the resin to compounds before producing the final end-use products. Custom compounders that make compounds for sale to PVC product fabricators purchase approximately 10% of the vinyl resin production. The remaining 16% is used by PVC resin producers that have their own integrated compounding facilities. These custom compounds are then sold to PVC fabricators in North America and throughout the world. Approximately 8% of the North American PVC resin production is exported annually.

STRUCTURE AND PROPERTIES

As a basis for discussing PVC's structure or morphology (3–5), some typical suspension-resin characteristics are shown in Table 1.

Table 1. Typical Characteristics of a PVC Suspension Resin

Molecular weight	
Inherent viscosity, ASTM D1243-95 (2000)	0.88–0.98
Weight average molecular weight	142,000–185,000
Number average molecular weight	55,000–62,000
Mean particle size, ASTM D1921-06	130–165 μm
Apparent bulk density, ASTM D1895-06 (2003)	0.450–0.550 g/cm^3
Porosity, ASTM D2873[a]	0.23–0.35 cm^3/g
Residual monomer, ASTM D 3749-95 (2002)	< 1.0 ppm

[a] Method withdrawn, no replacement.

Molecular Weight

The molecular weights of PVC resins produced in the United States are typically 0.55–1.50 inherent viscosity. As molecular weight increases, physical properties such as tensile strength and tear strength increase proportionately (6, 7), as does melt viscosity, which affects product processing. The tradeoff in selecting a PVC resin is to choose the minimum molecular weight to meet the end-product physical requirements while minimizing melt viscosity.

Particle Size

PVC particles are somewhat spherical as a result of the polymerization process (agitation, suspending agents, etc.). The resin particles generally have a size distribution of 70–250 μm in diameter, which results in a mean size of 130–165 μm.

Bulk Density

PVC has a specific gravity of approximately 1.40, but the resin's bulk density (8) is significantly less: 0.450–0.550 g/mL. Bulk density is directly related to the particle's morphology and specifically the resin's porosity, particle size and distribution, and particle surface characteristics.

Porosity

A single PVC resin particle from the reactor has a structure that contains many openings in its surface plus a measurable and accessible void within the particle. The amount of free volume within a resin particle is referred to as its *porosity*. This unique characteristic allows a PVC resin to absorb liquids such as plasticizer during the compounding operation. The amount of porosity and its accessibility play an important role when considering the amount and viscosity of the liquids added during compounding.

Residual Vinyl Chloride Monomer

During the polymerization of PVC, not all of the VCM is converted to polymer. Today the amount of residual monomer remaining in the dried PVC resin is significantly less than 1 ppm. This level establishes safe worker levels and provides acceptable levels in the product.

COMPOUNDING PVC

As discussed earlier, the addition of compounding additives enables PVC to be modified into many useful products. For example, the addition of a liquid plasticizer such as di(2-ethylhexyl)adipate (DEA) permits the production of a flexible film with the oxygen-transmission properties required for red meat packaging. The addition of a rubbery polymer such as methacrylate butadiene styrene (MBS) significantly improves the toughness or crack propagation characteristics as measured by impact tests (e.g., Gardner or Izod). PVC's tremendous versatility results from the ability to tailor those properties to the requirements of the application. With the proper additives, a rigid PVC bottle can be blow-molded for edible-oil packaging. Other ingredients allow the extrusion of a blown flexible film for produce wrapping. These formulations are generally highly proprietary and very specific to use applications and properties.

Stabilizers

Stabilizers give PVC the ability to withstand the thermal and shear conditions of processing without polymer degradation (9). Stabilizers used in food-contact applications, which must have FDA clearance, include Ca/Zn salts, epoxidized soybean oil, and octyl tin mercaptides. In other applications, stabilizers such as butyl or methyl tin mercaptides are used.

Plasticizers

There are numerous types of plasticizers, and each imparts a specific set of properties to the final product (10, 11). These liquid or polymeric additives generally reduce the T_g of PVC. At the same time, they reduce tensile strength and increase elongation. Certain plasticizers, such as di(2-ethylhexyl)phthalate (DEP), improve PVC's water-vapor barrier properties; DOZ (dioctyl azelate) significantly improves its low-temperature impact strength.

Lubricants

Generally, lubricants are added to PVC compounds to reduce the frictional properties between the compound and the metal surface of the processing equipment (12). They are also used to reduce the surface friction of the final product or to reduce the product's surface static properties. Lubricants include such families as paraffin waxes and metal stearates.

Impact Modifiers

Many types of impact modifiers have been developed for PVC packaging applications to improve PVC's toughness for transportation and handling. Examples include methacrylate butadiene styrene (MBS), chlorinated polyethylene, and acrylic polymers. The type used depends on application requirements such as clarity, cost efficiency, low-temperature impact, and metal-release properties.

Fillers and Pigments

Fillers such as $CaCO_3$ can reduce the raw-material costs of a PVC compound. They have little effect on physical properties at low levels. Some fillers can improve properties such as stiffness or abrasion resistance.

PVC IN PACKAGING

PVC packaging applications fall into three general categories: film and sheet, bottles, and others (including coatings and cap liners). About 25% of PVC in packaging involves food applications, 35% medical uses, and 40% nonfood end uses. These market percentages have remained remained fairly steady over the past 10 years.

Film & Sheet:

- Bister and clamshell packaging of toys, electronics, hardware, household goods
- Flexible film for produce and meat packaging
- Medical/Healthcare packaging for pharmaceuticals and medicine packaging, IV and blood bags
- Shrink wrap for tamper-proof over-the-counter medicines

Bottles:

- Jars for oils, peanut butter
- Personnel care products such as shampoo
- Pharmaceutical bottles for drugs and medicines
- Household bottles for cleaning fluid
- Automotive bottles for lubricants

Other:

- Cap and closure liners
- Can coatings

Figure 3. Typical PVC packaging uses.

Table 2. PVC Packaging Market Size[a] (million pounds)

	1994	2006
Film and sheet[b]	547	804
Bottles	188	160
Other packaging	80	36
Total	815	1000

[a] all figures in resin equivalents.
[b] Includes both flexible and rigid compounds.

Figure 3 describes the typical PVC packaging uses, and Table 2 gives the historic and current PVC packaging market sizes.

Film and sheet are the largest applications for PVC in packaging. Rigid blister pack and clamshell applications are the largest single use of PVC. PVC's toughness and clarity make it an ideal material to protect goods during shipping and while on the store shelf. As Figure 3 depicts, nearly 300 million pounds of PVC are used annually to make rigid sheet in thicknesses ranging from 0.010 to 0.150 in. PVC also has proved to be an excellent thermoforming plastic. Because of its ability to hold a form during the thermoforming process, its high impact resistance (even at low temperatures), and its excellent clarity, it has become widely used in the packaging of retail goods and medical products. One of the single most important growth applications has been in drug blister packaging, including unit-dose packets. PVC's performance and cost-effectiveness have led to its dominance of more than 95% of this market (13).

Flexible PVC film is used in food film for packaging meat, cheese, and produce. Among the advantages of PVC for these uses are its clarity, barrier properties, puncture resistance, and cling for good sealability (14). One of the unique advantages of PVC is its moderate oxygen permeability, which helps retard the transition of meat color from red to brown. Competition from modified atmosphere and high barrier films materials will likely limit the growth of PVC in this application.

PVC is used in bottles because of its clarity, impact resistance, ease of formability, chemical resistance, and cost-effectiveness. As a result, the PVC bottle market is primarily for cleaners, chemicals, toiletries, and cosmetics. The use in food packaging has continued to decrease because of competition from other materials such as PET, which has seen rapid acceptance worldwide in water bottles.

Approximately 350 million pounds of PVC is currently used annually in North America in various flexible and rigid medical packaging applications. PVC continues to find growing use because of its properties of clarity, impact, chemical resistance, barrier characteristics, and ability to be sterilized (15) with little loss of properties. Flexible PVC is the leading material for us in IV and blood bags. Despite growing concerns about the presence of plasticizers, since replacing glass for critical applications more than 35 years ago, PVC has proved to be safe, reliable, and the most cost-effective material available. PVC is also used in tubing for connecting various devices to patients.

Rigid PVC has also found growing use in blister packs, trays, and pouches as well as pharmaceutical bottles, particularly where barrier properties are required. Because of competing materials and attempts at substitution, PVC demand in medical applications is expected to grow no more than 3% per year over the next five years.

FDA STATUS

PVC is used extensively in food-contact applications such as meat wrap. It is prior-sanctioned for use in general food-contact applications by virtue of an article published in July 1951 in the *Journal of the Association of Food and Drug Officials of the United States* by A. L. Lehman of the FDA. In addition, PVC resins are listed in a number of specific FDA regulations relating to food-contact substances.

PVC AND THE ENVIRONMENT

Due to an anti-chlorine campaign led by environmental extremists, PVC is sometimes scrutinized and written about in misleading ways concerning its place in the environment. While some claim that PVC manufacturing is a large source of dioxin, in fact the United States Environmental Protection Agency (16) long ago concluded that this is far from being true. Their studies concluded that the manufacture of intermediate feedstocks for PVC is only a minor dioxin source (less than 11 grams per year for the entire industry) and that the PVC industry has made steady progress each year lowering the levels. The fact that over the last 20 years PVC production has tripled while dioxins in the environment have continued to decrease is difficult for PVC opponents to explain.

Other claims against PVC say that it is overwhelming our trash and recycling systems. Yet PVC is a small source in the municipal waste stream because most of its applications are durable, long-life products such as vinyl siding windows and pipe. In those applications, manufacturers are ready, willing, and able to provide recycling support if the material can be collected and separated efficiently. In fact, over a billion pounds per year of PVC is recycled on a post-industrial basis, implying that post-consumer recycling is mostly a matter of economic will. It is important to place criticisms of PVC into context and comparison with alternatives that would be substituted in its place. Recent European studies using life-cycle analysis (LCA) as a comparative environmental tool, have concluded that, overall, PVC has a similar environmental impact as alternatives.

The debate on PVC will long continue. However, it continues to prove to be a cost-effective and safe material for many applications, including packaging. Advocates against PVC in packaging continue to wage a spirited campaign and point to companies that have switched to alternative materials. In most cases, the switch occurred mainly for economic reasons; for example, as a bottlers production runs lengthened, switching to injection molding processes meant lower costs per unit and therefore a switch in materials was necessary. Given its product life-cycle phase, PVC use in packaging will likely continue at a mature pace and its history as a safe cost-effective material will likely never change.

POLY(LACTIC ACID)

Rafael Auras
School of Packaging, Michigan
State University, East Lansing,
Michigan

INTRODUCTION

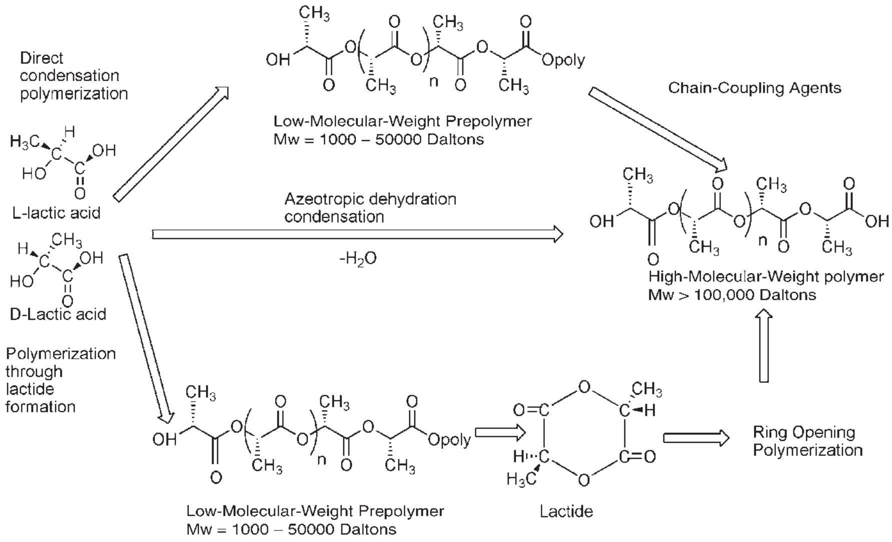
Poly(lactic acid) (PLA) polymers are biodegradable polyesters derived from lactic acid (LA) or 2-hydroxy propionic acid, which is generally obtained by bacterial fermentation of carbohydrates from agricultural crops such as corn, potato, and cassava. PLA has been used extensively for medical applications since the 1970s because of its bioresorbable and biocompatible properties in the human body. Its use in packaging and textile applications until now has been scarce because of its high initial costs. However, discoveries of new polymerization pathways and advances in manufacturing technologies have dramatically lowered PLA costs (1–5). PLA was approved by the U.S. Food & Drug Administration for use in contact with foods in 1992 (6), PLA resin can be produced entirely from biomass, and the final products can safely be recycled, composted, or incinerated (2). PLA has been recognized by industries, consumers, and governments as a candidate material to help in reducing the municipal solid waste produced by packaging and containers (7).

To date, the production of PLA has reached a large-scale industrial capacity (75 metric kt in 2007 and is expected to reach 325 metric kt by 2010), which makes it the most important biopolyester produced from renewable resources (4). NatureWorks LLC (Blair, NE), the former Cargill Inc., and Dow joint venture, which is nowadays owned by Cargill Inc. and Teijin Ltd., produces the largest amount of commercially available PLA resins with a total production of 140 ktpa as of January 2009. Nature Works is also planning to start building a second plant. Toyota has produced special PLAs since 2003 for automotive applications. Galactic and Total Petrochemicals, Uhde Inventa Fischer, and Pyramide Bioplastics have announced plans to produce commercial PLA by the end of 2009. PURAC and Sulzer have also announced joint efforts to produce PLA from solid lactide to obtain expanded PLA beads to target the market of expanded polystyrene (PS). Additional development of stereocomplex PLA by PURAC, Musashino Chemical Laboratory, and Teijin has gained attention for the production of a 50/50 blend of poly(L-lactic acid) PLLA and poly(D-lactic acid) PDLA with a high melting point targeting fiber applications. More pilot scale plants to produce PLA have been announced in China, and currently, PURAC has expanded its lactic acid capacity targeting the increase of PLA demand (2, 4).

PRODUCTION OF HIGH-MOLECULAR-WEIGHT PLA

The main constitutional unit of PLA is lactic acid. LA can exist in two main optical configurations: L or D. PLA polymers can be produced with varying degrees of L or D lactic acid. According to its molecular composition, PLA can be named as poly(XY-lactic acid), in which X and/or Y are the amount of L and D lactic acid, respectively. D lactic acid mainly comes from the racemic lactic acid (LD configuration). So, a PLA polymer’s label as poly(96% L-lactic acid) will be composed of 96% L-lactic acid and 4% D lactic acid.

PLA is mainly produced by three synthesis processes: (a) polymerization through lactide formation, (b) direct condensation polymerization, and (c) azeotropic dehydration condensation (see Scheme 1). Ring open polymerization process is the technology producing the most amount



Scheme 1. Synthesis methods for obtaining high-molecular-weight polylactide and poly(lactic acid); scheme is from Auras et al. (2) by permission of Wiley-VCH Verlag GmbH & Co. KGaA

of PLA in the market. In this process, PLA is derived from lactic acid existing in two stereochemical configurations (i.e., L or D lactic acid), which is catalytically converted under low pressure into LL-lactide, meso or LD-lactide, and DD-lactide, and then it is ring open polymerized into different structures of poly(L-lactic acid, D-lactic acid, or LD-lactic acid). In the direct condensation and azeotropic dehydration condensation polymerization, PLA is derived from L and D-LA, directly. So, high-molecular poly(L,D, or LD LA) can also be produced (2).

PLA resins between 92% L-LA and 98% L-LA, and stereocomplex PLA (50/50 blend of PLLA and PDLA) can be obtained commercially. These resin grades can be processed by extrusion/thermoforming, injection molding, biaxially oriented films, injection stretch blow molded bottles, fiber melt spinning, and spunbond items. All these resins are mainly targeted for particular application; therefore, their degree of L-and D-lactide varies according to the applications (4). The latest developed stereocomplex resins are mainly used for fibers, films, and thermoforming articles.

PROPERTIES

Structure

The principal peaks of PLA absorption in the infrared range are summarized in Table 1. The strong infrared (IR) band at 2997, 2946, and 2877 cm^{-1} are assigned to the CH stretching region, $n_{as}CH_3$, n_sCH_3, and nCH modes, respectively. The C═O stretching region is observed by a large band at 1748 cm^{-1}. The region between 1500 and 1360 cm^{-1} is characterized by the 1456 cm^{-1} CH_3 bend. The CH deformation and asymmetric bend appear at 1382 and 1365 cm^{-1}, respectively. The bands that appear at 1315 and 1300 cm^{-1} are caused by the CH bend modes. In the region from 1300 to 1000 cm^{-1}, the C–O stretching modes of the ester groups at 1225 cm^{-1} and the -O-C asymmetric mode at 1090 cm^{-1} are presented. Between 1000 and 800 cm^{-1}, we can observe peaks at 956.36 and 921.94 cm^{-1}, which can be attributed to the characteristic vibrations of the helical backbone, mixed with the CH_3 rocking modes. Two bands related to the crystalline and amorphous phases of PLA are found at 871 and 756 cm^{-1}. The peak at 871 cm^{-1} can be assigned to the amorphous phase, and the one at 756 cm^{-1} to the crystalline phase. The peaks below 300 cm^{-1} correspond mainly to CH_3 torsion modes and to the skeletal C-C torsions.

Semicrystalline PLAs have superior physical and structural performance compared with amorphous PLAs. Researchers have postulated that the improvements in mechanical and barrier properties of semicrystalline polymers are related directly to complex crystalline structures and their distribution in the amorphous matrix (8–10). The amorphous polymer region cannot be in the crystal lattice of the semicrystalline polymer, and so it must reside between the lamellar stacks (interlamellar) or in the interfibrillar region within the spherulites (interspherulitic). The variation in size and shape of the crystallites, their spatial distribution, the crystalline morphology (which depends on molecular weight, polydispersity index, and processing conditions), the degree of crystallinity, and the space and distribution available for the amorphous region will all dictate the final physical, mechanical, and barrier properties of PLA.

Depending on the preparation conditions, poly(L-lactic acid) crystallizes in three forms (α-, β-, and γ-) (2). The stable α-form exhibits a well-defined diffraction pattern with a space group orthorhombic $P2_12_12_1$, with a unit cell containing two antiparallel chains. The chain conformation is a 2-fold (15*2/7) helix distorted periodically form of the regular s(3*10/7 helix). The lattice parameters are $a = 10.66$ Å; $b = 6.16$ Å, and c (chain axis) $= 28.88$ Å, with a crystal density around 1.26 $\mathrm{g/cm}^3$. The β-form of PLA is generally prepared at a high draw ratio and high drawing temperature. The chain conformation is a left-handed 3-fold helix. The β-form of PLA has an orthorhombic unit cell (containing 6 chains) that contains a 31 (3 Å rise/1 monomeric unit) polymeric helix. The lattice parameters of the unit cell are $a = 10.31$ Å, $b = 18.21$ Å, and $c = 9.0$ Å. The α-structure is more stable than the β-structure, with a melting point of 185°C compared with 175°C for the

Table 1. Infrared spectroscopy data: Peak band assignments for PLA infrared spectra

Assignment	Peak Position, cm^{-1}
–OH stretch (free)	3571
–CH- stretch	2997 (asym), 2946(sym), 2877
–C═O carbonyl stretch	1748
–CH$_3$ bend	1456
–CH– deformation including symmetric and asymmetric bend	1382, 1365
–C═O bend	1225
–C–O– stretch	1194, 1130, 1093
–OH bend	1047
–C–C– stretch	926, 868

β-structure. Chain packing in the β-form has recently been termed a frustrated structure, where the crystal structure comprises a frustrated packing of three 3-fold helices in a trigonal unit cell of parameters a = b = 10.52 Å, c = 8.8 Å, and space group $P3_2$ (11). The γ-form is formed by epitaxial crystallization and contains two antiparallel s(3/2) helices in the pseudoorthorhombic unit cell a = 9.95 Å, b = 6.25 Å, and c = 8.8 Å, and it assumes the known 3-fold helix of poly(lactic acid) (2).

Optical, Thermo-Physical, Rheological, Mechanical, and Barrier

The optical, physical, mechanical, and barrier properties of PLA compared with PS and polyethylene terephtalate (PET) are shown in Table 2. PLA has similar density than PET, and a similar semycrystalline structure can be obtained during processing. Because the glass transition temperature (T_g) of PLA and its heat deflection temperatures (HDT) are very close, PLA suffers heat deformation when it is exposed to temperatures higher than 50°C. The tensile strength values obtained for PLA are within the range of values reported in the literature for PS under the same testing conditions. However, when compared with PET, PLA films showed lower values. Table 2 also shows the water, oxygen, carbon dioxide, and aroma barrier properties of PLA and these values are compared with those of PS and PET when data were available. PLA has a better barrier for carbon dioxide, oxygen, and water vapor permeability when compared with PS but a lower barrier when compared with PET. PLA has an aroma barrier similar to PET, so it makes a good polymer for the storage of products with high flavor. Theoretical predictions based on the solubility parameters indicate that PLA will interact with nitrogen compounds, anhydrides, and some alcohol but will not interact with aromatic hydrocarbons, ketones, esters, sulfur compounds, and water.

PROCESSING

PLA suffers hydrolysis, which is a reduction in molecular weight caused by the presence of water at temperatures near the glass transition temperature ($T_g \sim 55$°C), so for processing it must be dried below 250 ppm (12). Additional drying should be conducted for processes that have long residence time. Drying of semicrystalline PLA should be conducted in the range of 80 to 100°C and below T_g for amorphous PLA (4). Because PLA degrades at elevated temperatures and relative humidity (RH), the resins should be protected from hot and humid environments during storage. Henton et al. (12) reported that amorphous PLA can dramatically reduce its molecular weight (M_w) in less than a month when exposed to 60°C and 80% RH. More information about the drying condition of PLA can be found elsewhere (4).

The main way to process PLA is through extrusion and injection molding, blow molding, film blowing, and melt spinning. To ensure that all the crystalline PLA phases are melted and to achieve an optimal melt viscosity for processing, PLA is generally extruded around 160 to 195°C. In general, commercial-grade PLA resins can typically be processed using a conventional extruder. Cast and film sheet of PLA are produced with a screw diameter of 19.3 mm, compression ratio of 2:1, and length/diameter ratio of 25. The recommended compression ratio for PLA processing is in the range of 2:3 (13). High roller temperatures (i.e., 25–50°C) are generally used to cast PLA avoiding the building up of lactide around the die. General equipment to process PET and PS can be used and/or modified to process PLA. The physical properties of PLA as for other polymers can be enhanced by orientation. Resins with a higher D-lactide content allow a higher drawing ratio. A blown film of virgin PLA resin is difficult to obtain. So, blown PLA films contain additives, such as viscosity enhancers, are to strengthen PLA's melting strength, and slip additives are used to reduce the coefficient of friction (4).

Thermoforming of PLA is normally conducted to produce PLA clamshells and containers. The properties of thermoformed PLA containers have been compared with PS and PET showing that PLA could out perform PET and PS at lower temperatures (14, 15).

PLA bottles have been produced based on injection stretch blow molding (ISBM) techniques. The ISBM process produces biaxial-orientated PLA bottles and has better properties than injection molding of amorphous PLA (4). Most of these bottles are currently being used for noncarbonated drinks.

PLA foaming has been gaining attention because of its potential to reduce weight and reduce thermal conductivity. Foaming of PLA has been a niche application in tissue engineering and medical implant applications. As the price of PLA is dropping, PLA foam can find new applications in packaging, such as cups, bowls, and loose-fill packaging materials (4). Most of the challenge in foaming PLA is controlling the bubble size of the foam structure (16). Another special category of growing interest for PLA applications is fiber spinning and electrospinning of ultrafine fibers. The former application has mainly reached market applications in textile production, and it is having great acceptability because of lower water-barrier properties. However the electrospinng PLA ultrafine fibers is mainly being developed for tissue engineering and biomedical applications (4).

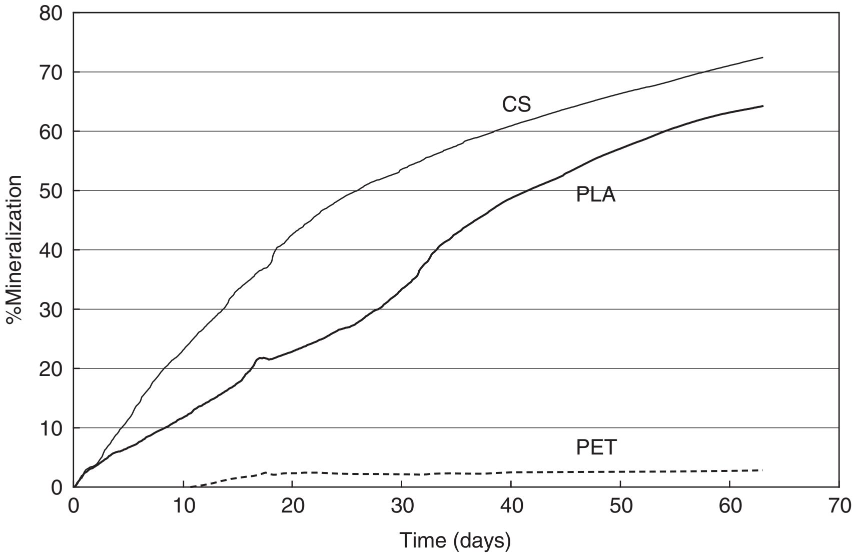

Figure 1. Percentage of mineralization of PLA, PET, and corn starch at 58±2°C and approximately 55±5% RH in yard waste compost (reproduced from Kijchavengkul et al. (27)) by permission from Elsevier B.V.

Blends of PLA with other polymers have been researched to improve PLA films bursting strength, elongation and tear strength, and impact resistance properties. Some main materials that have been blended with PLA are thermoplastic starch, poly(ethylene glycol), triacetin, tributyl citrate, poly(hydroalkanoates), and poly(3-hydroxyloctanoate) (4). Cost reduction is achieved when the blending counterpart has a lower cost. Besides PLA blending, compounding of PLA with inorganic or organic particles has investigated to enhance the barrier, thermal, and mechanical properties of the PLA composite. Special categories of compounding are nanocomposites which have been reinforced into PLA. Among the main nanocomposites used are layered silicates, carbon nanotube, hydroxyapaite, layered titanate, aluminum hydroxide, and cellulose nanowiskers (4). Layered silicate clays such as montmorillonite MMT have been researched extensively in the industry to produce PLA with higher mechanical and flexural properties, elevated heat distortion temperature, enhanced barrier properties, and accelerated biodegradation. Additional promise has been created with cellulose nanowiskers to produce PLA microwavable packages (4).

End-of-life Scenario

PLA can be recycled and has been certified as a compostable polymer according to ASTM D6400 and EN13432 by the main international certifying entities (7, 17). The composting of PLA is enhanced by hydrolysis because of the absorption of water resulting in the hydrolysis of the ester linkages. The rate of degradation is highly affected by temperature, moisture, and pH conditions of the

[a] Refractive index values for PLA were calculated by Gladstone and Dale, Vogel, and Lloyenga methods according to Ref. (20). PS and PET values are experimental values obtained from Ref. (20).

[b] Density of the amorphous PLA was obtained from Ref. (21), PS and PET values are from Ref. (20).

[c] Density of 100% PLA, PET, and PS was calculated according to the group contribution method (20).

[d] PLA, PET, and PS values were calculated using the group contribution method (20).

[e] PLA, PET, and PS values were obtained from Ref. (2).

[f] T_g and T_m of PLA, PS, and PET were obtained from Ref. (1).

[g] Td,0 and Td,1/2 of PLA was obtained from Ref. (18); PS and PET values were obtained from Ref. (20).

[h] PLA and PET values obtained from Ref. (22).

[i] PLA, PS, and PET values were obtained from Ref. (23).

[j] PLA, PS, and PET values were obtained from Ref. (4).

[k] PLA value was obtained from Ref. (2); PS and PET values were obtained from Ref. (20).

[l] PLA value was obtained from Ref , PS and PET values were obtained from Ref (20).

[m] PLA, PET, and PS values were obtained from Ref. (2).

[n] PLA and PS, PET values were measured at 200°C and 5 kg according ASTM D1238.

[o] PS and PET values were obtained from Ref. (20).

[p] PLA and PET, PS values were measured according to ASTM D445 and D446 (PLA values were determined in Tetrahydrofuran at 30 °C, PET values were determined in phenol and 1, 1, 2, 2-tetrachloroethane (60:40 by volume) at 25 °C.

[q] PLA, PET, and PS values were obtained from Ref. (2).

[r] PLA, PS, and PET values were obtained from Ref. (23).

[s] PLA, PET, and PS values were obtained from Ref. (1, 22); oxygen activation energy are reported for temperatures between 25 and 45°C.

[t] PLA, PET, and PS values were obtained from (1); carbon dioxide activation energy is reported for temperatures between 25 and 45°C.

[u] PLA values were obtained from Ref. (24); PET and PS values were obtained from Ref. (20).

[v] PLA, PS, and PET values were obtained from Refs. (1, 22); water activation energy is reported for temperatures between 10°C and 37.8°C.

[w] PLA, PS, and PET values were obtained from Refs. (25, 26) (ethyl acetate values of PLA and PET are at 3030 PA, and 30°C and 9435 Pa and 30°C, respectively; d-limonene of PLA and PET are at 245 Pa and 45°C and 45 Pa and 23°C, respectively).

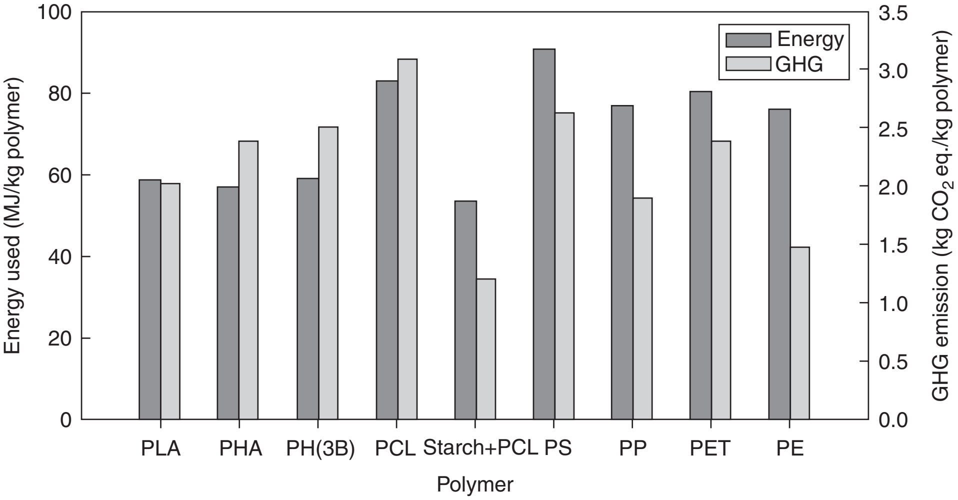

Figure 2. Energy used and amount of greenhouse gases (GHG) emission in CO_2 equivalent from producing 1 kg of polymer resin at the resin production plants (reproduced from Kijchavengkul and Auras (7) by permission from Wiley-VCH Verlag GmbH & Co. KGaA.)

compost (18, 19). PLA polymers with lower L-lactic acid content degrade faster in a compost environment. Figure 1 shows the mineralization of PLA bottles compared with PET bottles as a negative control in yard waste compost.

Figure 2 shows the energy used and amount of greenhouse gases emitted in CO_2 equivalents, from producing 1 kg of polymer resin (cradle-to-gate boundary). According to Figure 2, in general, production of these biodegradable polymers, except poly(caprolactone) (PCL), uses less energy than production of many nonbiodegradable plastics, such as PS, polypropylene (PP), PET, and polyethylene (PE). The production of PLA and PHA (polyhydroxyalkanoate) produces greenhouse gases in similar amounts as those of PS, PP, and PET. More research is necessary regarding the end-of-life scenario of these new biopolymers.

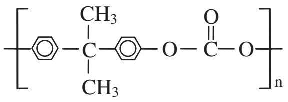
POLYCARBONATE

Updated by Staff

INTRODUCTION



Polycarbonate (PC) is an amorphous resin that does not require orientation to achieve its full property profile. The molten resin can be extruded by the blown or cast processes (see Extrusion), injection-molded (see Injection molding), or blow-molded by the extrusion-blow or injection-blow techniques (see Blow molding). As polycarbonate cools into film, sheet, or containers, it exhibits excellent dimensional stability, rigidity, impact resistance, and transparency over a wide range of temperatures and loading rates (see Table 1). Because PC is amorphous, its wide softening range and added strength in thermoforming (see Thermoforming) operations provides deep-draw capabilities.

Polycarbonate is now the second largest engineering plastic produced, behind crystalline nylon. Leading world producers are BASF, General Electric, and The Dow Chemical Company (1). Trade names include Lexan (GE), Makrolon (Bayer), Calibre (Dow), Panlite (Teijin), and Iuplon (Mitsubishi).

Polycarbonate is prepared by the Schotten–Baumann condensation reaction of phosgene and an aromatic diol using an amine catalyst or a based-catalyzed transesterification of bisphenol and a monomeric carbonate (2).

PROPERTIES

Polycarbonate provides an excellent combination of tensile strength and flexural modulus at high temperatures (see Table 2). Its heat resistance, combined with superior impact resistance at both high and low temperatures, makes it an excellent structural layer in coextruded or laminated packaging for hot fill at 180–210°F (82–99°C), retorting at 250°F (121°C), autoclaving at 270–280°F (132–138°C), and frozen-food packaging. In addition, PC can be sterilized with both gamma and electron-beam irradiation with good stability.

Polycarbonate has light-transmittance values of 88–91% as compared with 92% for clear plate glass. It has a haze factor of less than 1%, and it maintains these values throughout the temperature scale. Its high gloss and easy colorability and printing contribute to distinctive package design. Polycarbonate has high resistance to staining by tea, coffee, fruit juices, and tomato sauces, as well as lipstick, ink, soaps, detergents, and many other common household materials. Its relatively dense composition makes it immune to odors, and its hard, smooth surface facilitates easy removal of foodstuffs.

Some of the most significant attributes of polycarbonate stem from its very low water absorption. Added weight increase after 24-h immersion at room temperature is only 0.15%. This low absorption level helps account for the resin's excellent dimensional stability and stain resistance. It also indicates that the resin, itself tasteless and odorless, is unlikely to pick up food odors. PC is available in grades that meet FDA and USDA regulations and is recognized as safe for food-contact applications.

PACKAGING APPLICATIONS

Refillable Bottles

Polycarbonate is the material of choice for use in reusable bottles, particularly 5-gal (19-L) water bottles, which represent the resin's chief packaging application. These bottles take advantage of polycarbonate's toughness (to resist breakage) and clarity (to see the contents). The fact that PC is much lighter than glass provides fuel savings as well as productivity improvements, since several bottles can be carried at once. Systems have been developed to wash polycarbonate and provide clean bottles for reuse with minimum impact on trippage. Lexan (now sold under SABIC Innovative Plastics) can be washed and filled 50 times while maintaining excellent taste, neutrality, and a transparent glasslike appearance (3).

Table 1. Typical Property Values for Polycarbonate[a]

Property	ASTM Test Method	Melt Flow Indexes				PC Copolymer
		22	16	10	6	
Specific gravity	D792	1.20	1.20	1.20	1.20	1.20
Light transmittance, 0.125 in. (3.2 mm), %	D1003	89	89	89	89	85
Haze, 0.125 in. (3.2 mm), %	D1003	1	1	1	1	1–2
Deflection temperature at 264 psi (1.8 MPa) °F (°C)	D648	260 (127)	265 (129)	270 (132)	270 (132)	325 (163)

[a] Properties shown are average values that can be expected from typical manufacturing lots and are not intended for specification purposes. These values are for natural color only. Addition of pigments and other additives may alter some of the properties.

[b] This rating is not intended to reflect hazards of this or any other material under actual fire conditions.

Medical-Device Packaging

Polycarbonate meets many requirements of medical-device packaging (see Healthcare packaging). It is clear and tough, and it can be sterilized by commercial sterilization techniques: ethylene oxide (ETO), radiation, and autoclave sterilization (see Radiation, effects of). The development of coextrusion technology has afforded opportunities in all sterilization systems. Special grades have been developed to maintain clarity and resistance to yellowing upon gamma radiation (2). In thin films, PC can be coextruded with polyolefin heat-seal layers (see Coextrusions for flexible packaging; Coextrusions for semirigid packaging) to produce a cost-effective alternative to laminations based on oriented films (see Films, plastic). Because it is amorphous, heat sealing does not shrink or embrittle the film (see Sealing, heat). This virtually eliminates puckering, which can lead to hairline cracks and shattering upon opening. A soft blister package with good puncture resistance can be produced by thermoforming heavier-gauge film. For increased stability in the autoclave, a polycarbonate copolymer, poly(phthalate carbonate), can be incorporated into the structure. Properties of monolayer PC films are listed in Table 3.

Table 2. Tensile Strength and Modulus of Polycarbonate over a Temperature Range

Temperature, °F(°C)	Tensile Strength, psi (MPa)	Flexural Modulus, psi (MPa)
73 (23)	10,000 (68.9)	320,000 (2,206)
212 (100)	5,800 (40)	233,600 (1,610)
270 (132)	4,000 (27.6)	211,200 (1,456)

Food Packaging

Coextrusions of polycarbonate are being evaluated for use in several segments of the food-packaging market. The snack-food industry, along with other users of flexible-packaging materials, is discovering ways to use PC in coextrusions to replace laminated films in a portion of a structure or to replace the entire structure (see Multilayer flexible packaging). It is polycarbonate's toughness without orientation that makes it a good candidate for coextrusion. PC is used for food containers and baby bottles (4).

For frozen foods, the resin's low-temperature impact strength adds durability to dual-"ovenable" trays. In coextrusions, it can add toughness to crystallized polyester or polyetherimide trays. In cases where the wall thickness is determined by impact-strength requirements, gauge reductions up to 33% are possible.

In high-barrier multilayer containers, polycarbonate offers the rare combination of dimensional stability at retort and hot-fill temperatures, along with crystal clarity (see Retortable flexible and semirigid packages; Multilayer plastic bottles). To produce a 1% distortion in PC requires 3000 psi (20.7 MPa) stress. A similar distortion in polypropylene occurs at less than 500 psi (3.4 MPa) stress. Polycarbonate is about three times as expensive, but dimensional stability can be translated into value by making lighter containers with thinner walls by faster and more reliable closing a hot-fill temperatures, higher

retort temperatures with less critical overpressure control, and enhanced container-design flexibility.

An unexpected benefit from the use of PC in retort applications is an increase in the effectiveness of the barrier material EVOH (see Ethylene–vinyl alcohol). In a retort, moisture is driven into all layers of a plastic container. When the outside skin layer is polypropylene, the polypropylene prevents moisture from entering the structure, but it also prevents moisture trapped in the EVOH layer from escaping. Because polycarbonate has poorer moisture-barrier properties than polypropylene, it allows much more rapid drying of the EVOH layer and longer shelf life.

POLYESTERS, THERMOPLASTIC

Updated by Staff

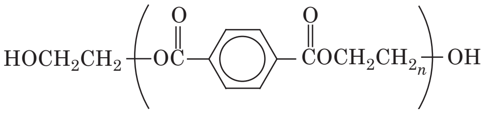
INTRODUCTION

Poly(ethylene terephthalate) (PET) was first developed by a British company, Calico Printers, in 1941 for use in synthetic fibers. The patent rights were then acquired by DuPont and Imperial Chemical Industries (ICI), which in turn sold regional rights to many other companies. Polyester fibers have since made a considerable impact on the textile industry. The second principal application of PET was film. In 1966, PET became available for the manufacture of injection-molded and extruded parts.

The amazing growth of PET in beverage packaging began in the early 1970s with the technical development of biaxially oriented PET bottles (see Blow molding) and with the introduction of the first 2-L PET beverage bottle in 1976. The total world market for PET botttle resin is still growing at a rapid rate. The total devoted to carbonated soft drink or PET bottles is very large and the United States is the largest consumer, with Europe next. China is now advancing with a potential of 25–30 billion PET beer bottles per annum. The annual output of all plastic packaging materials including PET bottle resins was 9.5 million tons in 2005 and is expected to reach 13.7

million tons in 2008. PET bottle demand seems to be assured because of its balance of properties and the ability to be recycled. There is a strong demand for packaging mineral waters in Europe and there is a large hot-fill market in Japan. A market survey of the United States beverage container market for 2002–2007 shows that the market for plastic bottles (largely PET) is still growing, while glass and metal metal cans are static or in slight decline (see Table 1) (1).

PET has the following formula:



where n=100–200.

MANUFACTURE OF PET

Raw Materials

The raw materials for PET (see Figure 1) are derived from crude oil. *Para*-xylene, one of the two starting materials, is part of the naphtha feedstock that used to be fully available for chemicals because it was a byproduct of limited value to the oil refiner. Now it has become the source of additives that replace lead in unleaded gasoline in many countries. Of the mixed xylenes, because they come from the reformer, only *p*-xylene is suitable for building straight polymer chains, and the straight configuration is necessary to give the polymer its fiber- and film-forming (or bottle-wall-forming) characteristics and ultimately its high tensile strength. The other raw material for polyester is ethylene, which is contained in the crude oil's gas fraction. It is converted to ethylene glycol by oxidation and hydrolysis. All of these raw materials are now derived from oil, but it is technically feasible to produce them from coal-tar distillation.

Intermediate Products

Two different routes are used to manufacture PET: One route is by way of dimethyl terephthalate (DMT), and the other is by way of terephthalic acid (TPA). Both are dibasic acids. Figure 1 shows both routes. The plants for intermediate and end products are shown together, but they are normally physically separated. The process of making DMT is relatively simple: One end of *p*-xylene is first oxidized with air and esterified with methanol to yield a half-ester that is subsequently converted at the other end. The resulting DMT is purified by distillation and repeated crystallization to remove isomers and other impurities. The TPA route is similar. TPA can be produced by oxidation of *p*-xylene in solution and purified by solvent extraction.

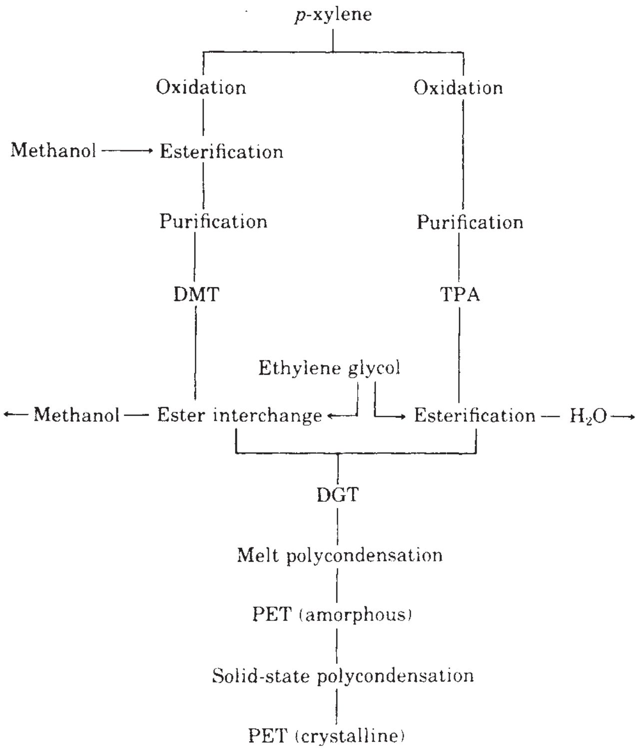

Figure 1. Manufacture of PET.

Melt Polycondensation

Both batch- and continuous-polycondensation processes are used. The continuous process inherently allows better product uniformity; the batch process is preferred for small quantities of specialty resins. On the DMT route, DMT and ethylene glycol (EG) are continuously metered into the ester interchanger, where the methyl end groups of the DMT are replaced by ethyl end groups to form diethylene glycol terephthalate (DGT), the monomer of PET. In this step, EG is consumed while methanol is evaporated and collected to be returned to the DMT plant. On the other route, TPA is esterified with EG to DGT, and water is removed as a byproduct. Subsequent polycondensation is the same for both routes. In EG takeoff, excess EG is removed and sent to the distillation plant for recovery. Polycondensation takes place in vacuum reactors designed to evaporate EG, the condensation byproduct, thereby shifting the equilibrium toward long polymer chains. The final step includes extrusion of the melt as strands or ribbon, quenching in water, and cutting to the desired chip size.

Solid-State Polycondensation

Melt polycondensation produces amorphous PET as used in most fiber and film applications. Unfortunately, this product is not suitable for the injection molding of food containers because the inherently high acetaldehyde level would affect the taste of some foods. A final solid-phase polymerization before stretch molding must be performed to remove the acetaldehyde (1). There are other impurities that might promote degradation during the injection-molding process; and amorphous resin tends to fuse and form lumps in the drying hopper. The polymer must be upgraded by the solid-state polycondensation process. Various agitation devices and polymer chip treatments have been described to prevent sticking (1). The chips are crystallized to avoid later sticking and then dried to reduce hydrolysis at high processing temperatures. Solid-state polycondensation takes place in the reactor, where the chips are subjected to high temperatures under vacuum (batch process) or in a nitrogen or dry-air stream (continuous process). The product's intrinsic viscosity (IV) is normally between 0.70 and 1.0. (Intrinsic viscosity is a method for the characterization of the average length of the molecule chains in PET.) High-viscosity resin is relatively expensive because its production is lengthy. High-viscosity PET (i.e., having longer molecule chains), offers better mechanical properties than the average-viscosity resin. These properties compensate for certain deficiencies of molded articles; for example, excessive volume expansion of beverage bottles can be limited by higher-viscosity resins that creep less under load. The final step is cooling, since the resin should not be exposed to moist air while it is hot.

HOMOPOLYMERS AND COPOLYMERS

PET is a homopolymer made from one part dibasic acid (i.e., TPA or DMT), and one part EG. A copolyester (copolymer) is made from more than one dibasic acid and/or glycol. Copolymers remove processing limitations and provide increased physical properties at elevated temperatures. In addition to DMT or TPA, isophthalic acid (IPA) can be used as a comonomer to reduce the rate and degree of crystallization to an extent that depends on its dosage. This broadens the processing parameters of food-container manufacturing machines.

Glycols offer several opportunities for modification. During polycondensation, EG reacts with itself to some extent to form diethylene glycol (DEG). Higher amounts of DEG affect many polymer properties. There are other glycols available as partial substitutes for EG (e.g., neopentyl glycol, cyclohexane dimethanol). All these modifications lead to desired polymer property changes (i.e., reduction of the crystallization rate, melting point, etc.). Cyclohexane dimethanol can react with a mixture of terephthalic and isophthalic acids in order to increase the melt strength of the polymer for extrusion processes (3).

On the other hand, some injection-molding (see Injection molding) and thermoforming (see Thermoforming) applications require accelerated crystallization rates in order to set up crystallization in the article, which prevents physical deformation at elevated temperatures. This objective can be achieved by nucleation, which involves the addition of other ingredients to the polymer. Inert, nonsoluble substances (e.g., mica, talc), organic substances (e.g., aromatic alcohols), and certain polymers (e.g., PP, PE) can be used as nucleation ingredients to increase crystallization rates.

The use of PET and optional added substances for food-packaging applications is governed by FDA Regulation No. 177-1630 of March 16, 1977 (revised April 1, 2007). Homopolymers and copolymers and additives must conform to this regulation.

PACKAGING APPLICATIONS

Homopolymers

By strict definition, most PET resins are modified homopolymers. These homopolymers are used to manufacture containers (i.e., bottles), by injection blow molding or injection-stretch blow molding (see Blow molding). Consumption of bottles for carbonated soft drinks runs into the billions of units in the United States alone. A main factor for bottle use is the permeability of the bottle wall to oxygen and carbon dioxide. Carbon dioxide pressure must remain during storage and oxygen from the air must not diffuse in. PET is semipermeable. Some early PET bottles had coatings of impermeable polymers, but the process involves extra steps and the bottles are not readily recyclable (1). The most marketable is plain PET with reduced permeability. PET bottles are also used for liquor, wine, food, toiletries, and pharmaceuticals, as well as for beer in some countries. Homopolymers cannot be processed by extrusion blow molding because of insufficient melt strength. For bottles containing beer and wine, the demands are far more severe than for carbonated soft drinks. Here it is important to keep oxygen out of the bottle. Oxygen permeability is a problem with PET. For high-barrier one-trip bottles, people are looking to coated or multilayer bottles to reduce oxygen permeability. There is much activity in Europe at the moment for plastic beer bottles. Ten percent of beer produced in Europe comes in PET bottles. In the United States, Anheuser Busch and Coors have started supplying their beers in 16-oz multilayer bottles (1).

Biaxially oriented PET film (see Film, oriented polyester) is usually manufactured by polycondensation and subsequent continuous casting of the film plus direct biaxial orientation; that is, molecule chains of the resin become biaxially oriented. Nonoriented PET film and sheet are manufactured by melting PET resin in an extruder and casting the melt through a flat die with subsequent calendering.

PET is also used for "ovenable" trays for frozen food and prepared meals. These trays are thermoformed from cast PET film and crystallized. Crystallization heat-sets the article to prevent deformation during cooking and serving. The main advantages of PET for this application include suitability for both conventional and microwave ovens,

Table 2. PET Polymer Resin Options for Different Manufacturing Processes and Applications

Manufacturing Process or Application (PET Resin Type)	Standard Homopolymer	Standard Bottle Resin	Slow-Crystallizing Copolymer	Fast-Crystallizing Homopolymer

Heat-set film				X
Crystallizable PET trays				X
PET coating for paperboard	X			

[a] Resin option depends in desired application.

light weight, and superior aesthetics (as compared with foil trays).

Copolymers

Commercially available copolymers offer improved melt strength for the vertically positioned extrusion blow-molding process. They are used to some extent for bottles, and to a greater extent as extruded sheet for blister-pack applications. Since the FDA regulation permits certain copolymers for food-contact use, new applications include packages for noncarbonated drinks, cooking oil, and vitamin preparations.

In India, work on a blend of PET with poly(trimethylene naphthalate) is being used for beer bottles. This blend exhibits 18 times the carbon dioxide barrier of PET and 9 times the barrier to oxygen (4).

Hot-fill applications is a growing market. PET suffers from a low glass-transition temperature (70°C), which causes severe bottle distortion if the contents of the bottle approaches this temperature. A recent approach to the hot-fill problem is by DuPont. An amorphous isosorbide homopolyer is blended with PET. This blend raises the glass-transition temperature to 94°C (5).

Polymer options, manufacturing processes, and applications are summarized in Table 2.

The manufacturing process of PBT is very similar to that of PET. Instead of EG, 1,4-butandiol $[\mathrm{HO}{+}\mathrm{CH_2}{+}_4\mathrm{OH}]$ is used to react with either TPA or DMT. PBT is rarely used in packaging applications.

RECYCLING

About 1 billion pounds of postconsumer PET containers were recycled in 2004, a recycling rate of 21.4%. Cleaning of the recovered plastic comprises washing, rinsing, and drying. PVC is a common impurity in PET. Melting PET containing PVC will produce black spots due to charring. It is difficult to separate the two polymers after the bottles have been ground into small particles. Froth flotation has been shown to be an effective means of separation. Originally, PET was used exclusively for packaging soft drinks. As a result, the waste stream was fairly homogeneous consisting of unpigmented 1- and 2-L bottles. However, PET is now used to package a wide variety of beverages including water, fruit juices, tea, and beer plus other products such as edible oils, butter, and ketchup. These containers come in a variety of sizes and shapes, and various label adhesives and barrier resins are combined with the PET. Careful sorting of these containers is needed and can reduce the quality and yield of product. In the United States, PET from recycled bottles is used primarily in fiber applications. Recycled PET for food containers typically requires FDA approval. Two tertiary recyling technologies have been used: methanolysis and glycolysis. Suitability for food contact is a critical property in selling recycled PET. The FDA has issued letters of nonobjection to operators using methanolysis or glycolysis processes. Two-liter soda bottles containing recycled PET manufactured by glycolysis or methanolysis are widely available. The FDA has also issued a letter of nonobjection for a trilayer PET material having a middle layer sandwiched between two virgin layers of PET (6).

POLYETHYLENE, HIGH-DENSITY

Stephen J. Carter
Solvay Polymers, Inc.
Deer Park, Texas
Updated by Staff

INTRODUCTION

High-density polyethylene (HDPE) is a semicrystalline polymer, conveniently defined by ASTM as having a density of 0.941 or greater, with a typical upper limit of 0.965. For commercial purposes, HDPE is described as a homopolymer when the density is ≥ 0.960, but as a copolymer when the density is below this figure. The polymer is available in a wide range of molecular weights as determined by either MI or HLMI (melt index or high-load melt index).

HDPE is one of the largest-volume plastics used in packaging for the simple reason that it can be successfully employed in numerous transformation processes. Blow molding and injection molding account for 45–54% of total consumption of HDPE (1). Table 1 lists some of the major processes used and the products that can be obtained from them.

MANUFACTURE

HDPE is commonly sold in pellet form and is manufactured in a two-stage process. Polymerization takes place in a reactor on a continuous basis using either of two types of catalyst: Ziegler or Phillips. The choice of hardware today is limited to the slurry and gas-phase processes, the solution process having largely been bypassed on both cost and environmental counts, except for specialty grades. The slurry (Phillips) process was developed by the Phillips Petroleum Company and was licensed worldwide in the 1960s (2). Figure 1 shows a simplified view of the process. Purified ethylene, isobutane (the slurry carrier), activated catalyst, and any comonomer are circulated within loop-style reactors under relatively narrow ranges of pressure and temperature. At periodic intervals, portions of slurry are withdrawn and separated into unreacted materials, carrier, and HDPE. The raw polymer powder is dried and then stored in tanks until compounded in an extruder, together with the requisite additives (stage 2 of the process).

Table 1. Examples of Packaging Applications

Conversion Process	Examples of Packages
Blow molding	0.1 to 5.0-gal juice, water, or milk bottles Bottles containing pet food to bleach industrial 55-gal drums Bottles for cosmetics and pharmaceuticals
Injection blow molding	Bottles for cosmetics, personal care, pharmaceuticals
Injection molding	Caps and closures Pails and buckets Thin-walled dairy cups/tubs Crates Foamed packaging
Blown or cast film	Multiwall bag liners Grocery, merchandise or produce bags Breakfast-cereal wrappers Snack-food wrappers
Thermoforming	Prepackaged-food containers Dairy cups and containers Tubs for personal care, hygiene items Pallets
Sheet extrusion	Foamed sheet for packaging
Rotational molding	Water and chemical tanks and shipping containers

The newer gas-phase process was originally developed by Union Carbide in the 1970s and was named Unipol; BP Chemicals licensed a competing process about 10 years later. The gas-phase hardware dispenses with liquid carrier and, as the name suggests, permits direct polymerization of ethylene using living polymer as a fluid-bed medium and using ethylene as the fluidizing gas. From a distance, a GP reactor looks very much like a water tower because of the elongated bulb sitting on top of the cylindrical tower housing the fluid bed. The bulb is the portion of the reactor where fines deentrainment takes place. Newer world-scale HDPE plants are typically rated at 400–500 MM lb/yr and are composed of one or more gas phase units closed-coupled to twin-screw compounding trains.

Whatever the hardware, the core of the polyolefin manufacturing operation is the catalyst. Ziegler formulations are traditionally based on combinations of aluminum alkyls with titanium compounds, often with proprietary modifiers to improve productivity, comonomer incorporation, or other parameters. The catalyst may be chemically or physically attached to a variety of bases (e.g., silica or magnesium chloride) to improve productivity and flowability through controlled particlesize distribution (many catalysts are self-supporting). Ziegler catalysts tend to be unrestricted in molecular-weight (MW) terms, although they produce relatively narrow molecular-weight distributions (MWD). Phillips catalysts, on the other hand, tend to be restricted to fractional melt-index (MI) grades, producing broader MWD HDPE with better environmental stress-crack resistance (ESCR) properties (3).

In the realm of catalysts, the most recent development has been the commercialization of the metallocene type. Metallocene resins have been used to produce extremely high-clarity resins (4). New non-metallocene bimetallic catalysts are being developed to produce blow-molding resin a a single reactor (5).

MOLECULAR STRUCTURE

There are four principal features of HDPE that affect its packaging and processing properties: density, degree and type of branching, molecular weight, and molecular-weight distribution. As comonomer is introduced into the reactor to control density (typically 1-butene or 1-hexene), short-chain branching (SCB) is incorporated into the backbone of the polymer (catalysts can also create some SCB in the

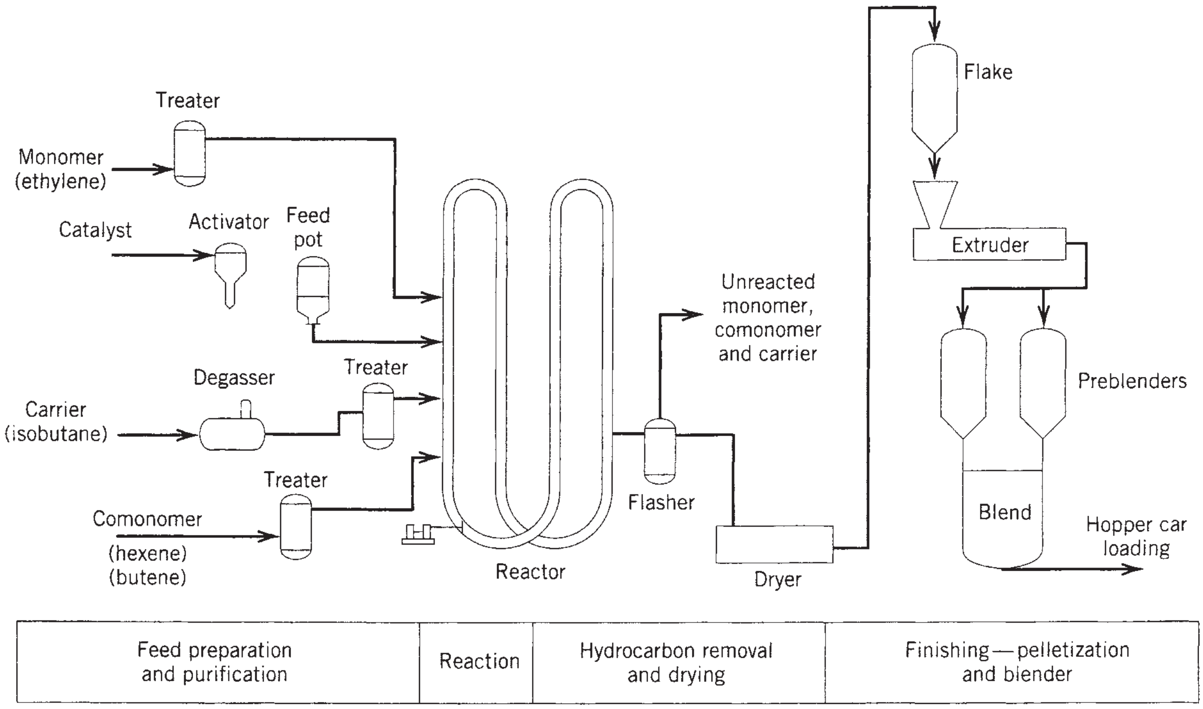

Figure 1. Simplified flow diagram for the Phillips (slurry) manufacturing process.

absence of comonomer). The nature and frequency of the SCB induce major disruptions in the HDPE crystallites, with the result that the density and degree of crystallinity are decreased. As little as one ethyl branch per 1000 carbon atoms can produce a density change of 0.01. As implied, the density of HDPE enjoys a rough linear relationship with regard to crystallinity. Commercial polymers exhibit degrees of crystallinity of 70–80% at 0.960, depending on the MW (MI) and type of SCB. A drop of 10% in crystallinity as one progresses from 0.960 to 0.940 is typical. There is increasing evidence that the "blockiness' of the branches is as important as the overall frequency (6). New information has been obtained using *temperature-rising-elution fractionation* (TREF), a relatively new technique for studying SCB that is independent of molecular weight and that fractionates polymers according to crystallinity, composition, and tacticity differences.

As a consequence of SCB, the morphology of HDPE in the solid state consists of three very different regions. The amorphous region contains polyethylene chains that are randomly oriented and acrystalline in nature, while the crystalline regions contain HDPE chains that are tightly packed in folds to yield differing types of geometries. Joining the two regions together is the interface. The crystalline regions imbue PE with its rigidity, tensile strength, and lack of permeability toward small molecules, while the extent of the amorphous areas affect impact resistance and ESCR.

Table 2 lists some of the major properties associated with changes in density, MW, and MWD. An increase in density causes a rise in tensile strength at yield, stiffness, and chemical resistance, while a decrease improves both ESCR and impact resistance. This results in compromises for many applications. For example, a 1-gal milk jug is manufactured from a homopolymer to extract the highest levels of top-load and lightweighting capability, while a bottle containing industrial chemicals (bleach, detergent, etc.) is blown from a lower-density resin to take advantage of the higher ESCR. Density is commonly measured by the gradient column method or, more recently, by an ASTM-approved acoustics technique.

The term *molecular weight* colloquially refers to the length of a polyethylene chain. Since all HDPE polymers possess a variety of chain lengths, it becomes necessary to mathematically define some MW terms in order to obtain meaningful information. Thus M_n, the number-average molecular weight, is $\Sigma N_i M_i / \Sigma N_i$, where N = number of polyethylene molecules and M = combined mass of the polyethylene molecules (e.g., 100 molecules at 10,000 + 100 molecules at 20,000 = 15,000). The weight-average molecular weight, M_w, is $\Sigma N_i M_i^2 / \Sigma N_i M_i$ (e.g., 100 molecules at 10,000 + 100 molecules at 20,000 = 16,667). For packaging applications, M_n ranges from about 7000 to 19,000 and M_w ranges between 80,000 and 250,000. When plastics people talk about MW, in reality they are referring to M_w.

Molecular weights are commonly estimated by rheological techniques (capillary/dynamic oscillatory rheometry), solution (intrinsic) viscosity, or the popular size-exclusion method, gel-permeation chromatography (GPC). However, each of these methods does give rise to considerable variation, especially for high-molecular-weight polymers, and any numbers quoted should be used only as a guide.

The most frequently used way of determining a measure of MW is the melt index (MI). For HDPE, this is condition E of ASTM D1238, which uses a well-delineated

Table 2. Influence of Density, Molecular Weight, and Molecular-Weight Distribution on Selected HDPE Properties

[c] Highly dependent on polymer type.

[d] Subject to cooling rate, part thickness, etc.

capillary rheometer, a temperature of 190°C, and a 2.16-kg load to push the extrudate out of the barrel.

The MI is simply the weight of polymer collected during a 10-min period under these conditions. For higher-MW polymers, the load is changed to 21.6 kg and the result is referred to as *high-load melt index* (HLMI). The ratio of HLMI/MI represents a crude measure of the molecular-weight distribution and is often the simplest technique for quality-control purposes. Polydispersity, formally M_w/M_n, is a more rigorous gauge of MWD and is usually obtained by GPC. Because this method gives a direct visual representation of the MWD, it can also supply other information that is absent from other techniques. Figure 2 shows typical MWD curves for a variety of polymer types. Note that such features as modality, symmetry, and MWD breadth are easily determined.

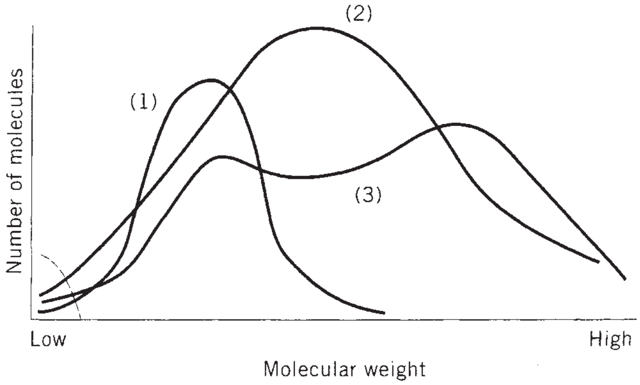

Figure 2. GPC curves for various types of HDPE polymers: curve 1—low-MW, symmetrical, narrow-MWD injection molding resin; curve 2—medium-MW unsymmetrical monomodal blow-molding resin; curve 3—high-MW bimodal film resin. The dashed line in the lower-left corner represents the oligomer region.

From Table 2 it can be seen that both MW and MWD affect virtually all common properties, especially melt parameters, processing, and impact strength.

One other type of branching is long-chain (LCB). These longer side chains to the PE backbone are characteristically 6–12 carbons long. They impact both melt elasticity (important for foamability, large parison stability, etc.) and processability (how easily a material can be transformed). In other end uses, LCB sites can be used to initiate crosslinking with a peroxide or other suitable radical generator. LCB can be imaged through elongational or short-die, capillary-die rheometry techniques.

PROPERTIES

Chemical

HDPE resists most chemicals, including dilute acids and bases, oxidizing agents, hydrocarbons, and some aldehydes/ketones. The major exceptions are chlorohydrocarbons and aromatics, which tend to swell and soften the polymer. Even some of these chemicals can be packaged in HDPE if the interior surface is fluorinated or sulfonated, or if a coextrusion with a barrier layer is incorporated (e.g., nylon).

The ability of an agent to degrade HDPE over a period of time is dependent on the ESCR of the polymer. The failure mechanism is the extension of a crack at a focal point, or local area of concentrated stress. On a microscopic level, one might consider this to be a plasticization of the strands of PE that link the crystals of HDPE together in the interfacial zone—in other words, a dissolution of the "glue" that binds the crystalline regions. Both density and MW have a profound effect on this parameter, so the trick is to make a grade of HDPE that has the highest density and lowest melt viscosity compatible with the application.

ESCR is usually measured by the *bent-strip test* (ASTM D1693), which involves taking a strip of HDPE, making a notch in it, and bending it in a jig, so that the notch provides a narrow area of constant strain. The strip is immersed in either 100% detergent (condition A), or 10% solution in water (condition B). The latter is considered a much more aggressive condition. For bottles, it is also possible to employ a more sophisticated, real-world test by applying a low constant pressure to a bottle that contains a small amount of water or other liquid [constant-pressure bottle test (CPBT)]. Failure occurs when either the bent strip snaps or, in the case of the CPBT test, the bottle bursts and leaks liquid. In either case, ESCR is reported in average number of hours to failure based on a statistical approach, or first to fail.

The permeability of HDPE toward small molecules is most dependent on the density, because it is the crystalline regions that present the highest impedance. Longer, more entangled, higher-MW chains also cause small molecules such as oxygen or water to take a more tortuous path. The transmission rates of gases such as moisture are dependent on the thickness of PE that they have to traverse, as well as the temperature and concentration of the gas. As the thickness of the HDPE is increased, the ability of the layer to prevent small molecules from passing through it decreases exponentially. As barrier polymers go, HDPE is only a fair performer. To get the smallest transmission rates through a film or bottle wall, it may be necessary to make a multilayer construct using coextrusion.

Preparation of the surface of HDPE for decoration is most commonly achieved by treating it with either a gas flame or corona discharge. In the case of either method, time should be taken to optimize the process. The polyethylene on the surface should become sufficiently oxidized so that the surface tension rises from 29 to at least 36 dyn/cm. Simple tests based on water dissipation or dye retention can often be used as a quick check. One should be aware that many additives such as antistats, lubricants, and slip agents can migrate quickly through the plastic and cause print delamination over a period of days. The same result is seen when the oligomer content is high.

Physical

Impact resistance of a bottle or container is one of the most important parameters in packaging. This property is improved by decreases in density and MWD, and an increase in MW. Often the needs for impact resistance are in direct conflict with load-deformation requirements. The degree of impact resistance can be assessed by a variety of tests performed on compression-molded plaques, such as Izod or Charpy, in both notched and unnotched conditions. Dropping heavy weights on plaques in ambient or cold temperatures using the Gardner apparatus is also practised widely (dart impact for films). Many manufacturing companies also drop loaded containers in various attitudes to verify performance and ensure that the design or molding process itself has not introduced a weakness.

Load deformation comes in two flavors: (i) instant, or top load, in which the stress is exerted on a bottle or other container during a momentary situation (e.g., during filling or capping); and (ii) constant loading, in which bottles are stacked on top of one another during a long storage period. If the material being contained is nonchemically aggressive, a homopolymer of medium MW should prove sufficient for the application. A more demanding ESCR service will require an HDPE of higher MW, or lower MI to compensate for the reduced stiffness of the lower-density material. The conventional gauge of stiffness is flexural modulus and typical numbers for HDPE range from 250,000 for a homopolymer to half that value for a 0.940-density material.

APPLICATIONS

Blow molding and injection molding are the dominant processes for preparing end products of HDPE. The important packaging use is for extrusion molding of bottles for milk, water, and liquid detergent (1, 5). HDPE coextrusions with LDPE, ethylene, and vinyl acetate copolymer or ionomer are widely used in liners for food cartons. Injection molding produces a wide variety of products including cups, pails, crates, trays, food containers, and caps and closures. Blown films are used for sacks and bags, trash can liners, and food packaging (5).

RECYCLING

In 2006, $17{,}645 \times 10^6$ lb of HDPE was produced in the United States (7). About 24.8% of produced HDPE is recycled in the United States, mainly milk and water jugs and liquid detergent bottles. Cleaning of the recovered plastic comrprises washing, rinsing, and drying. Removal of the labels is the worst problem in the washing and drying stages. Detergents are usually used to improve the efficiency of label removal. Metal-foil labels can introduce metal into the polymer. When metal-foil labels are heat-sealed onto the plastic, the only way to remove them is by using an extrusion-melt filter. This leads to plugging of the filter screens, causing more frequent changes and the increasing production costs. During the rinse cycle, polyethylene particles sink to the bottom of the bath and can be separated from the polyethylene. Recycled HDPE is used for nonfood bottles, pipes, lawn and garden products, film, lumber, pallets, crates, buckets, and automotive parts (8).

POLYETHYLENE, LINEAR AND VERY LOW-DENSITY

V. Firdaus

Mobil Chemical Company
Edison, New Jersey
Updated by Staff

INTRODUCTION

Polyethylene is a thermoplastic material well suited for packaging applications. It is a large-volume commodity resin. In 2006, U.S. and Canadian production of linear low-density polyethylene (LLDPE) was $13{,}037 \times 10^6$ lb. Sales and captive use totaled $13{,}050 \times 10^6$ lb (1). Market share corresponded to 28.7% of total consumption (2). LLDPE has established itself as the third major member of the global polyethylene market, which includes low-density polyethylene and high-density polyethylene. Polyethylene resins are available in a variety of molecular weights and densities tailored to specific end-use markets. Polyethylene can be generally classified into the product types listed in Table 1 on the basis of its density.

HISTORY

In the early 1950s, 20 years after ICI pioneered LDPE in the United Kingdom using a high-pressure process, Phillips Petroleum Company commercialized catalysts containing chromium oxide supported on silica. These catalysts were used to produce HDPE, which became the first commercial products of catalytic ethylene polymerization. Almost simultaneously, K. Ziegler and co-workers (2) discovered a new group of transition-metal catalysts that polymerize ethylene and other α-olefins under mild conditions. The first commercial introduction of LLDPE was made in a solution process by DuPont Canada in 1960 (3) using these catalysts. In 1976, W. Kaminsky and H. Sinn discovered a new family of catalysts for ethylene polymerization using metallocene complexes (4). These catalysts afford the synthesis of ethylene copolymers with a high degree of compositional uniformity. Currently, there are several commercial processes that produce LLDPE and VLDPE as described in the next section (5).

Table 1. Commercial Classification of Polyethylene Resins

Product	Density (g/mL)
High-density polyethylene (HDPE)	0.94–0.97
Medium-density polyethylene (MDPE)	0.926–0.939
Linear low-density polyethylene (VLDPE)	0.915–0.926
Very low-density polyethylene (VLDPE)	0.89–0.915
Low-density polyethylene (LDPE, produced via free-radical polymerization)	0.915–0.940

PROCESS

LLDPE and VLDPE resins are commercially produced by several processes, including gas-phase, solution, and slurry polymerization. The first gas-phase process using the fluid-bed process was developed by Union Carbide in 1979 and has been licensed worldwide. Another gas-phase process used globally is one developed by British Petroleum Company. Ethylene copolymers with butene, hexene, and 4-methyl-1-pentene are produced in the fluidized-bed reactors, a highly versatile, economical process that can accommodate various types of catalysts. Although Ziegler–Natta catalysts are most widely used, metallocene-based catalysts are also used in this gas-phase process (6).

The first solution processes were introduced in the late 1950s. Currently, there are two types of solution processes commonly used for the production of ethylene copolymers. The first process used heavy solvents (C_6–C_{10} hydrocarbons) to solubilize the ethylene and polyethylene at high temperatures and pressures. The process utilizes Ziegler–Natta or metallocene catalysts. The second type of solution polymerization process uses mixtures of supercritical ethylene and molten polyethylene as the medium for ethylene copolymerization reactions. In this case, retrofitted high-pressure reactors that were used previously for producing LDPE are currently being used to produce LLDPE and VLDPE.

The slurry polymerization process is the oldest catalytic polyethylene production technology. The main disadvantage of this technology, however, lies in the fact that the LLDPE resins produced by this process exhibit high swelling even when light solvents are used. The resultant stickiness in the polymer particles significantly limits the polymer density range and production rates that can be achieved via this process. Recent developments in this process have allowed the production of broad-MWD LLDPE using light solvents such as isobutane and isopentane.

POLYMER STRUCTURE AND PROPERTIES

Properties of LLDPE and VLDPE are usually specified in terms of density (ASTM method D792) and melt index (ASTM method D1238). Density is a measure of crystallinity, and melt index is related to the polymer molecular weight (see also Polymer properties).

Density is the most important parameter governing resin properties. Polyethylene is essentially a composite material consisting of a rigid crystalline phase and an elastic amorphous phase. As crystallinity decreases with decreasing density, the product becomes softer and more pliable, clarity increases, and toughness also increases. Density is controlled by the concentration of short-chain branching (SCB), which is introduced in polyethylene resins via copolymerization with α-olefins. Comonomers widely used are 1-butene, 1-hexene, 4-methyl 1-pentene, and 1-octene. The side branches serve to disrupt the polyethylene crystals, channel polymer chains into the amorphous phase, and thus reduce overall density. The comonomer type determines the length of the side branch. The short side branches of a butene copolymer can be partially incorporated into the polymer crystal, whereas those from the higher α-olefins (HAOs) cannot. As a result, the HAO copolymer chain is likely to leave a given crystal and enter another one to form a "tie chain" that helps bind the crystals together. For this reason, HAO copolymers are generally stronger and tougher than butene copolymers.

Another important structural characteristic is the polymer chain length or molecular weight (MW) and molecular-weight distribution (MWD). It is a common practice to characterize MW by means of the melt index (MI), which bears an inverse relation with MW; thus, lower MI values correspond to higher MW. The melt-flow ratio (MFR) is a ratio of the polyethylene viscosity at two different shear rates and is an indicator of the MWD. In general, long chains are entangled with one another and entanglements contribute to the resin's strength and toughness. However, the desire for higher strength needs to be balanced against processabilty, since MW and MWD have a profound influence on the flow behavior or rheological characteristics of the molten polymer. MW controls the overall viscosity level and MWD controls how viscosity depends on shear rate—that is, its shear-thinning response. Processability, related to flow at high shear rates, is therefore a function of both MW and MWD. Most LLDPE and VLDPEs have relatively narrow MWD and show low degree of shear-thinning (see Figure 1).

When compared to LDPE (whose shear-thinning is further enhanced by the presence of long-chain branching) of a similar melt index, LLDPE and VLDPE resins tend to build up high stresses during processing at relatively low shear rates. Other consequences of their narrow MWD are low-melt elasticity and "soft" stretching flow behavior. Low-melt elasticity implies rapid relaxation of polymer chains in the melt when subject to stress. For this reason, the tendency to induce molecular orientation during processing is low, and the product physical properties are not as sensitive to processing conditions. The "soft" stretching behavior implies a low extensional viscosity that enables easier drawdown of the molten resin bubble to thin gauges. By the same token, LLDPE and VLDPE resins have low melt strength and can be sensitive to bubble instability during blown-film extrusion.

A third influential factor in the LLDPE/VLDPE properties and processing is the short-chain branching distribution (SCBD) of the polymers. In general, LLDPE resins are structurally heterogeneous. Not only is there a distribution of MW, but there is also a distribution of SCB. The SCB is not uniform across all polymer chains; some chains have many branches, while others may be essentially linear. This characteristic of heterogeneous SCBD generally contributes to thicker crystallites, higher melting point, higher stiffness, and lower optical clarity in LLDPE when compared to LDPE at the same density. The SCBD also affects the fraction of the resin that can be extracted by solvents such as hexane. This fraction, commonly referred to as the "FDA extractables," is highly branched and low in MW. Both SCBD and MWD are determined by the catalyst system and, to a lesser extent, the reactor conditions. Polyethylene produced using metallocene catalysts have a very narrow MWD as well as a much more homogeneous SCBD. This leads to very low extractable levels in the final product.

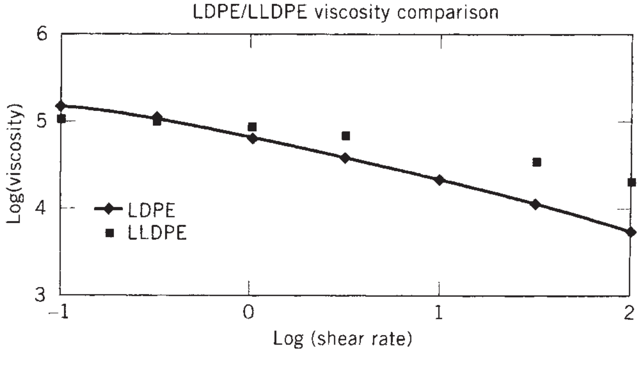

Figure 1. LDPE/LLDPE viscosity comparison.

Since VLDPE resins have lower density compared to LLDPE resins, the short-chain branching levels are higher. Conventional VLDPE resins (catalyzed by Ziegler–Natta catalysts) have high extractables, high strength, and clarity. Metallocene-catalyzed VLDPE resins, in spite of the low density, still offer the additional advantage of having very low extractable levels. This is a major advantage in medical applications where high purity is essential. Also due to the homogenous SCBD, the melting point of metallocene-catalyzed resins is significantly lower compared to conventional LLDPE and VLDPE. This leads to improved sealability in the final product.

In 2004, ~15% of LLDPE in the United States was produced using metallocene catalysts. This usage is expected to rise to ~25% by 2010. The latest addition to the catalyst family is a group of organometallics of various transition metals (6).

APPLICATIONS

LLDPE competes with LDPE for many applications, and has made significant inroads into traditional LDPE markets. This is mainly due to the significantly better downgauging potential, which allows thinner films with enhanced physical properties.

Film

Film is the largest application for LLDPE resins, greater that 55% in the United States in 2005 (6). This film has a high tensile strength and puncture resistance. The toughness and low-temperature properties of LLDPE film exceed those of conventional LDPE. The trash-bag market exceeds 700,700 t/yr: it is the largest market for LLDPE (see Table 2). Ethylene-1-butene copolymers, which are the cheapest, have a lower film strength compared to those of the high-strength ethylene-1-hexene and ethylene-1-octene copolymers. Bags for merchandise packaging manufactured from thin LLDPE film have excellent tensile strength, puncture resistance, and seal strength at thin gauges. This application includes bags on a roll, such as garment bags, laundry and dry cleaning bags, and ice bags. Several LLDPE and VLDPE films are competing for a special film market; elastic stretch film for packaging. The resins based on ethylene-1-hexene and ethylene-1-octene copolymers are particularly suited for these purposes. A significant volume of LLDPE is used for manufacturing large-size packaging for food and textiles. These bags are easily reused, take up less space, and are moisture-resistant.

Several VLDPE grades, especially those produced via metallocene catalysts, are used to prepare very clear film. High-clarity film is necessary in many packaging applications. Barrier properties and clarity are attractive properties for packaging poultry, frozen foods, and vegetables. Medical applications include film for blood bags and surgical disposable bags. Compositionally uniform LLPDE and VLDPE are especially attractive because of their sealability.

Injection Molded Products

Injection molded products is the second largest market for LLDPE. It accounted for ~7% of its consumption in 2005. Over one-half of the LLDPE consumed is used to produce housewares These housewares are stiffer and more resistant to impact and distortion at elevated temperatures than those of LDPPE. Lids for HDPE jars and containrs are made of LLDPE. They have excellent gloss and low warpage.

FABRICATION PROCESSES

As indicated in the previous section, LLDPE and VLDPE are used in a large variety of product types. Since film is the largest market segment, film extrusion is briefly summarized in the following paragraphs (7).

Film Extrusion

Polyethylene is converted from pellets into film using one of two techniques: blown- or cast-film extrusion. Depending on the end-use property requirements, the resin is either blown into a tubular film or cast into a thin flat sheet. Compared to cast films, blown films typically have higher haze, more balanced orientation, and good impact strength, and can generally achieve gauge uniformity within 10%. On the other hand, cast film tends to have better clarity and is highly oriented in the machine direction. Excellent gauge uniformity (within 3%) can be achieved by casting the film, which allows film production at very thin gauges (sometimes less than 0.5 mil). The film is quenched much sooner on cast film lines, and significantly higher extrusion rates are achieved. Some basics of film extrusion are explained below.

Table 2. Typical LLDPE/VLDPE Film Applications

Agricultural Rollstock	Ice Bags
Bakery bags	Industrial liners and sheet
Diaper backsheet	Medical packaging
Garbage bags, consumer	Newspaper bags
Garbage bags, institutional	Produce bags-on-roll
Grocery sacks	Shopping (retail) bags
Household food bags	Shrink wrap
Heavy-duty sacks	Stretch wrap

Blown Film. The process of converting pellets into blown tubular film consists of four basic steps: feed/recycle, extrusion, film blowing, and winding.

1. The feed section consists of a hopper in which virgin polymer is loaded. Usually, there is some mechanical means of blending in some recycled material. This could be either postconsumer recycle (PCR), which is mandated in some states and in some applications, or merely scrap film and edge trim that is fed through a grinder and combined into the feed stream with the virgin resin. The feed stream also may contain additives such as pigments and processing aids.

2. The function of the extruder is mainly to compress, melt, and convey the polymer to the discharge end. There are several different types of extruder screws. The original film equipment consisted of screws that were optimized for LDPE resins. When LLDPE was first introduced, it became evident that the LDPE screws would require some modification to process LLDPE, since the power efficiency was very low because of the rheological behavior of these mostly linear resins. The processing requirements of LLDPE were met by designing screws such as the barrier screw or decreasing-pitch screw that could handle a more viscous melt. By far the most commonly used screws for extruding LLDPE or LLDPE/LDPE blends are the barrier screws.

3. After the extruder, the polymer melt is forced into an annular blown-film die for extrusion into a tube. The thickness of the annular opening, the die gap, is generally between 25 and 100 mils. When processed through a narrow die gap, LLDPE resins generally require a processing aid to avoid melt fracture, a film deformity that occurs when a certain critical shear stress is exceeded. Although melt fracture does not cause film property loss (8) except at severe levels, it poses an appearance problem that can be a critical factor in several applications. After the polymer exits the die, it is drawn down in the machine and transverse directions (MD and TD) to achieve the desired film thickness. Film cooling is also an important part of the process. The frost-line height (FLH), where the polymer melt crystallizes, plays an important role in determining final film properties (9).

4. The final step consists of the buddle being flattened by collapsing frames, drawn through nip rolls and over idler rolls to a winder to produce rolls of blown film.

Cast Film. The cast-film process is similar in most aspects to the blown-film process outlined above, except in the film formation step. Here, the polymer melt exits the extruder and enters a “T” or coat-hanger die. The orientation of the die can vary depending on processing conditions. Typically, a vertically downward die is preferred. The molten polymer web is cast onto a polished roll that has an internal cooling mechanism to maintain a constant temperature. An air knife is generally used to

Table 3. Typical Properties of Commercially Available LLDPE Resins[a]

Comonomer	Butene	Standard Hexene	"Super" Hexene	Octane
Melt index (dg/min)	1.2	0.9	0.9	1.0
Density (g/mL)	0.918	0.917	0.917	0.920
MFR	24	28	25	30
Dart impact (g)	85	180	480	250
Elmendorf tear MD (g)	80	300	450	350

[a] 3.5-in. Gloucester, 2:1 BUR, 430°F, 100-mil die gap, 250 lb/h, 1.0-mil film.

press the molten polymer against the roll. Usually, two chill rolls are used to provide appropriate tension to the film. After this point, the film goes though nip rolls and into the winder to produce rolls of cast film.

Coextrusion

The reasons for using coextrusion are usually to achieve specific physical properties such as sealability, barrier, and strength. Also, there are economic benefits to using coextrusion including reduced costs (by using an inexpensive polymer in the noncritical layer) and reduced waste (by introducing a recycle layer). Coextruded film can be produced on both blown- and cast-film equipment, and involves multiple extruders feeding a single die. As many as nine-layer lines are now being used commercially, although two and three-layer lines remain the most common.

PHYSICAL PROPERTIES

Although LLDPE resins are generally considered as having superior physical properties compared to LDPE, the actual impact or tear strength is strongly dependent on the comonomer used, as well as on the melt index and density. Some key film properties that are critical for several film applications are explained below:

Dart Impact (ASTM D1709). This test measures the ability of a film to withstand the force of a falling dart, and is an indicator of film toughness. Dart impact is strongly affected by the molecular weight, density, and comonomer type.

Elmendorf Tear (ASTM D1922). The resistance to tear in either the machine direction (MD) or transverse direction (TD) is measured by this test. Typically, LLDPE films tend to have lower MD tear strength compared to TD. Since that becomes the limiting direction, only the MD tear values are often measured and reported, whereas the TD tear is not considered critical in most LLDPE film applications. Ideally, a balanced orientation, or MDT:TDT ratios close to 1.0, is desirable to maximize film performance.

Other Properties. Tensile and yield strength (ASTM D638) of the LLDPE resins are also considered critical end-use properties. Typically, the tensile strength of butene LLDPE is somewhat lower than the HAO-LLDPEs. Yield strength is primarily a function of resin-base density. Hexane and xylene extractables are also measured to ensure that the film meets FDA limits for food-packaging applications. Film blocking, the tendency of a bag to resist opening, is a function of resin-base density and MWD. Other properties such as puncture resistance, puncture propagation tear (PPT), sealability, haze, and gloss are also considered important, depending on the application.

Comonomer type plays a strong role in influencing the final film properties. In general, butene copolymers tend to have lower film strength, and they are used in low-end applications. Standard hexene copolymers show significantly improved strength properties over butene, but are not considered as strong as octene copolymers. However, a new class of "superstrength" hexene copolymers actually exceed the strength properties of standard octene copolymers. Film strength properties of some commercially available resins are shown in Table 3.

VLDPE resins generally offer much better optical properties and impact strength, due to (a) the increased level of comonomer or (b) low base density. As in the case of LLDPE, film properties vary with respect to melt index, density, and comonomer type. In general, VLDPE resins exhibit outstanding puncture resistance, flexibility, low-temperature stability, and good sealability.

The use of LLDPE in injection molding offers such advantages as higher stiffness, improved ESCR, and heat-distortion resistance, which can be coupled with higher melt indexes to provide faster cycle times and downgauged articles.

SAFETY AND HEALTH

Polyethylene is one of the most inert polymers and constitutes no hazard in normal handling (resin suppliers will provide Material Safety Data Sheets on request). It is generally recognized as a safe packaging material by the FDA. Resin suppliers will state which of their products comply with regulations governing polyethylenes used in food-contact applications.

LLDPE can present a certain health hazard when burned because smoke, fumes, and toxic decompositon products can be formed in the process.

POLYETHYLENE, LOW-DENSITY

Norma J. Marashin
Union Carbide Corporation,
Bound Brook New Jersey
Updated by Staff

INTRODUCTION

Polyethylene is a thermoplastic polymer formed from the polymerization of ethylene. It is available in a variety of molecular weights and densities, which have been tailored to specific end-use markets. ASTM has divided polyethylene into four general categories according to density:

Type	Nominal Density (g/mL)
I	0.910–0.925
II	0.926–0.940
III	0.941–0.959
IV	≥ 0.960

In general, the polyethylene industry does not always follow these designations but has broken polyethylene into two broader categories: high-density polyethylene (HDPE), density ≥ 0.940; and low-density polyethylene (LDPE), density 0.915–0.939. There is also now a type of polyethylene, very low-density polyethylene (VLDPE), with densities of <0.915. Dow Chemical offers VLDPEs under the trade name ATTANE and polyethylene with densities of 0.895–0.913 under the trade name FLEXOMER.

Low-density polyethylene was first produced in England in 1933 by Imperial Chemical Industries laboratories, when ethylene gas was compressed to high pressures and heated to high temperatures (1). ICI’s development of a commercial process for the manufacture of LDPE was closely followed by the wartime use of the product in critical areas such as high-frequency cables for ground- and airborne radar equipment.

In the early 1950s, another type of polyethylene, HDPE, was commercially introduced by several companies who had developed new low-pressure processes for its production (2). HDPE is a linear polymer without any of the long-chain branching characteristics of LDPE. Because of its different structure, HDPE possessed properties different from and complementary to those of LDPE and was quickly utilized in many new packaging applications. These two polyethylenes—differentiated with respect to density, properties, and manufacturing processes—coexisted and grew until the early 1960s, when a third type of polyethylene, LLDPE, was introduced. Because the molecular structure of this new type of LDPE was more similar to that of HDPE, the term *l*inear *l*ow-*d*ensity *p*olyethylene (LLDPE) was coined. Therefore, the polyethylene industry today is composed of three types of polyethylene: HDPE, LDPE (sometimes also referred to as high-pressure LDPE or HP-LDPE), and LLDPE. There is some confusion in the terminology used for LDPE and LLDPE. In some articles and publications, LDPE is used as a generic term for polyethylene below 0.935, thus covering both HP-LDPE and LLDPE. In other cases, LDPE is used to cover only HP-LDPE and LLDPE is a separate category of polymer. In this article, the second type of categorization is used. LLDPE is treated as a separate type of polyethylene and referred to only as LLDPE, while LDPE covers only low-density polyethylene produced by the high-pressure process. When written out (low-density polyethylene), both LDPE and HP-LDPE are included. LLDPE has made inroads in many of the markets currently served by LDPE and, in addition, is competing with HDPE in some new applications.

However, by the late 1980s, the penetration of LDPE markets by LLDPE appeared to be leveling off and LLDPE producers looked for new technology to regain momentum. The early 1990s saw an exciting explosion of new low-pressure, low-density PE products and technology designed to address some of the deficiencies of LLDPE compared to LDPE. For example, Phillips Petroleum announced LDLPE (*l*ow-*d*ensity *l*inear *PE*) and claimed that it was easier to process than conventional LLDPE (3). Union Carbide Corp. announced Unipol II, a technology that would be capable of making low-pressure products that were true “drop-ins” for conventional, commodity LDPE products (4). Himont built a new U.S. Gulf Coast facility to utilize its Spherilene process, which is claimed to produce polyethylene resins in spherical form directly from the reactor (5). The development of single-site catalyst technology that could make polyethylene homo-, co-, or terpolymers from 0.865 to 0.96 density was reported (6, 7). By early 1995, most major polyethylene producers began using metallocene or single-site programs and many had formed joint ventures to commercialize the products. At present, post-metallocene catalysts are being developed. Salicylaldimine complexes of group IV metals may show higher activity and the possibility of further refinement of molecular structure.

CHARACTERIZATION OF POLYETHYLENE

The properties of products made from polyethylene are dependent on some basic characteristics of polyethylene itself. Several of the terms commonly used to describe polyethylene are discussed in the following paragraphs.

Melt Index

The melt index (MI) of a polymer is used as an empirical measure of its molecular weight. To measure melt index according to ASTM D1238, a polymer sample is melted and forced through a small orifice of fixed size under a fixed pressure. The weight of polymer that is extruded in 10 min under 44 psi (303 kPa) of pressure is called the *melt index*. When the pressure is increased to 440 psi (3030 kPa), the weight of polymer extruded in 10 min is the *flow index* (FI). Since a polymer with very high molecular weight will be very viscous and resistant to flow, it will not pass through the small orifice quickly and the weight obtained in 10 min (or melt index) will be low. Melt index is therefore inversely proportional to molecular weight. Typical low-density polyethylene melt indices range from 0.2 to over 150 dg/min. In general, products in the lower-melt-index range are used for film extrusion and the higher-melt-index products for molding and extrusion coating. Within any fabrication process, the use of a lower-melt-index resin will result in a stronger product, although usually with some sacrifice in extrudability.

Melt-Flow Ratio

The melt-flow ratio (MFR) is a rough estimate of the molecular-weight distribution (MWD) of a resin. Since all polymer chains in a given resin are not exactly the same length, an MWD measurement will describe how dissimilar the chains are from each other. Melt-flow ratio is the ratio of the flow index to the melt index. The higher the ratio, the broader the molecular-weight distribution and the more dissimilar the chains are from each other. A polymer with every chain exactly the same length would have a very narrow molecular-weight distribution and a very low melt-flow ratio. Melt-flow ratios of commercial low-density polyethylenes vary from about 20 (very narrow) to about 100 (very broad). Polymers with narrow molecular-weight distributions give stronger products, but are more difficult to extrude than those with broad molecular-weight distributions.

Density

The density of a polymer is a measure of its crystallinity. Density measured according to ASTM D1505 consists of taking a small sample of polymer that has been molded in a carefully prescribed manner and dropping it into columns with solutions of different viscosities. The position of the unknown polymer is the column is then compared to standard samples of known density. The density of a film or molded article is only partly controlled by the density of the resin used to make the product. The rate at which the product is cooled also plays an important role. The faster a film or molded article is cooled, the less time there is for the polymer chains to crystallize and the lower the density of the final product. For example, the density of a sample cut from a blow-molded polyethylene bottle was 0.945 g/mL. The same polyethylene resin, when compression-molded into a plaque and cooled according to ASTM D1505, measured 0.954 g/mL. Product properties such as stiffness, rigidity, environmental stress-crack resistance (ESCR), and moisture vapor transmission rate (MVTR) are affected by density. The lower the density of a product, the more limp and flexible it is. A 0.918-g/mL polyethylene product will have better ESCR and higher MVTR than a product with a density of 0.930 g/mL.

LDPE PROCESS

LDPE is made by the high-pressure polymerization of ethylene (2, 8). In either a tubular or autoclave reactor, ethylene is pressurized to more than 20,000 psi (138 MPa) and heated to $>150\,^{\circ}\mathrm{C}$. Small amounts of an initiator, typically oxygen or peroxide, are added to start the polymerization process. Comonomers such as vinyl acetate or ethyl acrylate can be added to make EVA and EEA copolymers, respectively. Critical molecular characteristics such as molecular weight, molecular-weight distribution, and density are controlled by reaction temperature, ethylene pressure, and the concentration of chain-transfer agents. Constraints on the viscosity of the polymer solution in the reactor limit the rate at which products with high molecular weight and/or high density can be made in the high-pressure process. It has been found that the tubular high-pressure process gives products that differ subtly in the type and degree of branching from products made in the autoclave process. Density depression occurs in all types of polyethylene because of the presence of short branches along the backbone of the polyethylene chain. These short branches, typically one to five carbon atoms long, prevent the long polyethylene chains from folding together and forming crystals. However, early in the development of LDPE, it was found that the presence of these short branches did not totally explain some of the rheological properties of LDPE. It was then hypothesized and proved that LDPE also contains low levels of long-chain branching (9). These long chains, which can be over 1000 carbon atoms in length, have a very small effect on the density of LDPE but have major impact on the processing and properties of LDPE (Figure 1). The tubular reactor makes LDPE with a large number of long-chain branches. The branches are of relatively short length, however. The autoclave reactor, on the other hand, gives products with low levels of long-chain branches of extremely long length. Because of the difference in long-chain branch type and frequency, some specialization in product applications has occurred with these products. The autoclave reactors produces products that are especially useful

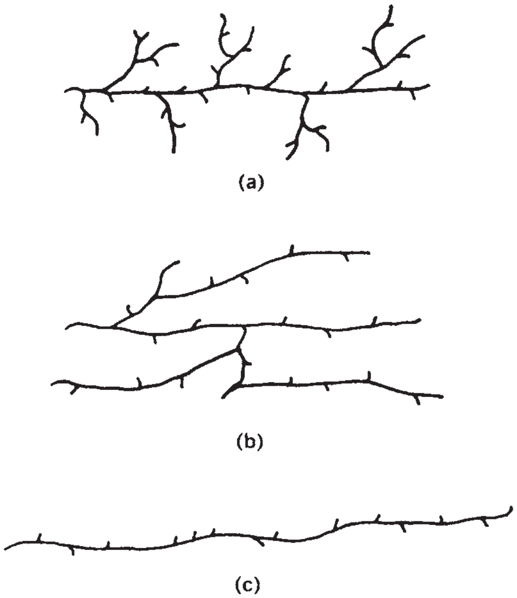

Figure 1. Molecular structures for LLDPE and HP-LDPE: (**a**) HP-tubular process; (**b**) HP-autoclave processes; (**c**) LLDPE.

in high-speed extrusion coating and in film applications requiring toughness. The tubular reactor gives products with optimal clarity and processing characteristics.

LLDPE PROCESS

Low-pressure processes for the polymerization of ethylene were developed in the 1950s (2, 8). These processes used organometallic catalysts to polymerize ethylene to form HDPE at moderate pressures (approximately 300 psi) and temperatures (approximately 100–200 °C). Three basic types of low pressure systems developed: *solution*, where the polymer was completely dissolved in a solvent at high temperatures; *slurry*, where the solid polymer particles were physically suspended in a solvent at lower temperatures; and *gas phase*, where the solid polymer was in contact with only the polymerization gases. Again, because of process constraints in the reactor, molecular weights and densities were thought to be limited, especially in the solution and slurry systems. The density limitations of the low-pressure and high-pressure processes were thought to form incompatible regions, with the low-pressure process making polythylenes above 0.935 density and the high-pressure process making polyethylene below 0.935 density.

The first commercial production of LLDPE was made in a solution process by DuPont Canada in 1960 (10). A large market for this new polymer did not develop until 1977, when Union Carbide started licensing their gas-phase process for the manufacture of linear low-density polyethylene. Since that time, several other polyethylene manufacturers have announced the conversion of low-pressure HDPE processes or even high-pressure LDPE processes to make LLDPE and some of these processes are available for licensing.

The structure of these new linear low-density polymers is very different from the LDPE made from the high-pressure process. In LLDPE, there is no long-chain branching. Density is controlled by the addition of comonomers such as butene, hexene, or octene to the ethylene. These comonomers give rise to short-chain branches of different lengths, two carbon atoms for butene, four for hexene, and six for octene. The length of the short-chain branches determines some of the strength characteristics of LLDPE. The absence of long-chain branches in LLDPE plays a significant role in the difference in extrusion characteristics between LLDPE and LDPE, as discussed in the sections on specific application areas.

LOW-DENSITY POLYETHYLENE PROPERTIES

Low-density polyethylene is one of the most widely used packaging materials in the market. Its utility in a variety of different applications is due not to some single outstanding property or characteristic, but usually to a combination of properties. The low price of polyethylene compared to wood, metal, and other polymers has accelerated its penetration into many applications. In addition to the low cost of polyethylene, the excellent toughness, flexibility, moisture barrier, chemical resistance, electrical insulation, and light weight of polyethylene films, bottles, pipes, cables, and other articles make them superior to articles made from conventional materials of construction. Since the introduction of LLDPE into the market, the superior properties of LLDPE have led to its use in new applications for polyethylene as well as the replacement of LDPE and/or HDPE in some areas. Compared to LDPE, LLDPE at the same melt index and density offers better toughness, rigidity, stress-crack resistance, elongation, melting point, and moisture barriers. (See article on polymer properties for more details.)

MARKETS/APPLICATIONS

Low-density polyethylene was the first thermoplastic polyolefin used commercially. The free-radical initiated polymerization process leads to a polymer with large amounts of long chain branching. This imparts an unusual rheological behavior in both shear and extension. LDPE is used in a variety of applications such as film, coating, molding, and wire and cable insulation.

The global market for polyethylene is undergoing extensive changes. Increases are concentrated in China and the Middle East. Consumption growth of LDPE is rather strong, despite the fact that a decline was expected with the advent of LLDPE to the market (11).

In 2006, 7.853×10^6 lb of LDPE were produced in the United States (12). Film applications are by far the largest market for LDPE, accounting for 55% of world use in 2006. Film demand is split between packaging and nonpacking uses. Extrusion coating is the second largest market for LDPE accounting for 9.9% of total in 2006.

Film and Sheet

About 50% of all the low-density polyethylene used in the world today goes into the film and sheet area. These applications include garbage bags, grocery sacks, garment bags, heavy-duty sacks, shrink film, stretch film, carrier film, pond liners, construction and agricultural film, and food packaging. Food applications include packaging for baked goods, dairy products, frozen food, meat and poultry, cookies, and candy. Polyethylene used in the film area range in melt index from 0.2 to 6 and in density from 0.915 to 0.935. The advantages of LDPE/LLDPE include low cost, flexibility, toughness, and chemical- and moisture-barrier properties (Tables 1–3). This has been the market most rapidly penetrated by LLDPE in the United States. This rapid penetration is due, in part, to the outstanding physical properties of LLDPE film (Table 4). Dart drop and Elmendorf tear measure the toughness of film in a high-speed test and give an indication of the failure behavior of film under catastrophic conditions. Puncture and tensile tests are done at relatively slow speeds and give an indication of intrinsic properties and failure modes that can occur with long-term use.

The differences in molecular structure between LLDPE and LDPE (linear vs branched molecules and molecular-weight distributions) affect the rheology of the two materials. LLDPE is more viscous at extrusion shear rates and requires more power to extrude. In addition, it is necessary to use a wide dip gap to avoid melt fracture when extruding 100% LLDPE. Therefore, in the early days of LLDPE introduction, minor modifications to the screw and die gap had to be made in order to extrude LLDPE on extruders designed for HP-LDPE and obtain optimum film properties Most extruders today have been designed to handle the different rheology of LLDPE, and such modifications are not necessary. In addition, there are additives now available that allow the extrusion of conventional LLDPE through narrow die gaps without melt fracture. The new generation of LLDPE film products, designed to be “drop-in” for LDPE products, will not require any modifications to extrusion equipment.

LDPE remais the resin of choice for shrink wrap and clarity films (13).

Injection Molding

This market includes lids, buckets, wash basins, housewares, toys, freezer containers, and general housewares. The advantages of low-density polyethylene include good low-temperature properties, low cost, light weight, and flexibility (Table 5). Low-density polyethylene in the melt-index range of 2–150 and density range of 0.920–0.930 is commonly used in injection-molding applications. LLDPE has made significant penetration into certain markets such as lids and housewares, where property advantages, such as higher stiffness and improved environmental stress-crack resistance and heat-distortion resistance, can be coupled with higher melt indices to result in faster cycle times and downgauged articles (Table 6) (14).

Extrusion Coating

In this application, polyethylene is used as a coating on another material such as paper, aluminum foil, and cardboard. These coated products are used for liquid packaging, such as milk and juice, and for the new aseptic packages of nonrefrigerated juices. The polyethylene serves as an adhesive, moisture barrier, seal layer, printable surface, and/or barrier to tear. Because of its molecular structure, that is, the type of long chain branching, polyethylene made in tbe high-pressure autoclave reactor is the most successful in this market. Resins with melt indices of 4–10 and densities of 0.920–0.930 are commonly used. Because of its linear structure, LLDPE has not penetrated the extrusion coating market, except as blends with LDPE.

Blow Molding

High-density polyethylene is the preferred material for this market because of its rigidity and barrier properties.

Low-density polyethylene may be used in those segments where flexibility and excellent stress-crack resistance are required, such as squeeze bottles, toys, and drum liners. Fractional-melt-index polyethylene (density 0.920–0.935) is typically used in this market. LLDPE offers better stiffness and improved stress-crack resistance compared to LDPE.

SAFETY AND HEALTH

Polyethylene is generally recognized as a safe packaging material by the Food and Drug Administration. Resin suppliers will state which of their resins comply with regulations governing polyethylenes used in food-contact applications. These regulations are covered in the U.S. Food, Drug, and Cosmetic Act as amended under Food Additive Regulation 21 *CFR* 177.1520. Polyethylene is a very stable polymer. However, proper material handling procedures are required to control dust and smoke and to provide adequate ventilation during extrusion. Copolymers containing EEA, EMA, and EVA should be used selectively on food contact applications. Resin suppliers will provide Material Safety Data Sheets and Materials Handling Guides for polyethylene resins on request.

ENVIRONMENTAL IMPACT

In recent years there has been quite a bit of adverse publicity around the use of plastics and the impact of litter on the environment. In the 1980s, the decision of fast food restauraants to discontinue the use of the expanded polystyrene clamshell burger container is one example of how plastics growth and use can be changed by public opinion. Many U.S. states have considered or passed regulations specifying the amount of recycled plastic that must be incorporated into new plastic articles. This has had a large impact on the polyethylene industry since polyethylene, including LDPE, is one of the more recyclable plastics being used today. The recycling effort has been hampered by the higher cost of collecting, separating, and cleaning the polyethylene containers compared to the cost of the virgin polymer.

Photo- and biodgradable LDPE copolymers have been offered as a solution to the litter problem. LDPE copolymers containing carbon monoxide have been produced. These photodegradable copolymers have been used to make beverage carrier rings, but have not been used in other commodity applications. The search for a biodegradable LDPE continues. Blends of starch-like fillers improve biodegradation, but at a significant sacrifice of physical properties. A new biodegradable/compostable technology has been developed, such that biodegradability can be triggered by heat, light, or stress. Products made with this technology are being marketed in Europe and South America (13).

POLYMER PROPERTIES

Ruben J. Hernandez
Michigan State University, East Lansing, Michigan

The properties of a polymer result from its chemical nature, morphology, formulation, processing, and even use conditions. Intrinsic polymer properties depend primarily on the chemical nature of the polymer; but since most polymers are polymorphic materials, their intrinsic properties may also depend on the polymer's morphology. Morphological changes at room temperature, however, are very slow and highly time-dependent. Formulation (compounding with additives) and processing have a direct impact in the final properties of a polymeric material. Furthermore, storage and use conditions (e.g., humidity and aging) may affect a plastic's performance.

Intrinsic properties of a polymer can be classified as either molecular or bulk. Intrinsic molecular properties depend mainly on the chemical structure of the polymer's constitutional units and, to a lesser degree, on its macromolecular character. The chemical nature of a constitutional unit, which results from the type and number of atoms, existing side groups, charge distribution, and type of secondary molecular forces, controls important properties. These properties are cohesive energy, molecular packing density, molecular relaxation (including glass-transition temperature), barrier, mechanical strength, frictional forces, surface tension, and adhesion characteristics. In PE, for example, the $–CH_2–$ group yields a set of properties values quite different from the constitutional unit $–OC(CH_2)_5NH–$ of nylon 6. The latter unit is larger and more polar than the first, and it tends to develop strong intermolecular hydrogen bonding.

Intrinsic bulk properties such as stiffness, melting temperature, heat-sealing temperature range, melt-flow index, and viscosity are largely influenced by the molecular mass and distribution, as well as the architecture of the polymer chain. Molecular mass and molecular distribution include the average molecular mass, dispersion index, and single- or multimodal distribution. The "architecture" of a polymer refers to the monomers layout in the polymer chain. In this respect, polymers can be linear, branched, or crosslinked, have different tacticity (e.g., atactic, isotactic, and syndiotactic polypropylene), and show various copolymer arrangements such as random, block, alternating, or graft.

Phase morphology affects, in varying degrees, the physical, mechanical, and optical properties of a polymer. Polymers can be isotropic (amorphous); that is, they are glassy (hard and brittle) below the glass-transition temperature and are rubber-like (soft and elastic) above it. As temperature increases, amorphous polymers become true liquids without any thermodynamic discontinuity. Polymers that are nonisotropic can crystallize in several arrangements; even two different crystal structures can coexist, depending on the values of temperature and pressure. Sometimes a crystalline polymer remains a liquid below the melting temperature, thus producing a supercooled material. In semicrystalline polymers, crystalline and noncrystalline regions may coexist, forming microcrystalline or paracrystalline regions. Polymers may also have a one- or a two-dimensional molecular order in the liquid state that forms thermotropic or lyotropic liquid crystalline mesophases. A simple example of how the morphology affects the properties is illustrated by the density of PE; the density of PE may range from 0.90 to 0.97 g/mL as the percent of crystallinity increases. Besides density, there are other properties proportional to the degree of crystallinity: rigidity, heat resistance, barrier, abrasion resistance, gloss, shrinkage, and parting-line difference. However, stress-crack resistance, clarity, folding endurance, impact strength, and parison sag decrease as crystallinity increases.

Process operation, on the other hand, can alter the morphology of a material. Film orientation, for instance, directly affects the polymer morphology by producing a slightly more compact molecular packing and a more transparent film. Similarly, a rapid cooling process will increase the amorphousness of a supercooled phase, while slow cooling will increase crystallinity. Thus, process conditions may affect properties such as the heat of fusion of a material and may also affect operations such as thermoforming operation and heat sealing. Since transparency (or opacity) is directly controlled by the crystallinity, morphological changes can influence the optical properties of a polymer. When additives are incorporated into a resin, however, they can substantially alter the resin's original properties.

DETERMINATION OF POLYMER PROPERTIES

Polymer properties can be measured experimentally (usually according to standardized methods) or be estimated from semiempirical correlations. Many intrinsic properties related to the molar constitutional unit can be estimated from group contributions or increment methods. Some polymer properties that can be estimated by group contribution include density, thermal expansion coefficient, thermal conductivity, specific heat, specific entropy of fusion, melting temperature, glass-transition temperature, cohesive-energy density, solubility parameter, surface tension, viscosity coefficient, dielectric constant, magnetic susceptibility, specific shear modulus, specific bulk modulus, and sound velocity (1).

The most common properties of polymers related to packaging applications are described next. For easy reference they are grouped under these headings: (1) density and thermophysical properties, (2) mechanical properties, (3) solubility and degradation properties, (4) barrier properties, (5) surface and adhesion properties, (6) electrical properties, and (7) optical-appearance properties.

DENSITY AND THERMOPHYSICAL PROPERTIES

Density. The density of a plastic is directly proportional to its crystallinity: $d = d_a + C(d_c - d_a)/100$, where d is the density, C is percent volumetric crystallinity, and d_a and

d_c are the amorphous and crystalline density, respectively. For example, $d_a = 0.855$ g/mL while $d_c = 1.0$ g/mL for PE (2). Polymer density values vary from 0.87 g/mL for polypropylene up to 1.86 g/mL for PVDC (3). The standard ASTM D1505 (4) describes the density gradient method to evaluate the density of films and resins.

Glass-Transition Temperature. The glass-transition temperature T_g, which is actually a relaxation temperature, is an important property in amorphous polymers. As a relaxation temperature, T_g is associated with the onset of the rotation and mobility of chain segments involving several monomers. Rather than a single-point temperature, T_g in semicrystalline polymers is a range of temperature values. The broadness of this range depends on the sample morphology. When the polymer is at a temperature below T_g, it becomes glassy and stiff, while above T_g it shows a plastic or rubbery behavior (5). The T_g values for polymers range from about -25°C (-125°C is also commonly reported) in polyethylene to 365°C for thermoplastic polyimide (1, 6). Both the T_g and the melting temperature set the application temperature range of a plastic container. For instance, a polypropylene container may become brittle at freezing temperature if its T_g is near 0°C; "crystal" polystyrene is brittle at room temperature because it has a T_g of $\sim 80^\circ$C and does not contain plasticizer. On the other hand, a container made of a low-melting-temperature (T_m) plastic will soften if heat-sterilized. Both differential thermal analysis (DTA) and differential scanning calorimetry (DSC) are used to determine T_m and T_g (these methods are described in ASTM D3418). Van Krevelen (1) showed that polymers have T_g/T_m ratios ranging from 0.5 to 0.76. Most polymers, however, have the T_g/T_m ratio centered at 0.67.

Heat Capacity. Heat capacity (or specific heat), c, is the amount of energy needed to change a unit of mass of a material one degree of temperature. The heat capacity of plastics, which are obtained at constant pressure, are temperature-dependent, especially near the glass-transition temperature. In a semicrystalline polymer, the heat capacity of the amorphous phase is greater than the heat capacity of the crystalline phase implying that the c values depend on the percent of polymer's crystallinity. The heat capacity values of polymers at 25°C vary from 0.9 to 1.6 J/(g · K) for amorphous polymers and from 0.96 to 2.3 J/(g · K) for crystalline polymers. Reliable data of the heat capacity of amorphous and crystalline phases are available for only a limited number of polymers (1, 2). Values of c for polymers can be found in the review by Wunderlich (7). The usual techniques to measure c are differential thermal analysis (DTA) and differential scanning calorimetry (DSC).

Heat of Fusion. The heat of fusion, ΔHm, is the energy involved during the formation and melting of crystalline regions. For semicrystalline polymers, the heat of fusion is proportional to the percent of crystallinity. Amorphous polymers or amorphous polymer regions do not have heat of crystallization, since amorphous structures have a smooth transition from the liquid amorphous state to the liquid state. Experimental values of crystalline heat of fusion for common packaging plastics vary from 8.2 kJ/mol for polyethylene to 43 kJ/mol for nylon 6,6 (1). ASTM D3417 describes a method for measuring the heat of fusion and crystallization of a polymer by differential scanning calorimetry (DSC).

Melting Temperature. The melting temperature T_m is a true transition temperature. This means that at T_m both the liquid and solid phases have the same free-energy value. Most semicrystalline polymers, instead of having a sharp melting point, show a melting temperature range, and for amorphous polymers there is no T_m. Similar to T_g, T_m can be estimated from contribution groups and empirical relationships between T_g and T_m (as indicated above). Values of T_m range from as low as 275 K (for polyisobutylene), to up to 728 K (for polyethylene terephthalamide) (1, 6). ASTM D2117 and D3418 describe methods for measuring T_m.

Thermal Conductivity. Thermal conductivity k is the parameter in Fourier's law relating the flow of heat to the temperature gradient. In practical terms, k is a measure of the ability of a material to conduct heat. The thermal conductivity of a polymer is the amount of heat conducted through a unit of thickness per unit area, unit time, and degree of temperature. Thermal conductivity values control the heat-transfer process in applications such as plastic processing, heat sealing, cooling and heating a package, and sterilization processes. The k values for plastics are much lower than those for metals; for instance, thermal conductivity for plastics ranges from 3×10^{-4} for PP to 12×10^{-4} cal/(s · cm · °C) for HDPE, while for aluminum $k = 0.3$ cal/(s · cm · °C) and for steel $k = 0.08$ cal/(s · cm · °C) (8). Plastic foams show k values much lower than those for the nonfoamed plastics because of the presence of air trapped within the cellular structure. Enhanced by low thermal conductivity of air, foams make excellent insulating materials and good cushioning packaging materials. Plastic fillers may increase the thermal conductivity of plastics. Methods for measuring k are given in ASTM D4351, C518, and C177.

Thermal Expansion. The coefficient of linear (or volume) thermal expansion is the change of length (volume) per unit of length (volume) per degree of temperature change at constant pressure: $\beta = (1/L)(dL/dT)$ and $\alpha = (1/V)(dV/dT)$. Units of α and β are K^{-1} or $^\circ F^{-1}$ (reciprocal degrees Kelvin and Fahrenheit). Compared to other materials, polymers have high values of thermal expansion coefficients. While metals and glass have values in the range 0.9–2.2 K^{-1} polymers range from 5.0 to 12.4 K^{-1} (8). Thermal expansion coefficients can be measured by thermomechanical analysis (TMA). ASTM D696 gives a method using a quartz dilatometer, and ASTM E831 describes the determination of the linear thermal expansion of solid materials. Volume contraction of a container from the molding operation temperature down to room temperature is called *shrinkage*, and its measurement is described in ASTM D955, D702, and D1299-55.

MECHANICAL PROPERTIES

The response of polymers subjected to mechanical forces is determined by the polymer's isoentropic elastic and viscoelastic behavior. Ideally, elastic behavior should be reversible for small deformations. Two types of small deformation are possible: tensile and shear. Hooke's law describes the response of plastics to tensile forces by relating tensile stress to elongation, while the law of shear deformation relates shear stress to both shear modulus and angle of shear. Viscoelastic behavior is observed in large deformations of solid polymers and polymer melts (9). In a creep experiment, the elongation of solid sample increases slowly as the weight hangs from the sample. When the force is released, the sample partially recovers its shape, decreasing the elongation. This behavior is due to the viscoelasticity behavior of the polymers: It partially recovers because it is elastic, and it creeps because it is viscous. This behavior is due to the continuous-chain molecular rearrangement that takes place at all temperatures. The time lapses associated with molecular rearrangement are much larger below than above the glass-transition temperature. The viscoelastic behavior affects almost all mechanical properties of a polymer and should be carefully considered in packaging design. Polymer strength increases with increasing molecular mass and with increasing intermolecular forces, but it decreases with the presence of plasticizers. For example, at the same molecular mass, polyamides, polyesters, or polyacrylonitriles are stronger than polyolefins, and plasticized PVC is weaker than rigid PVC.

Bursting Strength. This is the hydrostatic pressure, usually in pascal (or psi), required to produce rupture of the material when the pressure is applied at a controlled increased rate through a circular rubber diaphragm of 30.48 mm (1.2 in.) in diameter. "Points bursting strength" is the pressure expressed in psi. The measurement of the bursting strength of plastic films is described in ASTM method D774.

Dimensional Stability. *Dimensional stability* refers to the capability of a structure to maintain its dimensions under the changing conditions of temperature and humidity. Machine and transverse directions may produce different changes in dimensional stability, which is important in any flexible material converting process. During printing, for example, even small changes in dimensions may lead to serious problems in holding a print pattern. ASTM D1204 describes a standard method for linear dimensional changes of flexible thermoplastic films and sheets at elevated temperature.

Folding Endurance. This is a measure of the resistance of the material to flexure or creasing. Folding endurance is greatly influenced by the polymer's glass-transition temperature and the presence of plasticizers. ASTM D2176 describes the procedure to determine the number of folds necessary to break the sample film.

Impact Strength. Impact strength is the material's resistance to breakage under a high-velocity impact. Widely used impact tests are Izod (ASTM D256A) and Charpy (ASTM D256) for rigid materials, and for dart-drop impact (ASTM D4272) and pendulum-impact resistance (ASTM D3420) for flexible structures. A free-falling dart method for polyethylene films is described in ASTM D1709. Unlike low-speed uniaxial tensile tests, the pendulum-impact test measures the resistance of film to impact puncture simulating high-speed enduse applications. Dart drop measures the energy lost by a moderate-velocity blunt impact passing through the film. Both pendulum and impact tests measure the toughness of a flexible structure.

Melt-Flow Index. Most polymer melts follow a pseudoplastic behavior, which implies that the viscosity decreases with shear rate. In common extrusion processes, the shear-rate value varies from 100 to 100,000 s^{-1} (per second). It follows that a complete rheological description of an extrusion process should include a wide range of shear-rate values at suitable temperature range. The melt-flow index (MFI) is a widely used test to measure polymer flow properties, but it provides flow values at only one shear-rate value. MFI, also called *extrusion plastometer test*, is described in ASTM D1238. The melt-flow index measures the mass of polymer extruded during 10 min. Values of MFI vary between 0.3 and 20 g/10 min, corresponding to shear-rate values ranging from 1 to 50 s^{-1}. Variables that affect the MFI of a resin include average molecular mass, distribution of molecular mass, branching, and temperature (10).

Pinhole Flex Test. Pinhole flex resistance is the property of a film to resist the formation of pinholes during repeated folding. A related test is the folding endurance. Film having a low value of pinhole flex resistance will easily generate pinholes at the folding line, under repeated flexing. The test is described by the standard ASTM F456.

Poisson's Ratio. Poisson's ratio is the ratio of lateral strain to longitudinal strain measured simultaneously in a creep experiment. Its value varies from 0.5 (for totally deformed but nonelastic liquids), to 0 (for pure elastic incompressible solid materials). Typical values for rubber materials range from 0.49 to 0.499; and for plastic, from 0.20 to 0.40. This shows that when a polymer sample is elongated, its volume will increase. Because polymers are viscoelastic materials, the Poisson-ratio value is morphology- and time-dependent (1).

Tensile Properties. The mechanical behavior of a polymer can be evaluated by its stress–strain tensile characteristics. The stress is measured in force/area, which can be given in pascals or psi, and the strain is the dimensionless fractional length increase. *Modulus of elasticity, E,* is the elastic ratio between the stress applied and the strain produced, giving the material's resistance to elastic deformation. The tensile modulus also gives a measure of the material stiffness; the larger the modulus, the more *brittle* the material. For example, E of LDPE is 250 mPa, while for "crystal" PS it is 2500 mPa. Comparatively, values of tensile modulus in polymers (1.9×10^3 mPa for nylon) are much lower than for glass (60×10^3 mPa) or mild steel (220×10^3 mPa) (6). *Elastic elongation* is the maximum strain under elastic behavior. *Ultimate strength* or *tensile strength* is the maximum tensile stress the material can sustain. Ultimate elongation is the strain at which the sample ruptures. *Toughness* is how much energy a film can absorb before rupturing, and it is measured by the area under the stress–strain curve. *Brittleness* is the lack of toughness (11). Amorphous and semicrystalline polymers become brittle when cooled below their glass-transition temperature. Tests for tensile properties are described in ASTM D882, for flexural strength in ASTM D790, and for flexural modulus in ASTM D790 M.

Tear Strength. Tear-strength measurement considers the energy absorbed by the film sample in propagating a tear. Standard methods available are (a) ASTM standard D1004, which describes the measurement for initial tear resistance, and (b) ASTM D1922 and ASTM D1938, which refer to the energy absorbed by a test specimen in propagating the tear that has already been initiated. The value of tear strength in one film depends on the orientation stretching ratio, whether the measurement is performed along the crossdirection or along the machine direction (CD or MD).

Viscosity. Viscosity, a fundamental rheological property of fluids, is a measure of the molecular resistance to shear fluid deformation, generated by the action of external forces. When the external action is given by the shear stress and the shear flow deformation given by the rate of strain or shear rate, the *absolute viscosity* is equal to the ratio of shear stress/shear rate. The viscosity of a polymer will increase with the length of the polymer chain, with smaller dispersion index (narrow distribution), and with increasing intermolecular forces. An increase of temperature, however, will decrease the viscosity. The rheological behavior of thermoplastics is, in most cases, Newtonian or pseudoplastic (10). The viscosity of Newtonian fluids is constant at any shear rate value. This behavior is characteristic of fluids with low molecular mass. In pseudoplastic materials, the viscosity decreases with shear rate; that is, the viscosity depends on the value of shear rate. Pseudoplastic behavior is characteristic of polymer melts. The viscosity of polymer melts ranges between 100 and 10^7 N/(s $\cdot$ m^{-2}). Viscosity is also known as either kinematic viscosity or intrinsic viscosity. *Kinematic viscosity* is the absolute viscosity divided by the density. *Intrinsic viscosity* (IV) can be obtained as follows: (1) Solutions of different concentrations c of the polymer in a solvent (having viscosity η_0) are prepared; (2) the viscosity η of the solutions are measured; and (3) from the plot of viscosity number, $[(\eta - \eta_0)/\eta_0 c]$, versus concentration, the IV is obtained as the value of the viscosity at concentration zero (11). Therefore, intrinsic viscosity, is a measure of the polymer's capacity to enhance the viscosity of the solvent. The units of IV are mL/g. For PE, the relation between molecular weight (MW) and IV is accepted to be as follows: $\mathrm{MW} = 5.3 \times 10^4\ (\mathrm{IV})^{1.37}$ (8). An IV of 5, for example, corresponds to an MW of 500,000. Intrinsic viscosity values of polymers can be estimated by group contribution in terms of molar intrinsic viscosity (1). ASTM has published several methods for measuring viscosity.

SOLUBILITY AND CHEMICAL DEGRADATION

Plastics are chemically resistant to many gases, liquids, and solid products within a wide range of pH. Nevertheless, polymers are not inert materials. Given the right conditions (temperature, time, and concentration), polymers can be depolymerized, transformed by chemical reactions, and penetrated by solvents and vapors. They can be affected by environmental agents such as visible and UV radiation, oxygen, microbes, solvents, and organic compounds (12). The extent of the transformation depends on the thermodynamic and kinetics parameters, which, in turn, depend heavily on temperature. In hydrophilic polymers (e.g., nylons, EVOH, and PET) water acts as a plasticizer, consequently lowering the glass-transition temperature and changing oxygen permeability and other mechanical properties (13). Water can dissolve certain polymers such as PVOH. Hydrophobic polymers such as polyolefins, on the other hand, are not affected by water.

Chemical Degradation. Chemical degradation of polymers results in the fragmentation of large chains into smaller ones and, eventually, into atomic elements. One important type of polymer chemical degradation is oxidation (12). Often oxidation is promoted or induced by electromagnetic radiation (photodegradation) and by thermal energy at high temperature (thermal oxidation). Polymers such as PE, PP, and PVC are particularly prone to oxidation during melt processing. Tensile strength, elasticity, and impact strength are drastically affected by thermodegradation processes. Polymers may also be degraded by acids and alkalis. Test for resistance to acids, bases, and solvents is described in ASTM D543. Plastic resistance to grease and oil is covered in ASTM D722. The ASTM D756 test covers the effect of atmospheric humidity and temperature on plastics, and ASTM D570 covers the sorption of water of immersed plastics.

Environmental Stress Cracking. A plastic material may be resistant to a chemical compound in no-stress conditions. Nevertheless, the plastic may crack when subjected to a mechanical stress during exposure to that compound. Almost all plastics can show environmental stress cracking (ESC), when exposed to gases, liquids, or solids while under stress. The mechanism by which a plastic shows ESC is often complex. A practical evaluation of a plastic's resistance to liquids can be done by immersing a polymer sample in the liquid and then checking for the appearance of crazing, cracks, or even total failure of the sample. Also, a plastic container can be tested by filling it with the liquid, causing ESC. Stress conditions applied during testing may be of two types: constant stress or constant strain. The selection of the test method should correspond with the intended use of the container. Common ESC tests for PE bottles include bottle stress crack (ASTM D2561), top-load stress crack, and internal pressure (ASTM

D2561). For some applications, the temperatures recommended by ASTM for these tests may be too mild (14).

Flammability. The *flammability* behavior of a material is a broad term related to the easiness to ignite, burn, produce smoke, and endure burning. A flammable material ignites easily and has a rapid flaming combustion process. The initial step is decomposition (or pyrolysis), which is an endothermic process (the material absorbs heat). After ignition, products from pyrolysis are combusted and consequently, heat Q is generated. Some flame-retardant agents tend to minimize Q. The flammability characteristics of a polymer may be predicted from its chemical structure (1), and a method to measure flame resistance is the *oxygen index* (15). ASTM test D3713 describes the response of solid plastics to ignition by a small flame, and the ASTM D4100 method covers the gravimetric determination of smoke-particulate matter produced from combustion or pyrolysis of plastic materials. Testing plastics for practical fire situations is very complex and depends on many variables other than just chemical structure (16, 17).

Photodegradation. Sunlight is the source of energy for polymer photochemical degradation. Near-ultraviolet and visible radiation (290–710 nm) carry enough energy to break single covalent bonds such as C–C, C–O, or C–N. The absorption of these radiations is sometimes attributed to impurities in the polymer. Photodegradation processes generate chain ruptures and free-radical formation, resulting in color changes and increasing fragility (because of chain crosslinking and chain scissions). UV light stabilization of PP and other polyolefins can be achieved by the addition of hindered amine light stabilizers (HALSs) (18). These additives reduce the rate of photoinitiation and chain-reaction propagation by their ability to trap free radicals. ASTM D4674 describes the accelerated testing for color stability of plastics exposed to indoor fluorescent lighting and window-filtered daylight.

Solubility Parameter. Polymer solubility properties in organic liquids are controlled by the polymer's cohesive energy. The cohesive energy of a solid (or liquid) is the total energy necessary to remove one molecule from the bulk of the solid (or liquid). It is also an indication of the molecular internal pressure. The solubility of a polymer is given by its solubility parameter δ, which is the square root of the cohesive-energy density (CED), $\delta = (\mathrm{CED})^{1/2}$. In addition to cohesive energy density, polymer morphology and molecular mass also strongly affect the tendency of a polymer to dissolve. Crystalline structures, on the other hand, are insoluble below their melting temperature. Polymers have solubility parameter's ranging from 12 to 29 $(\mathrm{J/cm^3})^{1/2}$. Substances that have similar delta values [$<0.5\,(\mathrm{J/cm^3})^{1/2}$ apart] will tend to mutually dissolve. This substantiates the rule of thumb that "like dissolves like." Solubility parameters can be determined by solvent swelling (19) or intrinsic viscosity methods (20). Values of CED and solubility parameter of a polymer can be estimated by group contribution methods, based on the contribution of intermolecular forces: polar forces, dispersion forces, and hydrogen bonding (1). Extensive tables of δ are presented by Barton (21).

Solubility in Organic Solvents. Many organic compounds interact with polymers to produce slight swelling or staining, or total dissolution, depending on the polymer molecular mass, crystallinity, and solubility parameter. ASTM D2299 gives a method to assess the susceptibility of plastic staining by incidental contact with organic products. Common solvents for plastics are boiling xylene and trichlorobenzene; solvents for polyolefins, are styrene polymers, vinylchloride polymers, and polyacrylates; the solvent for polyamides and polyvinyl alcohol derivatives is formic acid; tetrahydrofuran is the solvent for all uncrosslinked polymers; nitrobenzene and *m*-cresol are the solvents for PET; water is the solvent for polyacrylamide and polyvinyl alcohol; and dimethylformamide is the solvent for polyacrylonitrile. In addition, polyvinyl acetate is dissolved by benzene, chloroform, methanol, acetone, and butyl acetate (22). ASTM D543 covers the testing of all plastic materials for resistance to chemical reagents.

Thermodegradation. Thermal degradation of polymers is the breaking of chain bonds by heat, in the absence of oxygen. Heat-stabilizing additives help prevent degradation, but impurities may have the contrary effect. Thermally stable polymers resist thermal degradation and will have high values of bond dissociation energy (1). As the temperature increases, chemical bonds with the lowest values of dissociation energy will be the first to break. Thermodegradation affects PE, PP, and PVC (18). The poor thermal stability of the PVC resin is caused mainly by dehydrochlorination. For each HCl eliminated from the polymer chain, a double bond is created, which, in turn, promotes oxygen chemical degradation. Heat stabilizers include inorganic and organic compounds. In the case of flexible PVC films, barium–zinc and calcium–zinc stabilizers are used, while organotin compounds are commonly used in PVC bottle containers.

BARRIER PROPERTIES

The *barrier property* of a material indicates its resistance to diffusion and sorption of foreign molecules. A high-barrier polymer has low values of both diffusion (D) and solubility (S) coefficients. Since the permeability coefficient P is a derived function of D and S, a high-barrier polymer has low permeability. The diffusion coefficient indicates how fast a penetrant will move within the polymer, while the solubility coefficient gives the amount of the penetrant taken (or sorbed) by the polymer from a contacting phase. Both diffusion and solubility can be applied to the reverse process of sorption—that is, the migration of compounds from the polymer to a surrounding medium. Several factors influence the effective value of the diffusion and solubility coefficients in polymers: (1) chemical compositions of the polymer and permeant, (2) polymer morphology (since diffusion and sorption occur mainly through the amorphous phase and not through crystals), (3) temperature (as temperature increases, diffusion increases while solubility decreases), (4) glass-transition temperature, and (5) the presence of plasticizers and fillers.

Diffusion Coefficient. In Fick's law, the diffusion coefficient D is a parameter that relates the flux of a penetrant in a medium to its concentration gradient. A diffusion-coefficient value is always given for a particular molecule–polymer pair. For solid polymers, the diffusion coefficient values may range from 1×10^{-8} to $1 \times 10^{-13}\,\text{cm}^2/\text{s}$. The diffusion theory shows that diffusion is an activated phenomenon that follows Arrhenius' law. In addition to temperature, penetrant concentration and plasticizers also affect the value of the diffusion coefficient. Excellent references covering the diffusion process are the books by Crank (23) and by Crank and Park (24).

Permeability Coefficient. The permeability coefficient (P) combines the effect of the diffusion and solubility coefficients. The barrier characteristic of a polymer is commonly associated with its permeability coefficient value. The well-known relationship $P = DS$ holds when D is concentration independent and S follows Henry's law. Methods for measuring the permeability to organic compounds are described by Hernandez et al. (25). ASTM E96 describes a method for measuring the water-vapor transmission rate (WVTR). ASTM D1434 covers a method for the determination of oxygen permeability.

Solubility Coefficient. The solubility coefficient indicates the sorption capacity of a polymer with respect to a particular sorbate. The simplest solubility coefficient is defined by Henry's law of solubility, which is valid at low concentration values. The solubility of CO_2 in PET at high pressure is described by combining Henry's and Langmuir's laws (26). In the case of organic compounds, the Flory–Huggins equation is applicable (24); and for sorption of water in nylons, a special model has been proposed (27).

SURFACE AND ADHESION

Adhesive Bond Strength. Adhesive bond strength between an adhesive and a solid substrate is a complex phenomenon and is controlled (at least in part) by the values of surface tension, solubility parameters, and adhesive viscosity. To obtain wettability and adhesion between a polymeric substrate and an adhesive, the surface tension of the adhesive must be lower than that of the substrate. Usually, the difference between the two values must be at least 10 dyn/cm. The similarity in solubility parameters between the two phases indicates the similarity of the intermolecular forces between the two phases. For good compatibility, the values of the solubility parameters must be very close. Low viscosity in the adhesive is necessary for good spreadability and wettability of the substrate (28).

Blocking. Blocking is the tendency of a polymer film to stick to itself simply by physical contact. This effect is controlled by the adhesion characteristic of the polymer. Blocking is enhanced by surface smoothness and by pressure on the films present in stacked sheets or compacted rolls. Blocking can be measured by the perpendicular force needed to separate two sheets, and it can be minimized by incorporating additives such as talc in the polymer film. ASTM D1893, ASTM D3354, and Packaging Institute procedure T3629 present methods to evaluate blocking.

Cohesive Bond Strength. Cohesive bond strength is the force within the adhesive itself when bonding two substrates. The cohesive bond strength depends mainly on the intermolecular forces of the adhesive, molecular mass, and temperature.

Friction. The coefficient of friction (COF) is a measure of the friction forces between two surfaces, and it characterizes a film's frictional behavior. The COF of a surface is determined by the surface adhesivity (surface tension and crystallinity), additives (slip, pigment, and antiblock agents), and surface finish. Cases in which the material's COF values require careful consideration include film passing over free-running rolls, bag forming, the wrapping of film around a product, and the stacking of bags and other containers. Besides the intrinsic variables affecting a material's COF, environmental factors such as machine speed, temperature, electrostatic buildup, and humidity also have considerable influence in its final value. The *static COF* is associated with the force needed to start moving an object. It is usually higher than the *kinetic coefficient*, which is the force needed to sustain movement. Determination of static COF is described in TAPPI standard T503 and ASTM D1894. Thompson (29) has also analyzed the action of additives on the value of COF of polypropylene.

Heat Sealing. An important property for wrapping, bagmaking, or sealing a flexible structure is the heat sealability of the material. At a given thickness, heat-sealing characteristics of flexible web material are determined by the material's composition (which controls strength), average molecular mass (controlling temperature and strength), molecular-mass distribution (setting temperature range and molecular entanglement), and the thermal conductivity (controlling dwell time (30). Tests normally conducted to evaluate the heat sealability of a polymeric material are the *cold-peel strength* (ASTM F88) and the *hot-tack strength* (31). Hot tack is the melt strength of a heat seal when the seal interface is still liquid and without mechanical support. The hot adhesivity is associated with the molecular entanglement of the polymer chains, viscosity, and intermolecular forces of the material.

Surface Tension. In solids and liquids, the forces associated with inside molecules are balanced because each molecule is surrounded by like molecules. On the other hand, molecules at the surface are not completely surrounded by the same type of molecules, thereby generating unbalanced forces. Therefore, at the surface, these molecules show additional free surface energy. The intensity of the free energy is proportional to the intermolecular forces of the material. The free surface energy of liquids and solids, called *surface tension*, can be expressed in mJ/m^2 (millijoules per square meter) or dyn/cm (dynes per centimeter). Values of surface tension in polymers range from 20 dyn/cm for Teflon to 46 dyn/cm for nylon 6,6. The measurement of surface tension by contact-angle measurement is covered by ASTM D2578. Several independent methods are used to estimate surface tension of liquids and solid polymers, including the molar parachor (1).

When two condensed phases are in close contact, the free energy at the interface is called *interfacial energy*. Interfacial energy and surface energy in polymeric materials control adhesion, wetting, printing, surface treatment, and fogging.

Wettability. Adhesion and printing operations on a plastic surface depend on the value of the substrate wettability or surface tension. A measure of the wettability of a surface is given by a material's surface tension as described in ASTM D2578.

ELECTRICAL PROPERTIES

Electrical conductivity, dielectric constants, dissipation factors, and triboelectric behavior are electrical properties of polymers subject to low electric-field strength. Materials can be classified as a function of their conductivity (κ) in $(\Omega/\text{cm})^{-1}$ (reciprocal ohms per centimeter) as follows: conductors, $0–10^{-5}$; dissipatives, $10^{-5}–10^{-12}$; and insulators, $\geqslant 10^{-12}$. Plastics are considered nonconductive materials (i.e., not counting the newly developed conducting materials).

Dielectric Constant. The relative dielectric constant of an insulating material (ε) is the ratio of the electric capacities of parallel-plate condenser with and without the material between the plates. A correlation between the dielectric constant and the solubility parameter (δ) is given by the relationship of $\delta \approx 7.0\varepsilon$ (1). There is also a relationship between *resistivity* R (inverse of conductivity) and the dielectric constant at 298 K: $\log R = 23 - 2\varepsilon$ (1). Values of ε for polymers are presented in Refs. (1) and (2).

Triboelectric Behavior. When two polymers are rubbed against each other, one becomes positively charged and the other becomes negatively charged, depending on the relative electron donor–acceptor characteristics of the polymers. A *triboelectric* series is the listing of polymers according to their charge intensity, which goes from the most negative charge (electron acceptor) to the most positive (electron donor). The charge of polymer films also takes place by friction during industrial operations such as form/fill/seal. The most negative polymers are (value in parentheses is the dielectric constant): PP ($\varepsilon = 2.2$), PE ($\varepsilon = 2.3$), and PS ($\varepsilon = 2.6$); neutral charged polymers include PVC ($\varepsilon = 2.8$), PVDC ($\varepsilon = 2.9$), and PAN ($\varepsilon = 3.1$); and positively charged polymers include cellulose ($\varepsilon = 3.7$) and nylon 6,6 ($\varepsilon = 4.0$). As these values suggest, the tribolectric series of dry polymers can be correlated with the polymer dielectric constant. Since hydrophilic polymers absorb water, they become more conductive, and their dielectric constants increase. Standard methods for measuring the triboelectric charge of films and foams are, at the time of this article, still under consideration by ASTM Committee D10.13 (32).

OPTICAL APPEARANCE

Among the most important optical properties of polymers are absorption, reflection, scattering, and refraction. Absorption of light takes place at the molecular level, when the electromagnetic energy is absorbed by atoms or group of atoms. If visible light is absorbed, a color will appear; however, most polymers show no specific absorption with visible light and, therefore, are colorless. Reflection is the light that is remitted on the surface and depends on the refractive indices of air and polymer. Scattering of light is caused by optical inhomogeneities reflecting the light in all directions. Refraction is the change in direction of light due to the difference between the polymer and air refraction indices. Transparency, opacity, and gloss of a polymer are not directly related to the chemical structure or molecular mass; they are determined mainly by the polymer morphology. Optical appearance properties are of two types: optical morphological properties, which correlate with transparency and opacity; and optical surface properties, which produce the specular reflectance and attenuated reflectance (1, 33).

Gloss. Gloss is the percentage of incident light that is reflected at an angle equal to the angle of the incident rays (normally 45°). It is a measure of the ability of a surface to reflect the incident light. If the specular reflectance is near zero, the surface is said to be "mat." A surface with high reflectance has a high gloss, which produces a sharp image of any light source and gives a pleasing sparkle. Surface roughness, irregularities, and scratches all decrease gloss. Test method is covered by ASTM 2457.

Haze. Haze is the percentage of transmitted light that, in passing through the sample, deviates by more than 2.5° from an incident parallel beam. The appearance of haze is caused by light being scattered by surface imperfections and nonhomogeneity. The measurement of haze is described in ASTM D1003.

Transparency and Opacity. Transmittance is the percent of incident light that passes through the sample and is determined by the intensity of the absorption and scattering effects. The absorption in polymers is insignificant; thus, if the scattering is zero, the sample will be transparent. An opaque material has low transmittance and, therefore, large scattering power. The scattering power of a polymer results from morphological inhomogeneities and/or the presence of crystals. Then, an amorphous homogeneous polymer such as "crystal" polystyrene will have little or no scattering power and therefore will be transparent, while a highly crystalline polymer such as

HDPE will be mostly opaque. Transmittance can be determined according to standard ASTM D1003. A transparent material has a transmittance value above 90%.

POLYMERIC OXYGEN SCAVENGING SYSTEMS

Kay Cooksey
Michigan State University, East
Lansing, Michigan

Oxygen scavengers are mainly used for food and pharmaceutical applications but also can be used for any product that needs a low oxygen storage atmosphere. Essentially, oxygen scavengers are so named because they preferentially absorb oxygen within the environment, thus, preventing the oxygen from reacting with the product. Many other terms have been used to describe oxygen scavengers, which include the following: antioxidants, interceptors, controllers, and absorbers. According to Brody, the definition of an oxygen scavenger is a material in which a chemical (or combination of reactive compounds); incorporated into a package structure may combine with oxygen and effectively remove oxygen from the inner package environment. The purpose of an oxygen scavenger is to limit the amount of oxygen available for deteriorative reactions that can lead to reduced functionality of the product. For foods and pharmaceutical products, deteriorative reactions include lipid oxidation, nutritional loss, changes in flavor and aroma, alteration of texture, and microbial spoilage. Typically, oxygen scavengers are used in packages that have air tight seals and are used in conjunction with other means of preservation, such as chemical preservatives, reduced water activity, reduced pH, vacuum packaging, or modified atmosphere packaging.

BACKGROUND AND HISTORY

Research on oxygen scavengers began in the 1920s for enclosed packages using a ferrous sulfate and moisture absorbing mixture (1). Rooney (2) indicates that a British patent from 1938 used iron, zinc, or manganese to scavenge oxygen from canned foods. Research continued throughout the 1940s with the bulk of the work performed in the United Kingdom and by the U.S. Army for military rations. During the 1970s the first major commercial oxygen scavenger was introduced by Mitsubishi Gas and Chemical Company in Japan, which was available in the United States by the late 1970s. The product eventually became known under the tradename Ageless® and functions using permeable sachet that contains a reduced iron salt and moisture absorbent material. Another company from Japan, Toppan Printing Company, also produced a commercially available oxygen scavenging system, but it functioned using ascorbic acid-based reaction. During the 1970s and 1980s, more oxygen scavenging systems were introduced by Japanese and American companies using several scavenging methods (1–2). During the 1980s, work began on oxygen scavenger development using singlet oxygen reaction by the Commonwealth Scientific Industrial Research Organization (CSIRO) in Australia. See sachets shown in Figures 1 and 2.

According to de Kruijf (3), oxygen scavengers are the most patented of all active packaging technologies with at least 50 patents through 1989 and 20 issued from 1990 to 1994. In the 1990s work focused more heavily on technologies to incorporate oxygen scavengers directly into film and other package forms such as closure liners, thermoformed cups, tubs, and trays rather than sachets. Part of the reason for this change was related to concern over consumers accidentally using the sachets as “flavor packets” and incidents whereupon the contents of the sachet may seep out into the food. These problems can lead to loss of product quality and can also lead to serious consumer safety concerns. For example, iron in concentrated amounts, can be toxic to children or pets, because of their small body mass. For this reason, the FDA mandated that iron-based sachets must be labeled with “Do not eat” on the sachets sold in the United States to avoid accidental ingestion of the contents. (4).

Based on information made available in 2002, oxygen scavengers in bottles made up the largest portion of the market with 43.8% of the market, followed by cap/liner/lidding representing 31.5%, sachets with 22.6%, and oxygen absorbing film with 2%.

Figure 1. Mitsubishi Ageless Sachets.

Figure 2. Multisorb Freshpax.

TYPES AND MECHANISMS OF ACTION

Iron-Based Systems. Iron-based sachets are the type of oxygen scavenging system that has been used commercially for many years. It generally involves a reaction between iron powder contained in a permeable sachet that also may contain a dessicant. Iron powder reacts with oxygen using the following reaction (6, 7):

$$\mathrm{Fe} \rightarrow \mathrm{Fe}^{2+} + 2\mathrm{e}^-$$

$$\tfrac{1}{2}\mathrm{O}_2 + \mathrm{H}_2\mathrm{O} + 2\mathrm{e}^- \rightarrow 2\mathrm{OH}^-$$

$$\mathrm{Fe}^{2+} + 2\mathrm{OH}^- \rightarrow \mathrm{Fe(OH)}_2$$

$$\mathrm{Fe(OH)}_2 + \tfrac{1}{4}\mathrm{O}_2 + \tfrac{1}{2}\mathrm{H}_2\mathrm{O} \rightarrow \mathrm{Fe(OH)}_3$$

Oxygen Scavenging Polymer Materials. Many polymers have been developed using a wide variety of chemistries (2), however, the most commercially successful materials have been homogenous blends of reactive substances with polymers. An effective oxygen scavenging polymer was developed in which dissolved reagents of known chemistry were incorporated into a polymer, and the trigger mechanism was light, which excited the reactive components in the film, thus, influencing oxygen diffusion into the polymer. The oxygen has to be in an excited singlet state, which required the use of a photsensitizing dye and exposure to visible light. Another approach was based on transition-metal-catalyzed oxidation of an aromatic nylon. The transition metal in this case was cobalt or cobalt salt. This material eventually became known under the tradename Oxbar™ The material easily could be blended with polyester eventually to become important for packaging wine and beer in plastic bottles, because it effectively could prevent oxidation in both products. Amoco Chemcials introduced a material called Amosorb™, which blended polyester and polybutadiene and was catalyzed by a transition metal salt. When the catalyst was added late in the injection molding process, the resulting material became an oxidizable polymer. Another material using light as a triggering mechanism was developed by Speer and coworkers (8). This patent process used a transition metal catalyst and a photosensitizer. The reaction was designed in such a way as to prevent the rupture of the polymer backbone as might normally occur through oxidation. The material was composed of unsaturated polymers such as poly(1,2 butdiene), which could scavenge ground state oxygen as opposed to singlet oxygen. This product is marketed under the trade name OS 1000™ or 2000™ by Cryovac Division of Sealed Air (Figure 3).

Other materials that incorporate active components into the polymer include material marketed by Chevron Chemical Company, which works by auto-oxidation of unsaturated groups on the polymer backbone. Oxidation of aromatic nylons and hydrocarbon polymers with active side groups use light to trigger the oxygen scavenging process. One method that differs from the light triggering systems involves the light excitation of a photoreducible component such as phenolic compound, which is reduced by oxygen, thereby scavenging oxygen.

Figure 3. Cryovac OS1000 oxygen scavenging film.

Designing an oxygen scavenging system for specific types of packaging is quite complex and still not well understood except by the vendors who specialize in such systems. Most oxygen scavengers are designed for packaging based on the removal of a specified amount of oxygen from the interior of the package over a period of a few days. Tewari and coworker (9) studied the oxygen absorption kinetics of six commercial oxygen scavengers that differed in oxygen scavenging capacity as well as oxygen scavenging methods (i.e., iron-based and enzyme based). It was determined that oxygen concentration was the primary limiting factor in the kinetics of oxygen scavengers in atmosphere of less than 500 ppm but other factors such as temperature, capacity, and variation between types of scavengers also occurred. Miltz and Perry (10) studied the performance of iron-based oxygen sachets to improve methods to apply them more effectively because their cost and lack of technical understanding has limited their use. Based on their study, the actual scavenging capacity was higher than the manufacturers specifications. They also found that, in modified atmosphere packages containing carbon dioxide, the sachets also absorbed the carbon dioxide as well as oxygen. Oxygen sachets were found to reduce the transient period time (time to reach equilibrium) for active modified atmosphere packaging by nearly half compared to passive modified atmosphere packaging without a sachet. This effect allowed the shelf life to be extended because of optimal atmosphere as soon as quickly as possible (11).

APPLICATIONS

Oxygen scavengers were initially used by the U.S. military for the meals ready to eat (MRE) rations. Foods with oxygen scavengers for MREs include the following: white and whole wheat bread, pound cake, fudge brownies, wheat snack bread, potato sticks, chow mein noodles, nut raisin mix, pretzels, waffles, and hamburger buns (1). In the retail market, typical uses in the United States include fresh pasta, beef jerky, pepperoni, beer (cap liner and some bottles), ketchup, juice, case-ready meats, prepared foods, and shredded cheese. Use of oxygen sachets is more prevalent and diverse in Japan for products such as seasonings, cheese, aseptically packaged cooked rice, dry pet foods, cough capsules, plant growth hormone, antibiotics, vitamins pills and tablets, medical kits to preserve reagents, kidney dialysis kits, and other products.

CURRENT RESEARCH ON SPECIFIC APPLICATIONS

Meat Packaging. Oxygen scavengers are used in meat packaging to control color in red meat packages. When the pigment for red meat (myglobin) is exposed to oxygen, the meat appears as a bright red color, which is associated with freshness and overall acceptability. However, when meat is exposed to too much oxygen over time, the pigment converts to metmyoglobin, which appears as a brown color and is not visually acceptable to consumers. Many studies have used oxygen scavengers in modified atmosphere packages to extend the display life of red meat packages. Gill and McGinnis (12) studied the conditions under which commercially available scavengers with an oxygen absorbing capacity of 200 ml/sachet could prevent transient discoloration of nitrogen flushed ground beef. The rate of oxygen absorption decreased with decreasing oxygen concentration when the oxygen concentration was between 10 and 20%, but the rate of oxygen absorption became exponentially proportional with time when the oxygen concentration was less than 1%. Oxygen concentration in packages needed to be reduced below 10 ppm in 30 minutes at 2 °C or 2 hours at 1.5 °C to prevent transient discoloration. It was determined that to achieve this, more sachets than were economically feasible would have been required at that time. Continued work on prevention of transient discoloration of beef was done by Tewari and others (13), who determined that steaks removed from a controlled atmosphere masterpack had less discoloration when packaged with an oxygen scavenger and that the number of sachets had more impact on discoloration prevention than the type of scavenger used. The same research group also studied the effect of oxygen scavengers inside retail trays, lidding and over-wrapped trays, which were all equally effective for extending the acceptable shelf life of modified atmosphere, display ready beef and pork cuts (14). They also found that eight oxygen scavengers with a capacity sufficient to achieve an oxygen half life of 0.6–0.7 were needed when oxygen concentration could otherwise remain at less than 500ppm during storage. Isdell (15) measured the redness of meat 96 hours after removal from a gas flushed mother pack. They found that redness of meat packaged in a retail tray containing oxygen scavengers was better than retail trays that did not contain an oxygen scavenger. In another study, researchers (16) found that, combined with a controlled atmosphere mother pack (outer bag), double flushed with 50% carbon dioxide and 50% nitrogen was effective for maintaining the display shelf life of variety of red meat cuts. The oxygen scavenger helped maintain a low level of oxygen (0.1%) to prevent formation of metmyoglobin.

Payne and others, (17) studied vacuum controlled atmosphere packaging with carbon dioxide, carbon dioxide flushed packages containing iron-based oxygen scavenging sachets, and packages that contain oxygen scavengers alone for beef stored for up to 20 weeks at −1.5 °C. Beef packaged with oxygen scavenger alone provided the best results with regard to drip loss, microbial and sensory properties. Martinez and coworkers (18) found that fresh pork sausages packaged in a 20% carbon dioxide, 80% nitrogen atmosphere with an iron-based oxygen scavenging sachet, had reduced psychrotropic aerobic counts and extended shelf life with regard to color and lipid stability for 20 days at 2 °C. Catfish steaks were packaged in barrier film and vacuum packaged with and without an iron-based sachet. Shelf life was extended 10 days (20 days with sachet v. 10 days without sachet) with the aid of the sachet based on sensory, microbiological, and volatile base nitrogen analysis. The oxygen in the packages containing the sachets reached 0.42% within 24 hours of packaging (19). Labels are manufactured that absorb 10–20 mL of oxygen, and larger labels are starting to become available that scavenge 100–200 mL O_2 (7). Besides labels, oxygen scavengers also can be incorporated into the polymer film. The film is capable of reducing oxygen in the headspace to less than 1 ppm in 4–10 days for products such as dried, smoked meat as well as processed meat products (20).

Bakery Products. Baked goods such as bread, pastries, cakes, and cookies can have an extended shelf life with use of oxygen scavengers combined with modified atmosphere packaging. The low-oxygen condition retard molds and other spoilage bacteria and also reduces lipid oxidation, which can produce off flavors. According to Kotsianis and coworkers (21), an advantage over using an oxygen scavenger system compared to modified atmosphere packaging alone was because of the fact that lower oxygen levels could be achieved, and oxygen can be reduced in case of leakage through defective seals. The disadvantages could be cost and possible consumer objection to a packet inserted inside the package that could become loose and cause accidental ingestion by a child or pet. A few studies have reported on the effectiveness of oxygen scavengers for bakery products. Sponge cakes (0.8–0.9 a_w) were packed in a modified atmosphere package (MAP) with oxygen absorber sachets of two different absorption capacities (100 and 210 mL). The cakes were analyzed for mold growth over a period of 28 days at 25 °C storage. MAP alone provided some benefits regarding mold prevention; however, combining oxygen scavengers (using either 100 or 210 mL) with modified atmosphere (30% CO_2) prevented mold growth entirely during the 28 days of storage. The results also indicated that a greater benefit existed for cakes with a higher a_w (0.9) compared to lower a_w (0.8) (22).

In another study (23), oxygen absorbers were added to wheat crackers formulated with high levels of oil for storage in hermetically sealed cans used as military rations. The study included storage at 15, 25, and 35 °C. Shelf life was assessed using sensory panels as well as hexane concentration and headspace oxygen measurements. As storage temperature increased, headspace oxygen decreased within the can. Overall, cans of crackers without oxygen sachets reached unacceptable levels of rancidity within 24 weeks at 25 and 35°C. Cans of crackers with oxygen sachets did not have rancid odors after 44 weeks of storage, regardless of storage temperature. Thus, shelf life of canned crackers was extended for 20 weeks with oxygen absorbers added to the can.

Other Products. In a study by Zerdin and coworkers (24), orange juice contained in aseptic packages with an oxygen scavenging barrier layer had better retention of ascorbic acid than packages with plain oxygen barrier film. Packages that contained oxygen scavengers had less mold growth on cheddar cheese compared to packages without the oxygen scavengers over a 16 week refrigerated storage period (25).

Milk processed using ultra-high temperature processing, (UHT) was packaged and stored in aseptic pouches that contain an oxygen scavenging film or a pouch without the scavenging film. The milk in the oxygen scavenging pouch had significantly lower levels of dissolved oxygen and levels of volatiles associated with staleness (26). Hazelnuts were packaged under controlled atmosphere conditions with and without iron-based oxygen sachets. The nuts packaged using the sachets were significantly less oxidized compared to the nuts without the sachets. However, when the sachets were analyzed for volatile compounds, other flavor compounds were also scavenged by the sachets (27)

REGULATORY STATUS

A program was developed by the EU Fair R&D program to establish and implement active and intelligent packaging technologies within existing EU regulations, which would enable technologies to be used and allow for products to be globally competitive with other technologies. The program included, inventory, classification, evaluation, and recommendations for regulation of active and intelligent packaging systems. Oxygen scavenging systems were examined as part of the evaluation step and was tested for migration into a variety of food simulants. It was determined (3) that migration from oxygen scavengers varied significantly depending upon type of system (sachet, cap, crown, or film) and food stimulant. For example, migration of oxygen scavenger in water (mg/sample) was 620, 74, 1.0, and 0.2 for sachet, cap, crown, and film, respectively. Based on a study by Lopez-Cervantes and coworkers (23), migration into liquid, solid, and gelled food stimulants using two different types of oxygen sachets were tested. Migration from oxygen scavengers did not exceed European Union migration limits as long as the sachet was properly located in the package, and the packaging process did not favor the content becoming wet from water released from the food.

FUTURE OF OXYGEN SCAVENGERS

New methods of producing oxygen scavengers will continue to be developed. For example, Alteiri and coworkers (29), suggested the use of aerobic microorganisms as the mechanism for oxygen scavenging. The microorganisms can be trapped in poly-vinyl alcohol and used as a coating for high humidity foods. Another use that may see increased application is addition of an oxygen sachet with biopolymer film. Polylactic acid film did not have oxygen barrier properties equal to the polyester film typically used for packaging semi-hard cheese (30). However, when an oxygen scavenger was added to the package, lipid oxidation of the cheese was significantly reduced and continued to improve with dark storage (Tables 1, 2).

Table 1. Oxygen Scavenging Components

Sulfites
Boron
Glycols and sugar alcohols
Unsaturated fatty acids and hydrocarbons
Palladium catalysts
Enzymes
Yeast
Ferrous-iron
Organometallic ligands
Photosensitive Dyes
Polydiene block copolymers
Polymer-bound olefins
Aromatic nylon

Another new method may involve radiation treatment of ethyl vinyl alcohol copolymers. Researchers (30), irradiated EVOH (29% ethylene) with 30 and 90 kGy dosages and found that as the dosage increased, the longer the polymer was able to react with oxygen.

Oxygen scavengers that function better under a variety of temperatures will also be used. A patent was issued for an oxygen scavenging film that acts under ambient and refrigerated conditions and can be incorporated uniformly into a multilayer film (32). Another development involves a patent that indicates that the activation of the oxygen scavenging component of a film can be triggered upon packaging with the product to prevent loss of scavenging capacity in films that may be active while film is in storage (prior to product packaging). The film would receive an initial trigger using actinic radiation, which would not be sufficient to activate the film fully and would receive the total dose necessary to trigger the oxygen scavenging component when desired (33).

An oxygen scavenger that also indicates the level of oxygen present has been developed, which makes it both an active, and intelligent package component. The scavenger is in a pouch form with a layer in the pouch that has a color changing substance that can be viewed through a clear window (34).

POLYPROPYLENE

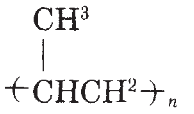
R.C. Miller
Montell USA, Inc., Wilmington, Delaware
Updated by Staff

INTRODUCTION

Polypropylene is an extremely versatile material in the packaging industry. The reason for its adaptability is the ease with which its polymer structure and additive packages can be tailored to meet diverse requirements. Many useful properties are inherent in polypropylene. It has low density (high yield), excellent chemical resistance, a relatively high melting point, and good strength, at modest cost.

GENERAL CATEGORIES AND DEFINITIONS

Polypropylene is the result of linking a large number (typically 1000 to over 30,000) of propylene molecules to build long polymer chains (see Figure 1). Polymers made up only of propylene are called homopolymers. If another monomer is added (typically ethylene), the polymer is



$$\left(\overset{\overset{\mathrm{CH^3}}{|}}{\mathrm{C}}\mathrm{HCH^2}\right)_n$$

Figure 1. Polypropylene.

called a copolymer. The order and regularity of the monomer units in the polymer control the properties of the product.

One end of a propylene molecule is different from the other. The end with three hydrogens is called the head; a head-to-tail linkage is called stereoregular. If the process links the monomers head-to-head about as often as they are linked head-to-tail, the resulting polymer has little order and does not crystallize (1). At room temperature, this material has a density of about 0.850 g/cm^3. It is called atactic or amorphous polypropylene and is soft, tacky, and soluble in many solvents. Such polymers are useful in hot-melt adhesives (see Adhesives) and several other applications.

If monomers are connected head-to-tail almost every time, the polymer is said to be isotactic and crystallizes (see Figure 2). Crystallinity is the reason for the solvent resistance, stiffness, and heat resistance of the commercial plastic material. At normal conditions, isotactic polypropylene is usually about half crystalline and has a density of 0.902 ± 0.005 g/cm^3. Normal polypropylene melts at about 329°F (165°C) when heated slowly and contains roughly 5% of atactic material as well as intermediate structures. In this article, the term *polypropylene* (PP) implies the plastic of commerce.

When discussing copolymers and alloys, an additional level of complexity is added. Alloys, also called blends, are mixtures of polymers. Copolymers are the result of polymerizing two or more monomers together. There are many possible types (structures) of copolymer (2), not all of which are useful.

Random copolymers result when a small amount of comonomer, usually ethylene, is polymerized at random intervals along the PP chain. Typical ethylene levels are from 1 to 5 wt%, and the product has only one phase. These copolymers are relatively clear and have lower and broader melting points than PP homopolymers. The lowering of the melting point is proportional to the randomness of incorporation and the amount of comonomer incorporated. At ethylene levels well above 10%, the product becomes less crystalline and is called EPR, or ethylene–propylene rubber. One cannot make an alloy (polymer blend) that resembles a random copolymer.

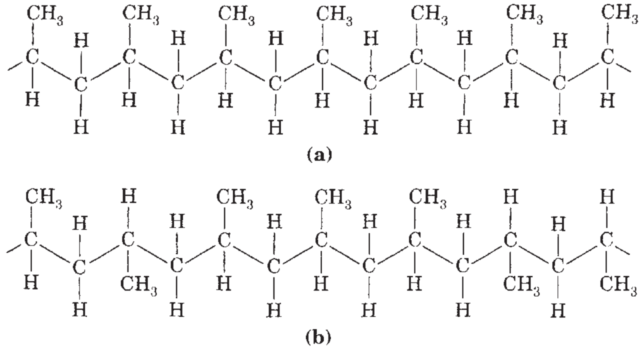


Figure 2. Comparison of the structures of isotactic and atactic polypropylenes: (**a**) isotactic PP–methyl groups in orderly alignment; (**b**) atactic PP–methyl groups in random alignment.

Impact copolymers generally contain larger amounts of ethylene monomer, typically 4 to >25%, and are heterophasic. The ethylene may be polymerized in the form of polyethylene and/or EPR. Usually, such products are made by polymerizing a homopolymer and changing the conditions to add ethylene to the polymer chain. Reasonably comparable materials can be made by mechanically blending polypropylene with EPR and/or polyethylene. If crystalline EPR or polyethylene is present, it can be detected by a second melting point at 224–271°F (118–133°C). These products are characterized by lower stiffness, much enhanced toughness at low temperatures, and a relatively opaque appearance (see Table 1).

The molecular weight (related to the average number of monomer units in a chain) and the molecular-weight distribution (MWD) are significant polymer characteristics. High-molecular-weight (HMW) polymers are highly viscous when melted and are difficult to injection-mold or push through restrictive dies, but they have high toughness and good "melt strength" (melt elasticity). Melts of low-molecular-weight (LMW) polymers are more fluid. They have less toughness and lower melt strength. In a narrow-MWD polymer, there is less variation in the length of the chains than in a broad-MWD polymer. Narrow MWD allows retention of the toughness of HMW grades (3) in a more easily processed material. Narrow MWD materials do not generally have high melt strength. They offer advantages in fiber spinning and injection molding.

Substantial modification in properties can be achieved by the use of additives (see Additives, plastics) and fillers. Virtually all commercial grades are stabilized to increase resistance to oxidation on aging or at elevated temperatures. Additives can confer resistance to sunlight, reduce the tendency to retain static electric charges, modify the coefficient of friction, and prevent surface tackiness.

The additives should be selected for the application. In food packaging, the stabilization should be chosen to avoid transfer of taste and odor to the package contents. Antistats reduce static electricity, which attracts dust and makes packages appear dirty. In sunlight, the damaging wavelengths are in the UV range. UV resistance is important for items that may be stored outdoors. Coefficient of friction and antiblocking properties are important in the winding and handling of film (see Slitting/rewinding). Frictional characteristics are also important in threaded closures (see Closures).

Fillers can greatly increase stiffness, improve processing behavior, confer conductivity, and change the

appearance of PP. Commonly used fillers are talc, calcium carbonate (usually powdered marble), glass fiber, mica, carbon black, clays, cellulose fibers, lubricants, and pigments. Many exotic fillers have been used for special purposes. The use of fillers in PP usually reduces toughness and raises density and cost per volume.

PROCESSING

Melt-flow rate (MFR) is one of the key variables in the processing of PP. ASTM International (formerly The American Society for Testing and Materials) (4) specifies that PP is to be tested at 446°F (230°C) under a pressure exerted by a nominal 4.4-1b (2-kg) mass in the apparatus specified under ASTM Standard D-238. The result is the weight of material extruded through the standard orifice in 10 min.This test is a crude measure of the melt viscosity of the plastic under low shear rate. Melt viscosity correlates to the weight-average molecular weight of the polymer. Commercial PP grades of interest in packaging span a MFR range of 0.3–40 g/10 min. The low flow grades (up to about 2.5 g/10 min) are used in sheet extrusion (see Extrusion) and blow molding (see Blow molding). Film is manufactured from intermediate-flow grades (MFR 2–15 g/10 min). Injection-molding processes (see Injection molding) ordinarily use PP with MFR of 3–40 g/10 min (see Table 2).

Thermoforming

Sheet extrusion for thermoforming (see Thermoforming) is a small, rapidly growing segment of the PP market. Until the late 1970s, few converters were willing to attempt thermoforming of PP. Since that time, thermoforming techniques and grades have been improved. Random copolymers and impact copolymers have a broader temperature "window" and are more easily formed than homopolymers. Several grades are available that promise excellent forming characteristics, even in homopolymers. The several available high-melt strength PP grades ease manufacture via improved material distribution and higher forming rates. The factors that promote the use of PP in thermoforming are low odor and taste transfer, good moisture barrier, chemical resistance, and adequate clarity in thin sections.

Blow Molding

In blow molding, most of the resin consumed is for consumer products. High melt strength is required for extrusion blow molding, which is used to produce relatively large containers up to 5.3 gal (20 L) in size. Injection blow molding usually requires MFR of 1–2.5 g/10 min. This process is particularly useful for relatively small containers. The ability to withstand temperatures or aggressive chemicals that would stress-crack or attack other materials is usually

Table 2. Effect of Molecular Weight (Melt Flow) on Homopolymer Properties

Property	Values			
Melt-flow condition L, g/10 min	0.4	2	12	35

the reason to blow-mold PP today. In detergent exposure tests that crack HDPE in a day or two, PP does not fail even after many weeks. Random and impact copolymers are most often used. The development of high-melt-strength resins will assist the growth of PP blow molding. Today, injection stretch blow-molded PP bottles are biaxially oriented and rival the clarity of PET. If the chains of PP are stretched, they line up to give remarkable strength, clarity, and toughness (even at low temperature). This process uses a preform that is stretched and blown while warm. Random copolymers are used since low temperature toughness is provided by biaxial orientation. Typical resin MFR is 1–3 g/10 min for these applications.

Polypropylene ususally has a milky appearance (paticularly when empty). However, the contact clarity is really quite remarakalbe, making a filled bottle look attractive. Full-shrink-sleeve decoaration changes the whole visual impact if total clarity is an issue.

Film

The use of PP in film is very large. Oriented films typically have high toughness and excellent clarity (see Film, oriented polypropylene). They can be produced by a high-expansion bubble process or a tenter process. Product variations are possible based on the amount of transverse- and machine-direction orientation. Nonoriented cast films are usually made by a chill-roll process, but there are also water-quench and water-quenched bubble processes in use (see Extrusion; Film, nonoriented polypropylene). Oriented films can have a stiff feel or “hand.” They sparkle and tend to “crinkle” audibly. These films are employed as cigarette wrap, candy wrap, and snack-food pouches, often in replacement of cellophane (see Cellophane). Oriented films have been tailored for superior barrier properties (by coating), heat-seal strength (by resin modification or coating), heat-shrink properties (see Films, shrink), printability, and electrical properties. A relatively new addition to the family of oriented films is opaque film. The opacity is produced by a filler and by controlled voiding. A type of decorative ribbon is foamed uniaxially oriented PP with a colorant (see Colorants). Foods stored in restaurants or microwaved are wrapped in films containing chloride. Vinyl chloride produces unsafe emissions upon burning. Polypropylene, as a nonchlorine-type resin, is being studied as an alternative wrap. Various additives have been proposed to overcome insufficient gas barrier and adhesion properties (5).

The use of woven slit tape or slit film for heavy-duty agricultural bags is not a major use in the United States, but these bags compete with jute and other natural fiber in carrying much of the world’s grain. A related product is strapping, which is made by extruding either sheet or tapes. If sheet is extruded, it is subsequently slit (see Slitting/rewinding). The filaments are then stretched while warm to give tensile strength values of $\geq 50{,}000$ psi (>345 MPa), ten times that of unoriented PP.

Nonoriented film is available in thicker gauges and has a softer “hand” at the same thickness. Some applications are release sheets, sanitary products, disposable-diaper layers, bandages, and apparel packaging. The use of PP in composite film and sheet materials is small, but growing rapidly. PP is used in combination with other PP structures, paper, metal foils, fabric (woven and nonwoven), and other plastics. Such composites can be made by coextrusion (see Coextrusion), lamination (see Laminating), or extrusion coating (see Extrusion coating). The motivation for making such structures is often related to barrier properties, temperature resistance, chemical resistance, and cost. The principal market for these products is in food packaging.

Most film processes use PP grades with a MFR in the range of 2–10 g/10 min. Extrusion coating uses materials with flow ranging from 10 to over 60 g/10 min. Selection of the additive package is an important consideration. Printing, winding, static-charge buildup, blocking (sticking together), odor, color, heat-seal strength, and other properties are influenced by the additives.

Injection Molding

Injection molding produces many familiar packaging items, including threaded, dispensing, and pump closures (see Closures); aerosol valves and overcaps (see Pressurized packaging); wide-mouthed jars, totes, crates (see Crates, Plastic), yogurt cups, snuff boxes, cosmetic containers, drug syringes, barrel bungs, dairy tubs, and many others. Most general-purpose PP molding grades are well-suited for packaging. In food and drug packaging, one must ensure that the particular grade is suitable for the product to be packaged. Conventional injection-molding grades span a MFR range of 2 to >70 g/10 min.Generally, the lower-flow materials are tougher and process less rapidly. New polymer production processes can produce very high-flow PP grades without narrowing the MWD. Although less tough than narrow-MWD grades of similar MFR, these grades are more easily molded. Copolymers with MFR up to 70 g/10 min are being used in thin-walled injection-molded (TWIM) containers, notable for quality appearance and ease of printing or decorating. Thin walls allow high productivity, low part weight, and low container cost. By using narrow-MWD or “controlled-rheology” resins, high MFR grades with good toughness can be made. These grades are appropriate choices for thin-walled moldings and for large multiple-cavity molds. They offer better dimensional control, but are not as stiff as broader-MWD material.

Normal homopolymers are brittle at refrigerator temperatures. The use of copolymers is recommended when shipping or use expose the part to low temperature impact.

HEALTH AND SAFETY ISSUES

Except for fire-retardant grades containing antimony, PP is generally a nontoxic material. Many grades are available that comply with FDA requirements for food packaging. PP is used in drug packaging and medical devices. It is fiber-spun for use in undergarments, upholstery, sanitary products, and bandages. It is not soluble at normal temperatures in food and beverages. PP is combustible and burns completely when adequate air is available to the flame. As sold by resin manufacturers, PP is usually in a coarse granular form and presents no unusual fire hazard. If it is finely divided (finer than 200 mesh or 74 μm), however, polypropylene can present a combustible dust hazard as do most organic materials. Like other organic materials (e.g., wood, wool, flour), the products of incomplete combustion include carbon monoxide and can include a number of unpleasant, partially oxidized pyrolysis products (aldehydes, ketones, etc.).

Under most processing conditions, little hazard exists with the use of PP. One should avoid contact with the molten polymer. If the plastic is exposed to air at temperatures above 500°F (260°C), proper ventilation should be used. The autoignition temperature is 675–700°F (357–371°C) for most grades. In summary, there are no unusual risks associated with the use of PP.

MARKETS AND APPLICATIONS

Polypropylene resins, along with polyester resins, are the fastest growing of commodity thermoplastics in the world. In 2006, production was 41.5 million tons with an estimated value of $66 billion (6).

Isotactic polypopylene is well suited for a variety of end uses. Polypropylene is recyclable, and this is an important consideration for packaging products. It can be incinerated without toxic emissions. Typical applications for polypropylene products include fibers and filaments, oriented and cast film, injection-molded products, blow-molded bottles and parts, and thermoformed containers. Random copolymers can be reproduced with excellent optical properties and sealing initiation temperatures in compliance with the U.S. Food and Drug Administration regulations for food contact (1). Polypropylene can be combined with polyethylene as blends for liquid packaging films (7).

INTRODUCTION

Polystyrene is the parent of the family of styrene-based plastics. By copolymerization of styrene with other monomers, a wide range of properties is obtainable. Polystyrene resin is one of the most versatile, easily fabricated, and cost-effective plastics. The largest end-use is in packaging, which accounts for 18% of expanadable polystyrene world use and 30% of general-purpose polystyrene world use. In 2004, world consumption of expandable polystyrene was $3.7\ X10^6$ t and general-purpose polystyrene was $11.5\ X10^6$ t. An annual average increase of about 3.6% is expected through 2009 (1).

General-purpose polystyrene (Table 1) is often called *crystal polystyrene*, which refers to the clarity of the resin. The commercial success of this resin is due to its transparency, ease of fabrication, thermal stability, low specific gravity, high modulus, excellent electrical properties, and low cost. It is commercially produced by two processes. Suspension polymerization is used primarily to produce foam-in-place beads and ion-exchange resin. The bulk of the resin is produced by solution polymerization in a continuous process consisting of one or more vessels followed by volatile removal at high temperatures and high vacuum. There are three common commercial grades of general-purpose polystyrene: easy flow, medium flow, and high heat. The choice of resin depends mostly on the fabrication method. Easy flow and medium flow are used primarily for injection molding and the high-heat extrusion applications.

High-heat polystyrene, such as Styron 685D (trademark of The Dow Chemical Company), has the highest molecular weight and contains the fewest additives. High-heat resins normally do not contain mineral oil or other flow additives and generally contain a mold release

Table 1. Typical Properties for General-Purpose Polystyrene

Property	ASTM Test Method	Units	High Heat	Medium Flow	Easy Flow
Melt-flow rate (condition G; 200°C/5 kg)	D1238	g/10 min	1.6	7.5	16.0

Molecular weight	SEC	Daltons	300,000	225,000	210,000
Molecular number	SEC	Daltons	130,000	92,000	75,000

additive or extrusion aid. The higher heat distortion and toughness are offset by low melt-flow rates. The high molecular weight improves the mechanical properties of the resin and also the ability to induce orientation during fabrication. Orientation of the polymeric chains tremendously increases the toughness of resin. For food-packaging applications, low residual levels are desirable to minimize taste or odor transmission to the food.

High-impact polystyrene (Table 2), sometimes called rubber-modified polystyrene, is normally produced by copolymerization of styrene and a synthetic rubber. This produces a two-phase system consisting of a dispersed rubber phase and a continuous polystyrene phase. This system uses a unique feature of polystyrene to allow elongation by the formation of energy-absorbing crazes. The dispersed rubber particles initiate astronomical numbers of crazes without crack formation, thus contributing to the development of very tough products. By varying the amount of rubber, normally 2–15 wt%, and morphology of the rubber-phase physical properties of the resin can be varied considerably. High-impact polystyrene has lower tensile strength and a tremendous increase in elongation and impact strength. The opacity of high-impact polystyrene precludes its use in applications requiring transparency.

FABRICATION

Processing of polystyrene can be accomplished by most fabricating techniques. Polystyrene resins are among the most widely used thermoplastics for both extrusion and injection-molding applications. Various formulations offer different properties specially suited for specific applications. This also results in slightly different processing conditions. Polystyrene resins are usually processed at melt temperatures of 360–500°F. In extrusion applications, extruders vary significantly in size. Extruder screws can range from small ($\frac{3}{4}$–in.-dia) to large (12-in.-dia) with varying L/D ratios from 20:1 to 42:1. The current trend in extruder design is toward 30:1 and 36:1 ratios using two-stage single screws and vented barrels. Both single- and two-stage screws are used because of polystyrene's excellent stability compression ratios, between 3:1 and 5:1, which are used to achieve good mixing and uniform delivery. Screw cooling of the feed section of the screw is recommended on large extruders when operating at high output rates or when high levels of regrind are being used. Because polystyrene is nonhygroscopic, drying of the granules prior to extrusion is usually unnecessary.

An optimum set of operating conditions can be determined only through experience with a particular extruder. Optimum running conditions require the proper balancing

Table 2. Typical Properties of High-Impact Polystyrene

Properties	ASTM Test Method	Units	Extrusion Resin	Injection-Molding Resin
Melt-flow rate (condition G, 200 °C/5 kg)	D1238	g/10 min	3.0	7.5

Table 3. Typical Sizes of Injection-Molding Machines

Nominal Rating of Clamping Capacity (kN)[a]	Shot Size (g PS)[b]	Rate of Fill (mL/min)[c]
1335	170–340	131–262
4450	1360–2155	410–738
8900	4536–5100	1148–1476

[a] To convert kN to tons, divide by 8.9.

[b] To convert g to oz, divide by 28.35.

[c] To convert cm^3/min to $in.^3$/min, divide by 16.4.

of many variables such as screw design, extruder size, extrusion rate, extruder conditions, polymer used, and desired end product. Suggested starting conditions using a typical polystyrene screw are as follows:

Hopper	Adequate Flow of Cooling Water
Feed section	350°F (176°C)
Transition section	400°F (204°C)
Metering section	440°F (226°C)

Extruder head pressures range from 1500 to 4000 psi. The die gap is normally set at 10–20% greater than the desired sheet thickness. Polystyrene resins are notably stable materials. Evidence of this is seen in the ability to use regrind and to recycle these resins. Many new packaging applications are being developed through the use of coextrusion. By incorporating layers of other resins such as EVOH and PVDC, barrier properties can be achieved, and the ease of polystyrene fabrication and effective cost and performance of polystyrene can be maintained.

In injection-molding applications, machines vary in size and capacity to permit molding very small to very large parts. Machine cost is primarily a function of clamping capacity, which is the force necessary to hold the mold halves together during high-pressure injection. This is directly related to the pressure needed to fill the mold cavity. Typical sizes are listed in Table 3. For best operating conditions, the preferred shot size is usually about 50–75% of the maximum shot size of the machine.

Cooling time is the major portion of an injection-molding cycle. The cooling times are influenced mainly by part wall thickness and the heat capacity of the polymer. In the case of crystalline polymers (e.g., polypropylene), the heat of crystallization is a large part of the heat that must be removed. The shorter cooling times for amorphous polymers, such as polystyrene resins, allow for higher production rates than are possible with many crystalline polymers. Typical injection-molding conditions for polystyrene are listed in Table 4.

Blow-molding is a multistep fabrication process for maufacturing hollow symmetrical objects. Styrene-based plastics are blow-molded to make speciality bottles and containers. However, blow-molding is primarily a process for polyethylene and poly(vinyl chloride) (2).

APPLICATIONS

Polystyrene is widely used in many packaging applications. These include injection-molded products such as beverage containers, dairy product containers, and packaging for personal care items. Extruded solid-sheet polystyrene products include salad boxes, dairy product and baked good containers, and vending cups and lids. Extruded foam sheet polystyrene packaging products include poultry and meat trays, produce trays, hinged lid containers, egg cartons, and foam cups. Blow- and foam-molded polystyrene products include vitamin bottles and loose fill packaging. Reported newly investigated products are (a) a paper-wrapped polystyrene foam beverage container that provides thermal insulation as well as a means to display high-quality printed matter (3) and (b) a food packaging tray of expanded polystyrene with the ability to absorb liquids inside (4).

RECYCLING

Polystyrene items separated from solid-waste streams are subjected to one or more of the following unit operations: densification, granulation, washing, drying, extrusion, and pelletizing. The pellets obtained have properties similar to virgin resin. Dissolution of polystyrene in various solvents removes solid contaminants. Volatilization and recovery of the solvent produces solid polystyrene for reuse (5). Solid

Table 4. Typical Injection-Molding Conditions

Controls	English Units	SI Units

New Jersey

Polyvinylidene chloride (PVDC) is a copolymer of vinylidene chloride (usually 70–90 mol %) and other monomers including vinyl chloride, acrylronitril, and alkyl acrylate. Homoploymer of vinylidene chloride (VDC) is not used in commerce. PVDC has been an important contributor to the plastic packaging that has increased the fraction of processed foods reaching the dinner table. PVDC provides exceptionally low permeabilities to gases and liquids. Furthermore, they are resistant to attack by many chemicals and are inert to most foodstuffs.

The overwhelming fraction of PVDC is used for food packaging. Lesser amounts are used for other packaging applications, fibers, specialty binders, and molded parts. The volume of PVDC use in packaging is small with the proportion less than 0.5% of the total polymers in Europe. The world market demand of PVDC resins is estimated as about 80,000 metric tons, in which 66% are for extrusion, 22% for solvent coating, and 12% for latex.

CHEMISTRY

Homopolymer of vinylidene chloride is not commercially useful because of its crystallinity and thermal instability. The melting temperature of the homopolymer is about 202°C, and the level of crystallinity is greater than 60%. Crystallization from the melt is rapid. As an extrudable resin, the polymer needs to be heated above the melting temperature for a few minutes. The degradation rates above 200°C are too rapid to allow time for extrusion. As a latex, the homopolymer can crystallize in the particles. Then, during drying after coating, the particles will not fuse to give a continuous film. As a resin for solvent coating, the crystals are too stable to be dissolved by convenient methods.

Copolymerization alleviates the problems with the homopolymer. A comonomer decreases the lamellar thickness of the crystals and lowers the melting temperature. A comonomer decreases the rate of the crystallization and allows a latex to remain completely amorphous longer. Hence, the casting will fuse easily and then crystallize. A comonomer gives a semicrystalline material that can dissolve in convenient solvents.

Vinylidene chloride is colorless liquid readily dissolving in most organic solvents, and it undergoes free-radical polymerization with many other monomers to form solid particles. The commercially important comonomers are vinyl chloride (VC), acrylonitrile, and methacrylonitrile, along with various methacrylates and alkylacrylates. For extrudable resins, vinyl chloride or methyl acrylate is commonly used to depress the melting temperature to the range of 140–175°C. For latex coatings, an alkylacrylate or alkylmethacrylate is used as comonomer. Terpolymers are common, and in some cases a surface active comonomer is included such as acrylic acid or 2-sulfoethyl methacrylate. For solvent coatings, acrylonitrile and methacrylonitrile are the most common comonomers.

Most extrudable resins are made in suspension by free-radical polymerization. The monomers are dispersed as droplets in water and stabilized by a protective suspending agent such as polyvinyl alcohol or methylcellulose. An oil-soluble free-radical initiator is used. The result is a free-flowing collection of nearly spherical, porous particles with diameters in the range of 200–300 μm.

Latexes are made by a free-radical, emulsion polymerization. Often, monomers are continuously added to the reaction vessel during polymerization. The latexes must be stabilized with surface active agents to prevent coagulation.

Resins for solvent coating are also made through a free-radical, emulsion polymerization. Often, monomers are continuously added into the reaction. A minimum amount of surface active agent is used because the higher amount deteriorates the stability of the polymer which should go through coagulation, dewatering, and drying after the polymerization step. Common solvents used in the coating include tetrahydrofuran (THF) or methyl ethyl ketone with toluene.

In addition to those materials that are required for polymerization, certain additives are commonly used with PVDC copolymers. Plasticizers, stabilizers, and extrusion aids are included in extrudable resins at low levels for high barrier applications and moderate levels for less demanding applications. A latex may contain an antimicrobial compound. A resin for solvent coating will contain some of the salt used to cause coagulation.

PVDC can degrade at elevated temperatures, thereby releasing HCI and leaving a double bond in the polymer backbone and consequently generating an allylic dichloromethylene unit susceptible to facile thermal radical dehydrohalogenation. Hence, at low levels of degradation a series of conjugated double bonds are formed which may impart color to the polymer. In extreme cases, the degradation can lead to a brittle char and even to carbon. The degradation is also catalyzed by Lewis acids, particularly iron cations formed from the interaction of process equipment with evolved hydrogen chloride. Hence, extrusion of PVDC resins should be done using the proper materials of construction and with training by experts. Strong bases can also cause degradation of PVDC. For example, contact with organic amines is not recommended, because such agents act to introduce the double bond sites initiating rapid thermal degradation.

GENERAL PRINCIPLES

All PVDC copolymers have certain common characteristics. Commercial copolymers have molecular weight ranges of about 65,000–150,000. Molecules of lower molecular weights tend to be brittle and have limited commercial value. The physical and chemical properties of copolymers depend largely on the VDC content, which ranges from 72 to 94 wt% in most commercial products. The axial symmetry of the VDC molecule permits tight packing of molecular chains with concomitant formation of crystals constituting 25–45 vol% of the total structure. Specific gravities range from 1.65 to 1.75.

These characteristics of PVDC resins are not significantly altered by the small amounts of processing and stabilizing aids used to facilitate extrusion and molding. A representative extrudable resin is a VDC–VC copolymer with about 85% VDC and a molecular weight of 120,000, with plasticizer sufficient for ease of extrusion.

Table 1. Transport Properties of a High-Barrier PVDC Extrudable Resin in Film or Sheet Form

Property	Value
Gas permeabilities at 23°C (73°F) (nmol m^{-1} s^{-1} GPa^{-1})[a]	
Oxygen	0.04–0.30
Nitrogen	0.02–0.10
Carbon dioxide	0.10–0.50
Water vapor transmission rate (WVTR) at 38°C (100°F), 90% RH (nmol m^{-1} s^{-1})[b]	0.01–0.10

[a] Multiply by 0.50 to obtain $cm^3 \cdot$ mil/(100 in.^{2} day atm).
[b] Multiply by 3.95 to obtain g $\cdot$ mil/(100 in.^{2} day).

Note that the barrier and strength properties of PVDC depend on the chemical compositions of the molecules, the degree of molecular orientation, and the direction of orientation in the finished form. Relatively high VDC content imparts relatively high barrier properties and gas resistance. A comparatively high degree of orientation imparts tensile strength. Higher crystallinity correlates with lower permeability.

PROPERTIES

The properties of PVDC copolymers most pertinent to food packaging include a unique combination of low permeability to atmospheric gases, moisture, and most flavor and aroma bodies and stress-crack resistance to a wide variety of agents. In addition, the ability to withstand the rigors of hot filling and retorting is important in commercial sterilization of foods in multilayer barrier containers.

The range of barrier properties for small molecules in extrudable resins is shown in Table 1. Furthermore, PVDC is excellent barrier to flavor and aroma compounds. The three major types of household film are compared in Table 2. A high-barrier PVDC film would have much lower permeabilities. The general-purpose and high-barrier films are compared in Table 3.

The bulk mechanical properties of PVDC-coated papers, films, and structures such as formed containers and blown bottles depend almost entirely on the properties of

Table 2. Permeability of Household Films at 25°C to Selected Permeants

Permeant	Plasticized PVDC (Saran Wrap™)	Film Type Plasticized PVC (Reynolds Plastic Wrap™)	Polyethylene (Handi-Wrap II™)

[a] Film 1 mil (25.4 μm) thick. Not to be confused with Saran Wrap™ household brand film.

[b] Machine (longitudinal) direction.

[c] Transverse direction.

[d] Humidity has no effect on the permeability of PVDC films.

the substrate material. On the other hand, the PVDC coating controls the specialized attributes providing barrier to permeation, chemical resistance, or heat or dielectric sealability to the substrate (see Table 4).

APPLICATIONS: EXTRUDABLE RESINS

Flexible Films

Monolayer films are used for household wrap, as unit-measure containers for pharmaceuticals and cosmetics, and as drum liners and food bags. Multilayer films, generally coextruded with polyolefins, are used to package meat, cheese, and other moisture- or gas-sensitive foods. The structures, which contain 80–90% polyolefin with an inner layer of PVDC, are usually shrinkable films that provide a tight barrier seal around the food product.

Semirigid Containers

PVDC is used as barrier layer in semirigid thermoformed containers. The sheet can be produced by coextrusion or by laminating monolayer or coextruded PVDC films to semirigid styrenic or olefinic substrates. PVDC can also be used as barrier layer in blow-molded bottles.

APPLICATIONS: COATINGS

Generally preferred forms of PVDC coatings on various substrates are shown in Table 5. Pretreatment with primers or electrotreatment may be required on some substrates. The form of the package (i.e., film, thermoformed sheet, or blown bottles) influences the choice as well, but the key differentiating elements are the porosity and chemical composition of the substrate.

Table 4. Properties of PVDC Films[a]-Made from Aqueous Latexes and from Solutions

Properties	Latexes[b]-Selected for High Barrier	 High Seal Strength[c]	Solution Resins[d]
Oxygen permeability at 23°C(73°F) (nmol m^{-1} s^{-1} GPa^{-1})	0.06–0.20	0.20	0.04-0.20
WVTR at 38°C (100°F) and 90% RH (nmol m^{-1} s^{-1})	0.012–0.015	0.012–0.380	0.005–0.025

Polyamides (nylons)	X	X
Styrenics	X	
Vinyls (PVC)[b]	X	

[a] Includes coated and dense forms, such as glassine.

[b] Plasticizers in highly plasticized PVC may migrate to the PVDC coating, thereby damaging the coating's effectiveness as a barrier.

Paper and Paperboard

Paper and paperboards coated with PVDC latex are used where moisture resistance, grease resistance, oxygen barrier, and water-vapor barrier are required.

Cellophane

About 90–95% of all cellophane produced in North America is coated with PVDC solution coatings to render the films moisture-resistant (thereby retaining the high gas barrier inherent to dry cellophane) and provide the needed moisture barrier.

Plastic Films

Latex coatings on plastic films provide barrier to gases, moisture, flavors, and odors, and, in some packaging, heat-seal capability. Heat-seal latexes are not often good gas barriers, and, conversely, the best PVDC barriers do not usually provide the best seals. When both heat sealability and barrier are required, it is best to apply two coatings, each designed for one purpose.

Semirigid Containers

Latex coatings impart barrier properties to thermoformable plastic sheet used to produce high-barrier food containers. Latex coatings on polyethylene terephthalate (PET) bottles impart barrier to oxygen, carbon dioxide, water, flavors, and odors.

PRODUCERS

The principal producer/suppliers of PVDC in forms of extrudable resin, latex emulsion, and solvent soluble resin include Dow Chemical, Asahi Kasei, Kureha Corp., Owensboro Specialty Polymers, Rohm and Haas, and Solvin. The Dow Chemical Company, the first developer and producer of PVDC film, produces Saran™ resins and films plus SARANEX™ multilayer films coextruded with polyolefins.

REGULATORY STATUS

VDC–VC copolymers containing about 10–27 wt% VC are considered to comply with the food-additive provisions of the Federal Food Drug and Cosmetics Act on the basis of "prior sanction". A variety of specific regulations govern PVDC copolymers other than those of VC. The potential user is encouraged to work with the supplier to compare the current regulations with the application.

PRESSURE CONTAINERS

MONTFORT A. JOHNSEN
Montfort A. Johnsen &
Associates, Ltd., Danville,
Illinois

Several distinct classes of pressure containers exist. All are used to dispense the contents into either open or closed environments. Among the largest are Hortonspheres, with capacities exceeding 1 million gal (3,850,000 L). For transport purposes, the largest pressure containers are "jumbo" tankcars, with capacities of about 31,000 gal (117,000 L). Cylinders down to about 500 gal (1900 L) are designated as bulk tanks. Smaller ones are variously known as "pig tanks," "ton cylinders," or simply as cylinders. Sometimes the intended use serves to identify the general size and shape as in the case of "propane cylinder" or "lecture bottle."

Pressure containers in sizes ranging from 3 to 1000 mL are used to dispense consumer specialties. In two of these, the primary container is pressurized. The most popular is the aerosol, where pressure is generated by a propellant gas. The other uses mechanical pressure from springs or elastomers under tension to propel products from a flexible inner container. A third form is the mechanical pump, such as the finger-pump or trigger-spray dispenser, in which pressure is generated by the user, but only within the valve body. In 2006 an estimated 3.65 billion aerosols were produced in the United States. The remainder of this article is restricted to aerosols (see also Aerosol containers).

An aerosol composition normally consists of a combination of concentrate and propellant. The propellant portion can range from about 0.5% to 100%, and at the 100% end the propellant functions as the product itself. The regulatory definition of an aerosol [by the U.S. Department of Transportation (DOT)] is a product that consists of "chemical ingredients pressurized by compressed gas." In a 1991 clarification the DOT further required that the product name reflect the intended use of the concentrate ingredients. This was designed to halt interstate shipments of commodities, under aerosol exemptions, which contained flammable propellants—to which trace amounts of two or more incidental chemicals had been added, with the sole purpose of satisfying the aerosol description in the tariff.

Virtually all aerosols are fitted with valves, for the purpose of dispensing the contents—most often in spray forms, but also as foams, streams, gels, gases, lotions, pastes, ointments, and so forth. Limited numbers of aerosols are packaged with screw-threaded closures, designed to be connected to valve-and-hose assemblies for such purposes as air-conditioner refills. About a dozen firms produce aerosol valves, and they offer a bewildering array of diverse styles, orifices, materials, and associated fitments. The scope of aerosol products is surprisingly large. Every consumer and institutional and/or industrial product category is included, such as pesticides, household products, pharmaceuticals, drugs, foods, cosmetics, and medical devices. Some liquid streams can be propelled 25 ft (8 m) to reach wasp nests and kill the insects and their eggs. Compressed-gas jets may be used to dedust the surfaces of electronic circuit boards, tapes, and CDs (compact disks). Sterile saline solutions are available for flushing cleaning solution residues from contact eyewear. Cheese and jelly products can be cleanly extruded from special valves onto other food items. Gels can be produced that magically spring into foams when stroked with the fingertip. Unlike pump sprayers, aerosols can produce sprays with an optimum particle size distribution for maximizing their knockdown and cidality to flying insects. Particles are produced that are small enough to remain airborne for long periods, yet not so small that they airflow around the bodies of flying pests. As a result, a maximum number of insects are impacted by lethal doses.

The scope of aerosols has been enhanced by the steadily growing numbers of bag-in-can and piston can products now on the market. The product is partitioned from the propellant by placing it inside a collapsable plastic, metal, or composite laminated bag, or above a piston. The propellant then simply acts to pressurize the system. Nonaerated products, such as lithium grease, toothpaste, gels, artist's pigment dispersions, and standard chemical solutions, can then be dispensed. Product viscosities up to about 2,000,000 cP can be easily handled. Originally restricted to the 2.125-in. (52-mm)-diameter aerosol can, these compartmentalized aerosols are now available in diameters ranging from about 1.378 in. (35 mm) to 2.588 in. (65.7 mm) and in several heights.

Among the myriad aerosol valve designs is the meter-spray type. Originally designed to dispense costly perfumes in dosages of about 0.02–0.05 mL, the primary use has now shifted to the metered-dose inhalents (MDIs).

AEROSOL CONTAINERS

About 82% of all aerosols produced in the United States during 2006 were steel [actually about 80% electrotinplate (ETP) and 5% electrochrome-coated steel (ECCS)]. Aluminum accounted for about 18%, while glass, plastic-coated glass, stainless steel, and plastic totaled about 1%. Terephthalate (B-OPET) should decrease because of reinterpretations of certain DOT shipping regulations.

The percentage of aluminum cans in U.S. aerosol units is perhaps the lowest in the world. Most countries use about 60% steel, 40% aluminum, and virtually no other container materials. The low percentage of aluminum in the United States is considered to be due to three factors: The consumer culture demands less packaging elegance, more large-size utility products are sold, and the prices of aluminum cans are significantly higher.

Steel

The usual steel aerosol can is produced from electrolytically tinplated sheet, and it consists of three segments: top (dome), body, and bottom (base). In the United Kingdom the top is called the *cone* and the base is known as the *dome*, which has led to some confusion in nomenclature from time to time. In 2007, the U.S. suppliers are the Crown Cork & Seal Company, B'way Corp. Aerosols Inc., Ball Corporation Aerosols and Packaging, The Sexton Can Company, and McKernan Packaging and Clearing House.

The Sexton Can Company produces both one-piece (35- and 38-mm) drawn cans and a line of two-piece cans, where a top shell is sealed to the base by double-seaming. A major portion of these last cans is used for pure HCFC-22 and HFC-134a air-conditioning and refrigerant gases, under two special DOT exemptions, since their pressures exceed the standard aerosol limits.

DC Containers Inc. is a newer firm. Their containers are unique in that about 92% of the sidewall is drawn and ironed to a thickness of only 0.0038 in. (0.096 mm). This operation acts to elongate the base–body "cup," formed by ordinary extrusion techniques. The cup is then trimmed to height and eventually double-seamed to an aerosol dome. For the small (35- and 38-mm diameter) cans, the drawn and ironed bottom shells are trimmed and then formed into a rounded dome and curl by a multistage ("female" only) die-shaping operation. They also produce two large sizes of 65-mm steel cans using the Protact process (Aerosol Containers).

It is not unusual for the can body of a three-piece steel aerosol can to represent about 65–75% of the total weight, depending on the can height. If the draw–iron process effectively thins some 92% of the body metal to half the normal thickness, the weight of the body will be reduced by some 46% and the weight of the entire can will diminish by about 32%. As a rule, about half the final net cost of the aerosol can is due to the cost of tinplate, so it follows that a 32% reduction in metal will equate to about a 16% reduction in can cost. This economic fact has many marketers interested in testing these new cans. Claims of environmental source reduction, lack of the slightly unsightly side seam and bottom double seam, and some other stated advantages serve to enhance interest.

The thickness of tinplated steel plate is specified in terms of the weight per "basis box" (see Cans, steel; Tinmill products). The *basis box* was an accounting term developed about 1730 in Pontypool, England and was used to note the weight of 112 tinplated steel sheets, 14 in. wide by 20 in. long (35.6 mm × 50.80 mm), thus having an area of 31,360 in.^{2} (20.2325 m^2) on each side. The Pontypool steel plate averaged 100 lb (45.45 kg) per basis box. After tinplating, it weighed about 101–102 lb per basis box; when crated, it constituted a load that was not overly heavy for Welsh longshoremen employed in lading ships bound for canmaking shops in London and continental Europe.

Untinned steel plate weighing 100 lb (45.45 kb) per basis box has an average thickness of 0.0110 in. (0.280 mm). The plate is simply called "100-lb stock." The thinest base weight steel now made is 47 lb (0.0052 in.) thick. It is experimental, but may find use in beer and beverage cans. For aerosol cans the minimum plate thickness is often important in meeting the DOT requirements. The steel-mill tolerance is usually ±10% on thin, canmaking plate, but the can companies have been successful in insisting that the 3σ (three-sigma) tolerance be −6% to 10%. For example, the very strong double-reduced temper 8 (DR-8) 75-lb stock widely used for aerosol can bodies will have a steel thickness range of 0.00776–0.00908 in. (averaging 0.00825 in. or 0.210 mm). The cause of this apparently large variability comes from the upward distortion of the heavy-duty rollers, used to make the plate, causing the center portion of the typical 54-in. (1.37-m)-wide strip to be thicker than at the edges.

The old English basis-box system was introduced to the United States in 1829, when the first tinplate was imported from Wales. It continued to be used in 1858 when the first tinplate was manufactured here. Although the English have (officially) converted from basis box to metric measurements, the United States has yet to do so.

Prior to 1937, all tinplate was produced by the hot-dip method, with both sides being coated equally. If 1.00 lb of tin was deposited per basis box, this meant that 0.50 lb was laid down on each side. Technically, such plate could be designated as 0.50/0.50-lb (227/227-g) ETP. When electrodeposition of tin became practical on a large scale, it also became possible to differentially coat the two sides of a given steel sheet. This advance led to some changes in nomenclature. The rule is to designate the tin weight on each side as if the plate were nondifferentially coated. For example, if 1.00 lb of tin were deposited per basis box, but with 0.75 lb on one side and 0.25 lb on the other, the designation would be D-150/50, meaning that the more heavily tinplated side would have the same weight of tin as nondifferential 1.50-lb plate and the light side would have the equivalent of nondifferential 0.50-lb plate. The nominal tin-coating weight on each side would be 0.375/0.125 lb (170/42.5 g). In the metric system, this plate would be designated as having an average of 16.8 g/m^2 of tin on the more heavily plated side and an average of 4.2 g/m^2 on the lighter side.

Differential plate is normally marked on the more heavily plated side, sometimes with a "D," but also with various lines, hexagons, triangles, or other figures, imprinted by roll printing a dilute solution of sodium carbonate onto the tin coating, prior to flow melting. This prevents plate reversal problems during canmaking. As a rule, the more heavily tinplated surface is oriented toward the product, to reduce possible corrosion. In a few instances, very lightly tinplated plate, such as D-05/15, is placed with the heavily tinned surface facing the atmosphere. An example is where the product is quite alkaline, such as some oven cleaners or other hard-surface cleaners, which quickly dissolve the amphoteric tin metal. In fact, the 0.05-lb tin coating is so thin and incomplete that the dark gray $SnFe_2$ alloy layer and gray steel itself can be seen through it. In this case the free tin is typically 1.36 μin. thick and the underlying $FeSn_2$ layer is about 0.19 μin. (0.08 g/m^2). By using the heavier 0.15-lb tin coating on the outside of the can, the white, shiny surface of the tin improves appearance. It even brightens the lithography in some instances.

Different thicknesses of tinplated steel plate are used in the preparation of three-piece aerosol cans. As can size increases, heavier plate must be used to obtain the same pressure resistance. The end sections (dome and base) are typically 60–80% thicker than the can body. They must resist eversion and possible separation, under high-pressure conditions. Even with can bodies as thin as about 0.004 in. (0.10 mm), the so-called "hoop effect" prevents any swelling or bursting, unless the body metal is softened by strong heating—as in a fire.

Plates used for three-piece cans extend from about 60 to 135 lb per basis box. Bodies range from 60 to 90 lb (0.0066–0.0099-in., or 0.168–0.251-mm average thickness), while end sections extend from 90 lb on small 112-diameter (45-mm) cans to 135 lb on the large 300-diameter (76-mm) containers. The use of these plate thicknesses, along with the basic pressure-resistant architecture of aerosol containers, allows even the lowest-strength cans to resist pressures to at least 160 psig (lb/in.^{2} gauge) (1.2 MPa) without deformation, and up to at least 226 psig (1.7 MPa) without bursting.

The canmaking plate is also continuously annealed to provide various tempers, or stiffness levels. Annealing also serves to remove certain work-hardening effects, obtain the desired mechanical properties, and achieve an optimum grain structure. The annealing process is fairly rapid. Plate is unreeled into an inert atmosphere oven and heated to about 1250°F (677°C) for about 20 s, then allowed to cool to 900°F (482°C) across the following 25–30 s. The rate of this initial cooling determines temper. The highest tempers are achieved by using the slowest rates of cooling—to allow the formation of a larger number of cementite (Fe_3C) grains per unit volume of the steel. For example, the very stiff temper No. 5 (or T-5) plate contains about 15,000 grains of cementite per mm^3. The various

Table 1. Tempers of Electrotinplated Steel (USA)

Temper Number	Hardness Range[b]	Aerosol Canmaking Applications
1	46–53	No longer used
2	50–56	Not used for aerosol cans
3	53–60	Sometimes used for can domes
4	58–64	Used for can bodies and commonly used for can domes
4-CA	54–68	No longer used for aerosols
5	62–68	Some slight use for can bodies
5-CA[a]	62–68	Used for can bases; some bodies
6	67–73	Now obsolete for aerosols
DR-7	72–76	Minor use for can bodies
DR-8	N/A	Used for most can bodies
DR-9	N/A	Not used
DR-10	N/A	Not used

[a] 5-CA is the successor to the “TU” plate of 1950–1985.

[b] Rockwell tester; R30 T range. Not applicable to DR-8, DR-9, and DR-10 plates, since the hardened ball pierces the tough, stiff plate before forming a depression. The preferred method for testing DR plate is by tensile strength. DR-9 and DR-10 are used for three-piece steel beer and beverage cans. Some aerosol testing is in progress. Tempers are inapplicable to impact-extruded and impact-extruded drawn-and-ironed shells.

tempered steels and their aerosol canmaking used are illustrated in Table 1.

The thickness and temper of aerosol canmaking plate must meet certain general guidelines. However, there are considerable variations between canmakers, regarding selection. The data presented in Table 2 can be considered as indicative only.

The plate for aerosol can bodies begins with multistage hot rolling, down to a thickness of about 0.10–0.06-in. (2.5–1.5 mm). The plate is then cold-rolled (temperature below ∼500°C) into a thickness range of ∼0.0014–0.0065 in. (0.036–0.017 mm). It is then annealed. This produces “CR,” or cold-reduced plate of the desired temper. CR plate is still widely used in can bodies. To make “DR,” or

[a] $202 = 2\frac{2}{16}$–in. (54-mm) dia, etc.

double (cold)-reduced plate, one starts with CR plate that is ~0.018–0.013-in. thick. Having annealed it, the stock is again cold-reduced, up to 50% in one pass, to produce tinplate with a thickness range of ~0.0094–0.0065-in. This corresponds to 85–60-lb DR tinplate—the gauges normally used in can-body constructions. The advantages of DR plate are that ~10–12% less weight can be used, compared to CR plates, while retaining the same strength. The lower apparent cost is offset by the higher manufacturing cost of the plate (since another operation is involved), a very slightly higher scrap rate, and sometimes a bit more variability in the double seams.

DIMENSIONS

The size of tinplate aerosol cans is still described as the diameter across the double seams, multiplied by the height from the base to the top of the top double seam. These designations nearly always have three digits, unless the can is extremely tall. The first is the inch value, and the next two are the number of $\frac{1}{16}$–in. increments added. Thus the over-the-seams diameter of a standard (non-necked-in) 202-diameter three-piece can would be 2.125-in. This corresponds to 53.99 mm, but this can be misleading, since the International Organization for Standardization (ISO) utilizes the inside diameter of the can for "can diameter," and in this case their figure (expressed to the nearest millimeter) is 52 mm.

A selection of commercially available, standard (straight-wall) three-piece cans is shown in Table 3.

Table 3. Dimensions and Capacities of Standard Three-Piece Cans[a]

[a] Metric measurements are by ISO convention.
[b] Capacities are on a brimfull basis. Subtract about 3 mL for crimped cup volume.

Several can diameters are now available in the necked-in style that are not available in the older, straight-wall can (e.g., 113, 205, and 214). The diameter over the top double seam is less than the diameter of the can body, and this has led to a curious nomenclature, where the top-seam diameter is described, followed by that of the can body, and then the height over the double seams. For example, the smallest three-piece tinplate can is described as a 111/113 × 214 container, and the largest is a 211/214 × 1006 can. The necked-in cans are more aesthetically pleasing than the standard or straight-wall types. They are also lighter. Because there are no protruding double seams, they fit into slightly smaller corrugate or tray/shrink-wrap shippers. An idea of the diverse necked-in can sizes can be seen from Table 4.

Construction and Linings. See the article on Aerosol containers.

PRESSURE RESISTANCE

The 70°F pressure range of aerosols is generally about 20–142 psig (320–1100 kPa), although most fall in the 30- to 100-psig (360- to 791-kPa) range. However, all aerosols having a capacity of more than 4.00 fl oz (118.2 mL) are regulated by the DOT Dangerous Goods Transport Tariff. Cans are divided into four groupings. The "nonspecification" can may be used for products having pressures of ≤140 psig (9.66 bars) at 130°F (54.4°C). They must hold the product, when heated to 130°F, without leakage or permanent distortion and must also tolerate a pressure one and one-half times that high without bursting. This can probably account for 85% of all steel aerosol-can sales.

The "DOT Specification 2P" can may be used with aerosols having pressures as high as 160 psig (11.03 bars) at 130°F (54.4°C), but must satisfy several requirements. They must not distort at 160 psig and must not burst below 240 psig (16.55 bars). They must have a minimum plate thickness of 0.007-in (0.0178 mm) and be imprinted with both the words "DOT-2P" and the registered canmaker's logo. One can in 25,000 must be pressure-tested to destruction to prove strength. Some canmakers reduce plate inventories by offering the same can specification for "nonspecification" and "DOT Specification 2P" containers; they simply omit the imprints and destructive testing in the case of "nonspecification" cans.

The third grouping consists of "DOT Specification 2Q" cans. They can be used with products having pressures of ≤180 psig (12.41 bars) at 130°F. The cans must tolerate 180 psig without deformation, and they must withstand 270 psig (18.62 bars) without bursting. The minimum plate thickness is 0.008 in. (0.203 mm). Finished cans must be imprinted with the word "DOT-2Q" and the registered logo of the can supplier. One can per 25,000 must be destructively tested, and results must be maintained on file. These cans are about 12–15% heavier than "nonspecification" or DOT-2P cans, and their higher prices reflect the added cost of metal. These heavy duty cans

represent 2% of the market. They must carry the DOT 2 Q words along with the registered logo of the manufacturer.

The final grouping is the "DOT special exemption" can. For the express purpose of approving (a) whipped creams, (b) HCFC-22, and (c) HFC-134a, the DOT has issued exemptions allowing certain cans to be shipped with products whose 130°F (54.4°C) pressures exceed 180 psig (12.41 bars). The whipped-cream can is a "DOT Specification 2Q" container, but fitted with a pressure-relief mechanism (PRM) on the top of the top double seam, which effectively prevents the can from bursting at excessive pressures by venting the contents in a controllable fashion. This can may hold whipped cream (only) at pressures of ≤ 210 psig (1.55 MPa) at 130°F (54.4°C). Such aerosols have a number of product advantages over those packed at lower internal pressures. The DOT also considered that these cans are shipped, stored, and used under refrigeration, making the chance of heat-generated deformation de minimus.

HCFC-22 ($CHClF_2$) has a pressure of 301 psig (2.19 MPa) at 130°F (54.4°C). It requires a very heavy can to safely hold it. The Sexton Can Company produces a two-piece can, with a base-centered pressure-relief attribute that can do so. Here there is no double seam. The firm developed various designs that are stamped into the can base, before it is double-seamed to the shell segment. These designs are often in the form of about 335° degrees of a circle, perhaps 10 mm in diamter. The tinplate is both thinned and work-hardened there so that when the base buckles under excessive contents pressure, the stamped area will fracture and lean outward so that the product can safely escape.

No exemptions have been made for aluminum cans because their bottoms are too variable in thickness to permit a relief mechanism to be incorporated.

The United States is virtually alone in requiring minimum plate thicknesses for specification aerosol cans. Some nations, such as Mexico, have no pressure regulations. The European Union members use the 12-, 15- , and 18-bar can. For example, the 18-bar can may be used to contain aerosols having pressure to 12 bars at 50°C and must not burst below 18 bars (261 psig). For many products, this pressure limit is equivalent to 13.9 bars at 54.4°C (202 psig at 130°F), although the can has a lower burst pressure than the DOT Specification 2Q. This permits the 18-bar can to hold such products as HFC-134a, which in the United States would require a DOT exemption. Currently, the United Nations is asking the U.S. DOT to revise their criteria to match those of Europe and Japan, among others. In Europe, the Federation of Aerosol Associations is petitioning the EU to establish a 2-bar extra-strength can, which would be useful for the improvement of formulations pressurized with nitrogen or compressed air.

ALUMINUM CANS

Aluminum cans have been available since at least 1948. Historically, they have almost always been of one-piece (monobloc) construction, and this is the only type currently made in North America—although one firm in Europe still makes a two-piece specialty can by attaching an aluminum or tinplate dome to a suitably flanged aluminum shell section.

United States aluminum can suppliers as of 2007 are CCL Container Company and the Exal Corporation. Some pharmaceutical marketers make their own very small cans—and some are imported.

While the smallest commercial tinplate can is 35 × 97 mm (86 mL), aluminum cans are made in sizes down to about 3 mL. At the other end of the size spectrum, the largest aluminum aerosols are about 66 × 275 mm (890 mL).

The essentials of the aluminum canmaking process involve taking a round slug (billet, or puck) and extruding it into a "cup" of essentially the same diameter, using a 25- to 50-ton ram. The top is trimmed to a fixed length, after which the metal is cleaned and enameled—normally inside and outside. The top is then die-formed into a dome and curl (or bead). The curl engages the aerosol valve—all "one-in" (1-in.) valves and most of the smaller, ferrule-type valves. The very small 13- and 15-mm-diameter cans may use noncurl finishes.

Aluminum cans have no seams, and thus the linings can be applied more effectively than on tinplates. Many formulas, such as the popular mousse types, may be commercially packed in aluminum without corrosion, whereas they almost always severely attack lined tinplate cans. The permeation of water-based solutions through aluminum-can linings is on the order of 0.1–1.0% as fast as in the case of double-lined and striped tinplate structures.

The smooth-wall construction of aluminum aerosol cans permits the insertion of plastic, floating-type pistons, so that certain products can be kept "nonaerated." This is important for the popular gel-type (postfoaming) shaving creams and the recently test-marketed toothpaste option, as well as dozens of other product types. In time, as one- and two-piece tinplate cans continue their development, some of this market may go to such containers.

GLASS AND PLASTIC

Historically, glass and plastic-coated glass aereosols have been restricted for use as containers for colognes, perfumes, and pharmaceutical liquids. Unfortunately, the flammable and bursting hazards, plus cost and a relative lack of aesthetics, have transferred most of their market to plain-glass bottles (nonpressurized) containing pump-action valves. Then, too, some of their pharmaceutical base has moved over to aluminum aerosols. As a result, the glass and plastic-coated glass market is currently very small, and only a few fillers participate.

There has been a lot of interest in the potential of certain plastics as aerosol containers. For most of this time, DOT regulations greatly limited such developments, since they would not permit the shipment of nonmetallic aerosols having capacities greater than 4 fl oz (118.2 mL). Meanwhile, products such as furniture polish, cleaning preparations, and even hair sprays have been successfully marketed in Europe and parts of South America—using biaxially oriented PET plastic. Aside from some minor concerns about distortion at temperatures over $\sim 122^\circ$F (50°C), this clear plastic seems almost ideal. Special bases and shrink-label attributes were needed to hide the often unappealing aerosol formulation, but these were minor concerns. Currently, the DOT has canceled their regulations to (a) permit plastic aerosols to be shipped and (b) reduce hot-water bath testing requirements.

VALVES

An estimated 95% of the U.S. aerosol valves are currently manufactured by three large firms: Precision Valve Corporation (PVC, Yonkers, NY), SeaquistPerfect Dispensing (Division of the Aptar Group) (S/P) (Cary, IL), and Summit Packaging Systems, Inc. (Manchester, NH). There are smaller domestic firms such as the Clayton Corporation (St. Louis, MO) and Newman-Green, Inc. (Addison, IL). A few marketers make their own valves, including some of the drug houses that fill metered-dose inhalant (MDI) aerosols. Two European-based international valve suppliers have now established sales and technical service offices in the U.S., but produce there valves elsewhere. They are Coster Tecnologie Speciali, s.p.a. (Milan, Italy) and the Lindal Packaging Group (Germany). The Emson Research, Inc. firm, now owned by S/P, specializes in the production of the ferrule-type valves, including the meter-spray types. The Majesty Valve Company (China) is said to be setting up a sales office facility in the United States.

The world's largest valve-maker is PVC, with about 24 plants in 18 countries. They produce about 4×109 valves per year, or about 34% of the world's production. Both S/P and Summit are also international.

COMPONENTS

Modern valves consist of six to seven components:

Actuator (sprayhead or foam spout)
Valve stem
Stem gasket
Body (housing or spring cup)
Spring
Mounting cup
Dip tube

These will vary according to the type of valve. Perhaps the simplest valves are the Clayton and ReddiWhip types, which consist of a very large spout (or stem), a large rubber gasket, and a mounting cup. Since these valves have no dip tube, the can must be inverted before pressing the stem sideways to extrude the product.

In the Newman–Green and other "female" valves the actuator and stem are molded on one piece of plastic (see Figure 1). There is a terminal orifice, often provided by a nylon insert, and a stem orifice that consists of slots in the hollow sidewall of the stem section. This design has several advantages. One basic valve can be tested with up to about 100 actuator/stem combinations, which is convenient for formulators trying to get the most desirable delivery rate and spray pattern. Also, if the valve plugs, the actuator/stem can easily be pulled upward and separated from the rest of the valve, so that it can be washed free of such things as paint pigments, starch powders, and possibly any extraneous textiles, cardboard fibers, or other detritus. The valve can then be reassembled.

Stems

Most valves have separate stem components. The stem ranges from about 3.18 to 3.96 mm (0.125" to 0.156") in outside diameter; and it protrudes different distances from the top of the mounting cup pedestal, which surrounds the lower half. Depressing the stem will serve to operate most valves, but a particular type of stem may be pressed sideways to gain the same effect. Such valves are commonly called tilt-action or toggle action. Note that "Toggle Action" is a registered trademark of the Seasquist-Perfect Dispensing firm. These valves have several advantages. The large slanted finger-pad on the actuator provides good spray directionality, even if one operates the

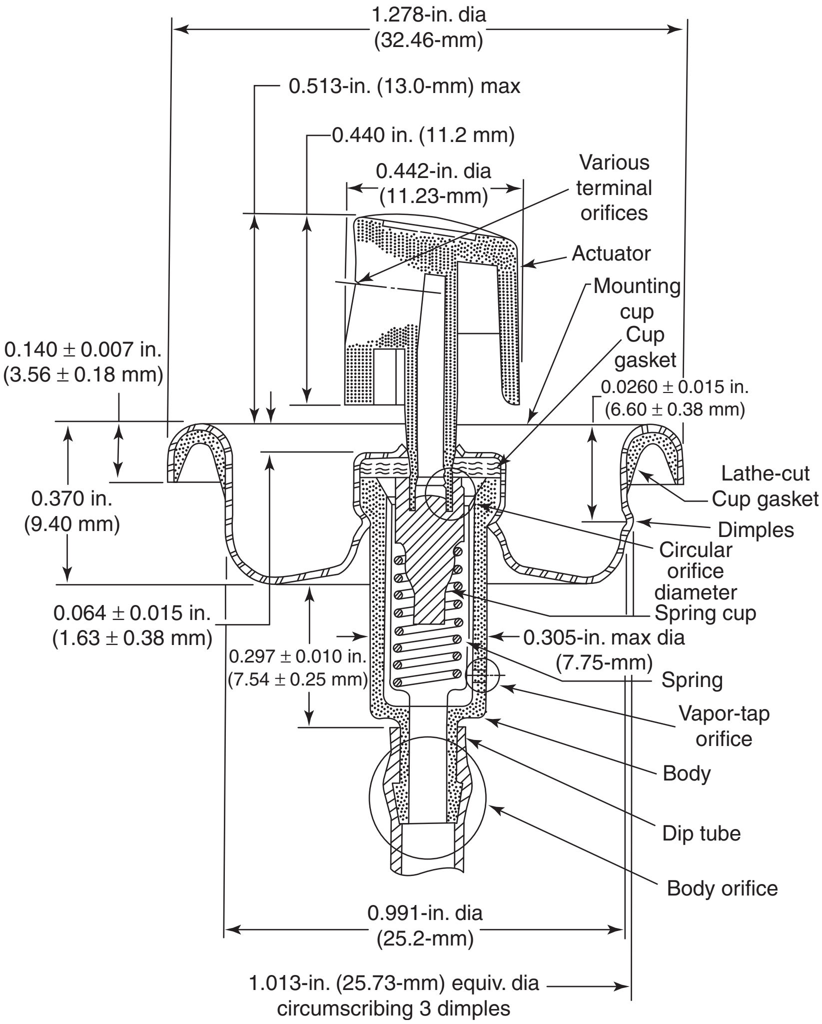

Figure 1. Cross section of female valve.

valve in poor lighting conditions, or in the case of poor eyesight. The button also requires only about 0.6 kg (1.32 lb) of finger force to operate, whereas the vertical sprays may require as much as 3 kg. (6.6 lb). This feature makes the valve popular with beauticians and others who must operate it frequently. The valve is somewhat sensitive to formulations that contain solids or which have solvents able to swell the components unduly. In such cases the vertical valves may be preferred.

The vertical-acting (reciprocating or up-down) "male" aerosol valve is the most popular type. It is relatively simple and trouble-free. The valve can be fitted with a variety of large spray-heads, spray domes, or spouts, each with comfortable finger pads, and these aesthetically pleasing fitments are a major factor in its relative popularity. When the stem is pressed downward sufficiently, the stem orifice, normally above or against the stem gasket, slides to a position below the stem gasket, thus opening a small hole through with the pressurized product can pass up the dip tube, through the valve body, past the stem orifice and into the actuator, from which it then is delivered as either a gas, spray, foam, gel or liquid stream. Most often, it is as a spray. Figure 2 is an exploded view of the two most popular valve designs. Male valves are characterized by having stems that are separate from the actuators. Figures 3 and 4 give a more detailed view of these valves.

Body/Spring

The valve body, or housing, contains a SS-302 spring that acts to close off the valve when the finger pressure is released. This is a major safety feature. It may also carry a tailpiece orifice and often a vapor-tap orifice. The tailpiece orifice is often not an orifice at all, but instead a 1.57- to 2.03-mm (0.062- to 0.080-in.) hole in the end of the dip tube to protrude into the head space, then only gas will be emitted. A number of corrective steps have been taken, over the years, to resolve this problem. The first was to place a directional dot (typically using a black "Magic Marker") on the crown of the mounting cup, to indicate the curvature of the dip tube, and then align the actuator to it. In that way the end of the dip tube would always be in the lowest position when the can is tilted (see Figure 5). Another method was to use a so-called "Jumbo dip tube," where the typically 7.25 mm (0.285 in.) inside diameter dip

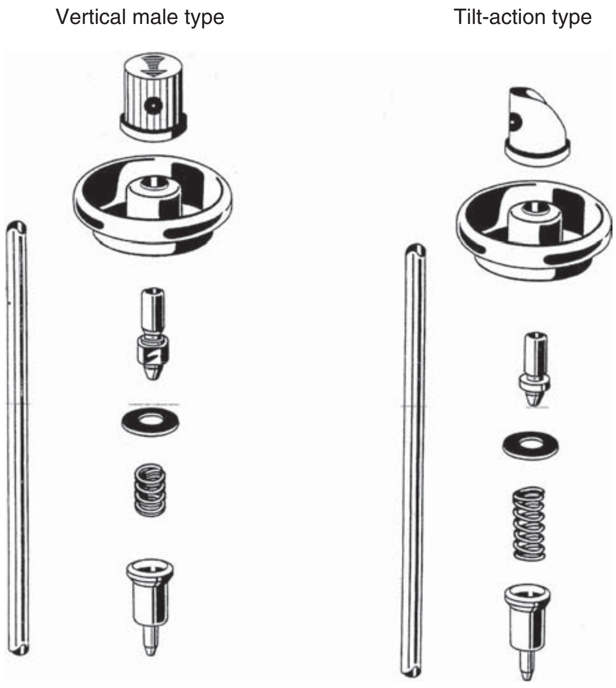

Figure 2. Exploded view of aerosol valve components.

tube could hold up to about 8 g of product. In this case the can could be inverted and operated for several seconds before the dip tube emptied and gas began to come out. This is a preferred option for disinfectant bathroom cleaners.

Another method is the "Spray Any Way" valve, where a 1.00-mm (0.039-in.) stainless steel ball is placed in a tiny runway. When the can is inverted the ball travels to the opposite end of the runway and seals off the orifice served by the dip tube, while opening one at the valve body. Liquid product then flows directly into the valve body, allowing the aerosol to function normally. This unit is an accessory that attaches to (or is made a part of) the valve body. The cost of the valve is increased accordingly.

The final approach is to use a compartmentalized aerosol package. In this case, one can select one of three versions: a piston can, a bag-on-can, and a bag-on-valve. Most generally, the propellant is separated from the product, being gassed into the "exo-space"—under the piston, or around the bags—so the product is continually squeezed and emerges as such when the valve is operated. Products of this type include cheese spreads, caulking compounds, and sunscreens. In some cases a small amount of low-pressure gas (typically 90% isopentane and 10% isobutane) is pre-mixed with a gelled aerosol product. When these products are used, the gel emerges through a foam-type spout. It is generally both clear and tinted blue or green. Upon stirring with the fingertip, the positive yield point of the gel is reduced so that the dispersed propellant can form a nice white puff of foam. This type of product has now captured the bulk of the shave cream market, with sales of over 200 × 106 cans per year in the United States during 2006.

Mounting Caps

The vast majority of aerosol valves are supplied in nominal "one-inch" (25.4-mm) mounting cups. These cups are designed to fit into the nominal "one-inch" hole of aerosol cans. A crimping operation is then used to hermetically seal the valve cup to the can. An elastomeric gasket is required in order to obtain good sealing, since metal-to-metal interfaces will always leak. In the past, the industry used a "Flowed-In" neoprene gasket, but this has almost totally disappeared worldwide, in favor of alternative gaskets. There are now three gasket choices: the 1.0- to 1.15-mm (0.039- to 0.045-in.) thick lathe-cut gasket, of buna, neoprene, or butyl rubber; the 0.356-mm (0.014-in.) thick PE-Sleeve; and the 0.203-mm (0.008-in.)-thick PP-laminate. The last two gaskets must fit between the vertical wall of the valve cup and the can bead, which means that the metal valve cups must be downsized accordingly. If the typical wall diameter of a valve with a PE-Sleeve is to be 25.25 mm (0.994 in.), then the mounting cup itself must be 24.54 mm.(0.966 in.).

Mounting cups are made of different profiles (flat, conical, and cone-conical) and from different metals (tinplate, heavier tinplate, and aluminum), according to specific requirements that relate to product pressure, corrosion aspects, and so on. The usual tinplate-mounting cup is about 0.267 mm (0.0105 in.) thick, while those of the softer aluminum metal are about 0.406 mm (0.0160 in.) thick. The heavy-duty, thicker tinplates are reserved for high-pressure aerosol formulations, including most of those based on U.S.DOT exemptions. Mounting cups with flat bottoms often distort slightly, becoming more conical, during the hot water-bathing of aerosols during production, when pressures usually get into the 8.27- to 12.41-bar (120- to 180-psig) range. This sometimes poses a problem, where a plastic fitment, such as a large spray-head or spout, may have to fit onto both the mounting cup (for attachment) and the stem (for actuation). The conical valve cups do not deform appreciably in this manner and are generally preferred. In fact, some valve-makers no longer offer the flat-bottomed mounting cups.

The hermetic seal between valve cup and can is accomplished by the use of a crimping machine. They are usually rotary devices, where an eight-segment collet descends to a precise depth, after which a mandrel spreads the eight tines to a precise circumscribing diameter. This action compresses the gasketing material and creates the seal. For the popular combination of a tinplate aerosol can and a tinplate valve with a PP-laminate, the preferred crimping dimensions are: diameter 27.27 mm (1.074 in.) and depth 4.65 mm (0.183 in.). These will vary slightly, according to the type of can and valve cup. The usual tolerance is only ±0.13 mm (0.005 in.) and the range for a given can should not exceed 0.178 mm (0.007 in.).

The effectiveness of the crimping operation is checked during hot water-bathing, after the can has passed through the gasser and been pressurized. If bubbles of gas are seen through the hot water, the can is extracted and discarded. Actually, cans leaking gas at rates of less than about 12 g per year produce gas bubbles so infrequently in the hot water bath that they are not detected by the operator.

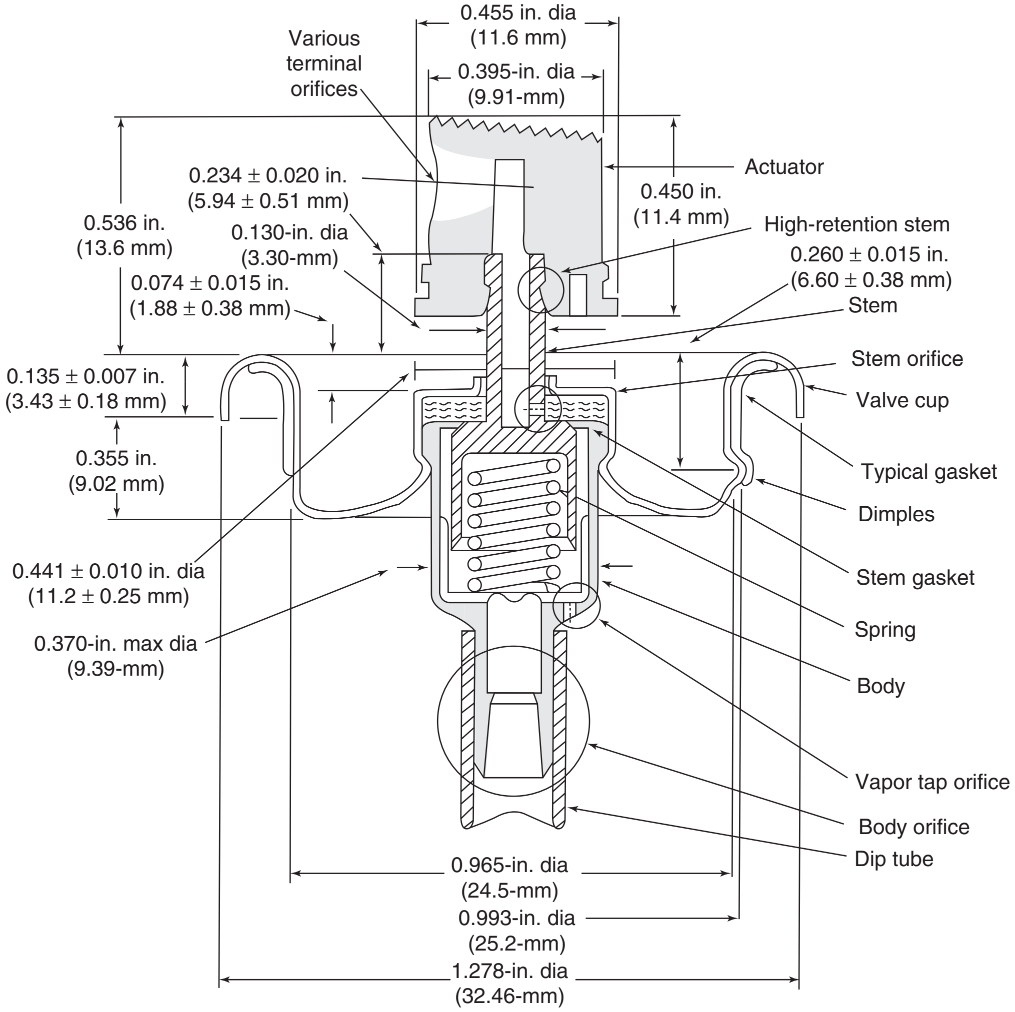

Figure 3. Aerosol valve: "one-inch" cup, vertical action, "male" type.

Dip Tube

The aerosol valve will generally have a dip tube, unless the can is designed to be used in the inverted position, such as whipped creams and the various mousse products. Also, for compartmentalized aerosols, there is no need for a dip tube, since the product is squeezed up against the valve regardless of can position.

Dip tubes come in essentially three sizes: capillaries, regular, and "jumbo." The capillary tubes are inserted into the valve body tailpiece, while the larger tubes are stretched over the body tailpiece. Some tailpieces are designed with encircling barbs, which look like fish hooks in cross section. They hold the polyethylene dip tubes so firmly that they stretch before they can be pulled off. This feature is used most frequently for those high-solvent aerosols (such as paints) that tend to swell dip tubes so that their connection with the valve body is loosened. On the other hand, the capillary dip tubes, which are generally made from either polypropylene (PP) of an alloy, such as PE/PP, tend to swell more than the nylon or delrin valve bodies when in contact with strong solvents. This makes their connection even tighter. Capillary dip tubes are now often used for products such as air fresheners and water-based insecticides, which form large layers of propellant (top) and concentrate (bottom) upon standing for a few minutes. If a regular diameter dip tube were to be used, when the can is shaken just before use, the main product would be redispersed, but that in the dip tube would tend to remain layered. In such cases the first product out of the aerosol would be the propellant, followed by the concentrate and then followed by the dispersion of both. The very small internal volume of the capillary tube minimizes this effect, and the valve generally also has a vapor tap orifice, which serves to help spray the tiny bit of concentrate. Also, the vapor-tap allows the contents in the dip tube to drop back down to the liquid level in the aerosol, after it is used. This further reduces the layering problem, so that it is never noticed by the consumer.

Actuator

The final valve component is the actuator. It is often the most critical. Originally, all actuators were small and had either straight bore, outward flaring, or inward flaring

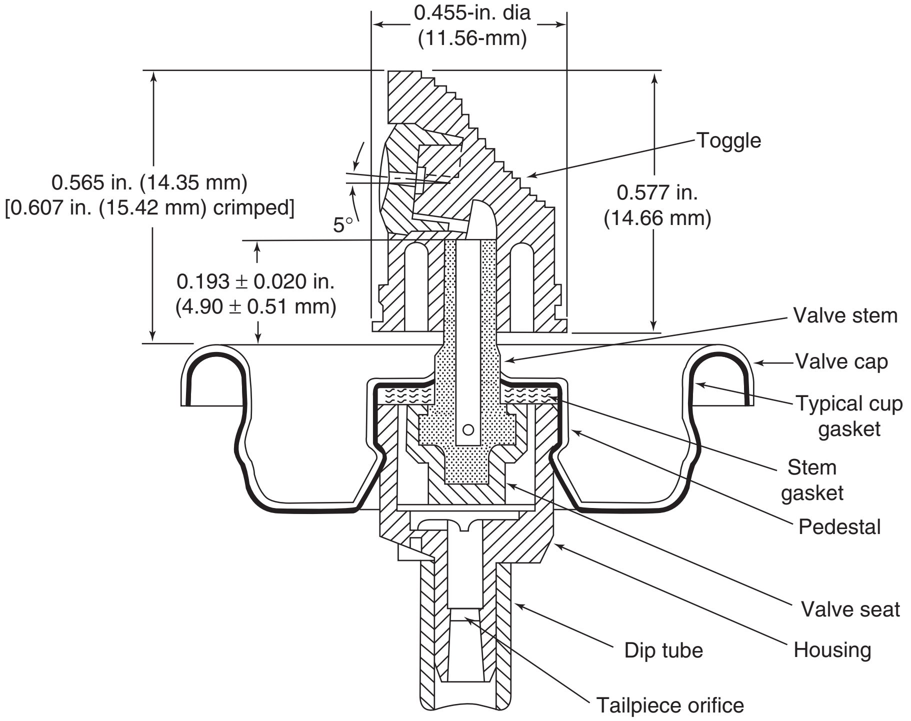

Figure 4. Aerosol valve: "one-inch" cup, toggle-action type.

(reverse taper) orifice designs in various diameters. While these are still available, many are now of the mechanical break-up (MB-U) design. These first came to the market in 1953, on cans of BonAmi Glass Cleaner. They utilize the swirling action caused by directing the liquid product through (typically) four tangential channels that feed a central straight-taper or reverse-taper terminal orifice. Most aerosol emerge from cans at speeds of about 6.1–9.2 m/s. (20–30 ft/s), so it follows that the product revolutions per minute within the terminal orifice is extremely high. The centrifugal force is correspondingly high in the emerging stream, which causes it to break up into a spray. By controlling the length of the terminal orifice (land), its diameter, and other aspects, sprays can be created with varying conical shapes, delivery rates, and other features. Mechanical break-up valves are usually made by adding an insert disc to the main structure of the actuator. The discs are of nylon and fit very snugly into the actuator opening. This is the only way to provide the necessary channels and swirl chamber. For spray uniformity, all the key dimensions must be produced with a high degree of precision.

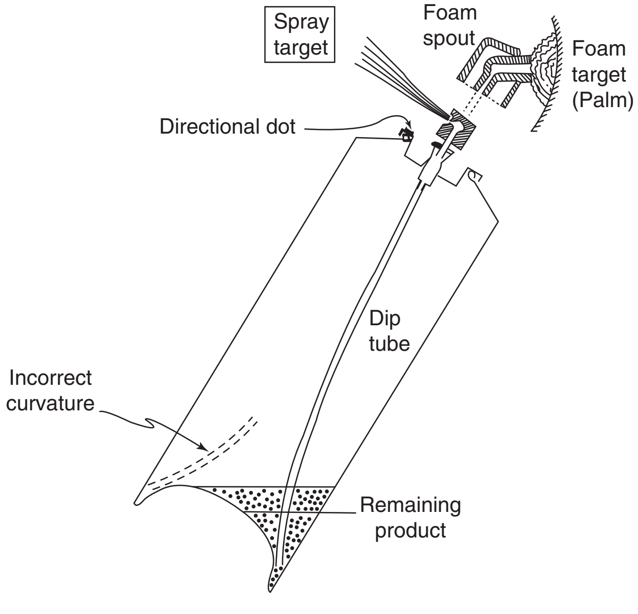

Figure 5. The importance of directional dot on the crown of the valve cup.

Another type of actuator is the foam or gel spout. This usually consists of a single large terminal orifice, but in some cases an attractive grid may be utilized. The usual foam spout is operated by pressing downward, although there are some that must be pressed sideways. They are always larger than the simple spray actuators.

In recent years there has been a major transition from small spray-heads and foam actuators to large fitments that incorporate these components. The fitment may cover the entire valve cup, or even the entire top of the dispenser. Quite often they make the inclusion of a cover, or hood, unnecessary. This is a plus for the consumer, who need no longer remove and reapply the cover each time the product is used. There is another marketing aspect. Consumers are still somewhat reluctant to purchase aerosols, probably harking back to the "CFC/ozone" issue of the mid-1970s, and all the bad press that accompanied it. Recently, 61% of survey responders said they would rather buy a non-aerosol, if it was just as good as the aerosol. Marketers have found that consumers tend to identify aerosols by their characteristic valve cups and perhaps the top contour of three-piece tinplate cans. By the use of large fitments, designed to cover up these attributes, the aerosol no longer appears mildly offensive to some consumers. As a corollary, since the press condemned “spray cans,” most consumers think cans that produce foams and gels are not aerosols.

The aerosol valve is a component of almost infinite variability, when one considers all the parts and all the variations of these parts. One valve executive calculated that his company could theoretically produce over 150,000,000 variables, not counting a diversity of dip tube lengths. Fifty years ago, valves were of very low quality and almost twice as costly as they are today. Now, valves are produced with so many online control checks and manual inspections that their quality is unsurpassed by any other aerosol chemical or component. They have an enormous breadth and versatility. For example, their delivery rates can be adjusted from 0.24 to 160.00 g/s. Particle sizes can range from mean diameters of about 2.3 to 125 μm. They certainly do their part in making the aerosol packaging form the basis for finely tuned, reliable products.

PRINTING: GRAVURE AND FLEXOGRAPHIC

Arthur J. Taggi

DuPont Printing and
Publishing, Wilmington,
Delaware

The four main printing processes are as follows: (*1*) planography or lithography, (*2*) intaglio or gravure, (*3*) porous or screen, and (*4*) relief (flexography or letterpress). In general, the process of printing involves generating two physically different areas, the printing or image area and the nonprinting, or nonimage, area. In relief printing, whether flexographic or letterpress, the image or printing area is raised above the nonprinting area. Ink is applied to the raised surface, which is brought into direct contact with the substrate on which the print is to appear. The flexographic relief printing process is used to print on a variety of paper and plastic packaging materials as well as for some magazines and newspapers, labels, and business forms. Water-based or solvent inks are used.

The most typical method of intaglio printing is the gravure process, which uses a nonprinting area that is at a common surface level while the printing area is recessed, which consists of wells etched or engraved, usually to different depths. Solvent inks are transferred to the printing surface, and a metal doctor blade is used to remove excess ink from the nonprinting surface. Ink is transferred directly to the substrate. Gravure printing is used to print long-run magazines, cartons, bags, labels and gift wraps, as well as plastic laminates, floor coverings, and even textiles. Other types of intaglio printing, such as steel plate or copper-plate printing, use metal plates that are hand- or machine-engraved or chemically etched to produce the lines and characters of the printed piece.

Direct printing refers to the transfer of the image directly from the image carrier to the paper. Most letterpress and gravure printing are done by this method. In indirect or offset printing, the image is transferred from the image carrier to an intermediate rubber-covered blanket cylinder, from which it is transferred to the paper. Letterpress and gravure can also be printed by the offset method.

Images are defined for these printing processes in a number of different ways. The images are produced on a support by chemical, mechanical, or increasingly by electronic imaging means. As of this writing (c.a., 1996), the greatest number of plates and images are made by photomechanical methods. These systems are characterized by photographic images and light-sensitive coatings that, by using chemical etching or other treatments, lead to the formation of a printing surface. Increasingly, however, this printing surface is produced directly by electronic imaging without the traditional photographic intermediates.

Although four types of commonly used printing exist, gravure and flexographic printing are widely used in packaging printing. These methods are considered in more detail in the remainder of this article.

GRAVURE

The gravure printing process, sometimes called *rotogravure*, uses a recessed-image plate cylinder to transfer the image to the substrate. The plate cylinder can be either chemically etched or mechanically engraved to generate the image cells. The volume of these cells determines the darkness or lightness of the image. If an area is darker, then the cells are larger; if the area is lighter, then the cells are smaller.

The gravure market can be considered to comprise three approximately equal segments that are as follows: publications, packaging, and specialty printing. In publications, gravure retains a significant proportion of the long-run magazine market. In packaging printing, in which paperboard and repeat-run cartons are encountered, gravure is the ideal process. The cylinder lasts virtually forever, and color consistency is high. The final third of the gravure market is specialty printing of such items as wallpaper, gift wrap, and floor coverings.

The fundamental strengths of gravure are that the process provides consistent color throughout long print runs, and, because of its ability to apply heavy ink coverage, can be used to print high-quality work or to print on a lower grade of paper than offset lithography while maintaining acceptable print quality.

In contrast, the primary process disadvantages of gravure are long lead time, high cost of manufacture for gravure cylinders, generally long press make-ready times, and environmental hazards associated with the use of solvent-based inks. These disadvantages need to be eliminated if the technique is to remain competitive.

The gravure printing process is based around an inking system that is extremely simple, which provides a high degree of consistency, particularly with regard to color printing. This consistency is difficult to match using other printing techniques. The system, shown in Figure 1, uses a liquid ink that has traditionally been solvent-based, although environmental pressures have also resulted in the development of aqueous-based inks. The environmental concerns associated with the use of toxic and flammable solvent inks are being addressed by ink manufacturers, who are working on the development of water-based products.

The gravure cylinder sits in the ink fountain and is squeegeed off with a doctor blade as it rotates. The impression cylinder is covered with a resilient rubber composition, which presses the paper into contact with the ink in the tiny cells of the printing surface. The image is thus transferred directly from the gravure cylinder to the substrate. Frequently, an electrostatic assist is used to help the ink transfer from the gravure cylinder to the substrate (1).

Gravure inks are composed of pigment, resin binder, and—most frequently—a volatile solvent. The ink is quite fluid and dries entirely by evaporation. In multicolor printing, where two or more gravure units operate in tandem, each color dries before the next is printed. This process is seen as a particular advantage for gravure over, for example, offset, where the placing of wet ink on wet ink can lead to inferior print quality. The wet ink on dry and the simple ink train, together with a long-run-length capability, have led to the belief that gravure sets the standard for high-quality printing.

Traditionally, a gravure cylinder was prepared chemically by using a chemical-etch process. Since the early 1970s, electromechanical engraving, in which a diamond stylus cuts the cells into cylinders, has become the preferred approach (2). Newer approaches include laser- and electron-beam engraving.

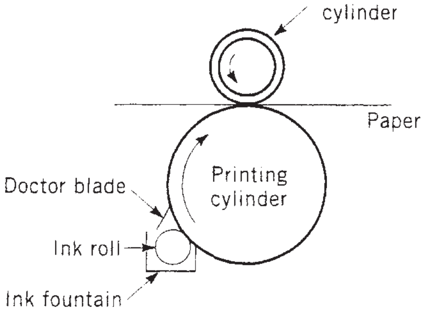

Figure 1. Gravure printing system.

In gravure, all elements within the image are screened. This screening is in contrast to flexographic and lithographic plates, which can contain true solids as well as halftones.

In the chemical process for preparing gravure cylinders, a light-sensitive film, typically gelatin that contains dichromate salts and carbon black, is exposed first through a gravure screen to establish the cell pattern, then through a continuous-tone photographic negative, which hardens the carbon tissue in the light exposed areas in proportion to the amount of light that passed through the negative. The exposed tissue is attached to a fresh copper-plated surface of a gravure cylinder. The unexposed gelatin is washed out, and the cylinder placed in a chemical etching bath that dissolves away the copper layer in proportion to the thickness of the remaining hardened gelatin layer, thus creating the ink-carrying cells. Since the cell pattern is established using a screen pattern, all cells are the same area, but vary in depth. The surface of the etched cylinder is then chrome-plated to impart wear resistance. Gravure cylinders can be recycled many times by removing the copper layer and replating.

In the case of electromechanically engraved cylinders, an electronic scanner reads the density of the photographic negative pixel by pixel, and translates the density into an electromechanical impulse that drives a diamond stylus into the soft copper layer of a cylinder. The completed cylinder is then chrome-plated and is ready for use. Because of the shape of the diamond stylus, the cells produced vary both in depth and area depending on how far into the copper surface the stylus is driven (3).

Electromechanical engraving avoids all the complexity, hazards, and toxic wastes involved with using chemical etching techniques, at the cost of increased capital investment in the engraving equipment. Electromechanical engraving is a slow process, but this is offset by the ability to use digital data, which better fits a modern electronic prepress workflow. Newer systems drive the engraving stylus (or multiple styli for improved efficiency) directly with digital data from an electronic prepress system, or engrave a cylinder using a high-power laser (4).

FLEXOGRAPHY

Flexography is a variation of letterpress printing used mainly for packaging applications. It is characterized by the use of an elastomeric printing plate, fast-drying inks, and an inkmetering (anilox) roll system. The principal advantages of flexography are reflected in the markets in which it is most often used. Flexo's ability to print on a wide range of substrates, which include plastic films, foils, coated and uncoated paper, paperboard, and corrugated board, make it ideal for many packaging uses as well as for printing continuous patterns, such as wallpaper and gift wrap.

Other advantages include low cost and short cycle time, the ability to change cylinder diameters to reduce stock waste, precise ink transfer with minimum on-press adjustments, and the ability to print one layer and laminate another layer over it in a continuous process.

Limitations of flexography include higher highlight-dot gain (spreading of halftone dots in low-density areas) and lower solid density as compared to gravure and offset lithography. The increased dot gain results from a combination of printing-plate deformation and ink spread on press. Another limitation is the inability to print uniform solids and halftones using the same plate without substantial make-ready. The increased pressure required for uniform solids increases dot gain in highlights.

A typical flexo print station is shown in Figure 2. The three basic types of flexographic presses are shown in Figure 3. Dryers generally separate individual print stations. In the stack press (Figure 3[a]), individual print stations are in sequence one on top of the other. This press is used primarily for paper and laminated films. Advantages include accessibility to print stations and the ability to reverse the web, thus allowing printing on both sides in one pass. In the central impression press (Figure 3[b]), the print stations are distributed around a large central impression cylinder, which is precisely geared to each print station and, thus, improves the registration. This press is used mainly to print high-quality, wide-web films. The in-line press (Figure 3[c]) is used mainly for printing corrugated and folding carton as well as for narrow-web tag and label.

The heart of the flexographic printing system is the anilox roll, a steel cylinder optionally coated with ceramic and engraved with a pattern of pits or cells. The function of the anilox roll is to meter a uniform film of ink from the ink fountain to the printing plate without the need for continuous adjustment. Many types of anilox rolls exist, distinguished by the mode of engraving, the materials of construction, the pattern of the cells, and the cell geometry. Anilox-roll variables include the screen count and screen angle as well as cell volume. Anilox rolls fall into two main families, the mechanically engraved chrome rolls and laser-engraved ceramic rolls.

Mechanically engraved chrome rolls are steel cylinders engraved by a precision tool. Following engraving, the rolls are plated with copper, which acts as a bonding layer, and chrome, which hardens the surface. Mechanically engraved chrome rolls have been the mainstay of the industry for many years. However, on the introduction of the reverse-angle doctor blade, which better controls ink metering, and the subsequent wear problems, the industry has been steadily shifting to laser-engraved ceramic rolls.

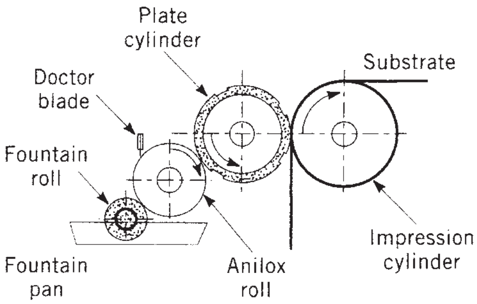

Figure 2. Flexographic printing station, where the fountain pan supplies ink to the rubber fountain roll, which, in turn, supplies ink to the anilox roll. The optional doctor blade removes excess ink from the surface of the anilox roll so that it transfers a uniform layer of ink to the printing plate. The printing plate then transfers this layer of ink to the substrate, which is supported by the impression roll.

Ceramic rolls are steel cylinders that have been coated with a ceramic, usually chromium oxide, layer and then engraved with the beam from a high-energy laser. By controlling the energy and timing of the laser pulse, the depth and diameter of the anilox cell can be tightly controlled. Unlike mechanically engraved rollers, the volume of laser-engraved rolls is independent of screen count, which allows a variety of rollers with a wider range of volumes and screen counts. The ceramic coating reduces doctor-blade wear by an order of magnitude, thus prolonging the life of the roll.

Flexography typically employs low-viscosity fast-drying inks. These inks are dispersions having 25–35% solids content, which consist mainly of nearly equal parts of a pigment or pigments dispersed in polymer resins. These resins form the ink film and attach the pigment to the substrate. Inks may also contain additives such as slip agents, surfactants, plasticizers, and antifoams. The solvent portion is usually a blend of alcohols and acetate esters. Drying rate can be varied by changing the ratio of acetate to alcohol in the solvent.

For aqueous inks, the resins are water- or alkali-soluble or dispersible, and the solvent is mostly water containing sufficient alcohol (as much as 25%) to help solubilize the resin. To keep the alkali-soluble resin in solution, pH must be maintained at the correct level. Advances include the development of uv inks. These are high viscosity inks that require no drying but are photocurable by uv radiation. In these formulations, the solvent is replaced by monomers and photoinitiators that can be crosslinked by exposure to uv radiation. The advantage of this system is the complete elimination of volatile organic compounds (VOCs) as components of the system and better halftone print quality. Aqueous and uv inks are becoming more popular as environmental pressure to reduce VOC increases.

Three primary types of flexographic printing plates are used and are as follows: molded rubber, solid-sheet photopolymer, and liquid photopolymer.

Initially, flexographic printing plates were made of handcut or molded rubber. The basic steps of rubber platemaking include preparing an engraving by exposing a photoresist-coated metal plate to uv light through a photographic negative, which washes away the unexposed resist with solvent, and acid-etching the unprotected metal surface, molding a phenolic matrix board using the metal engraving, and finally molding the rubber plate using the matrix mold.

Molded-rubber plates transfer ink well and, when large numbers of identical designs are needed, are inexpensive to make. However, environmental concerns over the use of acidetching solutions to prepare the metal engraving, poor thickness uniformity, and poor dimensional stability of the molded plates are disadvantages. Photopolymer plates, both solid and liquid, have replaced most engravings.

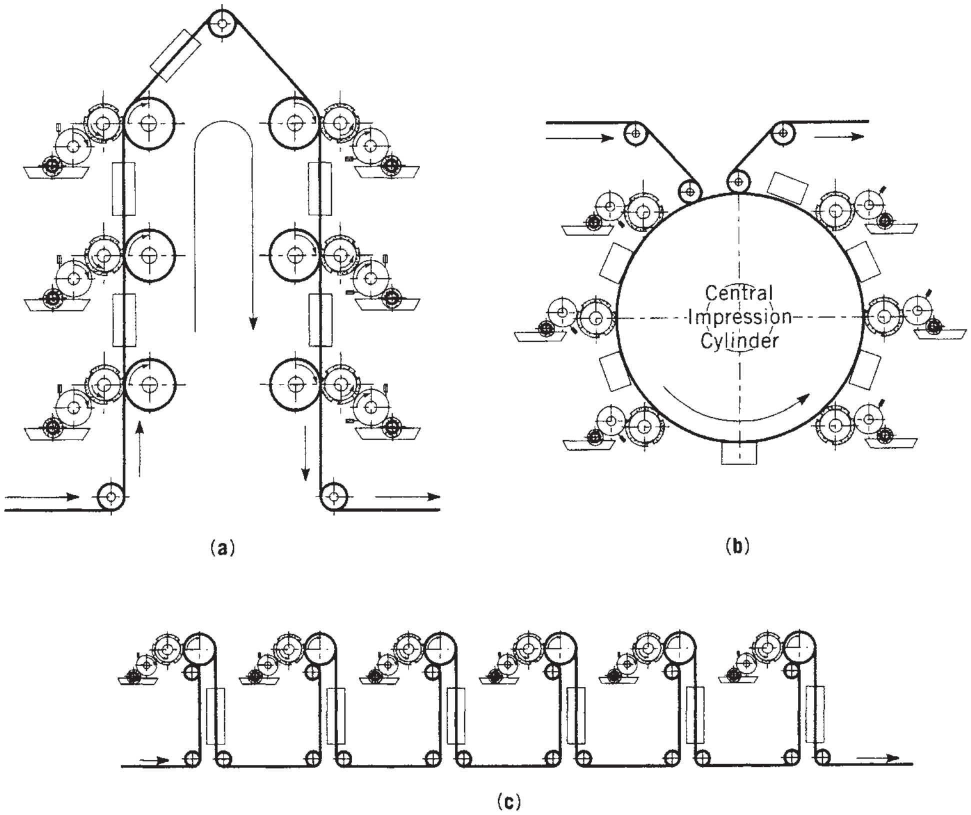

Figure 3. Schematics of flexographic presses, in which the arrow designates the direction of the web flow and θ represents an interstation dryer: (**a**) stack press; (**b**) central impression press; (**c**) in-line press.

Solid photopolymer plates consist of an elastomeric, photosensitive layer bonded to a polyester support. The plate formulation usually contains an elastomeric binder that provides the required properties of flexibility and resilience. The plates typically contain acrylic or methacrylic monomers, sensitizers, and photoinitiators, which, in the presence of sufficient ultraviolet (uv) energy, polymerize to reduce the solubility of the material. Photopolymer plates are made by exposure to uv through the back of the plate to consume stabilizers and define relief height, front uv exposure through a photographic negative (which is usually halftone-screened) to form the image, removal of unexposed areas with a solvent to form the relief image, drying to remove solvent, overall exposure to eliminate surface tack, and postexposure to more crosslink and toughen the plate (5). Advantages of solid-sheet photopolymer plates over rubber include improved dimensional stability derived from the polyester support, longer print run length, improved print quality that includes more predictable rendition of four-color process images, and better thickness uniformity.

Newer technology involves water-processable photopolymer plates. Many platemakers and printers are eager to switch to water processing in order to eliminate volatile organic solvents. The chemistry and process of use are similar to that of the solvent-processable plate, except the plate is formulated with water soluble materials.

The liquid photopolymer plate system is used successfully in corrugated and newspaper markets. The platemaking process is similar to the solid-sheet photopolymer plate except that before exposure to uv, the liquid photopolymer, which consists of liquid rubber oligomers and crosslinkers, is sandwiched between two layers of transparent plastic film to define a nominal and uniform thickness during exposure. Special equipment is used to meter the liquid plate material onto the bottom sheet while covering the top surface with the other plastic sheet. The platemaking process is similar to that of the solid photopolymer plates (6). Lower cost of materials is the main advantage over solid plates. Disadvantages include inferior thickness uniformity and limited run life.

As printers turn more to electronic prepress methods, direct writing of digital data to printing plates will increase in importance. Relief images can be made by laser-engraving a rubber-coated cylinder. The rubber layer is selectively ablated by a high-energy laser beam, which leaves a relief printing image. This method eliminates the need for a photographic negative and is ideal for printing continuous images. Laser imaging of rubber cannot reproduce the fine screen rulings obtainable with solid plates. Other direct digital imaging systems that use photopolymer plates with integral masks also have been shown (4).

PRODUCT QUALITY AND INFORMATION TRACEABILITY

Gilles Doyon
Marco Lagimonière
Research Branch
Agriculture and Agri-Food Canada, Ministry, Saint-Hyacinthe, Québec, Canada
Pierre Veilleux
GS1 Canada, Anjou, Québec, Canada

GENERAL INTRODUCTION

The packaging industry on a worldwide basis was estimated at about $460 billion, with the United States accounting for $127 billion or 28% of the global market (1). The quality characteristics or functions of the packaging and its material were described as follows: for microbial safety, chemical inertness, printing properties and ink support, protection against adulteration, advertising-readability, recyclability, ergonomic, convenience. Also, important is to provide some “intelligence” or interaction with the environment with electronic communications means for traceability as well as advanced logistical applications (2). These functions are critical elements in combination with our ingredients, fresh/raw, processed and further processing of food. The food that we consume or preserve, distribute, and trade at local, national, and international levels must be nutritious and safe and must respect specifications in composition and safety under national and international standards. Packaging is and remains a major constituent in our logistic systems, and some parts or surfaces are in direct contact with ingredients and foods. Moreover, many different clients and customers expect implicit or explicit quality characteristics and then either accept or reject the products or services.

Small- and medium-size enterprises, for market competitiveness, have to face many challenges to be successful. They have to (i) master the acquisition and management of the information, (ii) master knowledge of the demands now and in the future, (iii) master conception capacity, that is, means of projects management, value added analysis, ergonomics, safety and design new products, processes, and packaging; (iv) master production and organization skills, and (v) understand and participate in the integrated food supply chain (i.e., pre- and post-plant efficient), logistics, and traceability of necessary information; also relevant was automatic data collection, where the database had rapid response to recall or security threats.

New business situations arising for top management are often seen as new risks, some threats, or more opportunities. Their assessment and resolution could mean new business in product, services and partnership. Therefore, one needs to identify and prioritize them by type, the frequency of occurrence, as well as the level of monitoring with any actions readiness for now and for the future. No one desires to encounter critical risks and the consequences for nonconformity in quality assurance, poor logistics, and breach in traceability of their entities (i.e., packaging and information). In reality, the risks are the following if we do not master traceability: (a) our personal safety and well-being of our employees; (b) our company’s reputation, products, market (identify preservation, IP), and enterprise competitiveness; (c) our supply chain, production, purchasing power, processing capacity and capability, our total overseas distribution chain; (d) our quality assurance and monitoring systems (i.e., HACCP, GMP), traceability, and communication (database and telecommunication); (e) our liability and financial limits; (f) our national regulatory compliance and policy impact levels; (g) our loss of scientific, technological, innovative, and intellectual properties; (h) our loss of personal and scientific independence, as well as territorial and cross-cultural integrated autonomy; (i) deterioration of the environment, the public health as well as for my animals, plant, fish, poultry, and forest including air, water, and soil; and (j) our country’s loss of “brand recognition” and global perception of high quality and safety of foods.

Today’s quality assurance (QA) and packaging departments are involved jointly in research, development, and adaptation (RDA), and most of them are involved in HACCP and setting up traceability tools, database, detailing procedures, and so on, for client requests, for Regional, Federal Inspection, and Certification Agency, or for proof documents for exports.

TRACEABILITY TERMS, DEFINITIONS, CONCEPTS, PERSPECTIVES INCLUDING WORKING PRINCIPLES/ GUIDELINES AND INTERNATIONAL STANDARDS

To facilitate understanding of this chapter and the literature information, we present a list of abbreviations, definitions, and terminology most encountered or standardized.

Activity	A specific pursuit in which a person partakes. Also, a function to be performed. A piece of work that one must do (task). An organizational unit for performing a specific function.
ADC/AIDC/AIS	Automatic Data Capture/Automatic Identification and Data Capture /Automatic Identification System.
BC	Bar code/Bar coding. A bar code symbol is a pattern of bars (black or otherwise) and spaces (white or otherwise) following specific standards that, when read by a scanner, interpret the pattern in characters and numbers and that, when called up in a computer, provide various information, depending on the application, the industry and the type of code. Today, we have linear or one-dimensional codes, two-dimensional (2D) codes like PDF-417, Reduce Space Symbology (RSS or called DataBar), and three-dimensional (3D symbology) or bumpy BC exit.
EAN	European Article Number; an 8- or 13-digit code used by companies outside North America.
EAN International	Based in Brussels; a member organisation that jointly manages EAN. UCC system with UCC.
EDI	Electronic Data Interchange.
EDP	Electronic Data Processing.
ERP/MRP	Enterprise replenishment panning/ Material resource planning.
EPC	Electronic Product Code, which identifies the manufacturer, product category and individual item.
EPC Global	The joint venture of the EAN International with the Uniform Product Council, representing 100+ member organizations worldwide. It is based in Brussels and a member organization that jointly manages EAN. UCC system with UCC.
eXML	Extensible Mark-up Language.
GAP/GPP/GMP/ GLP	Good Agriculture Practice/Good Production Practice/Good Manufacturing Practice/Good Laboratory Practice.
GS1	Global Standard 1, a worldwide organisation.
GLN/GTIN	Global Location Number/Global Trade Item Number.
GPS/GIS	Global Positioning System (satellites or land cellular towers)/ Geographical or Geo-referenced Information System.
HACCP	Hazard Analysis Critical Control Points. Now under a new standard: ISO-22000 (2005).
ISO-8402	Quality Management and Quality Assurance: Vocabulary (1994). Is generally recognized and of current use. Some definitions are as follows:
1. Entity	An item that can be individually described and considered — that is, an activity, a process, processes (business like or how we do activity…), a product, an organization, a system, a person, or any combination thereof.
2. Organization	A company, a corporation, a firm or institution that could be public or private.
3. Procedure	A specified way to perform an activity. In many cases, procedures are documented (i.e., quality system procedure). It contains the purpose and the scope of an activity; what shall be done and by whom; and when, where, and how.
4. Process	A set of interrelated resources and activities that transform inputs into outputs. Here, resources may include personnel, finance, facilities, equipment, techniques, and methods.
5. Product	A result of activities or process, includes service, hardware, processed material, and software, or a combination thereof. Also, can be an intangible form as knowledge or concepts.
6. Quality (Q)	Totality of characteristics has an entity that bears on its ability to satisfy stated or implied needs.
7. Quality assurance (QA)	All the planned and systematic activities implemented within.
8. Quality control (QC)	Operational techniques and activities that are used to fulfill requirements for quality (to achieve economical effectiveness).
9. Quality management (QM)	All activities of the overall management function that determine the quality policy, objectives, and responsibilities, as well as implement them by

	means as quality planning, quality control, quality assurance, and quality improvement within the quality system.
10. Quality system (QS)	Organizational structure, procedures, processes, and resources needed to implant quality management. It is there to satisfy the intended managerial needs or costumers or regulatory agency, in most cases.
11. Record	A document that furnishes objective evidence of activities performed or results achieved. Could be handwritten, paper format, or electronic medium.
12. Traceability	The ability to trace the history, application or location of an entity by means of recorded identifications. In a product, it may relate to the origin of material and parts, the product processing history, and the distribution and location of the product after delivery (in combination with ISO-9001(2000) and ISO-22005).
13. Lot	The ensemble of units of the same reference that is decided to produce, manufacture, or package consecutively, under identical conditions. Or, the material we just bought, which, we can reference, with our specifications and purchasing order. Other definitions exist.
Logistic	The ensemble of tasks and activities that concur or converge to bring order to physical flows within an enterprise—that is, raw materials, various components, fabrication, operational research. It includes the purchase, stock handling, storage, client recalls, sales, administrative tasks, and quality management as well as information fluxes.
Pervasive technology/ Ubiquitous computing	Pervasive is what is going through, diffuse throughout every part of, and the word Ubiquitous means existing or being everywhere, constantly encountered or widespread. Pervasive computing is the trend toward increasing ubiquitous computing devices in the environment brought about by convergence of advance electronic, portable devices, wireless technology, and the internet interactions. Pervasive or ubiquitous computing within the context of Adaptive Business Network (ABN) is more than the ability to access information virtually anywhere and at any time. It provides a business with the ability to sense and respond to changing market more quickly.
PLU	Price look-up. Referring to the International Federation for Produce coding or IFPC, for fresh fruits and vegetables. A very small sticker on the produce or tag unit.
RFID	Radio-Frequency Identification or/and Radio-Frequency Identification and Detection
Risk (s)	The probability of unpleasant event (s) happening.
SSCC	Serial Shipping Container Code.
System & Process(es)	A system is the summation of all processes capable of accepting multiple situations without variations. Must be within limits to be under control. Process(es) mean all methods, various means also, with required competences, and technologies transforming inputs into outputs with a value added: including material as well as information. If, integrated, means internally and with partners externally within the food chain of interest.
Traceability: Ascending/ Upstream	Ability to find all steps for a given lot of finish product, up to retail clients per se, the complete history up and down to the origin of all raw materials including packaging/ingredients. Many times call or refer to *Trace* or *Tracing Back*: If, I am the processor, Level "0".
Traceability: Descending/ Downstream	Ability to retrieve all steps for a given lot of finish product; the complete industrial utilization and its global distribution from its fabrication. Many times call or refer to *Track* or *Tracking*: If, I am the processor, Level "0".
Traceability: Proximity/ Internal	Ability to use mass balance and time stamp on continuous or controlled production batches. With my MRP and ERP (material resource/enterprise resource replenishment planning) we measure the state of optimization or

	not. One can use statistical probability, on that machine and that lot produced to provide information on quality, rework, incoming recall lot, etc. Rapid information on no mixtures of lots appended and no breakage in trace/links (product and pertinent information). Requires an operational database (DB).
Total Traceability	Combines the proximity, minimum one step backward and step forward, plus ascending and descending complete elements. So, one can determine its limits of traceability in the Food Chain. Find a package with its ID and the right information.
TRU	Traceable Resource Unit for batch and batch process, decided by system designer.
UCC	Uniform Code Council. It is based in the United States of America. Uniform Code Council jointly manages EAN.UCC system with EAN.

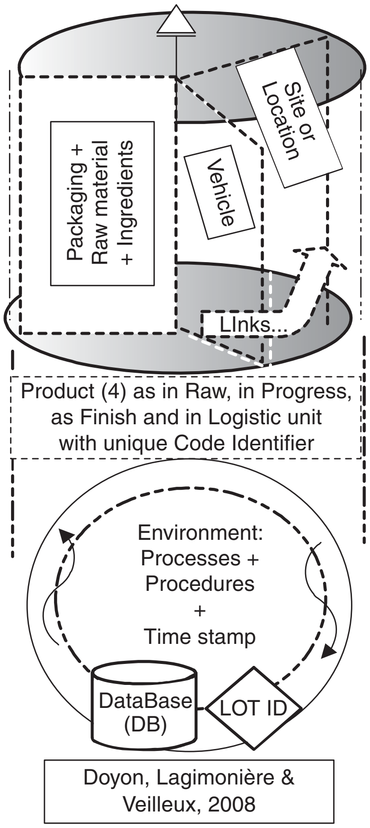

Figure 1. Multiple basic traceability components (16).

Looking at Figure 1, one can see the multiple, minimum, required components or elements (16) to construct an in-house traceability system as complement to any QA and HACCP systems. Sharing and retrieval of pertinent information "a step backward" and "a step forward" were a minimum.

Schaeffer and Caugant (3) presented in a practical guide the definitions, the applications, and the limits of traceability. The main interests were the communications, the commercial impact, and the usefulness, as a multifunction tool. Also, the guide is well-detailed with schematics, a glossary, and questions. A step-by-step methodology to build an internal and total system for the producers or the enterprises was presented. Examples were included.

AFNOR (4) was a soft-cover document that guides you through agri-food sector specific clusters or file sector. You find Good Manufacturing Practices (GMP) for the vegetable quality-model for reciprocal commitment between producers and organized production. It included identification and traceability; and the case for fresh potato production GMP and reception/delivery acceptance GMP was described to the reader. Finally, bar-coding operation and specifications/symbology RFID principles and operation were discussed.

Viruega (5) wrote a challenging book composed of three main segments: (i) evolution of traceability from 1960 to today; (ii) tools and methods, including an exhaustive terminology section; and (iii) "Market for Traceability," hybrid competence, and new perspectives. A new domain by itself for the 21st century was born!

Datamax (6) introduced, full traceability for the European fruit and vegetable supply chain. It was based on the well-structured and recognized European Article Numbering (EAN) family for products labeling to all points: grower/packer, shipper/logistics, and retailer levels. Food safety was defined as global concerns. The main thrust was toward GMO contamination, food-borne illness, and bio-terrorism threats. Minimum information available was specified for retail, shippers/logistics, and farmer/producer point. Schiefer (7), reviewed traceability and certification on quality assurance systems and major initiatives on policy agricultural groups and industries. The infrastructure was based on a large number of small production enterprises (farmers). It was a good tool to gain or ensure trust and certification. The *EAN International Fresh Produce Traceability Guidelines: 2001* (8) was presented and aimed at proposing a common approach to tracking and tracing produce by means of EAN.UCC internationally accepted numbering and bar coding. They defined the minimum requirements, and they accurately and timely identified products, origin, locations, with efficient recall. It was recommended to use common identification and communication standards. Pilot projects were completed in Belgium, Namibia, New Zealand, South Africa, and Spain. There was also a Bahamas supply chain traceability guideline. Additional information, the direct web access site, can be available under the correspondent reference number.

CPMA/PMA (9) was referred as a guide (edited in March 2005) to implementation, between PMA (US) and CPMA (Canada) Associations. It included an executive summary, data, and elements for traceability with two functions: mandatory and optional data. Mandatory encompassed two types: (a) master data that seldom change and (b) transactional data. This was in accordance with Can-Trace data standard. Data elements across the supply chain were divided into primary producers, processors, wholesalers, and distributors/retailers, including data to collect, to keep, and to share. Implementation approaches were (i) paper-based and human-readable; (ii) automatic-technology-based (bar codes) and (iii) based on RFID. The 10 best practices were also summarized. Additional information at the direct web access site can be available under the correspondent reference number.

Can-Trace (10) was a collaborative and open initiative committed to the development of traceability standard for food products in Canada. A second version of the Canadian Food Traceability Data Standard would be available by the first half of 2006. GSI Canada was the initiative's secretariat, the mission being to define and develop minimum requirements based on EAN.UCC system. Also, it offers global traceability information and links.

EAN.GENCOD (11) was a guide published in 2001 to act as common reference document for implementing traceable system between partners in a supply chain. It was composed of definitions from ISO-8402 with many explicit flows of information diagrams. It was composed of several chapters: traceability structural factors: essential issues, principles, and options; description of a traceability system; the implementation of it; conclusions; and case studies; also a bibliography, appendices, and a glossary are presented. Additional information at the direct web access site can be available under the correspondent reference number. EAN International (12) discussed a traceability management tools for agriculture, food, and beverage products as well as GS1 2006. The global traceability standard included supporting visibility, quality, and safety in the supply chain. The documentation from GS1 provided (a) global standards for bar coding, (b) global standard for electronic business messaging, (c) environment for global data synchronization, and (d) global standards for RFID-based identification. This was applicable across the supply chain. This new standard can be integrated with previous operational and detailed guidelines. Also, important was the new tools to view and navigate with the GS1 XML 2-02 language. Additional information at the direct web access site can be available under the correspondent reference number.

Furness and Smith (13) described the urgent need to harmonize a wide range of methods for identification and management of food entities. Here the individual stakeholder uses his own methods. It was critical to develop generic framework for all. The framework was explained in detail. The standardized approach was the EAN.UCC standards and guidelines.

Doyon et al. (14) put emphasis on terminology and definitions generally recognized in North America and with ISO-8402. Great discrepancies existed for lot definition and its understanding. Reliability, perception of value from the client, and probability of failure in the future was linked to spread of recall. Components of internal flow in processing and minimum components of trace system were schematized in color images.

Moe (15) explained fundamental features of traceability and adopted also the terms of ISO-8402. He added up four distinct contexts with different implied sense: product data, calibration, information technology (IT), and programming. He included a step, a chain, a product, and case entities with its essential descriptions and subdescriptions. He introduced also the TRU (Traceable Resource Unit) definition. Interesting reflection on chain versus internal traceability with their respective advantages was a good selling tool for both newcomers and professionals.

Food Traceability Report (16) This electronic press letter was first edited by CRC in 2001. Key words on traceability up to 2007 generated 200+ hit documents. Very informative news and events were available. It required a paid fee for access. Additional information at the direct web access site can be available under the correspondent reference number.

Viruéga (17) described 10 good reasons and five recommendations following the new EC Reg 178/2002, Article 18, effective on January 2005 from the European Community.

The International Standard Organization (ISO) is continually upgrading its quality management, food safety, and also traceability in feed and the food chain, including packaging basic requirements for system design.

The four main leitmotifs were (a) the new EU obligation to prove traceability, (b) the best tool for recall purpose, (c) an argumental tool facing regulatory framework and for extended needs such as for sales, and (d) a marketing impact relevant for suppliers' selection.

COMPUTER MODELING: ENTITY RELATION WITH QUALITY, DATABASE OPTIMIZATION, IDENTIFIER INTERACTION, AUTOMATIC COLLECTION, AND INFORMATION INTERCHANGE

Praat et al. (18) mapped fruit quality using supply chain information in Australia and New Zealand presented the basic tools of GMP, discussed product quality attributes using (a) electronic tags, and (b) near-infrared for Brix and dry matter, and discussed geographical information (GIS). Results of combined technologies were promising for orchard fruit mapping, and as well important for traceability proof.

Jansen-Vuller et al. (19) showed their approach to design information systems for traceability of food based on Gozinto Graph modeling of goods flow—that is, from raw materials to end product. Graphical data are translated into reference data model that shall become the foundation for designing information system. The bill of lots provided the necessary information to determine the composition of a material item out of component items. The system can be used to recall items and also to certify product quality. Very important was its capacity to adjust production process to fine optimization. The van Dorp thesis (20) discussed reference-data modeling for tracking and tracing, described its application, and described how to establish functionality within an object system. Three questions on reference models were targeted: (i) What are the expected advantage of using reference models? (ii) Which examples can we obtained? and (iii) On which elements of reference models do we focus? Research challenges and approaches were delimited. Four reference-data models were constructed and carefully elaborated. The cases included slaughter facility, food processor, a leather producer, and a pharmaceutical manufacturer. The models successfully allowed for the registration of historic relations between lots and batches, the registration of operations on lots and batches, the registration of associated operation variables and values, and, finally, the registration of capacity units on which operations were executed. From the industrial models, a reference-data model was constructed with success. Raynaud et al. (21) specifically compared governance of supply chains when a private brand assured quality to chains, and where official certifications assured product's quality for customers. In seven European countries the study was conducted on a set of 42 cases studies in the agri-food sectors: processed meats, cheese, fruit, and vegetables. They concluded that the relation between quality enforcement mechanisms used in transaction with consumers and the governance of the vertical chains were different. Following a transaction cost economics (TCE) framework, they argued that "*different quality enforcement device should be aligned with different governance of the supply chains*." For many transactions, they were able to evaluate dominant governance structure. Finally, we were closer to a hierarchy-like mode of governance in cases where reputation is the main quality factor, whereas market-like governance was more relevant in case of public certification.

Smith (22) described a computer approach "Re: Trace" to address the reception and quality control data for pallets tracking from field/grower to supplier, importer, and packing house to the final destination, the customer. Bar coding was combined with email and radio data terminal (hand-held). A new product and new company was created "Safe track.co.uk". The integrated database collected data for every links in the chain.

Da Silva et al. (23) demonstrated a solution for exchanging large quantities of data between retailers and suppliers in order to guarantee safety and quality of Portuguese market of fruit and vegetables. They proposed a new information system architecture. This, integrated well with ERP and support administrative functions through internet.

TRACEABILITY TOOLS: AUTOMATIC DATA COLLECTION (ADC), AND IDENTIFICATION SYSTEM (AIS), TECHNOLOGIES, SENSORS WITH COMPUTER (PC) AND CONNECTING LANGUAGES FOR UNIFORMITY IN TRANSMISSION

Traditional manual entering of data into computers, or handheld assistant, involved manual keying (MK) the information, collecting them on sheets of papers, and, finally, a drafted version report. It was unfortunate, but the error-prone ratio of characters entered this way was 1:300. If double verification occurred, then, automation of the collection with proper identifier and tag id and/or any other automated systems means (i.e., artificial vision, optical fiber, etc.) was required.

Doyon et al. (24) described the importance and the multiplicity of technologies besides BC and RFID to collect data and identification without manipulations. They were 2D (optical character recognition) symbology, smart card, machine vision, and biometric as the most current. Main logistic identifiers were GLN and GTIN; also, newly Reduce Space Symbology (RSS) was showing potential.

Of great interest was the work of Opara (25); in his paper he discussed the advancement in information technology (IT) and communication technology (CT) for data capture, storage, retrieval, nondestructive testing and geospatial science; he also discussed genetic analyses (DNA), nanotechnology for miniature machines, and, retinal images.

Tracking genes from seed to supermarket—techniques and trends—was reviewed by Auer (26). This was aiming at tracking plant genes as GMO (genetically modified organism) during pre-commercialization research and post-commercialization detection, identification, and quantification. A glossary and a comparison of principal laboratory techniques used were presented. Also a case study for beets was detailed. Science and policy challenged laboratory techniques, and labeling had an impact. Major critical areas were in the creation of standardized and validated methods and protocols.

Also vital were Pervasive Computer Technologies (PCT) with incredible interactions of sensors and portable devices and handheld (HH) to improve life quality and support adaptive structure anywhere (27). Additional information, direct web access site, was available under the correspondent reference number. In that same line of thought, Heinrich and Betts (28) had that vision to transform and adapt process creating interactive business network. Additional information on the direct web access site was available under the correspondent reference number. Giacomini et al. (29), in their paper on traceability by cooperatives, described the use of bar code technology, scanners, and LIMS (laboratory information management system) for quality control of plant residues analysis. Cost analysis was also included in the document.

Recent work by Rieback in Amsterdam Vrije University precluded serious danger for unprotected RFID systems. Information and educational material were provided in the web sites (30). Additional information on the direct web access site was available under the correspondent reference number. Nobel (31) described some potential and limitations in RFID. Revenue for 2006 would exceed $3.2 billion US and $9 billion by 2009. The success would depend on finding popular applications beyond retail distribution.

Boucher-Ferguson (32) mentioned many hurdles that remained to be resolved, such as lack of international standards, lack of return-on-investment (ROI) models, and the need to upgrade infrastructure to support RFID. The average price for tag was 25–30 cents US but would fall at 9 cents a clip.

Terry et al. (33) presented the application of biosensors to fresh produce and the wider food industries. Principles of biosensor technology were detailed and also defined. In general, the objective was to convert a biologically induced recognition event (i.e., enzyme, antibody) into a detectable signal via a transducer and processor. The end result was a display depicting both the presence and the concentration of the target analyte. Electrochemical, calorimetric, optical, acoustic, immunosensors, sensor arrays, and whole immobilized cells (usually bacteria) as recognition element was also described. The field is open for improvement of QC methods on fresh produce. Under tabulated format, we have described the range of analytes detection for produce and other food matrices. Future technology development and global food analysis market were discussed.

Wang et al. (34) provided an overview on recent development of wireless sensor technologies standards for communication. They discussed advantages and obstacles that prevent fast application adoption. They presented future trends and, in particular, high demand for food quality, health benefits, and safety. We are now in a ubiquitous computing age!

Kamoeka et al. (35) provided the setting up of sensing devices in combination with information system (database) to monitor quality at farm level in Japan. The standard language was XML. The produce under study was tomato plant, spinach, and lettuce under nondestructive testing with laser-induced fluorescence (LIF) and soil moisture by near-infrared (NIR). The database system was with Java Applet Typed analytical tools for color, shape, and spectroscopy. The Bio Information Exchange (BIX) system seemed to have potential for traceability of produce, field, and quality.

Golan et al. (36), in their investigation into traceability baseline in the United States, find that private sector firms had a substantial capacity to trace. The private sector had developed a number of mechanisms to correct problems: They used contracting out, third-party safety/quality audits, and industry-maintained standards. Benefits and costs were delimited and varied across industries. The studies covered fresh produce, grain, and oilseeds as well as cattle and beef; selected milestones in U.S. traceability requirements for foods were closing the report. Additional information in the direct web access site was available under the correspondent reference number.

Carantino (37) presented RFID as a promising tool, still limited by the price. Its application areas are industrial, logistical, and distributional. They allowed for reading and writing from very close to long distance. The pioneers are Wal-Mart, Tesco, Metro, and Carrefour in France. RFID has allowed the knowledge of the exact location of products into warehouse. Efficiency improved 12–17%, stolen goods were reduced by 11–18%, and products availability improved 9–14% following Future store and Metro trials. Tag prices are still an important limiting factor, and the dead zone in reading capability in shelves were of concern.

Anonymous (38) described the acceptance of GSI standard to harmonize logistical traceable practices, and equally important was interoperability of electronic data transmission. Therefore, pallets identification was with EAN-128 and notice of expedition, EDI. The codification of logistical unit was with SSCC (Serial Shipping Container Code). All product codes (trade units) were with GTIN (Global trade item number).

Osborne (39) reported that the e.centre, the UK authority for EAN-UCC system, celebrated its 25th anniversary. It was the champion of open standards. The main structures were the bar codes and computer-to-computer messaging. He maintained that the fresh produce supply chain channel had changed and was stabilized. In Europe, the large supermarkets were the biggest customers of fresh produce, with 79% of the whole market in 2001. Among six types of identifiers, the three most relevant were GTIN, GLN, and SSCC. Business electronic language was still EDI and XML. One remaining major concern was fresh produce individual coding and bar coding. Currently, retailers used PLU system. In North America, one potential solution was in small bar code or RSS (reduced surface symbology or databar) application. The cost–benefit analysis (CBA) was performed for 100 U.S. supermarkets: The savings resulting was from reduction in labor, improved inventory, and improved control would reach $2.3 million. Scanning, scale, and software equipment under two years old could also be upgraded around $2500 per store.

Schwägele (40) and Smith et al. (41) both reviewed papers from European and U.S. traceability perspectives, respectively, on feedstuffs and on processed meats for human consumption. Respective regulations, technologies, terms, and definitions were presented, and a comparison between countries regarding identification and trace system compliance locally, nationally, and internationally was reported in a daily newspaper. Governmental agencies were involved to minimize product recalls and make crisis protocols more effective in any event. Overall, traceability was becoming an integral feature of markets for all foods, and the application of biosensors (immunoelectrodes and optical fiber biosensors) was even more present. Computer modeling and risk assessment were being used to predict risks and better controls to protect human health.

Kleist et al. (42) described in detail into RFID basics, data transport layers, EPC and smart labels, industry initiatives, deployment models, case analysis; and proof of concept.

Finkenzeller (43) showed the fundamentals and applications of RFID. Physical and operating principles of systems were detailed. Applications examples with market potential were reviewed. Palmer (44) and Ash et al. (45) were two technical commercial application-driven documents that, educated scientific and nontechnical people to bar coding reading, printing, specification, and application. They included excellent photos, presented symbology explanations, and is taught how to be successful in Bar Coding.

CONCLUSION

A large portion of the references in the first part dealt with food quality assurance, GMP, HACCP, regulations, and food safety, including risk analysis and management. In the second part, software modeling (entity relation for database and tracking) was in development in combination with identification (AIDC) BC and RFID mainly and GPS-GIS; finally, the most common of commercial e-language were EDI and XML. The most favorite medium with personal computer (PC) and personal digital assistant (PDA) was the Web. Information structures proposed by EAN-UCC guidelines are showing the path. Looking at traceability family principles, definitions, and related terminology, the most interesting data where we have concensus are the following: ascending, descending, total, and integrated traceability. International Standard Organization (ISO) is continually upgrading its quality management, food safety, and also traceability in feed and the food chain, including packaging basic requirements for system design. The linkage is clear between ISO-8402 (1994), ISO-9001: (2000), ISO-22000 (2005), and ISO-22005 (2007) (46–48). Besides manual keying and written instruction, AIDC technologies were presented with some practical cases. Very little data or no information were available on advantages and costs related to traceable technology, training, and selection choices. And finally, a new updated 2006 version of the GS1 Global Traceability standard is for everyone. In many cases, packaging is the support for most identifier application on or within the material itself. Finally, packaging unit or entity remains a vital component of traceability in quality assurance for successful long-term trade.

PROPELLANTS, AEROSOL

MONTFORT A. JOHNSEN
Montfort A. Johnsen and
Associates, Ltd., Danville,
Illinois

Propellants are an integral part of every aerosol product. They may vary from about 0.5% to 100% of the total composition, and even with specific products there may be rather wide variations in propellant type and percentage. The most basic role of the propellant is to provide pressure inside the dispenser, so that when the valve actuator is pressed, the product emerges. But the propellant fills a number of other rolls as well.

Propellents can be divided into classes according to their generic makeup, pressures, and other attributes. The hydrocarbon class includes propane, *n*-butane, isobutane, and perhaps *n*-pentane and isopentane. When pure, these gas liquids are almost odorless, very low in density, and quite inert chemically except for their extreme flammability. They are the workhorses of the aerosol industry since they are used in 80% of all U.S. aerosols. Isobutane is the most popular due to it adequate but intermediate pressure of 31 psig at 70°F (21.4 bars at 21.1°C). The next group has one member: dimethyl ether (DME). DME has a pressure of 62.3 psi-g at 70°F (4.30 bars at 21.1°C), a low density, and exceptional solvency. The third groups consists of the hydrofluorocarbons: HFC-152a, HFC-134a, and HFC-227ea in order of popularity. HFC-152a (1,1-difluorethane) is popular because it is not a VOC (volatile organic chemical). HFC-134a (1,1,1,2-tetrafluoroethnae) has a global warming potential about 11 times higher than HFC-152a and is highly restricted in its availability. HFC-227ea (1,1,1,2,3,3,3,-heptafluoropropane) is almost unknown in the general aerosol industry. The propellants mentioned above are sometimes called liquid propellants or gas–liquids. The can be shipped by tank car or tank trucks and can be stored in bulk tanks having a capacity of 122,000 L (31,500 gal).

Both carbon dioxide and nitrous oxide are liquid propellants, since their critical points are slightly above room temperature. The solubility of these gases varies greatly with their formulation. The final group of aerosiol propellants is the permanent or noncondensable gas, typified by nitrogen and purified compressed air (CAIR). Since nitrogen is virtually insoluble in water and only very slightly available im organic solvents, it is often considered to act as a gaseous piston, placing aersol concentrates under pressure so they will be emitted when the valve is is operated. Compressed air, which contains 77.52 vol% nitrogen, has very similar properties.

For products in which the propellant is soluble (usually anhydrous types), the propellant can be used to control particle size. Increasing the percentage of propellant, or the use of a higher-pressure propellant, will serve to decrease the mean aerodynamic particle size of the spray. The importance can be illustrated in the case of insecticides. Sprays designed to kill flying insects must produce a preponderance of particles capable of floating about in the air for significant time periods. In the case of particles larger than $\sim 50\,\mu$m, they would fall onto tables and floors so rapidly that the insecticide would lose potency—known as "knockdown" and *cidality* properties. On the other hand, particles that are too small would tend to "airflow" over or under the flying insect. Some insect sprays, more properly identified as bug killers, contain only about 3–20% of propellant in the formula (depending on propellant choice), and these produce coarse sprays designed to coat baseboard areas where many crawling insects travel. The formulas usually contain relatively harsh toxicants that should not be inhaled to any significant degree.

The aerosol valve generally works hand-in-hand with the propellant to produce the desired product presentation. Valves are important in controlling delivery rate. They also have terminal orifices that can determine the width of the spray cone. Some of these orifices come with what is known as a mechanical breakup (MBU) insert, which can take what might be a solid stream of product and cause it to be emitted as a coarse spray. The functionality is rather similar to that of a garden-hose nozzle.

In those cases where sufficient dissolved propellant is available to create a spray, as the liquefied gas bursts into the gaseous state, the use of an MBU sprayhead can serve to make the spray particles somewhat finer and the spray pattern more uniform and elegant. MBU sprays are generally quieter than other types.

Most propellants are relatively insoluble in water, and thus in water-based products, but can be emulsified into them if some surfactant is added. This is the basis of aerosol foams: shaving creams, mousses, foam charcoal starters, and so on. Typically, 4–8% of hydrocarbon propellant is emulsified in the soap solution by gentle shaking before use. If one uses a spray-type actuator instead of a foam spout, foaming sprays can be generated. Hard-surface cleaners, textile spot removers, oven cleaners, and similar products are formulated this way.

About 45–50% of all aerosol valves have vapor-tap orifices: tiny holes pinned or drilled through the body, so that both liquid and gas enter the body chamber when the valve is actuated. The result is a spray with much lower delivery rate, a finer particle size, and a somewhat louder sound. Since much of the emerging propellant is already in the gas phase, the spray is warmer than that of regular sprays. This can be important in the case of underarm deodorants, antiperspirants, body sprays, and medicated foot sprays. The use of vapor-tap valves also allows liquid orifices to be larger. Vapor-taps are always seen on antiperspirants, partly to keep the finely powdered aluminum chlorhydrate astringent from clogging valve orifices. The vapor-tap feature permits the use of large, clog-resistant orifices, but without the stigma of excessive delivery rates.

One important consideration with vapor-tap valves is that sufficient propellant must be used to keep it from running low, due to the continual short-circuiting of the gas phase. For example, depending on the relative size of the liquid-tap and the vapor-tap orifices, a dispenser that starts with 45% propellant could end up with 35% propellant. This might mean a discernably coarser spray and lower delivery rate. A final interesting feature of vapor tap valves is that, if the liquid and vapor orifices are the same diameter, the aerosol will spray just the same way, if it is inverted. In such cases the regular aerosol types would only emit propellant gas.

HISTORY

The earliest aerosol propellants were carbon dioxide, followed by vinyl chloride, isobutane, dimethyl ether, and a few other gases. In 1938, when the chlorofluorocarbons (CFCs) became commercially available, these very low-odor, nonflammable, and relatively inexpensive gases virtually displaced all the others. Most early aerosols used about 85–90% CFCs—from the heavy “bug bombs” of World War II to the consumer aerosols that first appeared about 1948 in the United States. After 1954 very low-cost, low-odor hydrocarbons became available, and propane, *n*-butane, and isobutane began to be used to propel water-based products, such as window cleaners.

The very light-density hydrocarbon liquefied gases simply sat on top of the product as a discrete liquid layer, conferring a rather constant pressure. Under such conditions, the product itself flowed up the dip tube when the dispenser was actuated, turning into the desired coarse spray as it passed through the MBU valve orifice (see Figure 1). This type of operation had been impossible with the CFCs, since they are about 1.4 times as dense as water and would have formed a bottom layer of almost pure propellant. Actuating the valve would have swept the propellant up the diptube—and even if the diptube had been shortened, to extend only to the bottom of the product layer, tilting the dispenser during use would still have caused propellant discharge.

The window cleaner, oven cleaner, basin, tub, and tile cleaner, and similar products typically ran about 4–6% isobutane propellant (7.3–10.9 vol%). The top layer would diminish in size when the headspace was enlarged during sprayout. But a certain amount of propellant was also added as a contingency against the very real probability of occasional consumer misuse, such as trying to spray the can when it was severely tilted or even upside down.

The aerosol industry first learned about the “ozone/CFC” issue around 1974, at a time when various CFC propellants were used in about 53% of all aerosols. There was disbelief, since the evidence was nonempirical and speculative at first. But in 1978 the EPA and FDA acted to ban the CFCs from all but medical aerosols—while not doing anything about their continuing use in refrigeration, air conditioning, and all other applications. (The United States was also the only country in the world to take such an action.)

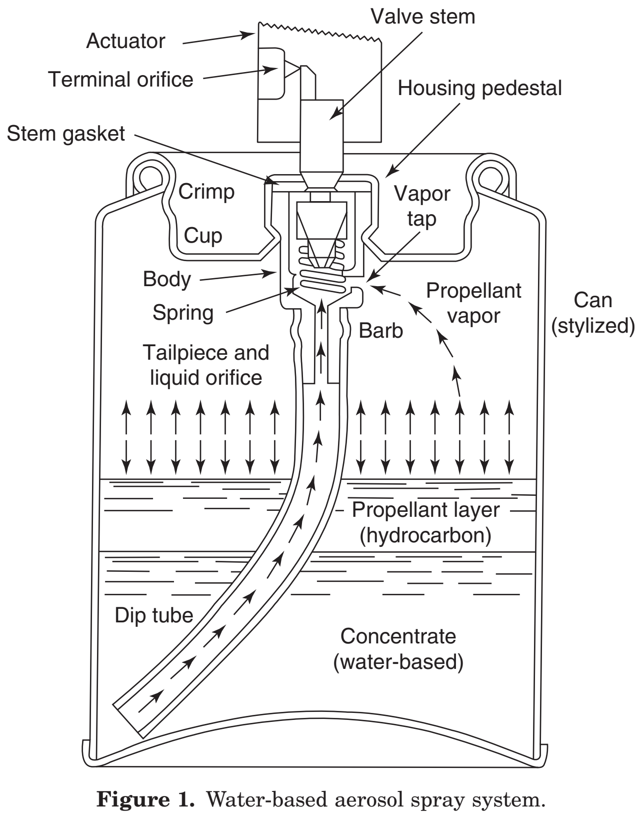

Figure 1. Water-based aerosol spray system.

Without the ability to continue using nonflammable CFCs for hair sprays and virtually all other aerosols, marketers turned to about the only viable alternatives: the liquefied petroleum gases (LPGs) (e.g., propane, *n*-butane, and isobutane). Elaborate reformulation programs were needed to evolve products of acceptably low flammability while still maintaining compatibility with active ingredients. One problem involved net weight per can. In the case of antiperspirants, which had used 90% CFC in the formula, the reformulated products now used ∼68–85% of very low-density hydrocarbons—generally isobutane. Since the density of the new antiperspirants was about 0.68 g/mL (at room temperature), compared to about 1.38 g/mL for the CFC predecessors, marketers could fit only about half the previous product weight into their cans. Consumers thought the cans were “only half full,” and this sparked a degree of discontentment that acted to plummet the sales of this particular product to about 25–30% of what they had been, prior to 1978.

In 1989 the U.S. Congress passed thr Clean Air Amendments Act (CAAA), which among many things directed the U.S. EPA to confirm the probable ozone depletion status of hydofluorocarbons propellants, the Halons, and a number of polychlorinated solvents. By 1993, all of these propellants and solvents were banned. In the years that followed, the aerosol industry had to cope with two more propellant sanctions. The first came in a finding that many VOCs, when released into the air, could directly increase the level of tropospheric ozone. This problem was the most intense in southern California. The California Air Resources Board (CARB) wanted reformulation of virtually every aerosol to reduce the VOC content. CARB plans to cascade the VOC contents of aerosols until at least 2023. The final, and still developing, threat relates to the global warming issues. The HFCs have been at the center of this issue. HFC-134a is primarily used in metered dose inhalants and life safety aerosols—for example, car tire sealants and inflators, air conditioner refill units, pepper sprays, boat horns, electronic de-dusters, and electric circuit board freezant testers. It has a rather high GWP, having a potency 1300 times that of carbon dioxide. HFC-152a is more important for aerosol purposes. It is used in underarm products and hairsprays. It is a mild global warming agent with a potency of 120 times that of carbon dioxide. HFC-227ea has had very little impact on the aerosols industry. See Table 1 for the globabl warming potentials of the various propellents.

By 2005, regulatory committees accelerated their pace of activities. European aerosol associations banned production of HFC-152a aerosols, although not much was used at the time. In 2010 or 2011, The European Economic

Table 1. Global Warming Potentials (GWP) of Aerosol Propellants

Propellant	Lifetime (yr)	GWP (100 yr ITH)
Carbon dioxide	~65	1.000
Propane	0.03	nil
Butanes	0.01	nil
Dimethyl ether (DME)	0.02	nil
HFC-152a	1.5	140
HFC-134a	14	1300
HFC-227ea	41	3300
Nitrous oxide	120	320

Community will vote whether to ban most HFC propellants Denmark and Austria have already voted. In 2007, the Province of Manitoba, Canada, enacted a ban on all aerosls containing HFC-134a.

California's new Public Law AB-32 requires the 25% of reduction of global warming gases by the year 2020 (translates to 70 × 106 metric tons). The Climate Action team has been formed to implement this goal. They will target any gas mentioned in the Kyoto Protocol, such as HFCs, nitrous oxide, and carbon dioxide in the case of aerosols. They may allow the use of HFC-134a, but will ban the introduction of any new products. They may also investigate the possibilty of replacing HFC-134a with HFC 152a, or a future propellant, HFC-16 (fluoroethane), which has an extremely low potency of just 12 times that of carbon dioxide and a half-life of 110 days. A number of clarifying amendments to the Act are scheduled in late 2008.

PROPELLANT CHEMISTRY

Propellants must meet numerous requirements to be ideal for aerosols. Many of these are as follows:

1. Reasonable boiling point and vapor pressure
2. Reasonable cost
3. Acceptable toxicology profile
   a. Acute
   b. Subacute
   c. Chronic
4. Acceptable low odor
5. Acceptable environmental aspects
   a. Minimum effect on stratospheric ozone
   b. Minimum effect on tropospheric ozone effects
6. Flammability consideration
7. Stability consideration
   a. Hydrolysis
   b. Alcoholysis
   c. Polymerization
8. Solvent properties
   a. Useful in some formulas
   b. Sometimes detrimental to elastomers
9. Purity

The CFCs came close to being ideal, except for their great chemical stability, which brought about the free-radical depletion of stratospheric ozone. Current propellants are all considerably less than ideal. The hydrocarbon gases (LPGs) indirectly act to produce tropospheric ozone, or smog, but their major drawback is their extreme flammability. Dimethyl ether is rather uniquely water-soluble, but it is also flammable and has such a strong solvent action that gaskets may be attacked and corrosion possibilities are enhanced. Carbon dioxide is nonflammable, but acidic if added to water. In any event, no more than about ~3–6% can generally be added before aerosol pressures reach the regulatory limits imposed on aerosols by the U.S. Department of Transportation. These and other general properties of the available propellants are given in Table 2.

A selection of the physical properties of aerosol propellants is presented in Table 3 (hydrocarbons), Table 4 (DME and HFC-152a), and Table 5 (compressed gases). The propellants may be mixed with other propellants, or with various aerosol concentrates, in order to achieve any reasonable product pressure. Entrapped air, present in all aerosol dispensers to varying degrees, adds about 6–21 psi (0.41–1.45 bar) to the propellant pressure.

The usual aerosol pressures vary within ~30–70 psig at 70°F (2.06–4.83 bar at 21°C). In the special cases of CO_2 and N_2O propellants, pressures are typically 85–95 psig at 70°F (5.86–6.55 bar at 21°C), and where nitrogen or compressed air (CAIR) are used, pressures may be as high as 141 psig at 70°F (9.72 bar at 21°C). All these ranges are designed to keep the aerosol pressure at or below 180 psig at 130°F (12.41 bar at 55.4°C), which is the

limit set by the U.S. Department of Transportation (DOT) for the strongest of the three standard aerosol cans. Pressures increase very rapidly with increasing temperature for those formulas that contain large amounts of lower pressure propellants, such as isobutane. On the other hand, nitrogen, which often has a negligible solubility in the concentrate, increases in pressure more or less in harmony with Charles' law.

Aerosols will buckle (permanently deform) and finally burst if overheated. The label almost invariably warns against heating higher than about 120°F. Some labels list 130°F. Bursting aerosol cans pose a severe hazard and may be life-threatening. In some cases the contents may also ignite, causing an additional hazard. A limited number of aerosol cans have fitments designed to allow the contents to be released in a controlled fashion if they are overheated. For three-piece ETP cans, about 10 small indentations may be notched into the top of the top double seam. The can is designed so that the dome sections will evert (or "jump up," somewhat) well below the minimum bursting pressure. When this occurs, the work-hardened indentations will reform into little apertures, releasing the overheated product. This is known as the *pressure-relief mechanism* (PRM). Aluminum cans and others without a top double seam may be relieved by means of various fixtures in the base.

Marketers have a concern that gas will be inadvertently dispensed. As a rule, a negligible amount of propellant is lost by leakage, through the valve or past the junction of valve cup and can bead. The consumer may hold the can in such a position that the dip tube end protrudes into the headspace, particularly near the end of the can, when little liquid is left and for a product such as surface sprays when the dispenser is tilted strongly downward to spray (see Figure 2). These episodes will act to partly depressurize the dispenser quickly changing the properties of the product. In severe cases, all products may not be delivered at the time the internal pressure sinks to zero (see Figure 2). There are two ways to solve this problem. The older way is to fill the can to 50 vol% rather than the usual 75–90 vol%. With a relatively large, well-pressurized headspace to start with, the drawdown pressure will be reduced as the dispenser is used up. The second is to use an initial higher pressure, which is not always possible because of the U.S. DOT ceiling of 180 psig at 130°F (12.41 bars at 54.4°C). A DOT exempted can would be required.

SAFETY

The aerosol industry had to learn, over the years, how to safely handle flammable propellants and gas them into dispensers. They must be manipulated in closed systems. In larger filling plants, flammable propellants are stored in 1 to ~10 bulk tanks, ranging up to 30,000 gal (113,500 L) in nominal capacity. Two-inch (51 mm) double-strength steel pipes lead from the bottom of each tank past valves to a low-pressure pump. From there the line may lead to a blending station, followed by a manifolding unit, to direct the liquefied gas (or mixture) to the appropriate gas house. In this enclosure, which is often outside the main establishment because of the potential hazards, the gas supply goes to piston-operated gassers. Two types are used. The earliest, now called a "through-the-valve" (T-t-V) gasser, charges the propellant backward through the valve and into the sealed can. The liquistatic pressure ranges from about 600 to 950 psig (41–66 bars), and the temperature is often controlled to about 104°F (40°C) for a number of technical reasons. Many valves are designed to backflow propellant at very high rates, so that a typical 18-head rotary T-t-V gasser may attain speeds of up to ~350–400 cans per minute.

The other gassing machine performs three consecutive functions: (i) After lifting the lossely inserted valve slightly, it draws a partial vacuum on the can; (ii) then it adds the liquid propellant under high pressure, around

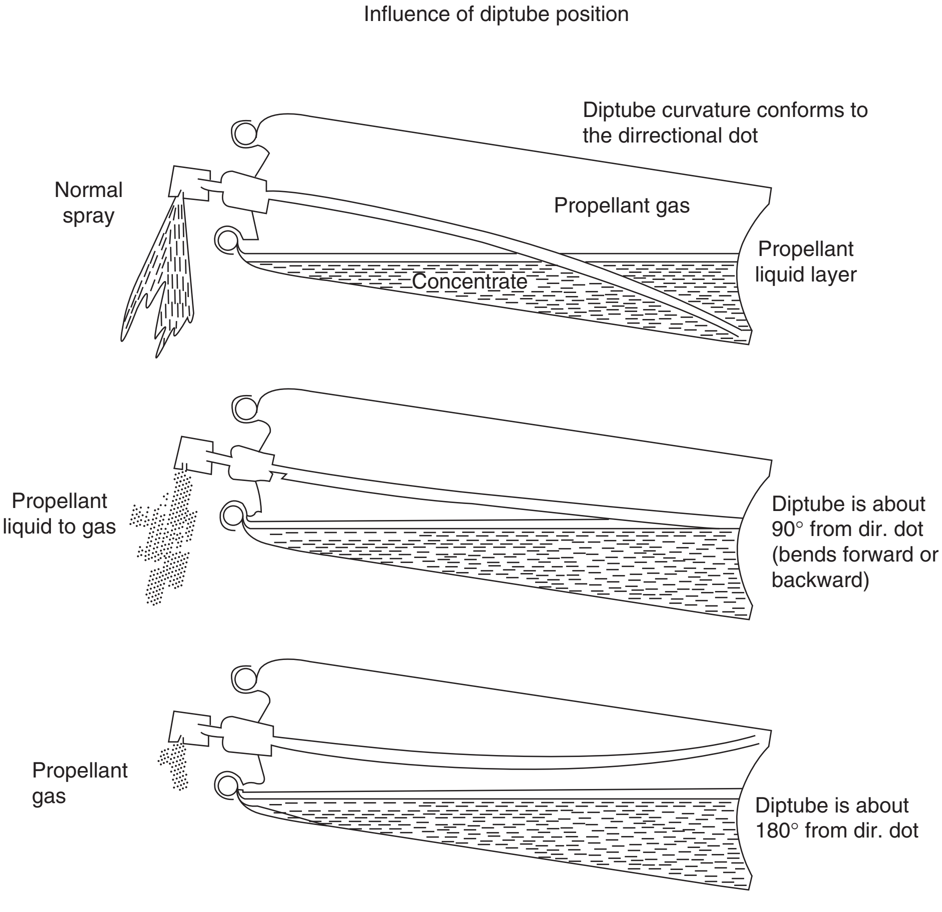
[a] Volume of gas per volume of liquid water, at 70ºF, or 21.1ºC and 1 atmosphere of absolute pressure.

the periphery of the lifted valve cup; and (iii) finally, it presses the cup firmly down on the can bead and performs a crimping (swaging) operation to hermetically seal the can. A minor disadvantage of this machine is that above 3.0 mL of liquid propellant is flashed off when the filling head lifts off the sealed can. This must be exhausted through a floor-sweeping ventilation system.

Ideally the gassing facility should be a strongly constructed room located at least 2 m (6.5 ft) from the main establishment. Since hydrocarbon gases will be released in this room, it is vital to install an adequate ventilation system. The best approach is to add "make-up' air through floor level registers along one wall of the the gashouse to remove it through registers a the bottom of the opposite wall. The ventilation should flow in a laminar fashion across the entire floor. The heavy hydrocarbon vapors will be captured and drawn up into the exhaust system at a point 3 m (10 ft) above the roofline. A gas sensor is used to provide assurance that excessive hydrocarbon vapors are not being produced. Frictonal sparks or static disharges can be detected by a double electric eye installation, which can turn on a water deluge system. In warm climates, the



The propellant layer has a volume of about 7% that of the concentrate layer.

Figure 2. Influence of diptube position.

gashouse may be replaced by open air gassing arrangements. Unfortunately, there are many aerosols lines where the gassing operation is done inside the main establishment. This is common in Japan. Other than excellent maintenance and normal ventilation, there is no provision for possible leakage of liquid hydrocarbons from pipes, hoses, valves or other equipment. Firms in the United States that cannot construct an outside gashouse, opt to enclose the gassing operation in very strong steel cubicles of minimum size equipped with excellent ventilation, gas sensors, and other engineering safety features.

The U.S. EPA is interested in plant emissions of volatile organic compounds (VOCs), especially in the case of facilities located in VOC nonattainment areas, such as larger cities. If one considers the loss of (say) isobutane from an intermediate to large aerosol plant, running a total of 1000 cans per minute; at 3.0-mL loss per can, the total loss will be ~47.5 gal (180 L) per hour, or 380 gal per 8-h shift. The EPA has required some plants to dramatically reduce their emission rates, either by changing gassers, adding conservation accessories to their U-t-C gassers, or collecting the bulk of the released gas and compressing it to liquid in a “gasser waste” storage tank. In some cases the “gasser waste” may be used as heating fuel for the plant boiler.

The extreme flammability of hydrocarbon gases has necessitated equipping gas houses with sophisticated sensing devices, halon-powered extinguishing equipment, deluge systems, regular and emergency ventilation attributes, and a complex electroprotective system. Employees must be carefully trained in fire safety. There is a minor but significant trend to depopulate gas houses, so that, if a catastrophe occurs, one or more lives will not be jeopardized.

As little as 0.58 fl oz (9.6 g) of isobutane, poured into an open-top 55-gal (200-L) steel drum and mixed with the air in the drum, will produce about a 500-L “fireball” if ignited. As little as 2.0 g, poured into the drum but unmixed, will produce flames that fill most of the drum if ignited. The following data show that the hydrocarbons cannot be detected by odor and are substantially heavier than air:

1. Odorless
2. Colorless
3. Heavier than air
   a. Two times
4. Narrow limits of flammability
   a. LEL 2%
   b. HEL 10%
5. Low ignition temperature
   a. 825–900°F
6. Expansion
   a. Liquid to vapor = 1–270

This means that they have a tendency to collect in floor-level areas. Mixtures of 1.86–2.04 vol% gas in air are potentially flammable. Fortunately for the industry, practically all hydrocarbon-type aerosols are used for only a few seconds at a time. But for those paints, total-release indoor insect foggers, and a few other products, where large amounts are sprayed at a time, good ventilation or dilution is quite important, and such admonitions will be seen on the can labels.

CONCLUSIONS

As can be seen, the technology of aerosol propellants is far from simplistic A fair number of personal care products may have as many as four different propellants, all contibuting to the desired properties and quality of the final formulation. Each propellant has its own profile of pressure, density, water solubilty, cost and other properties. They must be used to their greatest advantage by formulators and packaging experts.

PULP, MOLDED

Edwin H. Waldman
Keyes Fibre Company
Updated by Staff

INTRODUCTION

Like the paper-making process itself, the origins of pulp molding are pretty well obscured by antiquity. One assumes that artisans in early Oriental, Egyptian, and Greco-Roman civilizations who were involved with screen-felting of vegetable fibers into sheets of paper rapidly discovered benefits that derived from embossing the screening material to obtain contours. It is believed that ornate wall- and ceiling-molding artifacts of those civilizations were fabricated in this manner. With the rapid development of the paper industry around the turn of the twentieth century, disposable molded pulp products began to find their way into the mainstream of commercial life as protective vehicles for transport of fragile foods such as pies and eggs. The economics of manufacture of pie transfer plates and egg trays have kept these unglamorous products in the marketplace. Although certainly in the mature part of the viability curve, they remain of considerable commercial interest.

FABRICATION

The term "molded pulp" is used to describe three-dimensional packaging and food-service articles that are manufactured by forming from an aqueous slurry of cellulosic fibers into discrete products on screened, formaminated molds in a process analogous to continuous-sheet cylinder-board papermaking. It is not unusual to find the pulp-molding process grouped with other converting processes such as compression molding of fiber-reinforced resin parts and pressboard converting because of the similarities in finishing steps and common markets, but the molded-pulp process and its products are fundamentally unique. Two basic methods of fabrication are used: plain molding and precision molding (see Figure 1).

Products of plain molding are as fundamental as the triangular corner protector pads used in furniture and appliance packing crates, and they are as complex as

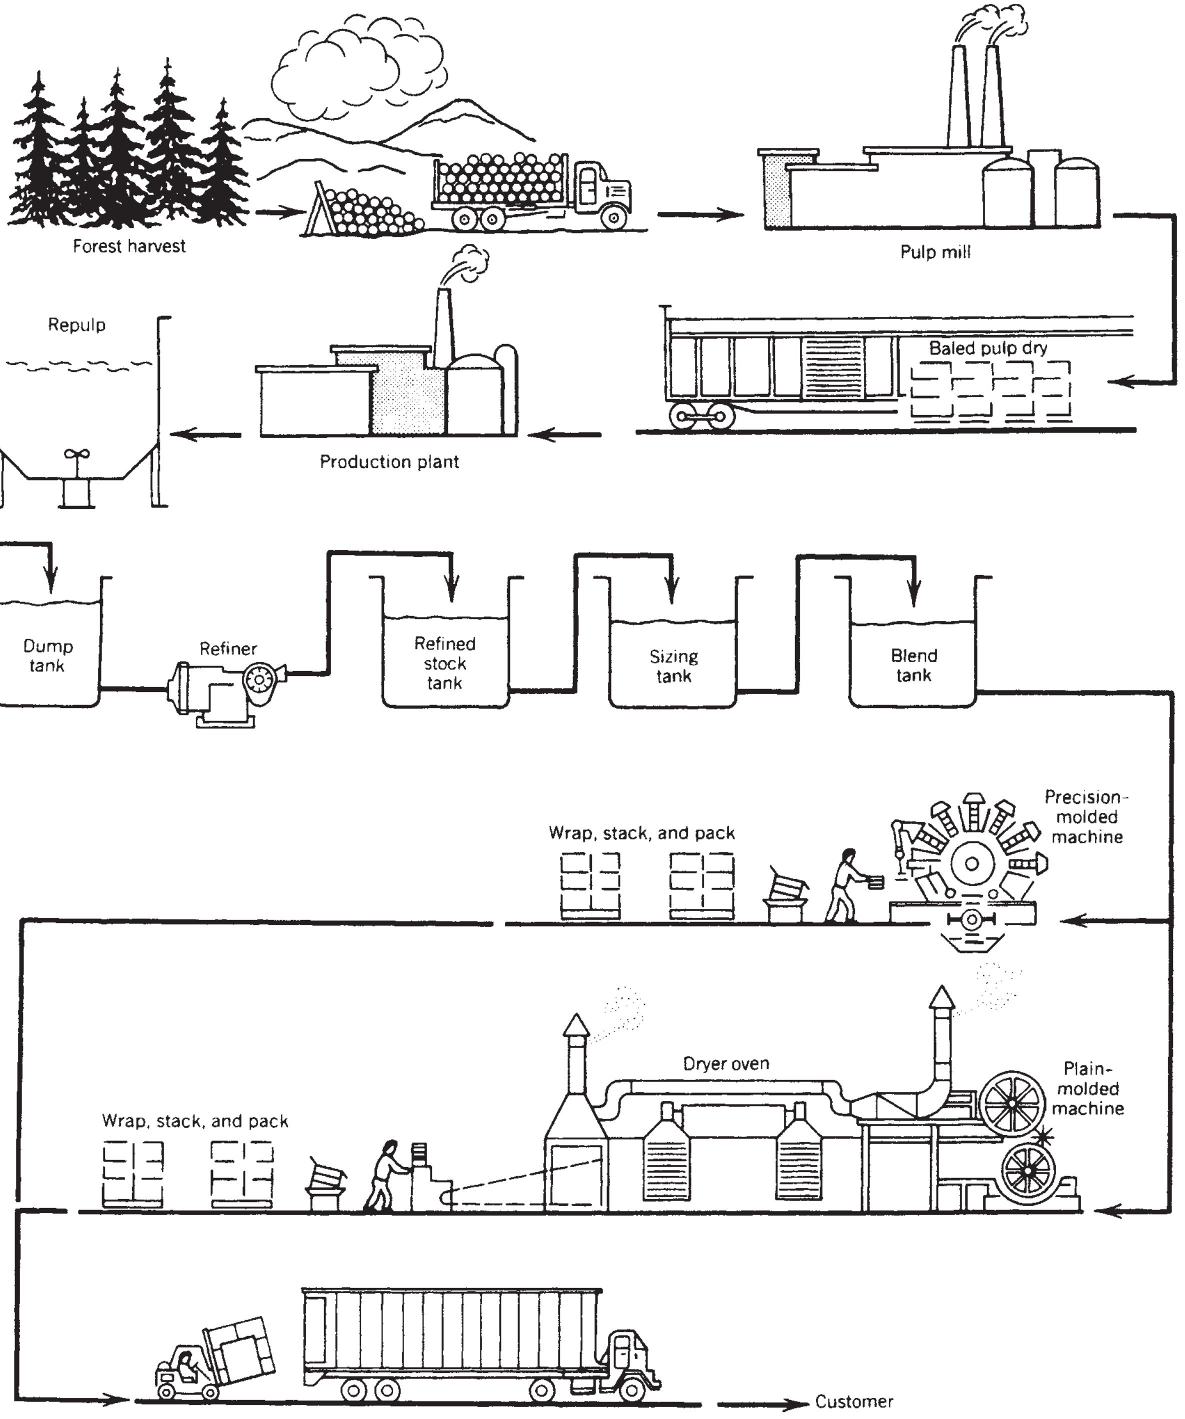

Figure 1. The molded-fiber process.

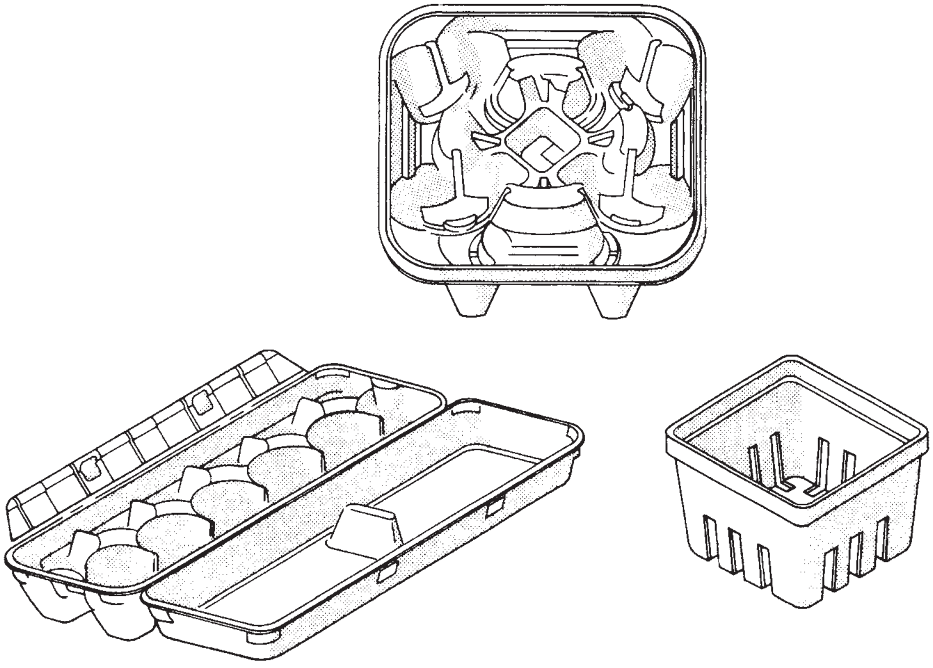

Figure 2. Examples of plain-molded products.

hinge-lidded, self-locking, one-dozen egg cartons enhanced by hot afterpressing and graphic print applications. Between these extremes are products such as berry punnets, peat pots, produce prepackaging trays, and egg and apple-locator trays (see Figure 2). Such products have commercial relevance because they are produced on highly automated and productive machine modules (>20 tons (>18.1 metric tons) per day), are nestable for efficient transport to users, are low in density in comparison to converted paperboard products (see Paperboard), and are fabricated from some of the least-costly raw materials available (recycled mechanical cellulosic fibers, groundwood, sphagnum peat fiber, etc).

Precision-molded processing differs from its higher-speed forerunner in drying methodology. Forming of the product and the removal of mechanically bound water by vacuum-assisted compaction is essentially the same; but at that point, final drying is accomplished by step- or continuously applied heat between matching mold surfaces (see Figure 3). Precision-molded products include disposable plates, dishes, bowls, and specialty products such as loudspeaker membranes and cones (see Figure 4). These products are typically denser, smoother, and more exactly dimensioned and contoured than their free dried counterparts. Virtually any plain-molded product can also be made in this manner, but they would be more costly because of the complexity of tooling and higher electrical energy required.

Many internal treatments are given to the slurries to render them more valuable to their users. By blending fibers that have received different process and refining treatments, "green" matrix strength can be enhanced; drainage, internal bond strength, and shrinkage can be altered; and biodegradability of products after or during use can be controlled. Colloidal rosin or wax emulsions are commonly added together with paper-making alum to convert hydrophilic fiber into the water-repellent products essential to food handling. Fluorocarbon chemicals in concert with cationic retention aids can be added to impart repellency to low-surface-tension oil or greasy liquids. Fertilizers, dyestuffs, flame retardants, and modified starches or wet-strength resins are among other additives that are also commonly added internally where specific end-use effects are desired.

Secondary treatments are sometimes given to nondisposable molded-pulp products. Cafeteria serving trays have been made by after-pressing laminates of molded-fiber preforms loaded with thermosetting polymers. Luggage shells, automobile trunk wells, glove compartments, and door liners are made this way. The hot afterpressing and decorative printing of egg cartons also represents secondary treatment that enhances printability and product automation. Colored molded packaging can be

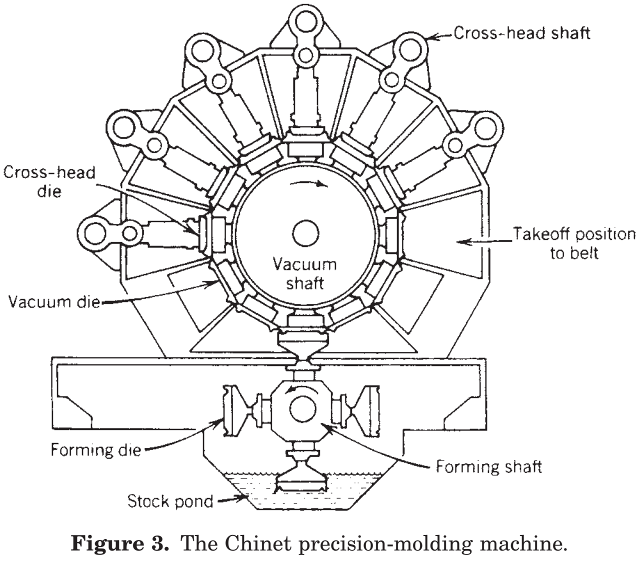

Figure 3. The Chinet precision-molding machine.

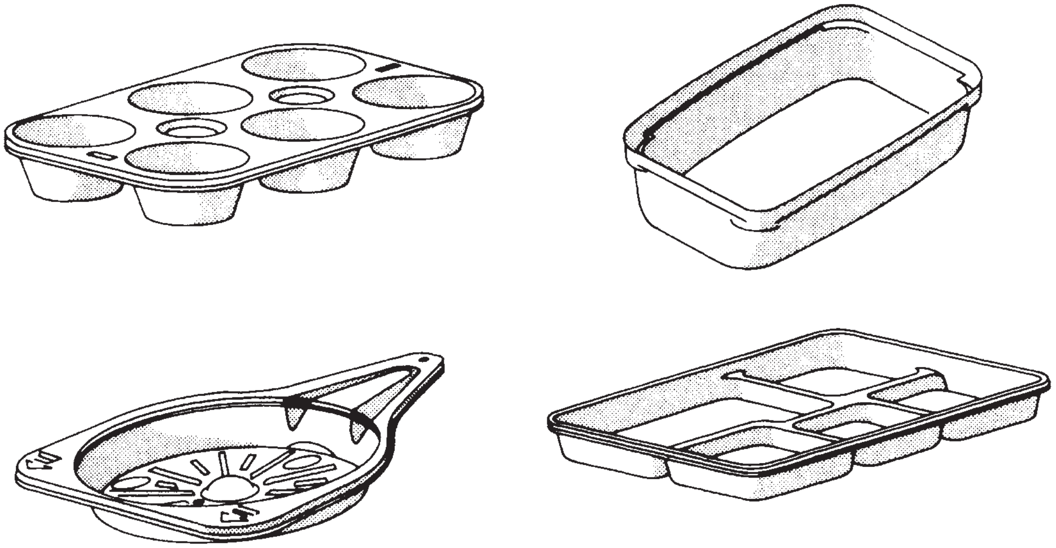

Figure 4. Examples of precision-molded machine products.

produced using a dyed pulp. Decorative finishes can be applied by spray gun. Text (such as brand and end-user's names) and symbols (such as the recyclable logo or trademarks) can be incorporated into the mold to produce an embossed or debossed effect.

An example of secondary treatment is the lamination of a thin thermoplastic film to one surface of molded-pulp trays by vacuum-thermoforming techniques. Products of this type are being used for frozen dinners because of their "dual ovenability" (i.e., their suitability for use in microwave and convection ovens).

The use of computer-aided design has facilitated mold design and enabled more complicated designs to be reproduced than before (1).

APPLICATIONS

Molded-pulp packaging provides a cost-effective solution for the packaging of a wide range of products, many of which are fragile such as eggs, fruits, and vials. Clamshell containers are used for eggs and bottles. Molded pulp packaging provides an important use of recovered paper and paperboard. Molded pulp is based on a renewable resource and provides the environmentlal benefits of recyclability and biodegradability.

Q

QUALIFYING

Qualifying is the act of setting up and administering a training program that ensures that the people who will be interfacing with the packaging line are given a thorough overview of the packaging line and a detailed program on what they need to know to complete their tasks without hesitation or guessing. All training must address the following questions:

When should training be done?
What training should be done?
How should we do training?
Where should we do training?
How much is enough training?
Manuals and other self-help tools?
Performance reviews and continuing improvement?
Company standards and policy?

INTRODUCTION

Packaging makes food more convenient and improves its shelf life by protecting it from micro-organisms, biological or chemical changes, and physical damage. As a result, packaging has become an indispensable element in the food manufacturing process (1). Plastic materials are also used in medical devices or surgical preparations (2).

The treatment of prepackaged foods with ionizing radiation such as γ- or X-ray is gradually becoming more popular as a food-preservation technique. The irradiation of prepackaged foods helps prevent subsequent microbial reinfection and insect increment (3). Generally, packaging prevents water loss and mechanical damage of foods, makes handling easier, and improves its marketability. Good packaging materials must maintain functional qualities such as impermeability, mechanical strength, seal stability, color, and haze in the course of the radiation process. Also, the packaging materials must not release additives or radiation-induced reaction products into the foods during irradiation, because these materials contaminate the prepackaged foods and affect the safety of consumers. Most polymers listed in the U.S. Code of Federal Regulation (CFR) 21 §179.45 were approved for γ-irradiation by the U.S. Food and Drug Administration (FDA) in the 1960s through petitions by the Atomic Energy Commission ($\leqslant$10 kGy) and the U.S. Army ($\leqslant$60 kGy) (4–6). Polymers used to package food intended for irradiation must currently receive separate U.S. FDA approvals for electron-beam (e-beam), γ-radiation, and X-radiation. These three forms of irradiation in a vacuum have virtually indistinguishable effects on polymers. However, in air, irradiation damage is favored by slow-dose rates such as γ-irradiation (7).

It is becoming more common to use ionizing radiation instead of a high-pressure autoclave or ethylene oxide treatment when sterilizing medical products (8). Specifically, radiation is popular because it is easier and more economically efficient than using a high-pressure autoclave or treating medical products with ethylene oxide (9). When using ionization radiation for the sterilization of medical devices, the International Atomic Energy Agency (IAEA) recommends packaging polymers such as polyethylene (PE), polyester, polypropylene (PP), nylon, poly (vinyl chloride) (PVC), and so forth (8).

The effects of radiation on polymers may be classified as scission, crosslinking, structural modifications, and chemical reactions based on different values of the absorbed dose. Scission of the polymer chains results in a decrease in molecular weight, whereas crosslinking results in an increase. Structural modifications are changes in the number of unsaturated polymer chains and presence of charged units in polymer chains. Chemical reactions lead to small volatile products and, eventually, organic radicals, which are potential contaminants of packaged foods (10, 11).

IRRADIATION OF PACKAGING MATERIALS

Status and Trends

Food irradiation is the treatment of food by a certain type of energy. The process involves exposing the food, either packaged or in bulk, to carefully regulated amounts of ionizing radiation for a specific time to achieve certain desirable objectives (12). The standard was adopted by the Codex Alimentarius Commission, a joint body of the Food and Agriculture Organization of the United Nations (FAO) and the World Health Organization (WHO), which is responsible for issuing food standards to protect consumer health and facilitate fair practices in food trade; the WHO represents more than 150 governments. The Codex General Standard for food irradiation was based on the findings of a Joint Expert Committee on Food Irradiation (JECFI) convened by the FAO, WHO and the International Atomic Energy Agency (IAEA) (13). The JECFI has evaluated available data in 1964, 1969, 1976, and 1980. In 1980, it concluded that “the irradiation of any food commodity” up to an overall average dose of 10 kGy “presents no toxicological hazard” and requires no more testing. It stated that irradiation up to 10 kGy “introduces no special nutritional or microbiological problems” in foods. In September 1997, a study group was jointly convened by the WHO, FAO, and IAEA to evaluate the wholesomeness of food irradiated with doses above 10 kGy. Food irradiation technologies are considered safe as long as the sensory qualities of food are maintained and harmful micro-organisms are destroyed (14, 15). Polymers listed in the U.S. CFR 21 §179.45 “Packaging Materials for Use during the Irradiation of Pre-packaged Foods” are shown in Table 1 (16). These early submissions requested approval for γ-treatment only. Although electron beam treatment was technically attainable, its use for routine polymer treatment was not economically favorable (17). Commercialization of X-ray treatment was even less attractive than that

of γ-ray use. X-rays are produced at low yields through electron beam bombardment of heavy metal targets. Over the past 20 years, the unit cost of electron beam treatment has declined steadily. The higher dose rates associated with an electron beam and the ability to switch radiation ON and OFF have made the treatment attractive to food processors. The economics of X-ray treatment still do not favor their wide-scale use in food irradiation. However, X-rays have the advantage of deep penetration, and the major advantage of electron beams continues to be that radiation can be switched ON and OFF as needed. For these reasons, the use of X-rays in the field of food irradiation will be neglected (7).

The requirements for the certification and routine control of the sterilization of medical devices by radiation are mentioned in the European standard EN 552. EN 552 provides two possible approaches in setting up the sterilizing dose. One is to use knowledge of the number and resistance to radiation (if known) of the inherent microbial population present on or in the medical device. The other is to use a minimum dose of 25 kGy. Because EN 552 was published in 1994, there has been broad discussion and debate about the degree to which this particular guidance should be applied. As a result, a consensus has emerged that evidence is required to support the effectiveness of 25 kGy against both the numbers of contaminating micro-organisms on the product and the resistance to radiation of these organisms. Therefore, the Panel has developed a definition of microbiological quality that encompasses both numbers of micro-organisms and their resistance to radiation (18, 19).

Irradiation Mechanisms for Polymeric Packaging Materials

The types of radiation used in material treatments are limited to radiations from high-energy γ-rays, X-rays, and accelerated electrons. X-rays with varying energies are generated by machines. γ-rays with specific energies come from the spontaneous disintegration of radionuclides. Naturally existing and man-made radionuclides, which are also called radioactive isotopes or radioisotopes, emit radiation as they spontaneously revert to a stable state. There is a half-life specific for each radionuclide of a distinct element. The becquerel (Bq) is the unit of radioactivity and equals one disintegration per second (Table 2). Energies from these radiation sources are too low to induce radioactivity in any material, including food and medical products. Cobalt-60 is a radionuclide used almost solely for the irradiation of food and medical products by γ-rays. It is produced by neutron bombardment in a nuclear reactor of the metal cobalt-59, and then it is doubly encapsulated in stainless steel to prevent any leakage during its use in an irradiator. The γ-rays produced are highly penetrating and can be used to treat full boxes of fresh or frozen food. Cesium-137 is the only other γ-emitting radionuclide acceptable for industrial processing of materials. It can be obtained from used nuclear fuel elements (14). However, there is no supply of commercial quantities of cesium-137. Cobalt-60 has therefore become the chosen source for γ-radiation. Over 80% of the cobalt-60 available in the world

Table 2. Unit of radiation dose and radioactivity (14)

	Absorbed dose	Radioactivity
Unit	gray (Gy)	becquel (Bq)
Definition	1 Gy = 1 J/kg	1 Bq = 1 disintegration/s
Former unit	rad	curie (Ci)
Conversion	1 rad = 0.01 Gy	1 Ci = 3.7×10^{10} Bq = 37 GBq
	1 krad = 10 Gy	1 kCi = 37 TBq
	1 mrad = 10 kGy	1 mCi = 37 PBq

market is produced in Canada. Other source producers are the Russian Federation, the People's Republic of China, India and South Africa (20). High-energy electron beams can be produced from machines that can accelerate electrons to near the speed of light using a linear accelerator. Because electrons cannot penetrate very far into food and medical products compared with γ-radiation or X-rays, they can only be used for processing food with thin packages. X-rays of various energies are produced when a beam of accelerated electrons bombards a metallic target. The efficiency of conversion from electrons to X-rays is generally less than 10%. Radiation dose is the quantity of radiation energy absorbed by the food or medical products as it passes through the radiation field during processing. It is measured using a unit called the gray (Gy). In terms of energy relationships, 1 Gy equals 1 J of energy absorbed per kilogram of food being irradiated. The maximum dose of 10 kGy recommended by the Codex General Standard for Irradiated Foods is equivalent to the heat energy required to increase the temperature of water by 2.4°C (Table 2). Irradiation is often referred to as a cold pasteurization process because it can accomplish the same objective as the thermal pasteurization of liquid foods, for example milk, without any substantial increase in product temperature (14). The use of X-rays is considered low-ionization-density radiation. As a result, X-rays tend to reveal deep penetration of over 1.0 M in organic media and deposit their energy in at most a few discrete steps. Incident electrons, in contrast, are charged, have mass, and interact readily with polymer electrons through coulombic repulsion. Their energy tends to be dissipated in an almost linear fashion through rapid interactions with countless polymer electrons (7, 21). X-rays and γ-rays are electromagnetic waves with a much shorter wavelength than visible and ultraviolet (UV) light. The energy levels of X-rays overlap with γ-rays. The X-ray is distinguished from γ-ray by its origin. γ-rays originate from atomic nuclei through isotopic decay, whereas X-rays are produced when high-energy electrons decelerate on impact with the nucleus of another molecule (22). When an X-ray or γ-ray with greater energy than ionization energy of the weakest electron collides with a polymer, the weakest electron is thrown out from the polymer and a positive ion remains.

$$\mathrm{AB} \rightarrow \mathrm{AB}^{+} + \mathrm{e}^{-}$$

Generally, the amount of energy needed to create this ion pair is about 32.5 eV, and this ionization effect is completed within about 10^{-12} s.

Free radicals are formed from the production of ion pairs and immediately results in molecular dissociation:

$$\mathrm{AB}\bullet \rightarrow \mathrm{A}^{+} + \mathrm{B}\bullet + \mathrm{e}$$

If the energy transferred to an electron is less than the ionization potential of the atom, then there may still be enough energy to promote the electron from its ground state to its excited state, which is referred to as excitation.

$$\mathrm{AB} \rightarrow \mathrm{AB}^{*}$$

Often, these excited states are identical with optical excitation states, and the excited molecules produce radiation-induced chemical reactions that are similar to those that result from excited states produced by the absorption of a quantum of light (21). As a result, the products of radiolysis are at least qualitatively similar to the products of photolysis in many systems.

Applications for Irradiation of Packaged Foods and Medical Products

With the exception of applications such as: (a) sprout inhibition in potatoes or onions, (b) insect disinfestation in bulk grains, or (c) the delay of post-harvest ripening of fruits, food irradiation processes are usually carried out on packaged food. There may be different reasons for the use of packaging: (1) prevention of microbial reinfection or insect growth, (2) prevention of water loss, (3) exclusion of oxygen, (4) prevention of mechanical damage during transport, or (5) improvement of handling and marketing. The packaging material used must not release radiation-induced degradation or addition products or additives into the food, and it should not lose functional qualities such as mechanical strength, seal stability, or impermeability after irradiation (23, 24).

Plastic films laminated with aluminum foil are routinely sterilized by radiation as part of the manufacturing process. They are used for sealed "bag-in-a-box" products, such as tomato paste, fruit juices, and wines. Other aseptic packaging materials, dairy product packaging, and single-serving containers, for example, cream and wine bottle corks, are also routinely sterilized by irradiation prior to filling and sealing to prevent product contamination. Other types of materials used to wrap food or other products are also routinely processed by radiation in many countries. The radiation process is used to crosslink the polymer chains for greater strength and heat resistance, for example, heat-shrink wrap (14).

The principles of International Standardization Organization (ISO) dose-setting Method 1 (ISO 11137) are basically identical to those embodied in Association for Advancement of Medical Instrumentation (AAMI) Method B1, which are described originally in the American National Standards Institute (ANSI)/AAMI ST 32-1991. The method for substantiation of 25 kGy as a medical products sterilization dose, given in ISO/TR 13409, is an adaptation of the same AAMI dose-setting method (25, 26).

PHYSICOCHEMICAL CHANGES OF POLYMERIC PACKAGING MATERIALS DURING IRRADIATION

Molecular Weight

The chemical behaviors of polystyrene (PS) and PVC at a dose of a 100-kGy electron beam were studied by size exclusion chromatography (SEC). After this treatment, the value of the weight average molecular weights (Mw) and z-average molecular weights (Mz) increased compared with control polymers. Thus, it suggested that the process of crosslinking had taken place in two polymers by in electron beam radiation. In addition, there was a slight decrease in the number of average molecular weight (Mn) after treatment. This change confirms that a splitting process occurred because Mn is sensitive to a reduction in small macromolecular species contained within the polymers (2). Degradation was the major occurrence after the initial step of γ- and electron-beam radiation of PP, which was not related to the atmosphere and/or antioxidant. However, double bond formation increased the production of branching and crosslinking reactions. A PP with a high melt strength at low dose was obtained, which indicates that controlling the branching reaction was useful for producing a polymer with special rheological properties (27).

Electron paramagnetic resonance (EPR) spectroscopy was used to characterize free radicals in γ-ray-irradiated biodegradable polymers. In general, polymers with high melting points and crystallinity had the highest yields of radicals at room temperature (28). Electron beam radiation was performed at both room temperature (293 K) and 77 K (29). The effects of γ-irradiation on the physicochemical characteristics of biaxially stretched poly (ethylene terephthalate) (PET) packaging film were investigated in the range of 0–200 kGy. The diethylene glycol (DEG) contents in PET chains were increased at low doses (5 and 10 kGy), whereas these values decreased at doses in the range of 30–200 kGy. Molecular weights, intrinsic viscosity, and the levels of carboxy end groups decreased slightly after treatment with a 60-kGy dose (30).

Polymer Structure

Polymer structure undergoes crosslinking at high doses of γ-radiation. Styrene-acrylonitrile copolymers and polybutadiene (PB) are not as resistant to radiation compared with PS but are still fairly stable. As in PS, the aromatic ring structure absorbs a large part of the radiation energy. Polybutadiene easily undergoes both crosslinking and degradation (11).

Mechanical Properties

The results of evaluations of (a) resistance to γ-radiation (0–25 kGy), (b) tensile strength, and (c) elongation at break for plastic films such as low-density polypropylene (LDPE) and bidirection copolypropylene were reported. When the radiation dose was increased to a range of 10–25 kGy, the tensile strength rate and elongation at break lowered slightly compared with the samples irradiated at a 5-kGy dose, although these samples still had values higher than those obtained from the unirradiated LDPE. This reveals that the mechanical properties of LDPE irradiated at these doses were improved. This correlates to the relation between gel formation and radiation dose. When samples of nylon/sarin/polyethylene or bidirection copolypropylene were irradiated at a dose of 5 kGy, there was a significant increase in tensile strength rate, and the elongation at break lowered slightly compared with unirradiated samples (8). In another study, the effects of γ-irradiation on ethylene vinyl alcohol copolymer (EVOH) were investigated. Irradiation increased tensile strength (TS) and elongation at break (*%E*) of EF-CR; whereas the TS of EF-XL was not significantly changed and *%E* of EF-XL decreased. Irradiation had no effect on TS and *%E* of nylon/EVOH/PP (31).

Gas Permeability

PP film samples were prepared with isotactic PP granules, which were hot pressed and cooled by three different methods to obtain three different crystalline states with various thicknesses and were γ-irradiated with a dose of 25 kGy. The diffusion of oxygen has an inverse relationship with crystallinity and film thickness (32). Irradiation of nylon/poly (vinylidene chloride) (PVDC)/ethylene vinylacetate (EVA) barrier film caused changes in mass transfers of the packaging material. γ-radiation induced higher amounts of mass transfer than beta radiation. Oxygen permeability was affected by irradiation. These concerns are particularly important in cases where barrier materials are used for maintaining the quality of prepackaged products, which are irradiated to obtain a longer shelf life (33). Oxygen permeability decreased as γ-irradiation dose increased in nonoriented and biaxially oriented EVOH and nylon/EVOH/PP (31).

Thermal Characteristics

The effect of γ irradiation and electron-beam irradiation on thermal characteristics of PP is examined with differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) coupled with Fourier transform infrared (FTIR). In the case of the higher doses, the loss of crystallinity is greater for γ-ray-treated PP than for electron-beam-treated PP. This suggests that both types of radiation cause a decrease in the length of the macromolecular chains, crosslinking, and other modifications in the crystal domains. This degradation mechanism is emphasized by the presence of air, which leads simultaneously to oxidation (34). The thermal properties of an LDPE/high-density polyethylene (HDPE) (75/25) blend after exposure to γ-radiation up to 2000 kGy have been measured. The melting and crystallization temperatures tended to decrease as the radiation dose increased and show a tendency to stabilize at higher values (35). The effects of γ-radiation dose on the isothermal and nonisothermal crystallization of LLDPE, LDPE and HDPE by DSC were studied (36). This includes a qualitative comparison of nonisothermal data and quantitative data for crystallization rate and nucleation mode. The isothermal crystallization allowed for the observation of changes in the crystallization rate related to a decrease in the crystallization temperature caused by the crosslinking of the polymer. In nonisothermal crystallization, the development of crystallites depends on the crystal sizes in the polymer.

Effects of Stabilizers in Polymer

The effect of γ-irradiation on PS without additives is negligible even when high doses are used. However, the role of antioxidants and stabilizers are decisive in PB and butadiene-containing copolymers (11). Dioctyl phthalate (DOP) and epoxy soybean oil (ESO) were added to PVC and irradiated up to 50 kGy. Mechanical properties, optical properties, and viscosity were measured and compared with nonirradiated PVC. In conclusion, DOP and ESO were shown to be effective in stabilizing the radiolytic abstraction of HCl from PVC. Both plasticizers gave good color stability and overall properties to the products (37). A breakage test on bending has shown that the PP containing a plasticizer and antioxidant improved radiation stability as compared with PP alone. Also the excellent color stability has shown in formulated PP not PP alone after irradiation treatments (38).

RELEASE OF ADDITIVES AND THEIR DEGRADATION PRODUCTS DURING IRRADIATION

Additives in Polymeric Packaging Films

Packaging has become an essential element in the food manufacturing process, and different types of additives, such as antioxidants, stabilizers, lubricants, antistatic agents, and anti-blocking agents have also been developed to improve the performance either during manufacturing or in the use of these polymeric packaging (1). In general, Commission of the European Communities (CEC) Directives introduced limits on the overall migration from plastics into food and food simulants. In addition, specific migration limits for free monomers in the final article have been set for some monomers. Currently, the limit for overall migration was set at 10 mg/dm or 60 mg/kg of a food simulant. It also includes the lists of permitted monomers together with the restrictions that apply to specific monomers (39). In the United States, the regulations include both the basic polymer resins used in food packaging and the adjuvants, which are added to a polymer in the process of manufacturing the final food package articles. Regulations frequently contain specifications for the resin, such as residual monomer content. The time, temperature, and solvent conditions for the short-term extraction tests are also referred to in the regulations (40). A large amount of research regarding the migration of volatiles, additives, monomers, and oligomers from plastic packaging materials into food were investigated.

Identification of Volatile Transformation Products After Irradiation

The volatile γ-radiolysis products of six medical polymers: PS, methyl methacrylate-acrylonitrile-butadiene-styrene (MABS), nylon, PVC, and PP, by thermal desorption (TDS)-gas chromatography (GC)-mass spectrometry (MS) after sterilizing doses of $\sim$25 kGy were identified (41, 42). The main radiolysis products of PS are acetophenone, benzaldehyde, phenol, 1-phenylethanol, and phenylacetaldehyde. The same volatiles are observed in MABS, which gives some separate aliphatic compounds. The main products of PVC and PP are fragments of additives, i.e., of stabilizers and phenol-type antioxidants, respectively. The volatile compounds produced in flexible food packaging materials, LDPE, EVA, and PET/PE/EVOH/PE, during electron-beam irradiation using the purge and trap technique and by combined GC-MS. Both primary, i.e., methyl-derivates, and so on, as well as secondary, i.e., oxidation products, ketones, aldehydes, alcohols, carboxylic acid, and so on, are produced during irradiation with doses of 5, 20, and 100 ky were isolated and identified (3). The polymer materials, PE, PP, PET, polyamide (PA), PS, and PVC were investigated after treating with an γ-radiation dose of 44 kGy. The quantitative changes in compositions of radiolysis products of each packaging material were measured. The polyolefine materials such as PE and PP showed an increase of low volatility compounds after irradiation due to an oxidative decomposition of the polymer, oligomers and additives. Other packaging materials such as PET, PA, and PS did not show a meaningfully change their amount of solvent-extractable compounds after irradiation with 44 kGy. The PVC packaging material used in this study was not resistant to irradiation treatment. Because of the release of hydrochloric acid during irradiation, a large amount of volatile substances could be extracted from the PVC sheet. Most attention should be paid to low-volatility radiolysis products, which are the most likely to migrate into a foodstuff or a pharmaceutical product (43). Volatile radiolysis products of LDPE and PP films were investigated by TDS-GC-MS after absorbed doses of up to 25 kGy. The radiation-induced compounds are mainly hydrocarbons, aldehydes, ketones, and carboxylic acids with concentrations one order of magnitude below that of the residual hydrocarbons. The radiolysis products are retained for considerable times in LDPE films, and they remained in PP films much longer than in LDPE films (42). Four volatile compounds: ε-caprolactam, 2-propyldecanol, 2-butyloctanol, and 2,3-diethyl-2,3-dimethyl-1,4-butanediol, were detected after γ-irradiation of EVOH. (31)

The Presence of Extractable Antioxidants After Irradiation

The effect of electron-beam irradiation on the migration behavior of additives present in food packaging material was studied with PP pouches that contained aqueous food simulants. The loss of some products of antioxidant degradation from the material can be correlated to the presence of these same products in the food simulants. This observation led us to assume that components of the packaging material could migrate into the aqueous food simulants (44). The chromatograms from reversed-phase (RP)–high-performance liquid chromatography (HPLC) for the extraction solutions corresponding to the PP control and those treated with γ-ray and electron beam were obtained. Two compounds were identified; the first is the antioxidant tris-(2,4-di-*tert*-butylphenyl) phosphite (Irgafos 168) and the second corresponds to its degradation product phosphate. For the lower dose of 25 kGy, irradiation induces a large decrease of phosphate levels but has little effect on the levels of phosphite. In the case of γ-ray-treated PP, the levels of phosphite antioxidant decrease as the absorbed irradiation dose increases. There were no noticeable trends in the electron-beam-treated PP. The amount of the phosphate compound is considerably lower after both radiation treatments (34). Tris-(2,4-di-*tert*-butylphenyl) phosphite (Irganox 168) and its corresponding phosphate in HDPE food trays as a function of γ-irradiation were identified and quantified. The complete degradation of phosphate to phosphate occurs at low

γ-irradiation doses, i.e., 5 kGy. Because treatment with such a low dose of γ-irradiation leads to the conversion of phosphite to mainly phosphate, the formation of phosphate during melt processing and radiation sterilization of these HDPE trays must take into account products from the irradiation of phosphate (45). Thermal desorption indicated the formation and release of 1,3-di-*tert*-butylbenzene (1,3-DTBB) during γ-irradiation of the HDPE (46). After γ-radiation of PE, PP, and PS, the contents of antioxidants significantly decreased. Irgafos 168 disappeared the fastest. 2,4-DTBP was detected not only after irradiation but also before irradiation, whereas 1,3-DTBB and 2,6-di-*tert*-butyl-p-benzoquione (2,6-DTB BQ) were detected only after irradiation (47, 48). Ninety-six percent of the initial phenolic stabilizer was undetectable after electron-beam radiation. A phosphite stabilizer and its reaction products accounted for 35% of the initial amount. The sum of all potential migrants derived from the additives accounted for less than 1% of global migration. This extensive migration was mainly caused by oligomers (49). Polyolefin polymers may undergo degradation through oxidation by air and UV light. Antioxidants are added to stabilize the polymer because they will be preferentially degraded. Hindered phenol and triphenyl phosphite as antioxidants are widely used in the polyolefin industry. Unfortunately, these compounds and their decomposed products can be released onto the foods during irradiation. Tests are still underway to determine the genetic effects, if any, of these compounds (1).

To evaluate the chemical or toxicological risk caused by irradiation, it is necessary to identify and quantify the compounds (50). The residues of antioxidants pentaerythrityl-tetra-kis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propionate] (Irganox 1010) and Irganox 1076 in PVC, PP, and PE were tested. Incremental increases in γ-radiation proportionally reduced the extractable levels of these compounds. Individual reductions were dictated by polymer and antioxidants type but were approximately 30% at 10 kGy (7). 2,4-DTBP and tris-(2,4-DTBP) phosphate come from Irgafos 168, and 2,6-DTBBQ comes from the Irganox 1010, after the irradiating of PP with electron beams at doses 2.5 and 10 kGy. Also, the above compounds were found in aqueous food simulants. Because the absorbed dose by food simulants could be lower than the dose absorbed by PP and the migrated compounds from PP were decomposed into unknown products, the quantities of the migrated compounds in food simulants were lower than those of compounds in PP (44, 50). A dose of $\sim$7 kGy γ-radiation in HDPE was required to drive the Irgafos 168 concentration to zero as determined by using infrared (IR) spectroscopy (45). The 2,4-DTBP was detected in the tray samples by thermal desorption, followed by GC-MS, and it may come from the storage hydrolysis of Irgafos 168 in HDPE (46). The kinetics of antioxidant migration from PP into fatty food simulants was studied via the diffusion coefficients (51).

The long-term influence of electron beam irradiation (2.5 and 10 kGy) on food packaging materials and oriented polypropylene (OPP) was studied. It was shown that a partial or complete disappearance of the antioxidants (Irganox 1010 and Irgafos 168) occurred over time and that a new compound was released as a result of antioxidant degradation (50). Effects of γ-irradiation on residual and migration levels of the antioxidants, tris-(2,4-di-*tert*-butylphenyl) phosphite (Irgafos 168), and octadecyl-3-(3,5-di-*tert*-butyl-4-hydroxyphenyl) propionate (Irganox 1076), as well as their radiolysis products, were investigated in the linear LDPE (LLDPE) packaging samples treated with doses from 0 to 200 kGy. Irgafos 168 was not detected in 5 kGy-treated samples, and the levels of Irganox 1076 decreased by 34.9% from the initial level in 10 kGy-treated samples. The radiolysis products 2,4-DTBP, 1,3-DTBB, and toluene were identified, and their concentrations gradually increased as the irradiation dose increased. Migration of Irgafos 168 from the LLDPE pouch into food simulants, distilled water, acetic acid (4 mL/100 mL distilled water), or ethanol (20 mL/100 mL distilled water) was not detected at dose levels up to 200 kGy, whereas that of the Irganox 1076 was detected in a decreasing manner with an increase in dose (52). The food packaging polymers PS, polycarbonate (PC), PA-6, and PVC, were irradiated with doses in the range of 5–200 kGy. The quantities of corresponding monomer residues (styrene monomer, bisphenol-A, ε-caprolactam, and vinyl chloride) released from target materials were analyzed using a SIM mode of GC/MSD. Styrene monomers in PS showed a slight increase from 740 to 777 ppm at 5–30 kGy and then decreased as the dose increased from 30 to 200 kGy. Bisphenol-A in PC was dose independent at the low doses of 5, 10, and 30 kGy, but its level increased from 173 to 473 ppm at 30 kGy and thereafter remained unchanged through 200 kGy. ε-Caprolactam in PA-6 was also dose independent in the range of 5–200 kGy, but its level (122–164 ppm) was found to be higher than those of nonirradiated samples (71 ppm). As for PVC, the quantity of vinyl chloride tended to increase from 8 to 18 ppm at 5–200 kGy (53).

RADIO FREQUENCY IDENTIFICATION (RFID)

William McCombie
Bruce A. Welt

Engineering Department,
University of Florida/IFAS,
Gainesville, Florida

INTRODUCTION

Radio-frequency identification (RFID) is a method for automatic identification that relies on storing and retrieving data from transponder "tags." RFID systems require readers equipped with one or more antennas connected to back-end computer systems. Tags are equipped with power generation and regulation, control circuitry, data memory, and communications capability. Readers activate tags to initiate data transfer via radio signals. Proponents expect RFID technology to replace conventional barcode technologies. To date, RFID has been evaluated and implemented in a number of applications including supply chain tracking, animal identification, and toll collection. Opponents to RFID suggest that the technology does, however, have some drawbacks, including cost of implementation, reliability, performance, and potential for privacy misuse issues.

HISTORY

RFID has roots in several technologies. One such technology dates back to World War II, when Great Britain implemented a system known as "Identity Friend or Foe" to identify incoming planes as either friendly or enemy. A ground transmitter would send a signal to a plane, and a transponder on the plane would respond with an encrypted message indicating whether the plane was friendly. Modern RFID works on the same basic principle.

The first patent for a passive RFID-type system was filed in 1970 (U.S. Patent 3,713,148). The term RFID was first used in U.S. Patent 4,384,288 entitled, "Portable radio frequency emitting identifier." Since then and particularly within the last decade, many RFID-related patents have been issued. Significant patent holding companies include Internic, Motorola, Alien Technology, and IBM. Modern technology has been able to produce microchips with RFID capability, allowing RFID to be used in many applications at relatively low cost. However, the question remains as to whether the costs are or will be low enough to replace barcodes.

Proponents of RFID technology envision a future in which any object can be wirelessly tracked. One vision involves the smart, automated supermarket. This vision has customers exiting supermarkets without stopping at the cashier. Instead, embedded RFID tags in merchandise packaging would automatically interface with readers located on the shelves and at the exit of the store. Payments would be processed with RFID-enabled payment cards. Simultaneously, "smart shelves" would detect those items removed for purchase to provide real-time inventory reporting allowing optimal logistics and supply, merchandizing, and therefore optimizing sales while and minimizing out-of-stock items.

This vision continues into the home. Purchased groceries would interface with smart appliances. A smart refrigerator would alert consumers to expired or finished merchandise and order new products as required in accordance with consumer defined rules. Smart ovens would properly cook foods by retrieving detailed cooking instructions tags embedded in packaging. Such devices have already been developed in numerous academic and corporate laboratories. One such device, already developed by Samsung, uses 2D barcodes printed on product packaging rather than RFID tags (1). Finally, when packages are disposed of or recycled, tags might be used to facilitate automated sorting in order to route materials for optimal recycling, energy conversion, or disposal.

Such technologies are in developmental stages today. The Metro Extra Future Store in Rheinberg, Germany performed an experiment with RFID in which certain items in the store were individually tagged. Several items were placed on "smart shelves," which detect removed items and signal back-end systems to request more stock. Some items had tags attached to the packaging, while

Table 1. Summary of RFID Technologies

Method	Company	Description	Progress
Fluidic self-assembly	Alien Technology	Chips are attached by flowing in a special fluid over holes shaped to catch the chips.	Alien claims that prices will continue to drop as FSA production increases.
PICA (parallel integrated chip assembly)	Symbol Technologies	Attaches RFID chips to inlays (antennas) in parallel.	Expected to be online in 2006; however, this is not the case.
Conventional methods	Various companies	Tags are manufactured by attaching each chip to each antenna individually.	

other items, such as Gillette razors, had tags embedded at the factory.

Digital video disks (DVDs) stocked by the store also contained RFID tags and were used in conjunction with interactive kiosks, allowing shoppers to watch movie previews. The store also embedded RFID tags in its customer loyalty cards, but this was later discontinued after privacy advocates protested the practice (2).

Currently, RFID tags cost as low as about 7¢ per tag when purchased in multimillion unit quantities. Manufacturing costs continue to be relatively high as manufacturing processes are improved and scaled. However, failure rates of RFID tags continue to be unsustainably high. Defective tag rates, postapplication tag failure rates, and overall tag longevity are not well known as manufacturers are reluctant to share such data. However, experience with various tag types suggest defective rates in the range of 30% and postapplication failure rates in the 5–20% range within one year of application. Rigorous, third-party studies are needed to more fully understand RFID tag failure modes and rates.

Alien Technology and Symbol Technologies (now Motorola) are both attempting to reduce this cost with Fluidic Self-Assembly (FSA) and Parallel Integrated Chip Assembly (PICA), respectively (3, 4). Table 1 summarizes these technologies.

INDUSTRY STANDARDS FOR AUTOMATIC IDENTIFICATION

Barcodes

Barcodes have been around for many years, and there are many standards. One of the most common in the United States is the Universal Product Code, which retailers use to identify merchandise. Other standards exist, many of them proprietary. Most barcodes, however, do not uniquely identify an item, but rather an item type (e.g. “case of super-widgets” versus “this case is the 82nd case of widgets.”)

UID

Universal Identification is a method used by the United States Department of Defense (DOD) to identify assets (5). DOD describes its needs for unique identification capabilities as follows (6):

> The Department must, of necessity, uniquely identify the items to which it takes title to provide for better asset accountability, valuation and life cycle management. Unique identification provides the Department the opportunity to differentiate an individual item from all others. Unique identification of items provides the Department with the source data to facilitate accomplishment of the following:
>
> - Improve the acquisition of equipment- and performance-based logistics services for the warfighter,
> - Capture timely, accurate, and reliable data on items (i.e., equipment, reparables, materials, and consumables),
> - Improve life-cycle asset management.
> - Track items in the department and industry systems for operational, logistic, and financial accountability purposes.

While DoD’s UID mandate requires physical marking of all items with a unique code, RFID is being used as a means to transfer UID information. UID is primarily implemented using two-dimensional “DataMatrix” style barcodes.

EPC Global

The Electronic Product Code (EPC) is a set of standards initiated by the Massachusetts Institute of Technology (MIT) Auto ID Labs and eventually overseen by EPC Global Inc. The EPC protocols intend to ensure that all tags, RFID or otherwise, are coded with unique values. EPC Global defines a set of standards for hardware, software, and the codes themselves. An EPC can contain a preexisting standard, such as Global Trade Identification Number (GTIN), Serial Shipping Container Code (SSCC), Global Location Number (GLN), Global Returnable Asset Identifier (GRAI), or Global Individual Asset Identifier (GIAI), and provides specifications for implementing such codes within an EPC (7).

The EPC standard dictates how data should be stored on tags, in addition to translating codes from one format to another. An example of how UPC/GTIN is implemented as a unique and serialized EPC SGTIN code follows.

Global Trade Identification Number (GTIN) is one method of identifying objects with an automated data capture system. GTIN, like UPC, does not, however, uniquely identify items. The EPC system includes a serialized GTIN, known as Serialized Global Trade

Table 2. Example of SGTIN-96 Encoding

Field	Header	Filter	Partition	Company	Item	Serial
Number of bits	8	3	3	20-40 (dependant on partition size)	24-4 (dependant on partition size)	38
Description	Set to 0×30 to indicate SGTIN-96 encoding	Determines the type of item, such as a pallet, carton, or item	Determines the size of the company and Item fields	Identifies the company that produced the item	Identifies the item the tag is attached to, such as a box of detergent	Serial number to uniquely identify a product (i.e., which box of detergent)

Identification Number. The code includes a header (used to identify the encoding to the reader, whether it is SGTIN or another standard, and the size of the tag in bits); a filter to separate loads by pallet, case, or item; a company identification number; a product identification number, and a serial number. This information can be used to query a database to find out more information about tagged items. The 64- and 96-bit EPC compliant tags are currently available; however, 64-bit tags are being phased out. Table 2 shows an example of SGTIN-96 encoding.

It is worth noting that although EPC was developed to be used with RIFD, industry is realizing that serialized codes can also be implemented with other identification methods, including barcodes.

Hardware. EPC Global standards define operational characteristics for hardware, including frequency and wireless communication protocols. These standards provide for common communications methods and interfaces that allow components from different companies to work together.

Software. RFID middleware is software used to interface between RFID readers and other components, including user interfaces, databases, and other applications. The main purpose of middleware is to simplify interfacing back end systems with new RFID hardware. As RFID gains acceptance, RFID software and backend systems are being developed to more easily integrate, thus putting into question the long-term need for middleware applications. There are several commercial and open source packages available on the market, including solutions from Microsoft, Inc., ConnecTerra, Inc. (now BEA Systems, Inc.), GlobeRanger, Inc., IBM, Inc., and Sun Microsystems, Inc.

Middleware packages are capable of interfacing directly with RFID devices and can translate information from the reader(s) into formats that can be used by other applications. An EPC Global encoded tag, for example, can be broken down into specific values for company, item, and serial number, while the middleware performs one action for carton tags and another for pallet tags. Another advantage of using middleware is compatibility with different brands and models of RFID readers.

It is worth noting that middleware is not necessarily limited to RFID technology. Most packages are compatible with conventional barcode systems and other systems as well.

RFID devices are being offered with increasing levels of middleware functionality built in. These are capable of doing basic middleware operations without the need for additional software. Alternatively, for some applications, such as those where only a single reader is used, custom software can be written to interpret tag information.

APPLICATIONS

One of the largest applications of RFID is supply chain management. This industry has used conventional barcodes for years with great success. RFID initiated serialization offers potential to greatly enhance supply chain visibility and enables suppliers and retailers to track goods from the point of manufacture to the store shelf and beyond.

The lowest level of RFID tracking is known as “item level” tagging and consists of placing RFID tags on individual items, in a manner similar to UPC labels on most grocery products. Item level tagging has been tested and implemented in several retail environments, such as at Wal-Mart stores and Metro Group’s *Extra Future Store* initiative in Germany. Most modern implementations, however, have been limited to case and pallet levels. Wal-Mart is one of the largest backers of the technology and has put it to use to in an effort to improve supply chain efficiency, reduce labor costs, and reduce shelf out-of-stocks, apparently resulting in increased sales (8, 9). Electronics retailer Best Buy Co. Inc. (Richfield, Minnesota) also experimented with item level RFID on DVDs and video games. The initial trial was linked to increased DVD sales due to reductions in out-of-stock merchandise (10).

The supply chain is not the only place where RFID has been implemented. Toll booths have used RFID to automatically collect tolls using transponders carried by motorists. Examples include SunPass (a toll collection system used in Florida) and EZ-Pass (a toll collection system used in the northeastern United States).

A primitive form of RFID is Electronic Article Surveillance (EAS). A major supplier of EAS systems is Tyco, Inc.’s (Pembroke, Bermuda) ADT Division (formerly Sensormatic of Boca Raton, FL). Instead of using a chip to store information, EAS tags use simple tuned circuits that respond to particular radio frequencies. Such systems are commonly used in retail stores to deter shoplifting, and they are also used in libraries to prevent removal of articles that have not been checked out. Such tags are either removed or deactivated at check-out to prevent

Figure 1. Checkpoint EAS antennas use special one-bit tags to detect unauthorized removal of products from premises.

them from triggering alarms when removed from the premises. Figure 1 shows Checkpoint Systems Inc. (Thorofare, NJ) EAS antennas at the entrance to the University of Florida bookstore. Upon removing an unpaid item (or an item that has not been deactivated properly), such as a textbook, an alarm will sound, alerting store staff. Checkpoint also manufacturers EPCGlobal compatible RFID products and produces a line of EAS devices that may be upgraded for use with RFID systems. Other applications of RFID include ExxonMobil's (Irving, Texas) SpeedPass, first used in 1997. It was a system that allowed cashless payments at Mobil/Exxon fueling stations, and also at McDonald's fast food restaurants with a simple keychain attachment (11).

Credit card manufacturers have also recently started embedding RFID chips within credit cards for cashless payments, and many cities have used RFID for transport payments. Examples include Visa's *payWave*, MasterCard's *PayPass,* and American Express's *ExpressPay.*

Animal tracking is another application of RFID. Domesticated pets and livestock can be injected with a subdermal RFID chip, improving herd management and allowing lost animals to be identified.

TYPES OF RFID

Passive RFID

Passive RFID is a type of RFID tagging in which tags are not self-powered. Passive tags are designed to harvest power from radio signals transmitted by an RFID reader at a particular frequency. When within the electromagnetic field emitted by the reader, passive tags activate and respond as required to interrogation. The two most common passive technologies involve high-frequency (HF) and ultra-high-frequency (UHF) energy. The HF mode uses the magnetic component of the field and has a very short read range. HF tags typically need to be within a few centimeters of a reader. UHF tags offer greater read ranges that are typically on the order of a 2–10 ft. UHF tags are more common for supply chain applications, whereas HF tags are finding greater use in asset management and other applications that require more intimate proximity between reader and tag (e.g., hospital patient bracelets for drug distribution). UHF tags communicate using the principle of backscatter radiation. Essentially, the tag reflects a portion of reader's energy back to the reader with a superimposed modulated signal (12). Tag performance depends upon antenna size and geometry.

Tag size is mainly due to the antenna. Larger antennas tend to provide longer read ranges. Current technology has enabled tags to be embedded in paper or under the skin. Hitachi's μChip, for example, is 7.5 μm thick (13). Passive RFID tags have been used for tracking pallets of goods, contactless "smart cards," and machine readable passports. Figure 2 shows some passive RFID tags.

Active RFID

Active RFID involves tags with an internal power source, such as a battery. One common application of active RFID technology is electronic toll collection. Active RFID tags may also be paired with one or more different types of sensors, such as temperature sensors. Toll collection devices may include some form of feedback, alerting the user when a toll is collected. Active RFID tags are much more expensive than passive RFID tags and are typically in the $5 to $100 range. Figure 3 shows an active RFID sensor developed at the University of Florida to assist in monitoring food freshness (14).

Semiactive/Semipassive

Semiactive/semipassive RFID tags, like active tags, also contain a power supply, but this power supply is only used to power the circuitry. The radio signal is transmitted using power from the incoming radio signal. Semiactive/semipassive RFID technology is being developed primarily for "smart" reusable containers and pallets.

Frequencies

Many RFID systems can interface with tags from other systems if the frequencies and protocols are the same. There are some standards to frequencies, and lower-frequency tags are generally less expensive but have a shorter range (Table 3) (15).

ADVANTAGES AND DISADVANTAGES OF RFID

Advantages

Unlike barcodes, which require a line of sight between reader and barcode, RFID tags interface with readers using radio signals. RFID chips are tiny while storing hundreds or thousands of bits of information, which allows tags to be hidden from view. By comparison, barcodes require clearly visible area on items or packaging, and this area requirement generally increases with the amount of data stored.

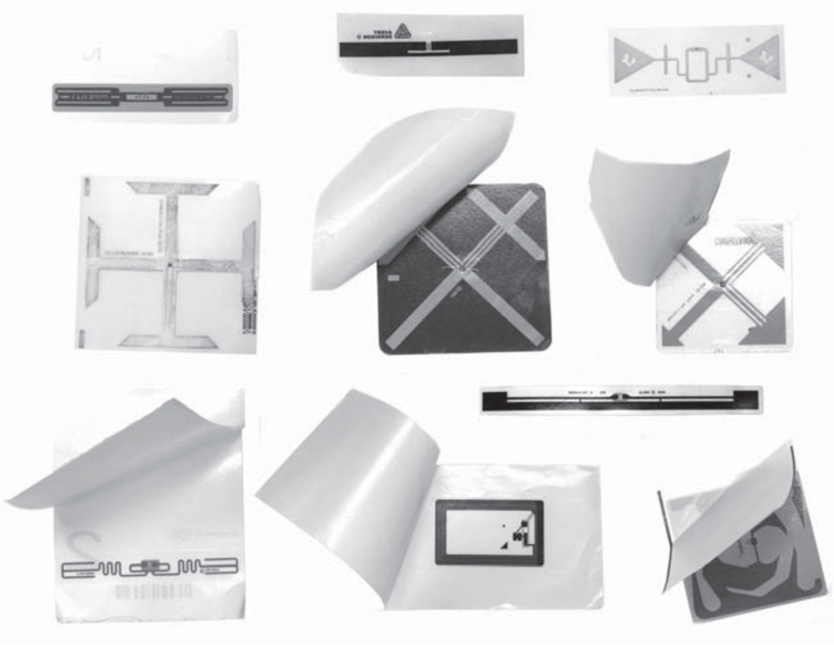

Figure 2. Assorted passive UHF RFID tags.

Data collection rate is the primary advantage of RFID. Since barcodes require line-of-sight for data collection, barcode read rates depend upon rates at which barcodes can be presented to readers. RFID tags communicate without line of sight and at high frequency allowing tens or hundreds of tags to be read each second. However, this inherent advantage of RFID is mitigated by the rates at which items such as containers, pallets, cases and items can be physically moved through the supply chain. Since barcode readers are capable of reading data on items at the highest speeds attainable within the supply chain, this RFID advantage may not be fully exploitable.

Figure 3. Active RFID freshness monitoring tag developed at the University of Florida.

Another advantage of RFID is that it helped to introduced standards and serialization to industry. With conventional UPC/EAN barcodes, each package of an item contains an identical product code. They identify only the manufacturer and the product type. A serialized RFID tag, on the other hand, contains a serial number, allowing a reader to determine which package of a product is being scanned. This information can be queried into a database to determine the source, expiration date, and other useful information about a particular item.

Disadvantages

Data Transmission. In theory, radio signals can be read without direct line of sight between tags and readers. In practice, however, something close to line of sight is often necessary due to dielectric properties of tagged items. Many products are good absorbers of electromagnetic energy used for RFID, which interferes with low power RFID transmissions. Additionally, many products contain metals or metal packaging. Metals shield, scatter, and reflect radio signals, resulting in unpredictable RFID performance. Therefore, maximum, or at least predictable, RFID performance is often obtained when the least material is placed between tag and reader, practically negating the purported “no line of sight” benefit.

Reliability. As with any electronic device, RFID tags have a tendency to fail. Most passive RFID tags consist of an integrated circuit connected to an antenna. Should the chip, antenna, or the connection between the chip and

Table 3.

Technology	Frequencies	Read Range (Approximate)	Characteristics	Applications
Low frequency	<135 KHz	<1 ft	Coiled antennas Can work around fluids and metals	Animal identification Automation Access control
High frequency	13.56 MHz	>3 ft	Common around the world Poor performance around metals	Payment and loyalty cards Access control Item level tracking People identification
Ultra-high frequency	433 MHz 860 MHz-930 MHz (depending on region)	>10 ft 100's of feet for some active systems	Interference from liquids and metals	Supply chain
Microwave	2.45 GHz, 5.8 GHz	Similar to UHF	Fast data transfer rates.	Access control
			May be active or passive	Toll collection Industrial automation

antenna become damaged, the tag will no longer function properly. Unlike barcodes, RFID tags are more dependent on the environment. One problem facing RFID implementation is difficulty reading tags attached to metals or liquid containers.

Additionally, some consumers have devised methods to detect and 'kill' RFID tags. One such example is the RFID Zapper, created using an off-the-shelf single-use camera and a coil of wire. The device uses the capacitor in the camera (normally used to power the flash) to pass a high voltage through the coil, overpowering the RFID tag and causing the circuit to overload (16). RFID tags can also be disabled by placing them in a microwave oven; however, this can be dangerous and can cause damage to the tagged item and the microwave oven as well as the RFID tag (17). In either case, the impact of disabled tags on supply chain peformance remains unmeasured.

Cost. RFID tags are extremely costly in comparison to barcodes, even at the industry's current target rate of 5 cents per RFID tag. In addition to direct costs, RFID tags cannot be produced in the field. Therefore, commitment to RFID technology requires a related commitment to actively managed RFID tag inventory. Unexpected shortages of tags could seriously disrupt operations. Alternatively, barcodes may be printed as required on virtually any substrate using a variety of well-established printing or marking techniques. By comparison, barcodes are 100 to 1000 times less expensive than RFID tags that contain similar data.

Disposable tags are not the only investment in implementation. RFID implementation requires RFID-enabled label printers, readers, and antennas, software, middleware, computers, and network infrastructure that are compatible with a particular generation of RFID tags. Currently, the switch to "Generation 2" tags quickly rendered first generation technology obsolete. It is likely that improvements in RFID technologies will result in required costly hardware upgrades that were similar to other computer networking products. Recall networking technology migrating from 1200 bps telephone modems to 56k modems to ISDN, T1, ADSL, and so on. While costly upgrades in networking technologies were quickly offset by productivity increases and new revenue generating opportunities, such immediate and apparent rewards are probably not awaiting capital expenditures for upgraded RFID hardware for basic supply chain management functionality.

Consumers

Privacy and Security. One obstacle in deploying RFID is consumer privacy. Advocacy organizations, such as Consumers Against Supermarket Privacy Invasion and Numbering (CASPIAN) and FoeBud, a German group of RFID and privacy activists, strongly oppose item level tracking, since these technologies may allow for undisclosed wireless customer tracking. One controversial example involves a system that collects photos of customers as products are removed from shelves (18). While the system was promoted as a means to reduce shoplifting, consumer advocacy groups fear that such technologies violate consumer rights.

While some retailers, including the Metro Extra Future Store, claim that RFID tags are useless once they leave the store, privacy advocates claim that the tags are still "live" and can be tracked by other readers beyond the store of purchase.

Opponents envision a "1984"-type society in which all people and objects are tracked using microchips embedded under the skin. In fact, such systems are now widely used for pets (19). The VeriChip or VeriPay (20) is a type of RFID chip that is designed to be implanted under the skin. While it may only contain a 16-digit serial number, this information is linked to a database and can also be picked up by any compatible reader. One such use of the VeriChip is at the Baja Beach Club, in Barcelona, Spain, which experimented with implanting chips in people to allow them to pay for drinks and obtain VIP benefits without the need to carry a wallet. Human-implantable chips have also been used in medical settings for patient identification, though they are not without health and privacy risks of their own (21). Religious groups have even linked such chips to the book of Revelation, which apparently describes a time in which people are required to take a mark in order to buy or sell (17).

Disposal. A significant, yet little publicized, challenge facing RFID is the issue of disposal. Passive RFID tags have been designed to be discarded, and electronic waste is a growing problem in the United States (21). RFID tagging may contribute to the problem because RFID tags are fabricated in ways that make them difficult to recycle; and because they are designed to be attached to or part of other items, RFID tags interfere with established recycling technologies. One study on the impact of RFID tags on corrugated recycling found that (1) laminated copper antennas do not readily break down and are removed early in the pulping process as a nonrecyclable solid waste and (2) conductive silver inks used as an alternative to copper on nonlaminated labels remain with paper substrates and are not easily extractable from finished paper (22).

Interference and Spurious Reads. As with any radio-frequency device, RFID systems are susceptible to electromagnetic interference. Interference may interrupt, obstruct, or degrade performance of RFID systems. There are many sources of interference, particularly in industrial settings. The Packaging Science Laboratory at the University of Florida has relied upon a hand-held spectrum analyzer to identify and mitigate potential sources of interference (Figure 4).

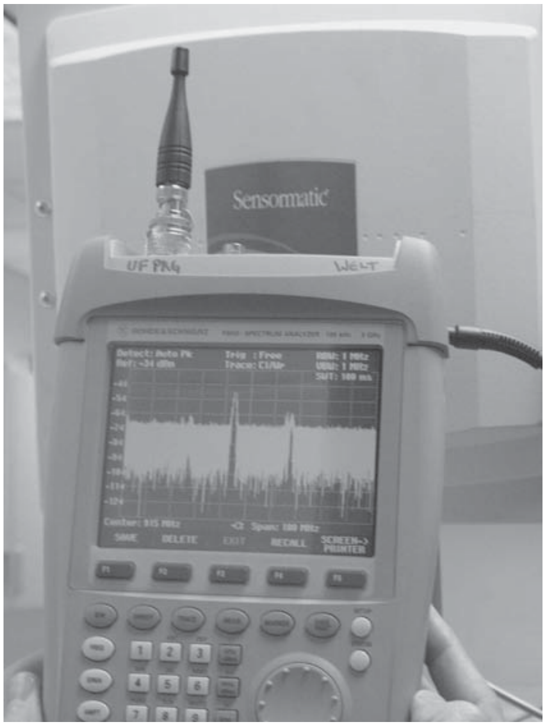

Figure 4. Handheld spectrum analyzer at the University of Florida Packaging Lab.

Figure 5. RFID tag that fell from palletized product. (Photo by Bruce Welt, University of Florida.)

The EPC Global RFID air operating protocol requires that complying RFID reader manufacturers use frequency hopping spread spectrum (FHSS) to mitigate electromagnetic interference issues (23).

RFID systems are also quite susceptible to spurious reads. Spurious reads involve reading tags that are not intended to be read. Spurious read may occur for many reasons including tags that become separated from packaging. Figure 5 shows an example of a tag that may interfere with normal RFID operation.

Spurious reads are a particular problem in multireader environments. Also, manual handling of tagged items in reader environments can also be problematic because items might be carried through read zones in directions opposite to expected flow. Spurious reads could also be a serious problem in automatic checkout and payment applications in retail outlets, where items from one customer's cart are charged to another customer.

IMPLEMENTATION OF RFID IN THE INDUSTRY

Mandates by Companies

Wal-Mart. Wal-Mart, Inc. made a big push into RFID primarily as a way to reduce labor costs and occurrences of out-of-stock merchandise. In 2003, Wal-Mart announced that it would require its top 100 suppliers to use ultra-high-frequency RFID tags conforming to EPC Global standards on pallets and cases destined to specific distribution test centers by January 2005. Additionally, Wal-Mart insisted that no price increases to cover RFID investments would be tolerated. This requirement was later eased to 65% of pallets and cartons due to issues with reading tags on metal and liquid (15). Wal-Mart then extended the requirement to other suppliers, expecting all suppliers to use RFID by December 2006.

Wal-Mart RFID specifications stated an expectation to be able to read 100% of *pallet* tags in the pallet/portal configuration and 100% of *case* tags for cases in any orientation moving at up to 600 ft/min on conveyor equipment (24). These specifications led to considerable anxiety, confusion, and capital expenditure as companies scrambled to acquire limited quantities of first-generation RFID hardware. Additionally, RFID testing laboratories began to sprout all over the United States where work focused on equipment performance comparisons, tag read rates, tag placement on cases and pallets, read ranges, product interference issues, and so on (12). Of particular note is the amount of work devoted to improving read rates of palletized cases moving through RFID portals even though Wal-Mart's specifications did not require case tags to be read in this configuration (25, 26). The practical result of this work, however, was the realization that line-of-site was practically necessary in order to be sure that the pallet tags and case tags could be read as required.

Wal-Mart and RFID proponents generally supported use of nonproprietary, EPC Global standards in order to allow the industry to quickly grow to a necessary critical mass to ensure survival. Several years of effort went into development of "Generation 2" technology, which eliminated issues related to incompatible tags and equipment. Ultimately, Generation 2 technology was to be freely available to all participants. However, once these standards were ratified, Intermec, Inc. (Everett, Washington) caused a stir by indicating that its intention to make its patents available did not mean that they would be available without cost. Intermec's RFID patent portfolio currently covers critical aspects of RFID as ratified in the Generation 2 standard. To avoid prolonged legal wrangling, Intermec devised an apparently effective plan to properly reward its shareholders while allowing the RFID industry to move forward. Its plan involved offering access to its complete patent portfolio under a preferred royalty plan, but only for a limited time of 90 days. Companies that did not sign up within the 90-day period would be required to negotiate terms on a patent-by-patent basis as well as face patent infringement actions. Intermec's plan was apparently successful; and even archrival and sole holdout, Symbol Technologies, Inc. (now part of Motorola), ultimately acquiesced and arrived at an agreement with Intermec, albeit after the 90-day window closed.

US DoD. The United States Department of Defense (DoD) has a large number of assets; and at any time, many of these assets are in transit. The DoD needed a way to track these assets. It assigned each asset with a Unique Identifier (UID), and uses RFID to read UID values from objects. It mandated all shipments to be equipped with RFID tags (5, 7). The DoD uses standard EPCglobal compliant tags. As with other RFID applications, adoption has been slow, but the DoD attributes this to its necessary focus on current intensive military operations (27).

ALTERNATIVES TO RFID

RFID has provided industry with two potentially valuable advances. First, RFID made code serialization feasible and accessible. By serializing identification codes, each tagged item can be independently tracked through the supply chain. This realization has helped to create new opportunities for improving supply chain logistics. Second, RFID brought people and companies together to create standards and operating procedures that provide for more efficient data transfer and collaboration.

While RFID might be credited for helping to bring these advances, the cruel irony is that many are starting to realize that all of the benefits from these advances may be realized without RFID. Ultimately, RFID is simply a means to collect data via radio waves. Other well-established technologies are also available that are useful for collecting data, and these may be simpler and cheaper to implement than RFID. Barcodes and image processing are two promising alternative methods for collecting data. Technological advances in electronics have been increasing the power, speed, and capabilities of barcode and image processing systems while reducing costs.

Chipless RFID

Chipless RFID is a recent innovation that combines RFID and barcodes. Unlike conventional RFID tags, chipless RFID does not rely on a central integrated circuit to transmit and receive information and instead uses a series of chemicals, each tuned to resonate at a certain frequency when excited by incoming radio waves. Each chemical represents a bit, with a chemical's presence representing a 1 and its absence representing a 0. Such a system can be printed relatively inexpensively onto an item, similar to how barcodes are printed. The developers of such a technology intend for chipless RFID to assist in anti-counterfeiting and anti-copying measures (28). Unlike conventional RFID, however, chipless RFID does not provide features commonly found on RFID chips, such as error and interference detection and avoidance.

1D Barcodes

Barcodes were invented shortly after World War II in response to a need to manage grocery inventory. In September 1969 the Grocery Manufacturers of America (GMA) and the National Association of Food Chains met to express a need for an "inter-industry product code." The effort of an ad hoc committee resulted in an 11-digit code now commonly known as the Universal Product Code (UPC) (Figure 6). After considerable time and development, on June 6, 1974 a pack of Wrigley's gum was checked out of Marsh's Supermarket in Troy, OH using a barcode scanner developed by NCR, formerly National Cash Register Company (29, 30).

1 23456 78901 2

Figure 6. UPC barcode example for (123456789012).

While UPC barcodes served the grocery industry well, other code standards were developed for other industries. Today there are barcode standards that can include numbers, letters, and the special characters that make up the complete ASCII character set. Table 4 summarizes these barcode standards. The UPC code standard has been widely adopted throughout the world as a slightly modified barcode known as European Article Numbering (EAN). The 11-digit UPC code actually presents 12 digits because the last digit serves as a checksum digit to ensure reading accuracy. The EAN-13 symbology is a superset of the UPC symbology and contains 13 digits in order to accommodate country identification codes, which are required in Europe and other parts of the world. The UPC and EAN contain a string of numbers indicating the source or company associated with the item as well as a code identifying the item type. The UPC, however, does not store a serial number, which means that each chocolate bar has an identical UPC.

UPC/EAN codes can also be represented as Global Trade Identification (GTIN) numbers, which is the current basis for identifying goods in transit throughout the world. RFID added unique serial numbers to GTIN, which are now known as serialized global identification numbers (S-GTIN). The EPC Global, Inc. electronic product code (EPC) is a superset of S-GTIN and contains additional information about the nature of the particular type of RFID tag that is used, which are not needed for non-radio-based systems. The important question at this time is whether RFID is the appropriate technology to carry serialization forward.

The main problem with adding serial numbers to linear barcodes is that they require significant amounts of printing area, which most companies would rather devote to informational or promotional content. One promising technology that is squeezing more data into smaller areas was originally known as reduced space symbology (RSS). RSS is actually a family of symbologies, each developed for some marketplace efficiency such as speed, size, or readability. The name "RSS" created confusion due to another unrelated technology for syndicating web content ("really simple syndication"), which was also known as RSS. Therefore, the term RSS is being rebranded as GS1 Databar™ (31). Currently, a GS1 Databar version of the UPC code requires about 1/3 of the area currently consumed by the UPC/EAN barcode (32). This provides ample opportunity to include serialization and/or other useful data in the future. GS1 Databar will likely prove to be a serious challenger to RFID technology in the near future as GS1 Databar technology is scheduled to sunrise in 2010 (Figure 7).

OCR

Optical Character Recognition (OCR) is a technology in which a computer or machine is used to read standard text. Such technology is in use by postal services, for example, to read address labels and direct mail to correct destinations. A variation, Magnetic Ink Character Recognition (MICR), is commonly used by banks and retailers to process checks. Figure 8 shows human readable version of EPC data being captured by a Cognex, Inc. vision system. Figure 9 shows both the 2D barcode and human-readable text being interpreted by the camera software.

OCR algorithms are not currently as robust as barcode readers at this time; however, technological improvements in hardware and software along with cost reductions will likely open opportunities for human-readable data in the future.

2D Barcodes

Two-dimensional barcodes are a relatively new technology that store more data than conventional linear barcodes. While they carry the same advantages and disadvantages of linear barcodes, the ability to store more data makes it more practical to store information such as a serial number. 2D barcodes have been used by UPS for package tracking, by state governments for Driver Licenses/ID cards, and by NASA for part identification.

One of the most common 2D barcode standards is DataMatrix (Figure 10). It is designed such that it can be printed or engraved on objects as small as the head of a pin (5) or as large as several feet across. The symbols themselves can hold up to 2335 alphanumeric characters, and they include error detection and correction algorithms that produce a valid read even if a significant portion of the symbol is damaged or absent. DataMatrix codes, like RFID, can be used to store serialized EPC and UID codes. Figure 11 shows a 2D barcode with some damage. Even though some data are missing, some or all of the data can still be read.

Figure 12 shows 2D barcode information used to store digital sound data on a roll of movie film in two different formats.

Another advantage of tracking using 2D barcodes is backward compatibility. 2D barcode equipment can print and read linear barcodes without the need for additional hardware.

PRACTICAL TESTING AND IMPLEMENTATION

Universal tracking of items in rapidly moving supply chains requires robust systems. To successfully implement such systems, testing is required to understand basic performance characteristics, weaknesses, and limitations. Such evaluations can be extensive, complex, and tedious.

RFID Hardware

A simple RFID system consists of a tag, a reader, and an antenna. The reader transmits and receives signals to and from the tag through the antenna.

RFID Printer. While RFID tags can be programmed at the factory or by readers, it may be desirable to program RFID tags using a specially designed label printer. Such printers print onto labels with embedded RFID tags. The printer contains an RFID device that programs tags as labels are printed. This method allows easy mass encoding of RFID tags. Currently, however, encoding RFID tags while printing tags significantly slows the printing process.

Table 4. Summary of Barcode Standards

Standard	Description	Applications	Sample
Plessey	Two bar widths with white space, easy to print using dot-matrix printers. Does not include built-in error checking.	Libraries, some retailers	
UPC	Robust barcode algorithm for retail use. Stores numbers only with manufacturer and product. Last digit is used as a check digit.	Retail in the United States	1 23456 78901 2
Codabar	Capable of being printed with dot-matrix printers. Self checking. Stores numbers and can store some letters.	Libraries, air-bills, blood banks.	12345678901
Code 39	Compatible with many readers; however, data density is low. Contains alphanumeric characters and some symbols.		0123456789ABCDEF
Code 93	Higher density and more robust than Code 39. Two check characters.	Canadian Post Office	0123456789ABCDEF
Code 128	High density, can store any character.	Shipping and packaging industries	0123456789ABCDEF
EAN-13	Superset of UPC symbology with additional country code.	Worldwide retail	0 123456 789012
GS1-128 (UCC/ EAN-128)	Implementation of Code 128 used for storing various types of data such as a Global Trade Item Numbers or an Expiration Date.		(00) 1 0123456 789123456 7
GS1 DataBar (RSS)	Can encode 14-digit GTIN values. Smaller than conventional UPC/ EAN barcodes.	Healthcare industry, intended for retail	(01) 0 0123456 78901 2

(*Continued*)

Table 4. Continued

Standard	Description	Applications	Sample
POSTNET	Encodes a Zip+4 code and optionally a delivery point. To be replaced by OneCode.	US Postal Service	
OneCode	Intended to replace POSTNET and PLANET symbologies.	US Postal Service	
MSI	Based on Plessey. Store numeric characters.	Inventory control	12345678901
Telepen	Encodes 128 ASCII characters without the need to use “shift” characters.	Libraries	12345678901
Interleaved 2 of 5			012345678901

Companies will need to plan accordingly for slower printing speeds. Figure 13 shows a DataMax I-Series RFID-enabled printer used in the University of Florida Packaging Lab.

Portal. A portal is an RFID “gate” located at a dock or a doorway. It usually has several antennas designed to read tags on items passing through it. A pellet load often contains tens to hundreds of cases, and each case often holds tens of items. Entire pallet loads move through portals. Wal-Mart requests that only one pallet tag, representing the entire pallet, is expected to be read from the portal. Figure 14 shows a typical RFID portal, set up in the University of Florida Packaging Lab.

Conveyor. In the supply chain, individual cases and shippers often move on conveyor systems. The conveyor can be equipped with RFID antennas to detect cases. Figure 15 shows a conveyor belt configuration in the University of Florida Packaging Lab.

Forklift/Mobile Reader. An alternative to the RFID portal is an RFID enabled forklift. The RFID forklift is equipped with a reader that records EPCs for pallets carried (33). RFID enabled forklifts may also need tags located at fixed positions on floors, posts, walls, doorways, and/or shelving in order to relate pallets to locations.

Figure 7. Databar-14.

Handheld Devices. Handheld devices, such as PDAs (Portable Digital Assistants) and PDTs (Portable Data Terminals), are commonly used in retail environments to locate goods, set planograms (merchandise presentation schematics), and stock merchandise. Many are equipped with barcode scanners and wireless communication with a central server, although some newer devices, such as the device pictured in Figure 16, are equipped with RFID capability.

Testing Apparatus. A typical testing apparatus would consist of a conveyor belt, RFID hardware, machine vision hardware, and a method of capturing and logging the data, usually with a standard PC.

RFID Variables

To accurately test RFID read rates, several variables need to be taken into account.

Frequency Variances. Different RFID tags operate at different frequencies. In the supply chain, the most common are EPC compatible UHF tags.

Tag Technology (Class 1, gen-2, etc.). High-requency EPC tags come in several variations. There are older Class 0 (read only tags), Class 0+ (Class 0 tags with write capability), Class 1 (writable tags), and the newer Gen 2 tags (writable). The older Class 0 and Class 1 tags have been used on the supply chain and are not compatible with one another, but they are being phased out in favor of the newer Gen 2 tags. Many modern RFID devices are compatible with all three tag types. Some older devices can be updated to work with the newer tags.

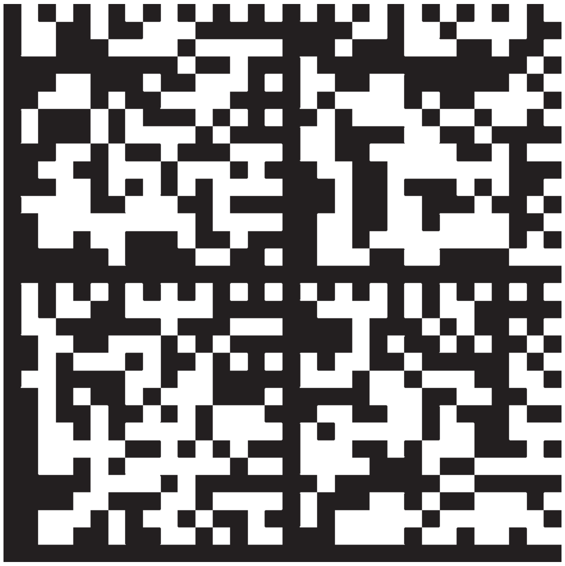

Figure 10. 2 × 2 DataMatrix symbol.

Speed of Conveyor. Wal-Mart desires the ability to read RFID tags on a conveyor belt moving at speeds of up to 600 ft/min. At the higher speeds, the RFID equipment has less time to interrogate tags, making it more difficult to obtain accurate reads.

Reader and Antenna Variances. RFID readers may have special settings that can be configured. Such variables include RF power level and polling frequency. Higher polling frequency typically leads to more reads within a period of time. A higher power level may result in more successful reads; however, it can also result in spurious reads from nearby tags. Some RFID readers can be configured to broadcast a signal when an external trigger occurs, such as a carton breaking an infrared beam, (e.g., Intelletto Technologies LineMaster).

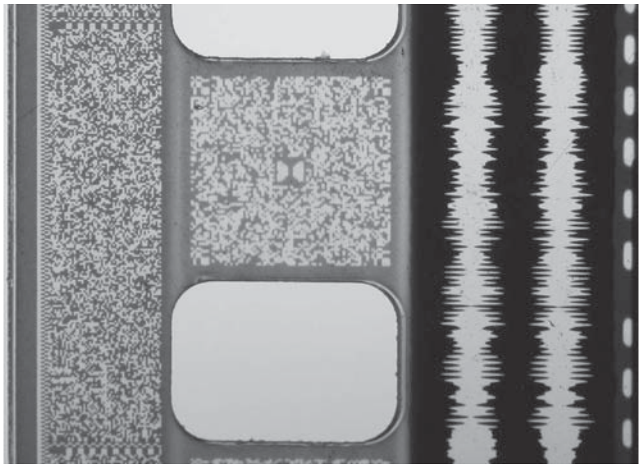

Figure 12. 2D barcodes used to encode digital sound data on movie film (public domain image).

Figure 13. Datamax, Inc. (Orlando, FL) Model I-4210 RFID-enabled thermal transfer printer in the packaging laboratory at the University of Florida. (Photo by Bruce Welt University of Florida.)

Antenna positioning also plays an important role in RFID. Various studies have been conducted to determine optimal positioning of the antennas. Antennas also come in various shapes and sizes, which can also cause variations in read rates.

Environment. Environment can affect read rates of RFID tags. Factors such as heat, humidity, and corrosion can hinder successful reads. Many tags can decay or be more likely to fail under some conditions. Figure 17 shows Gen-2 RFID tags after being exposed to air for several weeks.

2D Barcode Variables

To implement a 2D barcode system, some variables must also be taken into account.

Figure 14. A pallet passes through an RFID portal in the packaging laboratory at the University of Florida. (Photo by Bruce Welt, University of Florida.)

Figure 15. Tagged cartons pass RFID antennas on a conveyor belt in packaging laboratory at the University of Florida. (Photo by Bruce Welt, University of Florida.)

Types of Barcodes. There are several standards of 2D barcodes, along with “stacked” linear barcodes. One of the most common is DataMatrix, which has been used by the Department of Defense and other organizations to identify items. Other standards include Aztec, MaxiCode (used by the United Parcel Service, based in Sandy Springs, Georgia), and PDF417.

Figure 16. Symbol Personal Digital Assistant (PDA) with embedded barcode reader and RFID functionality.

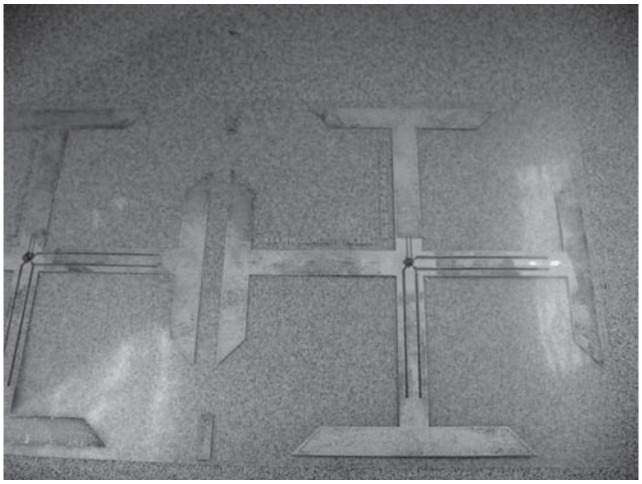

Figure 17. Oxidation apparent on Gen-2 RFID inlays antennas after several weeks exposure to ambient air of the packaging laboratory at the University of Florida.

In addition to standard 2D barcodes, some companies have experimented with color barcodes. One such example is the High Capacity Color Barcode, developed by Microsoft (Redmond, WA) to complement standard UPC barcodes on DVDs and video games. The barcodes can be read using camera phones or webcams to link the user to special content (31).

Speed of Conveyor. As with RFID, the speed of the conveyor system is also a factor. With 2D barcodes, the conveyor speed can have a significant impact on the accuracy of reads.

A typical 2D barcode system uses a CCD array (camera) to read symbols; and with a standard camera, the exposure time and aperture size have an impact. A shorter exposure time will result in a better picture for moving objects, but with result in less light entering the lens. More light can be let into the camera by increasing the aperture size; however, this reduces depth of field that can be used for focusing.

This problem can be countered by using a light source to illuminate the barcode while it is being read, in a similar manner as a flash on a camera. High-speed strobes are often used to freeze images of moving items when using imaging systems. Companies such as Advanced Illumination (Rochester, VT) offer such equipment.

Printing Methods and Materials. The method of printing may have some variances in the results, and also the durability of the labels. Thermal transfer is one of the most common methods of printing labels; however, laser, dot matrix, and inkjet printers can also be used.

Thermal Contact Paper. Thermal contact paper is another method used in label printers. With this method, the paper is chemically treated such that it will change color when heated. This method is common for printing receipts at a point-of-sale. Since other heat sources will continue to darken thermal contact paper and markings may fade over time, this method is not used when persistence of critical data is required.

Laser Engraving. Laser engraving (also known as laser etching) is a method of using lasers to burn designs directly onto a surface, including woods and plastics. Since laser engraving does not require (a) physical contact and (b) messy and expensive inks or solvents, this approach is gaining marketshare in many industries. Figure 18 shows a simple laser engraving apparatus.

Light Variations. Lighting can play a factor in reading barcodes. External lighting can overexpose or underexpose an image captured by a camera, and the reflectivity of some surfaces can hinder successful reads. Thermal transfer, for example, may cause problems if the transfer reflects light from a light source directly into the image sensor.

General Testing Laboratory

A facility involved in testing RFID and related technologies should maintain certain basic equipment and capabilities. These include the following:

Conveyor Systems. The conveyor is the main platform across which tagged items travel. Materials and construction may play a role in testing.

Computer Systems. The ability to run various software applications is required.

RFID Software. To interface with the RFID devices, one may need to use a middleware package. These packages can interface with different brands of readers and process the data.

Vision Software. To decode 2D barcodes, vision software is needed. Some cameras, such as Cognex Inc.'s (Natick, MA) InSight series, include a programmable interface to input a trigger signal, capture an image, decode the image, and output data to a serial or Ethernet connection. The intelligent

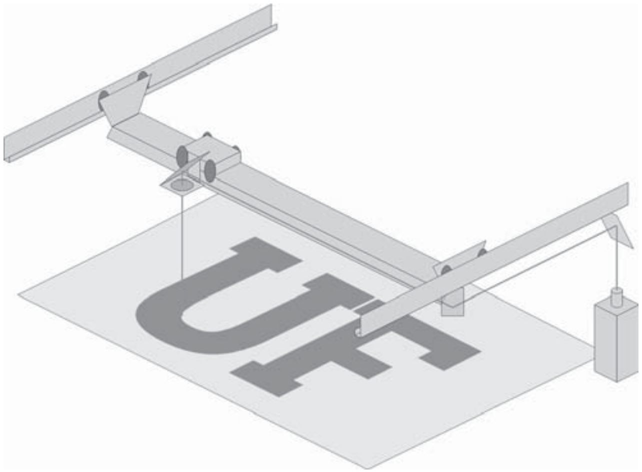

Figure 18. Laser engraving technology.

Figure 19. Sirit InFinity 210 OEM device.

camera may be programmed with or without a host PC. Some cameras do not include software and simply relay images to computers for processing (e.g., Cognex Inc's VisionPro).

Intelligent cameras are generally more expensive, but do not require a host computer to perform all functions. This results in lower overall power and space requirements.

A software-based camera, such as Point Gray Research's (Vancouver, BC, Canada) *Flea,* does not have on-board programming capability and must interface with a computer to be of use. One advantage of software-based cameras is the ease of using multiple cameras and the increased power and flexibility of a computer for image processing

Development Software. To transfer data between the camera software, hardware, and a database interface, development software may be desired. Microsoft Visual Studio, for example, includes Application Programming Interfaces (APIs) to interface with serial ports and TCP/IP. Cognex's VisionPro also includes an interface for use with Visual Studio and can generate applications that can be compiled and edited from within Visual Studio. Other solutions also exist, such as those by Borland and Sun Microsystems.

Database software. A database may be desired to log data captured from RFID, barcode, and/or machine vision devices. Some packages available include Microsoft SQL Server (commercial product), Microsoft SQL Express (free), MySQL (free), and Microsoft Access (commercial). The programming environment can interface with the database using ODBC or JDBC drivers.

PLC. A programmable logic controller may be desired to control trigger signals. The Flea camera, for example, is designed to input 3.3-V signals, while the Cognex Insight will take a 24-V signal.

Sensors. Instead of constantly searching for a tag, an RFID sensor and/or camera can be configured to read a tag when triggered. A common way to do this is by using a simple optical sensor.

Light Source. The read rate of 2D barcodes can be improved significantly at higher speeds with the use of an external light source. Modern light-emitting diodes (LEDs) can emit a bright light onto the barcode, allowing more light to be captured by the camera.

RFID Devices. There are several different types of RFID devices available on the market. Some include built-in antennas, while others use external antennas. Some devices are designed as original equipment manufacturer (OEM) devices and are also designed to be combined with or embedded within another device. Such devices will only have basic RFID functionality. One such example of an OEM device is the Sirit Inc.'s (Toronto, Ontario, Canada) InFinity 210 (shown in Figure 19), which could serve as an RFID core for a branded RFID reader. Data are transmitted to and from the device using special serial commands. It can use either an on-board antenna or connected to a larger external antenna. Other devices are designed for direct interfacing with the user. They may have a user-friendly interface and come with additional features and interfaces. One such example is Intelletto's (Markham, Ontario, Canada) Linemaster, a device designed to be used in conjunction with a barcode scanner (Figure 20).

Antennas. Most supply chain RFID implementations use UHF RFID tags, and as such, will require UHF compatible antennas. Some readers are compatible with multiple frequencies, but may require dedicated antennas for each frequency. Figure 21 shows different antennas used for high-frequency and ultra-high Frequency RFID tags.

Image Sensor. For standard one-color 2D barcodes, a monochrome camera is all that is required and may perform better than a color camera. A color camera can also be used, but for monochrome symbols the color information will be discarded by the symbol

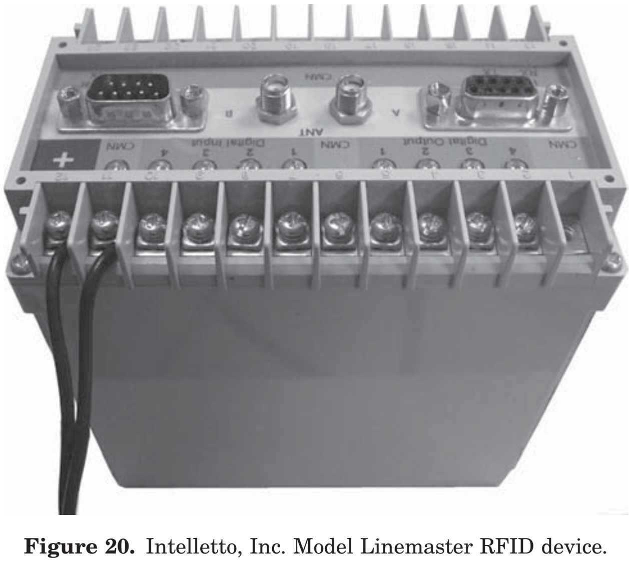

Figure 20. Intelletto, Inc. Model Linemaster RFID device.

Figure 21. UHF (left) and HF (right) RFID antennas.

reading algorithm. A hardware-based camera may interface with the host system using a serial or Ethernet connection, while a software-based camera will use an IEEE 1394 (Firewire) interface for fast data transfer.

Sample Performance Comparison

Tests with such systems are common in the University of Florida Packaging Science Laboratory.

A description of a simple performance comparison between a specific RFID installation and machine vision capture of Datamatrix barcodes follows.

Materials and Methods

Gen-2 Tags. Tags used for the RFID tests included 96-bit Class 1 Gen-2 tags (Figure 22). Each box of tags included 506 tags. The tags were packaged in a static-resistant bag on a spindle in a corrugated regular slotted container. The tags used are actually RFID "inlays" that are designed to be incorporated into conventional labels. For this work, the inlays were used directly.

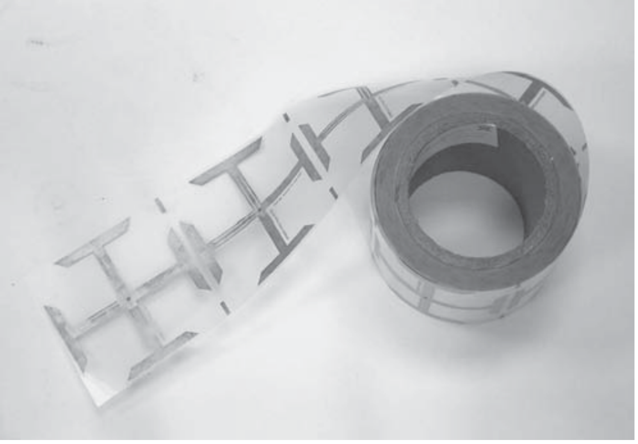

Figure 22. Gen-2 tags used for testing.

Programming. Tags were programmed manually using the Sirit InFinity 210 reader. Once all the tags were programmed, data were verified, with defective tags being replaced.

Upon testing, read rates were reasonable using empty boxes on a conveyor, but not close to the 100% requirement desired by Wal-Mart. Some tags functioned well during the first few trials, but stopped functioning on later trials.

Environment. The inlays did not hold up very well to the lab environment without additional protection. Oxidation was readily apparent on RFID tag antennas.

Read Methods. RFID tags were read with a Sirit Infinity 210 RFID device. For initial testing, tags were placed on empty corrugated fiberboard containers and placed on a conveyor belt. Reads were performed when a container tripped an IR sensor. In addition to RFID, a machine vision system using Cognex's VisionPro software package was used to read 2D DataMatrix barcodes. The 2D barcodes were each placed in a similar location on each carton.

Results and Findings. Data showed that the vision system had more accurate reads. When boxes were placed on the conveyor belt with uniform direction, the vision system was able to pick up every box that passed through. The RFID rates, however, were significantly lower. In addition to tags not being picked accurately by the reader, some tags failed completely.

Results of this particular test (shown in Figure 23) show some actual read rates from a trial using 10 tags, each sent along the conveyor five times each. Also notable is Tag #2, which did not have any RFID reads after being successfully coded and verified. This indicates that the tag had stopped functioning and needed to be replaced. Tag #1, however, worked all five times, indicating that there may be inter-tag differences. While this example does not represent a comprehensive comparison between vision systems and RFID, it does suggest that RFID may not

Figure 23. Sample results of trial with 10 tags, each repeated five times.

be without competition for collecting serialized identification codes going forward.

RECYCLING

JOHN K. BORCHARDT
Southhaven Communications,
Houston, Texas

INTRODUCTION

Recycling is steadily increasing in both developed and underdeveloped countries. World population is both growing rapidly and becoming more concentrated in urban areas. Increased urbanization will increase the concentration of packaging wastes, thus improving collection economics. A United Nations study indicates that increased recycling rates are accompanied by job creation and improved living conditions (see also Environmental Laws, North America and International Org).

In the United States, the recycling industry employs about 1.1 million people, with an annual payroll of $37 billion (1).

Paper and board are the most widely used packaging materials in terms of weight. In the United Kingdom, paper and board account for 43% by weight of all packaging (2). Paper and board packaging make up 6.4% of the overall content of typical household waste. For further information on paper and cardboard recycling, see Waste Watch's Paper information sheet. Plastics account for 20% of the weight of all packaging. Glass accounts for 20% of the weight of all packaging and 10% of all goods are packaged in glass.

In the United States, approximately 251 million tons of MSW was generated in 2006 (3). Containers and packaging comprised 40.2% (79.6 million tons) of total municipal solid waste generation. Excluding composting, the amount of MSW recycled increased to 60 million tons, an increase of 1.26 million tons from 2005. The tons recovered for composting rose slightly to 21 million tons in 2006, up from 20.6 million tons in 2005. The recovery rate for recycling (including composting) was 32.5% in 2006 up from 32.1% in 2005

Major sources of packaging wastes are grocery stores, restaurants, and office buildings. Residential collection of waste materials is increasing, although sorting of the wastes is often a major expense. The average composition of U.S. municipal solid wastes (2006) is given in Table 1.

Both economic factors and governmental regulation are driving recycling. Energy costs associated with recycling are almost always less than in manufacture of products from virgin materials. For example, recycled aluminum requires only about 2.8 kWh/kg of metal produced, while primary aluminum production requires about 45 kWh/kg of metal produced (4). Steel and glass recycling consume about 50% of the energy needed to make these products from ore and silica. Plastics recycling takes only 10–15% of the energy needed to refine petroleum and manufacture virgin resins. Incineration of plastics is a less efficient means of saving energy. For example, 100 lb (45.4 kg) of high-density polyethylene (HDPE) has a fuel value of 20×10^6 Btu (19 kJ). Recycling saves twice this: 40×10^6 Btu (38 kJ). Lower energy consumption associated with recycling reduces emissions of carbon dioxide, a greenhouse gas believed to be associated with global warming. For example, producing aluminum by recycling creates only about 4% as much CO_2 as is created when virgin aluminum is produced (4).

Both economic and environmental factors have led to government regulations designed to promote recycling. Economic concerns are related to balance of payment issues when virgin raw materials for packaging products are imported. For example, in China and Japan, limited forest resources means that many paper products have to be imported. Recycling reduces these imports. In fact, Japan imports used paper products from the United States and elsewhere to recycle them.

In some areas, the number of landfill sites is becoming limited. Although the number of landfills in the United States is declining, the remaining sites are large, modern facilities. Concerns about landfill disposal costs are becoming less of a factor in promoting North American recycling.

Environmental concerns include forest depletion and the effects of wastes on the environment. One concern receiving much publicity is the harmful effects that plastics, when eaten, can have on marine animal life such as dolphins.

SEPARATION OF COMMINGLED MATERIALS

Solid wastes, particularly from residential curbside collection programs, arrive at material recovery facilities

Table 1. Composition of U.S. Municipal Solid Wastes

Component	Percent by Weight
Paper	33.9
Plastics	11.7
Metals	7.6
Glass	5.3
Rubber, leather, textiles	7.3
Yard trimmings	12.9
Food scraps	12.4

Source: Reference 3.

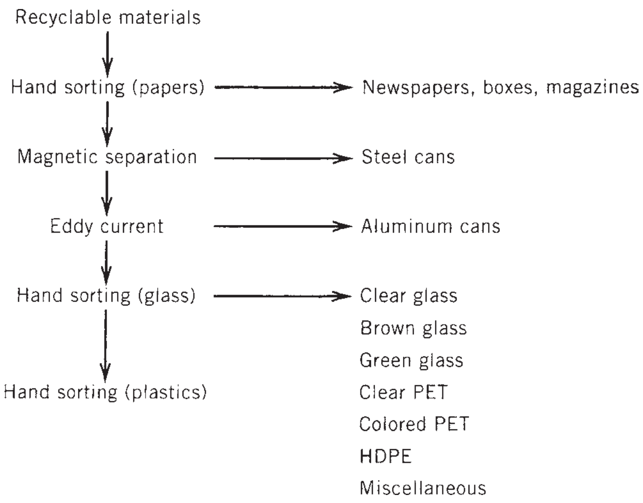

Figure 1. Basic unit operations in sorting waste plastics.

(MRFs) as a complex mixture. MRFs are typically built to process 100–500 tons of waste per day (5). Unit operations are summarized in Figure 1. The wastes are dumped on a tipping floor, where paper products are separated from metals and plastics. Metals and plastics, mostly containers, are pushed onto a conveyer belt. Two types of magnetic separators remove steel and aluminum from plastics and glass. Density differences or manual sorting are used to separate glass from plastics. The glass containers are hard-sorted by color. The plastics are separated into individual polymer types by the MRF or in separate reclaiming facilities (5). Plastic bottles are classified into: clear poly(ethylene terephthalate) (PET) soft-drink bottles; green PET soft-drink bottles; translucent high-density polyethylene milk, water, and juice bottles; pigmented HDPE detergent bottles; poly(vinyl chloride) (PVC) water bottles; and food containers such as polypropylene ketchup bottles (5).

METALS

Ferrous Metals

Iron and steel scrap account for more than one-third of the cast iron and steel produced in the United States. Much of this is “home scrap” produced during production of cast iron and steel. Home scrap is always recycled. “Prompt industrial scrap” is produced by industries while manufacturing products from steel or cast iron. Postconsumer scrap comes primarily from automobiles. Other sources include railroad rails and other machinery. Municipal solid waste is a growing source of postconsumer scrap in the United States. In some countries with low labor costs, ship breaking is a major source of postconsumer scrap.

Shredders received whole or baled vehicle bodies from salvage yards. Typical shredders process 200–1500 cars per day. All major automobile producing countries have adequate capacity to shred their available supply of discarded automobiles. In the United States, approximately 1.21 million tons of steel are recovered annually from 9 million scrap vehicles (6). Steel fuel tanks are removed from automobiles before the vehicles are shredded. These are sold for metal recovery.

A hammermill shreds the vehicle into fist-sized fragments. These are separated into a magnetic fraction (ferrous metals) and a nonmagnetic fraction. The nonmagnetic fraction is separated using air or water to form a low-density nonmetallic fraction and a high-density fraction consisting mostly of zinc, copper, and aluminum.

Tin must be removed when recycling tinplate cans. As little as 0.01% tin can form hard spots in steel and causes difficulties in rolling (6). Therefore, only low levels of steel can scrap can be used directly in furnaces. By processing cans with hot caustic and an oxidizing agent, tin can be removed from tinplated steel cans. The use of steel beverage cans is declining. Those used often contain no tin. Therefore, few mills operate detinning operations. Can scrap has been used as a precipitant in copper leaching mining. However, this is a low-volume application.

Minimills using electric arc furnaces use scrap iron and steel as their only feedstock. The amount of scrap that may be used in basic oxygen furnishes is limited to about 33% of the charge because the only heat source for melting the scrap is carbon and silicon added with iron ore.

Nonferrous Metals

When processing municipal solid wastes, an eddy-current separation unit is often used to separate aluminum and other nonferrous metals from the waste stream. This is done after removal of the ferrous metals (Figure 1). The eddy-current separator produces an electromagnetic field through which the waste passes. The nonferrous metals produce currents having a magnetic moment that is phased to repel the moment of the applied magnetic field. The repulsion causes the nonferrous metals to be thrown out of the process stream away from nonmetallic objects (7).

Another separation device that may be used is the mineral jig. This unit produces a loose vibrating bed of particles in a liquid medium. The vibrations segregate the solids into layers by density. The dense nonferrous metals—primarily lead, zinc, and copper—are at the bottom, while organics are at the top. The middle layer is primarily glass.

Aluminum is the largest-volume nonferrous metal recovered and recycled. More than 95% of beer and carbonated soft-drink containers are two-piece aluminum cans (8). Aluminum is also used for aerosol cans and as foil–plastic–paper laminates to package cereal and frozen foods. Aluminum is also used for food trays and pie plates. All of these are found in and collected from municipal solid wastes.

The energy savings associated with recycling aluminum are driving the aluminum energy to increasingly rely upon remelting of aluminum scrap and less on primary production (9).

Aluminum produced from recycled material requires only about 2.8 kWh/kg, while primary aluminum production requires about 45 kWh/kg of metal produced (10). Primary aluminum production relies on electricity produced largely by coal-fired electricity generating plants, while recycling uses natural gas. Natural gas combustion produces less air pollutants and greenhouse gases than does burning coal.

The Aluminum Industry Technology Roadmap issued in 2003 set a U.S. target to recycle 100% of aluminum by 2020 (11). Achieving this goal will require:

- Designing remelting furnaces that minimize melt lost while increasing melt rates, cost effectiveness, energy efficiency, and safety while reducing emissions of polluting gases.
- Developing low-cost aluminum purification processes to remove impurities such as magnesium, iron, lead, lithium, silicon, and titanium to produce high-purity aluminum from mixed scrap.
- Developing alloys that better match scrap to specifications, allowing for increased utilization.
- Minimizing aluminum loss caused by oxidation and dross formation during remelting.
- Improving separation of metal from dross or salt cake.

Another advantage is that fluoride emission, long a major concern in aluminum smelting, is reduced to the degree that the plant processes recycled aluminum (12). (The U.S. aluminum industry uses 15 kg of fluoride ion per metric ton of virgin aluminum produced. About 10–15% of this fluoride is lost during the production process.)

Organic coatings must be removed before the recovered aluminum can be used to make new sheet stock (7). This is done in special furnaces. About 90% of recovered aluminum cans is converted into new cans. The remainder are used to make other aluminum products.

Removing tin from steel cans is the only U.S. domestic source of this metal. As noted earlier, treatment of steel cans with caustic and an oxidizing agent is used to separate the tin. Recycled lead amounts to about 60% of the U.S. lead industry production. Most recycled lead comes from automobile batteries.

Total U.S. recovery of nonferrous metals from vehicle shredding is 0.8 million tons annually (6). The metals are mostly zinc, copper, and aluminum. About 8 kg of copper can be recovered from each automobile copper radiator. Their recovery and sale contributes significantly to shredder profits.

Precious metals are recovered profitably from automobile catalytic converters.

GLASS

Three-quarters of glass container shipments are for beverages. The largest glass packaging markets are soft drink, beer, wine, and hard-liquor bottles (13). Some glass bottles are used in food, drugs, and cosmetics packaging. About 75% of the containers are narrow-neck bottles (14). Energy costs drop about 2–3% for every 10% cullet used in the manufacturing process. For every six tons of recycled container glass used, one less ton of carbon dioxide, a greenhouse gas, is reduced compared to manufacturing glass.

When processing municipal solid wastes, glass is generally removed by hand sorting after separating paper and metals. The mineral jig may be used to separate glass particles from other particles. Particles should be less than 5 cm in their longest dimension. Glass occurs in the middle layer of the slurry formed by the mineral jig. Froth flotation may be used to separate glass particles from denser particles. Froth flotation is most efficient for particles less than 850 μm in size. A cationic fatty-acid amine surfactant has been used to improve the efficiency of froth flotation of glass.

The color distribution of glass in municipal solid waste averages 65% colorless, 20% amber, and 15% green. [As manufactured, 85% of container glass is clear (13).] Hand sorting of containers or optical sorting of particles can be used to separate glass of different colors. In optical sorting, interruption of a light beam by a colored or opaque particle will activate an air jet that blows the particle out of the process stream. Mixed colored glass can be used in amber and green glass bottle furnaces in proportions of $\leq 5\%$ and $\leq 20\%$, respectively.

Most collected glass containers are used in the manufacture of new glass containers (15). The amount of cullet (recovered glass) used in glass production typically constitutes 46% of the charge used to manufacture amber soda-lime container glass. About 25% of this cullet is from postconsumer sources, while the rest is waste from the glassmaking process. Recycled glass used at levels as high as 80 percent when available (14). Since glass has an unlimited life, it can be recycled repeatedly.

While most recycled glass is used in the manufacture of new glass, glass can be used without purification or other processing by other industries. Crushed glass is used in construction as aggregate for roadways, in building bricks, in synthetic slate products, and for glass-wool insulation and honeycomb structural materials.

PAPER

In 2006, a record 53.4% of the paper consumed in the U.S. (53.5 million tons) was recovered for recycling (16).

The primary process steps in recycling old corrugated containers (OCCs) and other paper packing materials are pulping, high-density cleaning, coarse and fine screening, centrifugal (reverse) cleaning, fiber fractionation, and refining. Pulping disintegrates the containers into individual fibers dispersed in water. High-density cleaning removes large dense particles such as nails and large staples (17). Coarse screening removes large low-density contaminants such as unpulped tapes and large adhesive particles (18). Coarse screen hole size ranges from 6 to 20 mm. Fine screens are fitted with slots as small as 0.15–0.30 mm. These separate smaller ($\geq$250-μm) contaminant particles such as plastic, wax, and adhesive particles (19). A type of hydrocyclone device called a centrifugal or reverse cleaner is used to remove low-density (adhesive) particles in the 70 to 250-μm size range (17).

Despite the use of screening and reverse cleaning to remove adhesive particles or "stickies," their removal is often inefficient. Stickies in pulp cause paper-mill operating problems by reducing pulp drainage rates on paper machines (20). They do this by forming deposits on paper-machine wires, dryer fabrics, press rolls, and drying cylinders. Reduced drainage rates force operators to run paper machines at slower speeds or shut them down to clean the fabrics. Both result in lower mill production rates and reduced profitability. Stickies also prevent good fiber–fiber bonding, reducing paper strength, an important consideration for corrugated containers. Both hot-melt adhesives and pressure-sensitive adhesives can form stickies.

Fractionation separates fine particles and short, weak cellulose fibers from longer, stronger fibers (21). Refining is used to develop the desired pulp drainage properties on the paper machine and control paper bulk and density, strength, surface smoothness, and porosity (22, 23). Caustic soaking is also used to improve OCC fiber properties (24).

Extensive bleaching of OCC can produce a high-brightness pulp suitable for use in manufacturing office paper (25). Economics compare favorably to those obtained for manufacturing office paper from de-inked recovered office paper (26).

A considerable fraction of corrugated containers are coated with wax to increase water resistance. Waxes and hot-melt adhesives can form a thin film when making linerboard from OCC and result in a slippery surface (27). This can cause "telescoping" when the linerboard is wound on a roll. When recycling OCC, removal of this wax is difficult. Flotation has been found to remove the wax efficiently (27). However, high paper fiber losses make this process uneconomical.

PLASTICS

Plastics recycling has several advantages (28):

- Conservation of nonrenewable fossil fuels: Plastic production uses 8% of the world oil production, 4% as feedstock and 4% for manufacture.
- Reduced consumption of energy.
- Reduced emissions of carbon dioxide, nitrogen oxide and sulfur dioxide (SO_2).
- Reduced amounts of solid waste going to landfills.

The economic attractiveness of plastics recycling is dependent upon the cost of the plastics feedstocks, crude oil, and natural gas. For example, the price of recycled polyethylene can vary from 85% to 105% of the virgin polyethylene price, depending upon feedstock prices. If the crude oil price doubles, as occurred in 2004–2005, and the energy cost is 25% of the total cost of the virgin or the recycled polymer, virgin polymer cost increases 75% while recycled polymer cost increases 25%.

Primary recycling is the recycling of plastics that are plant scrap and have not been sold for consumer use. Secondary recycling is the physical cleaning and processing of postconsumer plastic products. Tertiary recycling is the chemical treatment of polymers. This treatment is usually depolymerization to produce monomers that are purified and then polymerized to produce new polymer. Using tertiary recycling, materials such as fillers and fibers can be physically removed from the monomer. The monomers can also be purified by distillation and other processes prior to polymerization. The leading example of tertiary recycling is poly(ethylene terephthalate) (PET).

Table 2. Residential Recovery Rate by Package Type

Package Type	Percent Recovery
Beverage bottles	65
Liquid detergent bottles	50
Other rigid containers	10
Packaging film	5
Average of all plastics	30

Source: Reference 6.

Residential collection programs indicate high collection rates for easily recognized types of containers (Table 2).

Sorted plastic packaging materials are shipped, usually in bales, to processing plants to be converted to polymer resins. The bales are broken and the bottles sorted to ensure that only one type of polymer is further processed. Processing consists of chopping and grinding the bottles into flakes. These flakes are washed. Processing steps such as flotation are used to remove polymeric contaminants from the flakes. The flakes are melted and converted into pellets. Process costs are summarized in Table 3.

For high-value food-packaging applications, minimal migration of contaminants into food products is critical. Currently the FDA requirement is a maximum 0.5 part per billion (ppb) of noncarcinogenic compounds by dietary exposure (29).

Poly(ethylene Terephthalate) (PET)

Originally, PET was used virtually exclusively to package soft drinks. As a result the recyling stream was quite homogeneous, consisting of unpigmented one- and two-liter bottles with a small percentage of green bottles. However, PET is now used to package a wide variety of beverages besides soft drinks including water, fruit juice, tea, and beer, plus other products such as peanut butter, ketchup, and edible oils. These products are often packaged in bottles with a wide range of pigments in many sizes and shapes. In addition, various adhesives and barrier resins are combined with PET (30).

Table 3. Approximate Polymer Recycling Costs

	Costs	
Process Step	$ per Pound	Percent
Collection	0.10	27
Sorting	0.12	32
(Subtotal cost)	(0.22)	(59)
Grinding and cleaning	0.15	41
Total	0.37	100

Source: Reference 6.

In 2006, 30.9% of plastic soft drink bottles were recycled. Initial polyethylene terephthalate (PET) processing is similar to that outlined in Table 3. Cleaning comprises washing, rinsing, and drying. Poly(vinyl chloride) (PVC) and PET have very similar density values; both will sink to the bottom of the waterbath during rinsing. Therefore it is difficult to separate the two polymers after the bottles have been ground into small particles (31). Melting PET containing PVC will produce black spots due to charring of the PVC during processing to produce new bottles (32, 33).

For food applications, improved cleaning of PET produced by secondary recycling is needed. Supercritical fluid extraction using carbon dioxide (34) and solvents such as propylene glycol (35) have been proposed. High temperature and the use of vacuum to remove volatile impurities has also been suggested (35). Stripping of volatile components at temperatures above 160 °C for 3 min has been reported (36). Application of a multilayer approach, the manufacture of a bottle with an inner layer of recycled PET sandwiched between surface layers of virgin PET, is used commercially for soft drink applications (37).

Two PET tertiary recycling technologies are used commercially: methanolysis (38) and glycolysis (39). Both cleave the ester linkages in the polymer to form monomers. In methanolysis, methanol is used to cleave the polymer ester linkages, producing stoichiometric amounts of dimethyl terephthalate and ethylene glycol (38, 40). The ethylene glycol is separated and purified by distillation. The dimethyl terephthalate is purified by crystallization and distillation. Both bis-hydroxyethylterephthalate and oligomers are formed in glycolysis (37, 40). These are recovered and purified by vacuum distillation and then polymerized in the presence of ethylene glycol to form PET. Glycolysis is claimed to be somewhat less costly than methanolysis (38).

Hydrolysis yielding terephthalic acid and ethylene glycol is a third process. High temperatures and pressures are required for this currently noncommercial process. The purification of the terephthalic acid is costly and is the reason the hydrolysis process is no longer commercial.

High-Density Polyethylene

Process steps in recycling high-density polyethylene (HDPE) are similar to those outlined in Table 3. Cleaning comprises washing, rinsing, and drying (32). Removing labels is the worst problem in washing and drying stages. Detergents are often used to improve the efficiency of label removal. Metal foil labels can introduce metals into the polymer. When metal foil labels are heat-sealed onto plastic, the only way to remove them is using an extrusion melt filter. This leads to plugging of the filter screens causing more frequent changes and increasing production costs.

During the rinse cycle, polyethylene particles float to the surface of the waterbath. The higher-density PET and PVC particles sink to the bottom of the bath and can be separated from the polyethylene.

Blends of PET and HDPE have been suggested to exploit the availability of these clean recycled polymers. The blends could combine the inherent chemical resistance of PET with the processing characteristics of HDPE. Since the two polymers are mutually immiscible, about 5% compatibilizer must be added to the molten mixture (38). The properties of polymer blends containing 80–90% PET/ 20–10% HDPE have been reported (41). Use of 5–15% compatibilizer produces polymers more suitable for extrusion blow molding than pure PET.

Polypropylene

In 2005, polypropylene recycling was 10.1 million pounds recovered. Polypropylene (PP) is used in packaging applications as films and in rigid containers. Battery cases could be considered another packaging application. Dead batteries are often collected at the point of sale of new batteries. In the United States, some states have laws mandating this. Lead, acid, and plastics, particularly PP from battery casings, are recovered and recycled (6). PP is also recovered from bale wrap and other PP fabrics used for wrapping in the textile industry and from other containers (42).

Steps in polypropylene recycling include size reduction by grinding, washing, rinsing, and drying to remove contaminants and produce PP flakes (42). After extrusion, molten polymer is filtered through screen packs. The polymer may be separated into different melt flow ranges to produce more uniform product grades.

Polystyrene

Polystyrene (PS) packaging applications include injection-molded products such as beverage containers, dairy product containers, and packaging for personal-care products (43). Extruded solid-sheet PS packaging products include salad boxes, dairy-product containers, baked-goods containers, and vending cups and lids. Extruded foam sheet PS packaging products include poultry and meat trays, produce trays, hinged-lid containers, egg cartons, and foam cups. One formerly large-volume PS use, fast-food clamshell containers, has greatly diminished because of concerns over slow biodegradation of discarded polystyrene containers. Blow- and foam-molded PS packaging products include vitamin bottles, loose-fill packaging, and cushion packaging.

Polystyrene recycling processing steps include densification (for foams), granulation to reduce particle size, washing, drying, extrusion, and pelletizing. High-density baling is used to increase the bulk density of polystyrene, often by a factor of 2. Contaminants are more easily removed before this densification step than after. A demonstration plant chemically decomposes polystyrene to produce monomer (43).

Consumers readily recognize polystyrene foam products and turn these products in for recycling. However, recovery rates for other PS packaging products is significantly less (43).

Commingled Plastic Wastes

A relatively small amount of PVC goes into packaging applications and appears in municipal solid waste (33). The greatest concern with PVC is as a contaminant in other polymers being recycled, particularly PET.

Table 4. Representative Composition of Automobile Shredder Residue

Material	Percent by Weight
Plastics	27
Rubber	7
Glass	16
Textiles	12
Fluids	17
Other	21

Source: Reference 6.

The composition of nonmetal residues produced in shredding automobiles is summarized in Table 4. Each vehicle generates 500–800 lb of residue. The annual U.S. total is about 3.5 million tons or about 1.3% of the municipal solid waste generated annually (3). The mixture is too complex to separate and recycle. Depending on the amount of glass, water, metal, and dirt present, the residue has a heating value of 4800–6800 Btu/lb (6, 44). Incineration reduces residue weight by 50% and volume by 80%.

Advanced waste recycling is the high-temperature/high-pressure conversion of commingled plastic wastes to form petrochemical process streams (45). Research is in progress to determine the conditions that will favor formation of certain types of chemical feedstocks, including synthesis gas (hydrogen + carbon monoxide), hydrogen, crude pyrolysis oil (containing benzene, toluene, and xylene), olefins, and oxygenates (methanol, esters, methyl formate, etc). This technology has also been evaluated for producing fuels: (a) medium-Btu gas for boilers and (b) liquid fuels such as diesel oil. None of these processes is currently economic.

ECONOMICS AND STATISTICS

In the United States the number of beverage containers sold increased approximately 25% between 1996 and 2006. However, the number recycled remained essentially flat at approximately 75 billion weighing approximately 4 million short tons (46). Between 1990 and 2006, the recycling rate for all beverage containers declined from 49% to 39% after reaching a high of 53% in 1992 (Anonymous, Container Recycling Institute, http://www.container-recycling.org/images/allrates/recrate-90-06.gif).

The materials used in beverage containers has changed substantially between 1993 and 2004. The fraction of aluminum containers has declined from 67% to 50% in this period, while the fraction of class containers has declined from 32% to 18% (47). In contrast, the fraction of PET bottles has increased from 9% to 25%.

Overall, 2005 recycling for all packaging is over 25% in a number of old EU Member States (Austria, Belgium, Germany, Italy, the Netherlands, Norway, Sweden, and Switzerland). In addition, new Member States like the Czech Republic and Slovenia exceed 25% (48). In 2005, 35% of all PET bottles were recycled in the EI , equivalent to 0.8 million metric tons.

Paper

Paper recovery now averages 346 pounds for each man, woman, and child in the United States. Exports of paper to be recycled have doubled since the late 1990s, according to the American Forestry & Paper Association (49).

Eighty-one percent of the paper recovered is recycled by U.S. mills. Sixteen percent is exported to foreign markets. The rest is used domestically to manufacture products such as molded packaging, compost, and kity litter. Mills buy recycled paper loose or in bales. Grades of paper include mixed paper, mixed office paper, sorted white ledger, sorted colored ledger, computer printout, newspaper, corrugated containers, and magazines (50).

More than 228 U.S. mills and industrial facilities convert corrugated containers and other paper packaging to new paper products and construction materials (51). More than 60 of these produce linerboard and corrugated medium with a recycle content of 100% (52). In North America, minimills designed to process old corrugated containers are becoming increasingly common. Located in or near major cities, minimills are 25–50% the size of conventional paper mills.

Metals

The U.S. aluminum industry recycled 51.9 billion aluminum cans in 2006, half a billion more than in 2005 (53). It has the highest recycling rate of any beverage container at 51.6%. However, the recycling rate has declined from its 1997 high of over 65% (54).

An estimated five billion aluminium cans were used in the UK in 2001, 42% of which were recycled (55).

In the United States, the recycling rate for steel packaging was 63% in 1999 (56). In the United Kingdom, the recycling rate for steel packaging, including transport packaging, such as steel drums and bale wire, was 42% in 2002 (57). In 2005, over 2.3 million metric tons of steel packaging were recycled in the 25 countries of the European Union (58). This represents an increase of 6% compared to 2004 and a recycling rate of 63%.

Glass

In 2005, 25.3% of all glass containers were recycled (59). The recycling rate of glass beverage containers declined from 30% to 20% between 1996 and 2006 (60). Glass makes up about 6% by weight of the material in municipal waste streams recycled (59). Cullet from recycled glass costs 80–95% of the virgin raw materials used in glass production. In addition, the use of cullet saves 15% of the energy costs associated with glass production from virgin raw materials. This energy savings arises from the lower melting temperature of cullet compared to virgin raw materials and lower operating costs for pollution-abatement equipment.

Seven billion glass containers were produced in the United Kingdom in 2003 and the recycling rate has remained relatively constant at approximately 33% since 2000 (61). This contrasts with much higher recycling rates of 80–90% in European countries with more extensive waste collection systems.

Plastics

The total pounds of plastic bottles recycled in 2005 in the United States reached a new record high of 2.102 billion pounds (62). PET and HDPE together comprise over 95% of the plastic bottle market and 99.6% of the recycled pounds (63).

In 2005, the recovery rate for plastics in the European Union was 47% (64).

In 2005, 5.075 billion pounds of PET bottles and jars were available for recycling in the United States (65). Of this, 1.170 billion pounds was collected and sold. Of this, 58% were used by U.S. processors and 42% exported. The favorable economics of PET recycling have been attributed in part to forward integrated PET recyclers consuming their own product to make bottle resin (32).

In 2005, the HDPE bottle recycling rate increased 1.2% to 27.1%. Exports of collected HDPE bottles for recycling overseas were 162.4 million pounds, nearly 18% of the HDPE collected (63).

The largest used for recycled PET and HDPE resins is fabrication of new bottles (63).

In 2005, 10.1 million pounds of polypropylene was recycled in the United States (63). Most of this is derived from the recovery of polypropylene bottle closures during PET recycling. In addition, polypropylene bottles are commonly recycled with high-density polyethylene (HDPE). At levels up to 5% by weight, polypropylene has a negligible impact on the properties of recycled HDPE resins.

The costs of recycling commingled plastics has been estimated at $1700 per ton (66). This is 10 times more expensive than recycling easily separated homogeneous products such as PET and HDPE.

ROLL HANDLING

In web processes, such as slitting and rewinding, coating and laminating, printing, as well as other applications, rolls must be loaded from the rewind station after the process. Because of weight and size, handling of rolls is done by general-purpose equipment, such as cranes and forklifts. For greater productivity, roll-handling equipment is engineered to suit the characteristics of the web-process equipment. An important fringe benefit of engineered handling systems is the reduction of safety hazards associated with general-purpose equipment.

Slitter/Rewinder Overview. A slitter/rewinder (see Slitting-rewinding machinery) converts master rolls into high-quality, narrow-width, rewound rolls that may or may not be the final product. Variables in the web characteristics and in the final form of the product determine which of the several types of slitting and rewinding techniques is used. The slitter/rewinder machine is typically composed of unwind, slitting, and rewind stations. A turret used for unwinding allows the loading of new master rolls while the machine is slitting and rewinding. Continuous unwinding can be attained by automatic splicing equipment.

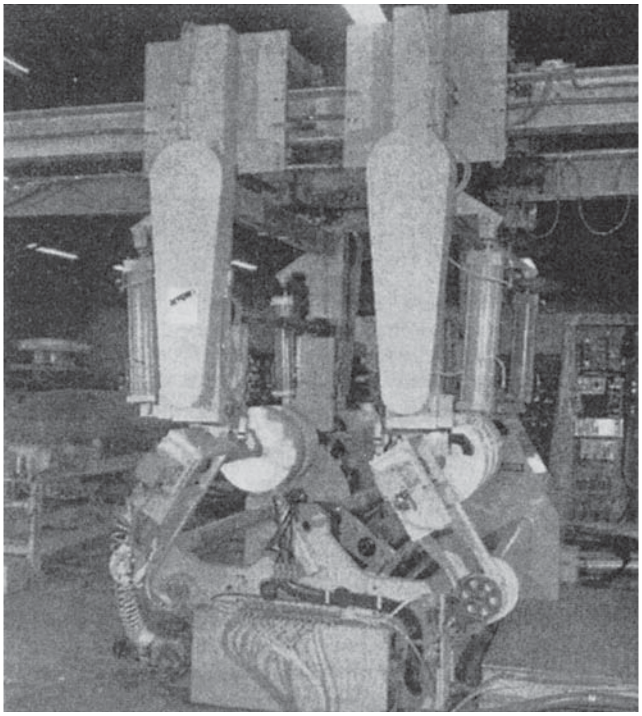

Figure 1. A duplex slitter/rewinder with roll-handling system. Turret carriages are in full-roll downward position at slitter/rewind station. New mandrels are in an upward position awaiting turret index.

The slitting methods used depend on the material characteristics and quality of the slit edge desired. Razor slitting is used primarily on films and score slitting on many types of fabrics, nonwovens, and textiles. Shear slitting is excellent for most materials but requires a relatively high initial investment and operator expertise. Locked-core rewinding is successful on good caliper webs and pressure-sensitive tapes with relatively small roll diameters. Differential rewinding is required for off-caliper materials and large-diameter rolls.

An effective method of rewinding is to alternate the slit webs on two rewinding shafts. This method, termed "duplex rewinding", is particularly suited for narrow-width slit material. Winding on a single shaft, called simplex winding, is generally effective for slit and unslit paper, nonwovens, and textiles.

Shaft Extraction/Insertion System. On duplex and simplex slitter/rewinders, webs are slit and rewound on cores supported by rewind mandrels. Rewind mandrels may be extremely heavy, i.e., several thousand pounds (kilograms), or cumbersome to handle manually. Each machine cycle requires that a rewind mandrel be loaded up with cores, put into the rewind station, removed from the rewind station, and then extracted from the rewound rolls. This process might take place many times a day, and an operator might have to lift and maneuver many tons of rewind mandrels per shift. Apart from the burden on the operator, manual shaft handling hinders production, because the cycle time for loading and unloading is relatively long.

The use of a shaft extraction/insertion system minimizes cycle time as well as operator fatigue. With this concept, the finished rolls and rewind mandrels are transferred to a lift table where shaft extrators pull the rewind mandrel from the rolls. The shaft is supported in the extracted position until the rolls are removed from the extractor table. Fixtures called core boxes are sometimes engineered into the extractor table to locate cores in their proper positions. The extractor inserts the shaft back into the cores. The cored shafts then are brought back into the rewind stations.

Shaft extractors are easily interfaced in close proximity to turret winders, unwinders, and other simplex winders, which often require the handling of steel shafts 6–10 in. (15–25 cm) in diameter by several hundred inches (several meters) long.

Handling Systems for Duplex Rewinders. A duplex slitter/rewinder (see Figure 1), with the rewind stations

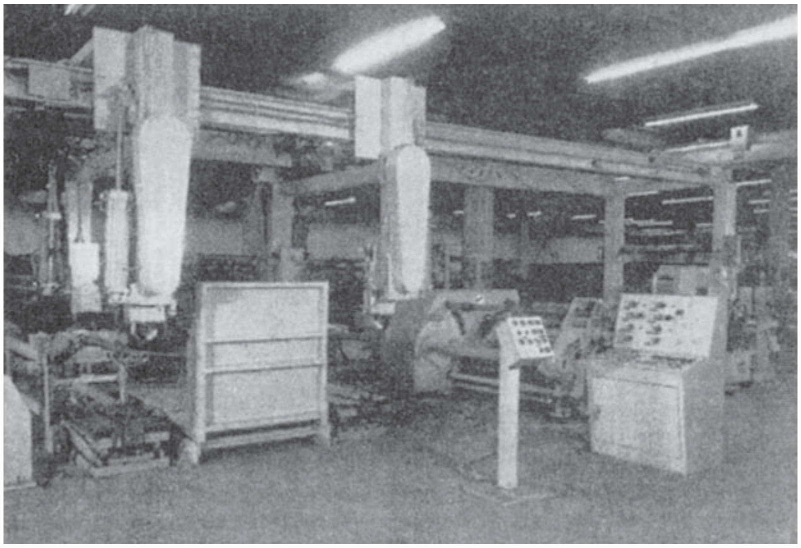

Figure 2. A slitter/rewinder roll-handling system with a shaft-type unwind stand. This two-motor drive system has an adjustable vacuum winding capability and an overhead mandrel lift/transfer mechanism.

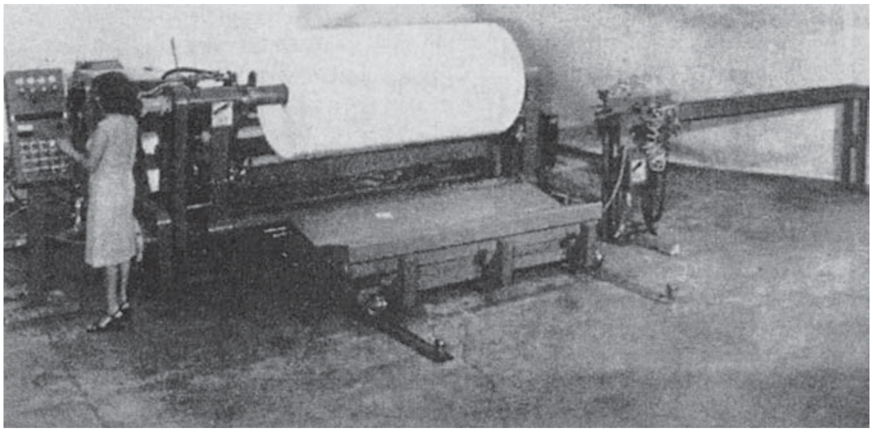

Figure 3. A surface center slitter/rewinder with hydraulically pivoting rewind arms, preset constant surfacing pressing in the center surface rewinding mode, and an automatic minimum gap for center winding.

located above the main machine, interfaces well with an overhead roll-handling system. After the rewind cycle, the shafts with the rewound rolls are lifted out and the new shafts with cores must be inserted into the machine.

A typical system (see Figure 2) may have an overhead-powered carriage that supports dual vertically adjustable shaft-clamp assemblies. With two clamps for each vertical lifting mechanism, new shafts with cores can be loaded into the machine immediately after the shafts with the finished rolls are removed. In other words, a machine with two rewind stations has four shafts circulating through the system simultaneously. As the new rewind cycle begins, the shafts with rolls are conveyed overhead to the shaft extractors where the slit and rewound rolls become free of the shafts and may be upended on pallets for conveyor or forklift removal into storage.

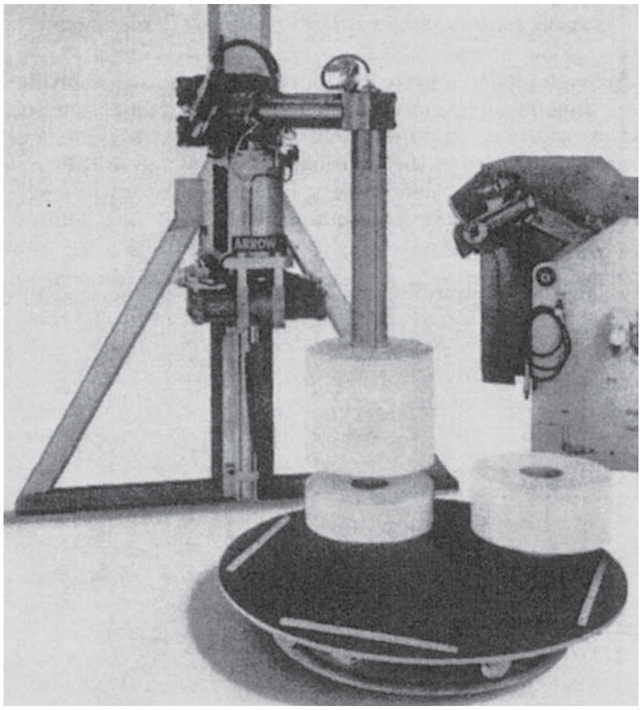

Figure 4. A roll unloading and stacking robot with hydraulically controlled cantilever mounted boom with 90° rotational capability on vertical and horizontal axes for pallet offload.

Floor Loading and Unloading. Floor loading and unloading features are available as an integral part of many unwinds and simplex rewinds. These units use hydraulically pivoting arms to raise and lower rolls to the floor. The need for auxiliary equipment is eliminated. Lift tables, shaft extractors, and upenders are designed to work with simplex (single-position) rewinders that produce large-diameter rolls of paper, laminates, and nonwovens (see Figure 3). Driven "V"-trough conveyors can then move the rolls from the rewinders to weighing stations, stretch wrapping, and storage conveyors.

Robotic Roll Handling. An example of robotics in special-purpose roll handling is shown in Figure 4. A simplex slitter/rewinder with an automatic roll pusher pushes the slit and wound rolls onto the robot shaft. The robot shaft then expands to lock the cores to the shaft. The robot is programmed to shift the axes of the rolls 90° and to automatically position them over a pallet. A rotary table supports the pallet and will index every 90° to allow unloading of finished stacks of rolls in the four quadrants of the pallet.

Total Automation. The ultimate in roll handling is shown in Figure 5. This slitter/rewinder for duct tape automatically cuts cores, loads cores at their proper location on dual rewind shafts, feeds the loaded shafts into rewind stations, winds the slit tapes, unloads the rewound

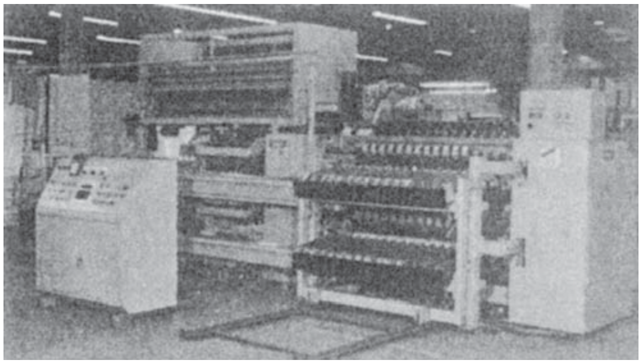

Figure 5. A fully automatic, pressure-sensitive tape turret slitter/rewinder with automatic core cutter and loader.

rolls from the machine, and feeds the empty shafts back in for core loading. This completely "hands-off" machine is microprocessor-controlled. Cycle times are better than 30 s.

ROTATIONAL MOLDING

Phil Dodge
Quantum Chemical Company
Cincinnati, Ohio

Reusable, large industrial containers can be made by rotational molding. Rotational molding generally is not thought of as a technique for making packaging. However, some manufacturers use this process, which can make complex, hollow, and seamless products of all sizes and shapes to produce large bulk containers for shipment of powders and liquids, 5–55-gal drums, trash and recycling containers, insulated food-product containers, and double-wall shipping trays for equipment components.

ADVANTAGES

Compared with blow molding or thermoforming, rotational molding offers significant advantages:

- Mold costs are low and comparable with those for blow molding and thermoforming.
- The process is economical for short production runs.
- Secondary tooling is minimal or not needed.
- There can be little or no scrap.

Numerous design features are possible; for example, double-walled parts, good surface detail, intricate contours and undercuts, stress-free parts, minimal cross-sectional deformation and warping, and molded-in inserts can be used.

POLYETHYLENES MOST WIDELY USED

Generally, powdered resins are used in rotational molding. However, a few liquid resins are available and some high-flow resins, such as nylons, have been used in small pellet form.

Although many thermoplastics can be rotationally molded, only a few actually are used to make commercial products. Polyethylenes—low-density (LDPE), linear low-density (LLDPE), high-density (HDPE), and copolymers—are the most widely used materials (see also Thermosetting polymers).

LLDPE rotational molding grades typically have densities ranging from 0.935 to 0.940 g/mL and a melt index (MI) of 3–10 g/10 min. LLDPE rotational molding resins offer good stiffness and low-temperature impact strength, excellent environmental stress-crack resistance (ESCR), and warp resistance.

LDPE rotational molding grades generally have densities of 0.915–0.920 g/mL and an MI of 10–25 g/10 min. LDPE rotational molding resins offer good impact strength, low shrink-age, good warp resistance, and flexibility.

HDPE rotational molding grades have densities of 0.942–0.950 g/mL and an MI of 2–8 g/10 min. HDPE rotational molding resins offer high stiffness, high impact strength, and excellent chemical resistance.

Ethylene-vinyl acetate (EVA) copolymers for rotational molding have densities of 0.925–0.945 and an MI of 10–25 g/10 min. EVAs offer good low-temperature impact strength and flexibility.

Postconsumer polyethylene resins (PCR) are made from HDPE blow-molded containers. HDPE PCRs have much lower melt indices than the MI of typical rotational molding resins. Therefore, for rotational molding, a HDPE PCR is blended with a virgin resin. HDPE PCR content in blends can range between 10–25%. The blends can be made by either melt compounding or dry blending PCR/virgin blends.

How the PCR/virgin resin blend is prepared affects the inner surfaces of rotationally molded parts. Parts rotationally molded from dry blends can have very rough inner surfaces. Parts made from HDPE PCR/virgin resin extrusion blends exhibit smooth inner surfaces.

The color of parts rotationally molded from HDPE PCR/virgin resin blends will be influenced by the type of HDPE PCR in the blend. Because some HDPE PCR are green (e.g., PCR based on HDPE copolymers), rotational molding resins made with these resins have a green tint. Other HDPE PCR are gray and have black specks. Thus, parts rotationally molded from blends made with these HDPE PCR have a dirty white color.

Compared to the virgin LLDPE resin, the toughness of HDPE PCR/virgin resin blends is much less, and it decreases as HDPE PCR content increases.

The environmental stress-crack resistance (ESCR) of HDPE PCR/virgin resin blends is considerably lower than that of the virgin polyolefin resins.

Crosslinked polyethylene rotational moldings can be made by using materials that contain a chemical crosslinking agent. Crosslinking improves physical properties, in particular impact strength, dimensional stability, creep resistance, and environmental stress crack resistance (ESCR).

Polyethylene rotational moldings also can be crosslinked using electron-beam treatment. Electron-beam processing allows the degree of crosslinking to be controlled; therefore, the level of property improvements can be controlled. Also, parts can be recycled before they are subjected to the EB treatment. Thus, scrap losses are reduced.

Polypropylene rotational molding resins provide higher heat resistance (containers can be autoclaved) and have higher stiffness than polyethylenes. Reactor-produced poly propylene copolymers (TPOs), i.e., copolymers produced in a reactor, have not been subjected to the mechanical and thermal degradation associated with melt blending of rubber compounds into a polypropylene base. Other advantages of the reactor-produced TPOs include their inherent temperature and chemical resistance, low specific gravity, and high flexibility. Also, unlike rubber blends—which can degrade or crosslink—the reactor-produced TPOs are readily rotationally molded.

Nylon rotational molding resins, both liquid and pellet, offer good heat resistance, toughness, good wear and abrasion resistance, high strength and stiffness, and good chemical resistance.

Polycarbonate rotational molding resins offer high heat resistance, good impact strength, and clarity.

Vinyl rotational molding resins, both powder and liquid, are available. Vinyl plastisols are liquid rotational molding resins that offer a wide range of stiffness, from very soft (low-durometer) to very rigid (high durometer).

A SIMPLE, BUT VERSATILE PROCESS

Six basic steps exist to the rotational molding process and are as follows:

1. A predetermined amount of resin is placed in the bottom half of a two-piece mold.
2. The mold halves are closed.
3. The mold is placed in a heated oven and rotated biaxially.
4. The resin melts against the inside surface of the mold, fuses, and then densifies into the shape of the mold cavity.
5. The mold is removed from the oven and placed in a cooling chamber. A combination of air and water is used to slowly cool the mold.
6. The mold is transferred from the cooling chamber and opened, and then the finished part is removed.

Many variations exist of the basic rotational molding process.

Generally, the walls of rotational moldings are made of one material. However, multilayer rotational moldings can be made. For example, there can be a foam layer, a solid layer, a layer of recycled material, a crosslinked layer, and different-colored layers.

The standard technique for making multilayer rotational moldings is to use a “dump box.” After the first layer is molded, the dump box—which is attached to the mold—is opened to allow the material for the second layer to enter. The dump-box cover is closed, and the second layer is molded.

Foam filling, which uses rigid polyurethane foam, injected into the hollow space between the walls of rotational moldings adds stiffness and structural strength.

Integral skin foam moldings also are possible with resins that contain foaming agents. These one-step foaming resins expand inside the mold, and the material directly against the mold surface forms a dense skin. This approach to multilayer foam molding is faster than other techniques, and tooling costs are less.

Molded-in decoration also is possible with rotational molding. By embedding a graphic into the surface of a rotational molding, the graphic becomes permanent and will not peel and cannot be scratched or rubbed off. Molded-in graphics eliminate surface pretreating required with other decorating methods. Also, no paints or painting equipment are required.

Precolored polyethylene powders save rotational molders from the hassle of dry-blending pigments with natural-colored resin powder.

Rotolining is a process that chemically bonds a reactive polymer to the inner surface of hollow metal products. The metal product is mounted on the rotational molding arm as opposed to a mold.

SEVERAL TYPES OF EQUIPMENT

Many different types of rotational molding equipment exist.

Open-Flame and Slush Molding Machines. These machines (Figure 1), which are the oldest type of equipment, usually rotate on only one axis. This equipment is used mostly to produce open containers.

Carousel Machines. These machines (Figure 2) are the most common type. Carousels consist of a heating station or oven, a cooling station or enclosed chamber, and a loading and unloading station. The carousel can have three to six spindles or arms for mounting molds. Most carousels have the freedom to rotate in a complete circle.

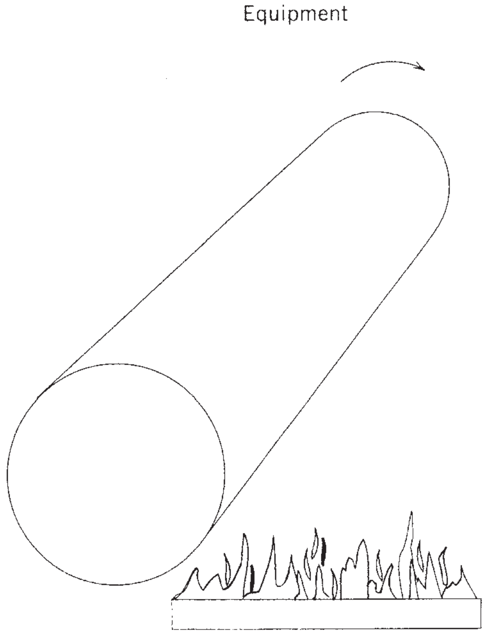

Figure 1. Rotational-molding equipment.

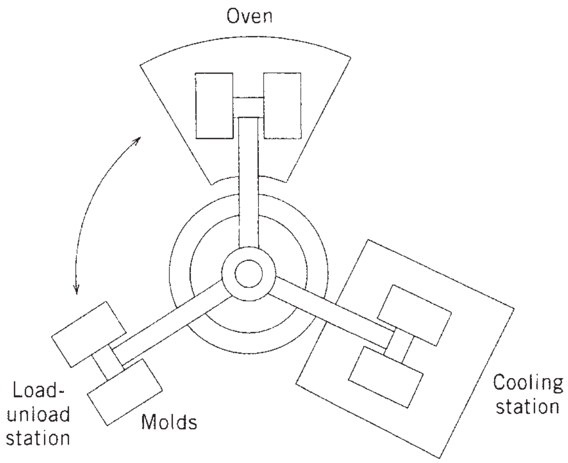

Figure 2. Carousel/turret machines have a center pivot with three, four, or five arms that hold molds. The arms index simultaneously from station to station, i.e., load/unload station, to oven and to cooler.

Clamshell Machines. These machines (Figure 3) have only one arm, and the heating, cooling, and loading/unloading stations are all in the same location.

Rock-and-Roll Machines. These machines (Figure 4), which rotate on one axis and tilt on another, are used for long items.

Shuttle Machines. These machines (Figure 5) generally are used to make large parts. A frame for holding one mold is mounted on a movable bed. The bed is on a track that allows the mold and the bed to move into and out of the oven. After the heating cycle is complete, the mold is moved into an open cooling station. A duplicate bed with a mold is then sent into the oven from the opposite end.

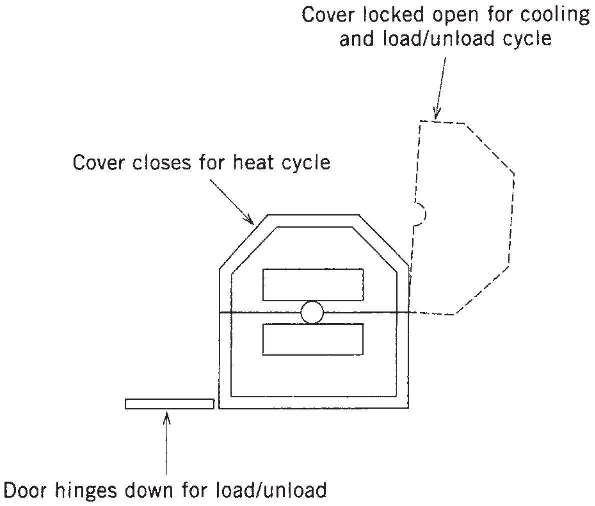

Figure 3. Single-station machines, also called clamshell machines, have an oven that has a hinged cover and a hinged front panel. The mold rotation arm can swing into and out of the oven. The cover and front panel are closed during heating and are opened for part cooling, removal, and reloading of the mold.

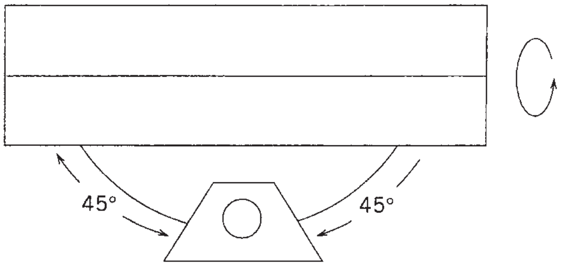

Figure 4. Rotational moldings with long length:diameter (L/D) ratios can be made on equipment called “rock-and-roll machines.” The mold is rocked back and forth on a stationary, horizontal axis while it is rotated about a moving axis that is perpendicular to the rotating axis.

RECENT TRENDS

Considerable progress has been made in recent years to improve processing controls. Microprocessors, which indicate processing set points and conditions, greatly improve precision. Mold-cycle data for the oven and cooling chambers can be stored for future production of parts. Cycle time, oven temperature, major and minor axis speeds, as well as fan and water-spray times are other functions under computer control. New temperature-monitoring systems also are available.

A key benefit of rotational molding is the low relative cost of its tooling. Cast aluminum molds are most frequently used, especially for small-to-medium-sized parts. Cast aluminum has good heat transfer and is cost-effective when several molds for the same part are required.

Sheet-metal molds are normally used for larger parts. These molds are easy to make because sections can be welded together. Other molds, such as electroformed and vapor-formed nickel molds, yield an end product with fine detail. Cost for these is typically higher.

To assist in part removal, most rotational molds require a mold-release agent, which is either baked or wiped on. Many molds now use a fluoropolymer coating to eliminate the use of mold release. Also, waterborne release agents,

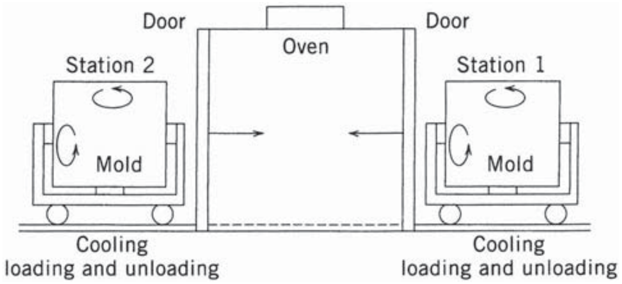

Figure 5. Shuttle machines either move the mold, along an oval or straight track, from the load/unload station, to the oven, and to the cooling station.

as a result of the U.S. Clean Air Act of 1993, are being used in place of CFC- and solvent-borne release agents.

FUTURE TRENDS

The ability of rotational molding to economically make large, complex, hollow, and seamless products is becoming more interesting to the industrial packaging industry. Other attractive advantages of this process are its ability to economically make low-volume production runs, the wide range of resins that are available, and its multilayer capabilities.

The rotational molding industry is growing rapidly. At present, well over 200 rotational molding plants operate in the United States.

Rotational molding technology is constantly improving. Many new developments in rotational molding materials are announced each year.

A great deal of technical information is readily available about rotational molding from the Association of Rotational Molders. The industry organization offers many technical brochures and copies of recent technical papers.

SEALING, HEAT

Barry A. Morris
DuPont Packaging and
Industrial Polymers,
Wilmington, Delaware

Duncan Darby
Packaging Science, Clemson
University, Clemson,
South Carolina

Most flexible and semirigid packaging structures use thermoplastic resins in their construction. When energy is applied, the thermoplastic resins melt and fuse together to form a seal. A heat seal can be defined as a method of closing a package using a thermoplastic material whose temperature is elevated by some addition of energy that results in heat. It is commonly accepted that, to achieve a seal, heat (energy), time and pressure are required. Energy is required to cause softening of the resin, pressure is required to bring the surfaces into intimate contact, and time is required to allow the heat transfer and molecular motion. How the energy and pressure are supplied to the seal area is what distinguishes the different methods of sealing. This article describes how the energy and pressure are supplied in flexible and semirigid packaging in order to achieve acceptable seals.

Flexible packaging materials can be classified into two categories: multilayer packaging materials (see Laminating; Multilayer flexible packaging) and monolayer films (see Films, plastic). Multilayer materials include laminations and coextruded films. Monolayer films consist of just one thermoplastic material. Coextrusions consist of multiple thermoplastic layers. Laminations are multilayer constructions of thermoplastics and/or nonthermoplastics, including thermoplastic layers for sealing purposes.

When laminated flexible materials are to be sealed, the outer face of the material is generally nonthermoplastic (such as paper or paperboard) or a thermoplastic with a melting point sufficiently higher than that of the sealant. Likewise, the outer face of a coextruded film used for sealing may be a thermoplastic with a melting point higher than that of the sealant. In both cases, this makes it possible to apply a heated bar (or other heated tooling) directly to the outer face in order to get the energy to the sealing interfaces and join the two package members. Heated tooling cannot usually be applied directly to monolayer unsupported films because they melt and stick to the surface of the sealing bar. The seal area is destroyed in the process. For this reason, other methods of sealing (impulse sealing, hot knife sealing, etc.) are used to seal such materials.

If the package members are too thick and too insulating, other means must be used to get energy to the sealing interfaces. Since heated tooling (commonly known as hot bar) sealing uses the least expensive equipment, it is more widely used for sealing than any other method. The other methods described below are used in applications where bar sealing is not suitable. When sealing thin materials together, it may be sufficient to introduce heat from one side of the construction. When using thicker materials, or if higher speeds are required with thinner materials, heat may be introduced from both sides. The fundamental principles in heat sealing are to provide heat at the interfaces, provide pressure to bring them intimately in contact, and complete a weld, all within an acceptable time period. An exception to this is one of the forms of radiant sealing, which relies on film orientation and surface tension as a substitute for applied pressure. Most of the important sealing methods are listed in Table 1.

From a polymer science perspective, the heat seal process consists of several steps. When the materials are first brought together, the surfaces are rough on a molecular scale and no adhesion occurs. As the heat reaches the interface, the surface begins to melt. The melting helps smooth the surface and, along with the application of pressure, creates more intimate contact for wetting and bonding. With sufficient time and temperature, molecular segments may diffuse across the interface. The nature of the attractive forces between molecular segments dictates the amount of diffusion that is needed to build strength at the interface. For nonpolar sealants such as polyethylene, it is believed that enough diffusion must take place for the segments to entangle. When polar forces are present, as in EVAs, acid copolymers, and ionomers, less diffusion is needed because hydrogen bonding and ionic forces help build strength. After the heat is removed and the interface cools down, co-crystallization may also help enhance the seal strength.

During heat sealing, the weight of the product being packaged or other forces (such as the natural spring-back force of a gusseted area) may act to open the seal before it has had a chance to solidify. The resistance to opening forces while the seal is still hot is known as hot tack. Hot tack strength is a function of (a) how much molecular diffusion and entanglement has occurred in the seal area and (b) the melt strength of the polymer. Sealants with outstanding hot tack strength such as ionomers (see Ionomers) may also have high hot tack strength over a broad sealing temperature range. This can be important for a variety of sealing operations with variable line speeds and poor control of seal bar temperatures.

HEATED TOOLING SEALING (COMMONLY CALLED HOT BAR SEALING)

Heated tooling sealing is the most widely used method for sealing. It is commonly called hot bar sealing or bar sealing, but there are many different geometries beyond the bar that use heated metal to affect the seal. Seal tooling geometries include flat bars, serrated bars, rings, rectangular shapes, flat or shaped platens, heated rollers,

Table 1. Sealing Methods

Bar	*Concept:* Jaw sealer with one or two heated opposed bars. *Applications:* Manufacture and closing of laminated pouches, cup lidding, form/fill/seal packaging (e.g., potato-chip bags).
Band	Concept: Two moving bands backed by heated and cooled metal jaws. *Applications:* Sealing filled pouches, including those made from unsupported materials.
Impulse	*Concept:* Jaw sealer backed with resilient silicone rubber. Electric current flows through Nichrome ribbon stretched over one or both surfaces and covered with high-temperature release film or fabric. *Applications:* Sealing tacky materials, unsupported thermoplastic films (eg, frozen vegetable bags).
Wire or knife	*Concept:* Hot wire or knife seals and cuts film. *Applications:* Bagmaking and bagclosing; overwrap for toys, records.
Ultrasonic	*Concept:* Tooling hammers or rubs materials together at high frequency, generating heat for sealing. *Applications:* Sealing biaxially oriented films, thick webs, aluminum foil, rigid container components.
Friction	*Concept:* Frictional heat generated by rubbing components together generates heat for sealing. *Applications:* Assembly of round containers, sealing ends of strapping.
Gas	*Concept:* Hot air or gas flame applied to both surfaces and removed; molten surfaces are then pressed together. *Applications:* Manufacture and closing of polyethylene-coated paperboard milk containers.
Contact	*Concept:* Plate is placed between surfaces to be sealed and is then withdrawn, and the molten surfaces are pressed together. *Applications:* Sealing ends of strapping, tubing.
Hot-melt	*Concept:* Continuous strip or dots of hot, molten thermoplastic sealant are applied between two surfaces just before pressing them together. The hot melt contains sufficient heat to effect seal, and surfaces absorb heat to cool melt rapidly. *Applications:* Paperboard containers, peelable seals, case packers.
Pneumatic	*Concept:* Heated film is sealed to another surface by application of air pressure. *Applications:* Skin packaging.
Dielectric	*Concept:* High-frequency electric field melts materials held under pressure. *Applications:* Unsupported PVC, PVC-coated paper (not for polyolefins).
Magnetic	*Concept:* Gasket with iron-containing compound pressed between surfaces, assembly placed in magnetic field. *Applications:* Heavy-gauge polyolefins (e.g., cap liners or lids).
Induction	*Concept:* Alternating current is induced in metallic foil, usually aluminum, which heats and melts surfaces pressed against the foil. *Applications:* Tamper-evident closure liners; lids.
Radiant	*Concept:* Infrared radiation sealing without pressure. *Applications:* Sealing uncoated highly oriented films and nonwovens, including polyester, nylon, and polyolefins.
Solvent	*Concept:* Solvent liquefies surfaces that are then pressed together. *Applications:* Sealing configurations where heat may degrade the thermoplastic or is not practical to apply.

and others. This type of sealing is used to make and seal pouches, as well as for sealing lidding to blisters, cups, and trays in form fill and seal equipment.

When very long seals are to be made, it is essential that the seal bars be designed to avoid any deflection in order to ensure uniform pressure throughout the length of the seal. Since it is important to avoid wrinkles in seals, means are frequently provided to stretch out the seal area of the packaging materials in order to ensure that they are flat when sealed. Another approach is to have mating serrations incorporated into the seal bar faces, which will stretch the packaging materials, and, hopefully, remove any wrinkles. Care must be taken to ensure that the serrations do not puncture the films during sealing. Serrated bars are used where good mechanical strength is required and the risk of some tiny leaks in the seal can be tolerated.

When hermetic and/or liquid-resistant seals are desired, they can be made by a flat-faced heater bar, opposed by a bar that has a resilient surface. Silicone rubber is generally used for this purpose. It is best if the resilient surface is curved when viewed from the end of the seal bar. When the bars come together, they first create a line of pressure throughout the length of the seal bar. As the bars

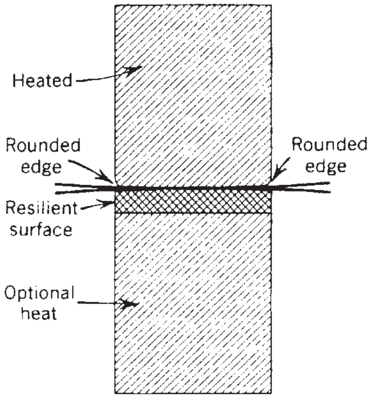

Figure 1. Bar sealer.

close further, this line broadens into a band. The pressure along the initial line is at a maximum and at a minimum along the edges of this band. This ensures that the optimum sealing pressures are present somewhere in between. In the event that drops of liquid are in the seal area, this pressure profile expanding from a line will tend to push these droplets out of the seal area. If the droplets contain water and they are not pushed out of the seal area, they become steam and rupture the seal. As an alternative to curving the section of the resilient bar, the heated metal bar can be curved. This is generally not done since it is more difficult to maintain a curved section than a flat section on a metal seal bar. It is also important that the edges of metal seal bars be gently rounded to avoid puncturing the packaging materials. Figures 1 and 2 show the best constructions used for straight seal bars.

Heated tooling sealing is also used for applying lidding to cups and trays. The upper heated tool is shaped to match the shape of the rim of the container being covered. The bottom tool is shaped to fit under the rim and support the container. In order to assure good seals, it is essential that uniform seal pressure be obtained around the entire rim of the container. Factors contributing to nonuniform pressure are variations in the thickness of the rim of the container and warping of the opposed sealing tools. Using a resilient sealing surface under the rim of the container can correct these deficiencies. Another approach is to design the rim of the container to be curved upward in section. When the seal is made, this curved rim deflects much like a resilient backup member.

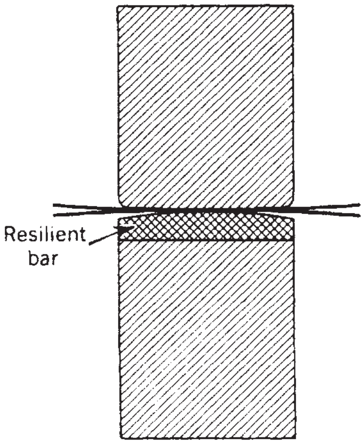

Figure 2. Rounded resilient bar.

For some applications, continuous seals can be made by passing materials between heated rollers. Unfortunately, the dwell time for actual sealing under pressure between rotating rollers is extremely short. Rotary sealing works well for low-speed machines and for highly conductive materials, as well as in applications where preheating can be utilized.

Modern heated tooling systems use thermostatic controls, maintaining a constant temperature in the tooling. Rheostatically controlled systems on older lines still exist, but for packages with thermoplastic outer layers, thermostatic control offers better performance.

Heated tooling sealing is by far the most common form of sealing. This is due to (a) the low costs of resistance heaters and steel and (b) the versatility with respect to seal shape. The most important disadvantage of heated tooling sealing is the fact that the seal leaves the tooling with residual heat. If any pressure is exerted on the seal after it is made, the still-molten polymer in the seal area can creep, even to the point of opening. In this type of situation, the hot tack of the polymer becomes important.

HOT-WIRE AND HOT-KNIFE SEALING

Hot-wire and knife sealing are similar to heated tooling sealing in that the seal system is heated by resistance-type heaters. The wire (or knife) is mounted in or on the surfaces of a heated bar and is heated by conductive contact with the bar. The relatively small surface of contact causes all of the force of sealing to be transmitted through a small area, thus pressure in the seal area becomes very high. High temperatures, along with these high pressures, allow this type of sealing system to be an effective cutting method, as well as a sealing system. Hot wire and hot knife sealing are adaptable to very high-speed operations and are used for both sealing and cutting apart polyethylene bags on bag-making equipment (see Bags, plastic). Unsupported films, when trim sealed by this method, tend to form a strong bead in their seal areas due to surface tension and orientation. This method is also used to a limited degree with laminated constructions. Hot-wire cutoff is also used in film-dispensing equipment and with L bar sealers used on shrink-wrapping machines.

BAND SEALING

In band sealing, a filled pouch is introduced between two moving bands, which are pressed together by heated bars (see Figure 3). The heat passes through the bands and into the pouch material, softening it for sealing. As the pouch continues along between the bands, the bands are next pressed together by chilled bars that withdraw heat from the pouch seal through the bands. The bands then progress to release the pouch. Band sealing is fast and widely used

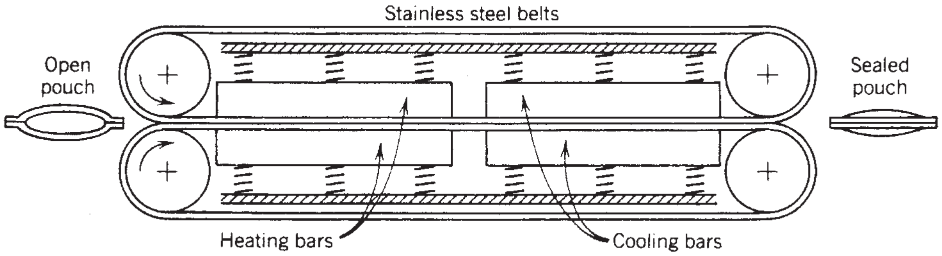

Figure 3. Band sealer.

for closing pouches filled with product. It is important that the pouch mouth be flattened before entering the bands if wrinkles in the seals are to be avoided. Band sealing provides a continuous method for sealing, avoiding the problems found in sealing between rotating heated tooling sealers. It also provides cooling for the seals, overcoming the main disadvantage of heated tooling sealing.

IMPULSE SEALING

Impulse sealers have the same general configuration and mechanical construction used for bar sealers. The difference between the two systems lies in the sealing jaws (see Figure 4). Each of the opposed jaws in an impulse sealer is generally covered with a resilient surface, such as silicone rubber. A taut Nichrome ribbon is then laid over the resilient jaw and covered with an electrically insulating layer of thin heat-resistant material, such as silicone-rubber-coated fiberglass, Teflon® fluoropolymer-coated fiberglass, or Teflon®-coated Kapton® polyimide film (DuPont). A pouch mouth is placed between the jaws, and the jaws are closed. An electric current passes through the Nichrome ribbon for a brief period of time and is then turned off. While the seal jaws remain closed, heat is withdrawn from the pouch mouth and the ribbon through the resilient jaw surfaces, as well as through the jaws. Next, water recirculating through a tube behind the impulse ribbon cools the plastic to set the heat seal. The jaws are then opened and the sealed pouch is removed. This permits the sealing of constructions that have low hot tack. It also permits the sealing of unsupported thermoplastic materials, which would stick to heated bars and pull the seal open when heated bars are opened.

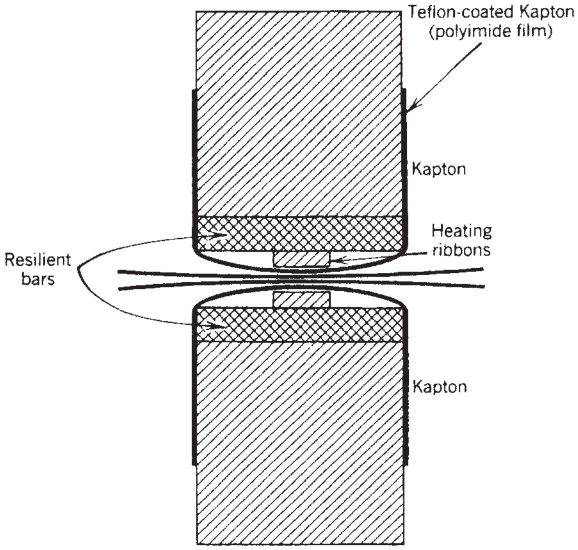

Figure 4. Impulse sealer.

The advantage of impulse sealing over heated tooling sealing is that the seal is cooled to achieve adequate strength before the jaws are opened. The material that covers the Nichrome ribbon has release properties, so that it does not stick to unsupported thermoplastics or to many of the coatings that are used on the outside of packaging laminations. Such coatings include PVDC, ink, and varnish. Although impulse sealing does not have the versatility of heated tooling, some vendors offer shaped impulse-sealing ribbons for securing lids to cups and trays.

The dominant drawback of impulse sealing is high maintenance cost. The impulse ribbons slowly deteriorate and the release coverings over the ribbons degrade, requiring frequent replacement. On a production basis, impulse sealing should be used only where heated tooling sealing does not do the job properly. Additionally, impulse sealing is less versatile than heated tooling sealing. Since impulse sealing applies current across both ends of a wire or ribbon, this system does not lend itself well to round or rectangular sealing systems, and it is not really suitable for platen sealing.

ULTRASONIC SEALING

In ultrasonic sealing, the sealing energy is transmitted to the seal interface by mechanically hammering or rubbing the packaging materials together at high (ultrasonic) frequencies. Frequencies typically range between 20 and 40 kHz. The mechanical energy transforms to heat at the interface through friction, viscoeleastic response, or some combination of the two. This type of sealing is useful to seal materials that are too thick to permit conductive heat transfer through them for sealing. Ultrasonic sealing has been proven to be a good system for sealing through contamination. Because the seal tooling is not heated, the system also offers advantages over heated tooling sealing with respect to cleaning. If a product gets on an ultrasonic sealing horn, it does not oxidize. Ultrasonic welding is the only method used for welding aluminum foil in its production.

The energy delivery in ultrasonic systems begins with a converter, which uses piezoelectronics to convert electrical energy into mechanical energy. The vibrations are then transmitted through a stack and into the horn. The horn is analogous to the sealing tool in other forms of sealing in that it is the surface that contacts the sealable packaging. Like heated tooling sealing, ultrasonic sealing is versatile with respect to shape. It can be used for pouches, cartons, cup/lidding, tray/lidding, and blister/lidding systems. Some tooling limitations exist for very long seals, although some ultrasonic sealer manufacturers can compensate with multiple converter/stack systems driving a single horn.

The biggest disadvantage to ultrasonic sealing is its cost. The seal tooling (horn) must be carefully designed to properly transmit the mechanical energy to the sealing interface. These tools are typically designed using finite element analysis. When a tool is worn or damaged, restoring its performance requires precise milling. Additionally, the tooling systems must, of course, be resilient with respect to high-speed vibration. This cost is justifiable in some applications and not in others.

FRICTION SEALING

Friction sealing is the name of a family of sealing systems that utilize mechanical energy resulting in friction as the energy source. In spin welding, the top and bottom halves of cylindrical containers may be easily joined. The bottom member is held against rotation by a friction brake; the top member is pressed against the bottom member and rotated. The heat generated by friction at the interface between the two halves melts their surfaces, and the viscous interface causes the bottom half to rotate in unison with the upper half. This produces the seal. Thermoplastics with surfaces that become somewhat slippery when heated are best suited to friction welding. Thermoplastics that become dough-like present problems. A thermoplastic with a very low coefficient of friction may not generate enough friction to be a viable candidate for spin welding. Spin welding is generally the most economical way to make spherical shapes for packaging. It is also used to manufacture two-piece cups.

There are other forms of friction welding used in packaging. Seals are also made between the ends of package strapping, which are rubbed together at high speed until the interface melts, causing them to weld. Friction welding is also used to manufacture plastic pallets.

HOT AIR/HOT GAS/FLAME SEALING

Hot air and hot gas sealing can be used in applications where paperboard and thicker thermoplastic materials offer too much resistance to the conduction of sealing heat. In this case, heat is applied directly to the surfaces to be sealed by a gas. The gas may be hot air, a more inert heated gas (nitrogen or CO_2), or a gas flame. An important application of this method is the manufacture of paper containers for dairy products. Closing sealable tubes after filling is another application where hot air sealing is commonly used. Hot air sealing can also be used to seal bags of landscaping goods, due to the thickness of the material and the risk of damage to the seal jaws. The primary advantage of these sealing techniques is the ability to heat the sealable surface without dependence on the conduction of heat. The main disadvantage of this type of sealing is the risk of overheating and oxidizing the sealing surfaces.

In flame sealing, a gas flame is played on the surfaces about to be sealed, after which they are clamped together between chilled bars. Hot air and hot gas sealing utilize the same technique, but use heated gas rather than flame. Sufficient sealant must be used on the surfaces in order to fill all the fissures formed at the joints in the paperboard.

CONTACT SEALING

Another technique to heat the sealing surface rather than depend on conduction is contact sealing. In this case, one or both of the sealing interfaces are contacted by a heated surface before being pressed together. This technique replaces the forced convection heat transfer of hot air or hot gas sealing with conductive heat transfer. The heated surfaces include plates, flat bars, tapered bars, and even shaped tooling. This has been used for strapping as an alternative to friction sealing. Some modern fitment sealing machines use this technique for preheating the surface of pouch fitments before they are sealed to the pouch material. The main disadvantage of this sealing process is tacking of the sealant materials to the heated surface. PTFE coatings may be employed to prevent this.

DIELECTRIC SEALING (ALSO KNOWN AS RF SEALING)

In dielectric sealing, used with polar materials such as PVC and APET, a high-frequency electric field generates heat for sealing. The members are pressed together between a cold bar, generally made of brass, and a cold flat metal surface. An alternating electric field is generated between the bar and the lower surface. The field alternates at several megahertz, hence the “radio frequency” name. The dipoles in the polymers vibrate in response to the alternating electric field. Molecular resistance to the vibration, which is pronounced in large molecules such as polymers, causes the energy to dissipate into heat and ultimately melt the polymer. The main bodies of the members are kept cold to withdraw any residual heat from the materials that have been sealed. This technique is commonly used for sealing of theft-prevention clamshells found in the electronics departments of retail stores.

The primary disadvantage of dielectric sealing is the requirement for a polar molecule. Nonpolar materials such as polyethylene and polypropylene do not respond adequately to an alternating electrical field.

INDUCTION SEALING (ALSO KNOWN AS RF SEALING)

Induction sealing utilizes the property of some metals to heat inductively, using an alternating magnetic field. The magnetic field is alternated in polarity at radio frequencies. The magnetic field induces electric currents in the metal. The metal resists the flow sufficiently to heat resistively, eventually building enough temperature to conduct out of the metal and into nearby thermoplastic sealing materials.

A common use of induction sealing is to produce a tamper-evident seal over the top of a bottle. The aluminum foil-based cap seal is generally incorporated under the closure liner (see Closure liners). The assembly is placed in the alternating field, and a current is induced in the foil. This current heats the foil, and energy is conducted into the sealant, sealing it to the bottle.

In another variant of this type of sealing, a gasket, shaped to fit between the sealing faces of the two package members, is made from the same thermoplastic as the package, but has milled into it an iron-containing compound that has a high hysteresis loss. The package portions are pressed together with the gasket between their sealing surfaces and placed in a magnetic field oscillating at a frequency high enough to melt the gasket. This, in turn, melts the sealing surfaces and causes them to weld together. As an alternative to a gasket, an iron-containing material can be pre-applied to one or both of the sealing surfaces, producing the same result.

RADIANT SEALING

There are two completely different techniques that can be classified as radiant sealing. The first is similar to hot air/hot gas sealing in that the packaging material is heated and then subsequently subjected to pressure. This type of radiant sealing is typically used to close pouches on high-speed horizontal form fill and seal lines such as those used to package sugar. The top seal travels between two radiant heat bars to soften the polymer. At the end of the radiant heating zone, two crimp wheels close the package. The radiant heat bars are set much higher in temperature than that needed for conductive heating due to the lower effectiveness of radiant heating. These high temperatures and the fact that the material is not supported in the radiant heat zone means that some sort of thermally stable material needs to be part of the construction. Typically on this type of machine, paper is contained in the structure.

In the other form of radiant sealing, the two surfaces are held in contact by two cooled jaws with ends of the material extending beyond the jaws. These exposed ends are subjected to radiant heat to the point of fusing the package closed. This form of radiant sealing makes it possible to seal many materials used in packaging that might be considered either difficult or impossible to seal without coatings (see Figure 5). Polyester film (see Film, oriented polyester), long used in packaging constructions and many nonwoven (see Nonwovens) materials, can be sealed by this method. These include: Tyvek® (DuPont), a nonwoven polyolefin used in packaging and for protective garments; Reemay®, a nonwoven polyester, used in filters; Cerex®, a nonwoven nylon, used as a carpet backing and in filters; and nonwovens made from polypropylene and other base materials. This method can also used for sealing other oriented films, such as polypropylene and polyethylene. OPET pouches are commercially made for document preservation. OPET is approved by the Library of Congress for use in contact with valuable documents. In addition to making pouches, this sealing method can also be used to produce continuous seals to edge-join rolls of materials at high speed.

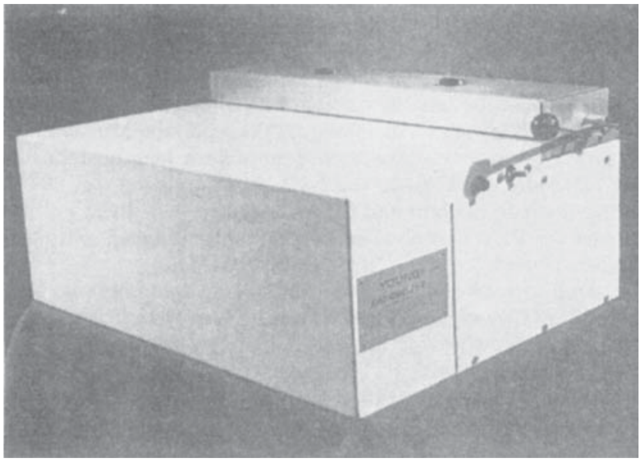

Figure 5. Radiant sealer.

HOT-MELT SEALING

Hot-melt sealing is performed by depositing either a continuous strip, or dots, of a thermoplastic material on a packaging member, just before the next member is pressed against it. It is used as an alternative to glue, since the packaging members quickly remove heat from the melt, making it tacky enough to hold the members together quickly to prevent the springback forces from opening them up (in sealing the covers of a shipping container). With glue, the members must be held together until enough of the glue's solvent is absorbed by the packaging material to make it tacky. Hot melts are also used where applied heat might damage a packaging member or where peelability is desired (see Adhesives; Waxes).

PNEUMATIC SEALING

Pneumatic sealing is used for skin packaging (see Carded packaging), where pressure from the atmosphere pushes a hot, tacky film into close conformity with an object and seals the film to a substrate on which the object is placed. It is also used in hermetic skin packaging for fresh red meat. The energy source for this type of sealing comes from the polymer being sealed, which has been preheated.

SOLVENT WELDING

Solvent welding is used to join together package configurations that may not lend themselves to heat sealing. It is also used for joining materials that are either not susceptible to heat sealing, or may be damaged by the application of heat (e.g., shrink sleeves). In this type of sealing, the solvent dissolves the polymer, which increases the mobility of the chains. In this case, chains can diffuse across the interface not because of heat, but because the polymer chains are more mobile in solution. When the solvents dry, the chains are left entangled. Solvent welding is commonly used for shrink sleeves. In the case of shrink sleeves, solvent is applied to one side of the material, which is folded over to create the weld. Its primary disadvantage is that the materials to be used must be reasonably soluble in commonly used solvents.

SELECTING A SEALING METHOD

For laminations and coextrusions with high-temperature outer layers, heated tooling sealing is the least expensive of all sealing methods. It should be considered first before other methods. If sticking to or contamination of the seal bar is a problem, the following should be tried out before abandoning heated tooling sealing:

1. Coating or impregnating the seal bar with Teflon® fluoropolymer (DuPont).
2. Periodically wiping the seal bar with a silicone grease.
3. Mounting a release material, such as Kapton® polyimide film (DuPont), between the seal bar and the packaging material.

If all of these fail, alternate sealing methods should be considered next. This article is not suited to be a complete reference for a seal method selection, but important items to be considered and possible sealing methods include:

Does the seal need to be cooled before the pressure is released? (Band/impulse sealing)
Does the seal need to separate the packages also? (Hot knife & hot wire sealing)
Is the package material very thick? (Ultrasonic, hot air/gas, contact)
Is the package material thick and aluminum foil-based? (Induction)
Does the sealer need to cut through significant contamination? (Ultrasonic)
Is this a cap seal application with aluminum? (Induction sealing)
Is the package material polar (dielectric)?
Is the package material an oriented film? (Second radiant sealing method)

When packaging materials are sealed, the package and its function dictate the properties to be achieved. Mechanical strength is important, since the seals should not fail under normal handling. Hermetic integrity is important in food, pharmaceutical, medical, and chemical packaging. Although small wrinkles in a seal area may have slight effect on its mechanical strength, they are completely unacceptable if a hermetic-type package is required. The best approach to avoid seal wrinkles is to hold the seal region of the construction under tension during sealing. If this is impractical, increasing the thickness of the sealant portion of a lamination may ensure good seals, even though small wrinkles may be present.

Incorporating EVA in polyethylene, or substituting ionomer (see Ionomers) as a sealant, results in improved flow properties and better tolerance of small wrinkles. The most reliable seals for hermetic packaging consist of true fusion welds between the opposed sealant members of a lamination. A true weld can be identified by pulling apart the lamination and noting where seal failure occurs. If it occurs along the interface between the materials, a true weld was not attained. If failure migrates from the interface, through the sealant, and to the outer portion of the lamination, a homogeneous seal has been achieved (see Multilayer flexible packaging).

If a peelable seal is desired, one should understand the risks of relying on control of temperature and/or pressure to achieve peelability. Seals made in this way may be peelable, but they can come apart by themselves with handling. Another way to achieve dependable peelability is to have an interface formulated to be peelable. There are three general strategies for achieving peelable seals. One is to "contaminate" the sealant so that it does not bond as strongly to itself during the seal process. This is known as an interfacial seal since it fails along the sealant-to-sealant interface. A second strategy is to control the adhesion between the sealant layer and the layer adjacent to it in a multilayer structure. As the seal is pulled apart, the opening forces burst through the sealant layer and the seal fails at the sealant-adjacent layer interface. This is known as a delamination or burst peel peelable seal. The initial seal strength is controlled by the thickness and tear strength of the sealant and the steady-state seal strength by the adhesion between layers. Delamination-type peel seals typically are less sensitive to seal bar temperature as a result. The third strategy is to design a sealant that has poor cohesive strength; failure occurs within the sealant layer as the seal is opened. This is known as a cohesive-type mechanism.

SEAL TESTING

The American Society of Testing and Materials (ASTM) has set up standards for the testing of the seal strength of flexible barrier materials. Their designation for the testing procedure is ASTM F88-06 and F2029-00. Hot tack testing is covered by ASTM F1921-98. There are also European standards such as those from the Deutsches Institute for Normung (DIN): DIN 55-529, 55-543, and 55-445. These German standards will likely be incorporated into European Union ISO standards at some time in the future.

These standards describe how the specimens are to be prepared, along with the equipment and methods to be employed for testing. Tests in accordance with these standards are extremely useful in comparing the seal strength achieved with various materials under consideration for a particular application. Seal strength and hot tack, however, are not the only criteria to be evaluated for many applications. Although some seals may test well in the laboratory, they may fail in service. Reasons for this failure include absence of a true fusion weld of the interfaces of the materials being sealed, among other reasons. Occasionally, unwelded seals perform well under mechanical testing, but fail in the actual applications. When there is not a true fusion weld, portions of the packaged product may find their way out of the package through the seal. For seals that must be reliable, particularly where sterility must be ensured in a package (see Healthcare packaging), sections of the seals should be examined under the microscope. Unless examination shows that the interface between the sealant portions of the laminations has been completely obliterated, the seals should be suspect; with a true fusion weld, there is no visible interface remaining.

The exception to this is peelable seals. The only way to ensure that these are acceptable for the long term is to subject them to rough-handling testing for extended times, exceeding the environmental extremes likely to be encountered. If heat processing is involved, good sense dictates that the tests be carried out for at least twice the period of time that the product is heat processed. Tests should also be conducted to simulate environmental pressure fluctuations at something in excess of the maximum temperature expected to be used in processing. For the packaging of chemicals, or other corrosive products, testing should be carried out with filled packages, subjected to rough handling, elevated temperatures, and any other severe conditions that might be experienced.

When dealing with flexible material constructions, even small wrinkles in the seal area produce a statistically significant percentage of leakers. Aside from visual inspection, no satisfactory automatic system has yet been devised to isolate packages with small seal wrinkles, although a great deal of time and money has been spent in this area. When developing a packaging system where seal integrity is paramount, everything should be done in the design of the system and its equipment to eliminate chances for seal wrinkles. The best way is to keep the packaging materials under tension in two directions while they are being sealed. This can do more to achieve success in eliminating seal wrinkles than any other single effort that might be made. Frequently, design of the packaging can be improved for the sole purpose of reducing the possibility of wrinkles in the seals.

Packaging testing can be also be conducted to evaluate the seal integrity of packages. Typically, this involves vacuum testing or pressurization testing. These tests can be conducted to the point of failure or set to test for pressure decay within the package. Vacuum tests can be conducted dry or under water. Pressure tests can be conducted by compression or inflation. In inflation pressure tests, the packages can be restrained or unrestrained. Additional options include dye leak tests and testing for leaking of gas out of or into the package.

Attempts have also been made to adopt online tests for seal integrity. These include optical comparators, deflection tests, infrared tests to evaluate the heat profile, and ultrasonic imaging techniques. All of these techniques have advantages and disadvantages. None are considered to give complete assurance of well-sealed packages.

SHEET, PETG

JOHN WININGER
Eastman Chemical Co.
Kingsport, Tennessee

PETG copolyester is a clear amorphous polymer with a glass-transition temperature (T_g) of approximately 81°C (178°F) as determined by differential scanning calorimetry (DSC). It is manufactured by an addition of a second glycol to polyethylene terephthalate (PET) to eliminate crystallization; therefore, all PETG-finished products are amorphous. PETG has a number-average molecular weight (M_n) of approximately 26,000. As with all thermoplastic polyesters, PETG is subject to hydrolysis (during processing) in the melt state. Although some reduction in molecular weight is a normal consequence of melt extrusion, insufficient drying of PETG can result in an excessive inherent (or intrinsic) viscosity (IV) breakdown that is reflected in lower physical properties—particularly impact strength.

A harmful degree of hydrolytic degradation can be prevented if PETG is dried in a dehumidifying dryer at 65°C (149°F) for 4 h to reduce the moisture level to less than 0.08% before processing.

The molecular weight of either PETG pellets or extruded sheet can be correlated to IV, which is normally determined with a capillary viscometer; however, because this procedure is complex and the required solvents are hazardous, a simpler melt-flow-rate test is preferable. The resulting flow-rate number can later be converted (via the calibration curves) to the more standard polyester IV units.

Thermal and electrical properties of PETG copolyester are shown in Tables 1 and 2.

Unstressed sheet extruded from PETG copolyester exhibits good resistance to dilute aqueous solutions of mineral acids, bases, salts, soaps, aliphatic hydrocarbons, alcohols, and a variety of oils.

Halogenated hydrocarbons, low-molecular-weight ketones, and aromatic hydrocarbons will swell or dissolve the plastic.

A plastic sheet extruded from PETG copolyester has good transparency, low haze, and high surface gloss. It has high stiffness and good impact strength. The physical properties for a 3-mm (0.12-in.) PETG sheet are shown in Table 1.

PETG COPOLYESTER SHEET EXTRUSION

PETG copolyester can be extruded into a clear, tough, amorphous sheet at melt temperatures that usually range within 230–250°C (446–482°F). The sheet thickness is limited only by the cooling capacity of the processing rollstock and/or the capability of the downstream takeoff equipment, but otherwise it might typically range from 1 mm (0.04 in.) to 13 mm (0.50 in.) or thicker.

The extrusion of PETG copolyester is straightforward, and good results can be expected when suitable equipment and proper procedures are used, which include pellet drying, melt extrusion into sheet, and nip polishing on a chrome-plated three-roll stack to ensure an excellent surface finish and good transverse-direction gauge control. Machine-direction gauge control is dependent on the uniformity of extruder output. Excellent uniformity can be obtained using a gear pump with PETG, but its use is especially suggested when regrind is included in the PETG feedstock.

At a given speed, a gear pump provides a constant volumetric rate of copolymer melt to the sheet die. The pressure between the extruder discharge and the entrance to the gear pump is controlled by varying the extruder screw rpm. The variation in extruder output caused by changes in the percentage of regrind or particle shape and size are isolated from the extrusion, die, and the effect on the plastic sheet gauge is minimized. For example, a gear pump set at a suction pressure of 6.9 MPa (1000 psi) would typically control PETG sheet gauge to approximately $\pm 4\%$.

A barrier screw that is cored for water cooling in the feed zone is typically used to extrude the PETG sheet. Industry practice for all polyesters, including PETG copolyester, usually requires an extruder screw with a minimum length/diameter (L/D) ratio of 24:1. As the L/D ratio increases (e.g., 30:1), output capacity (lb/h) and output stability (–/+ lb/h) will improve for PETG copolyester, if a suitably designed extrusion screw is used.

Melt filtration is normally used to trap contaminants and/or other types of particulate matter such as “fines,” which can be associated with regrind use. A simple screen pack assembly is often used with PETG copolyester, but several different types of automated filtration systems are commercially available for polyesters.

SECONDARY FABRICATION OF PETG SHEET

The manufacture of plastic articles from PETG copolyester sheet normally involves secondary operations such as sawing, drilling, bending, decorating, and assembling. PETG sheet can be worked with most tools that are suitable for use with wood or metal; however, the tool speed normally must be reduced to prevent friction melting.

PETG copolyester sheet thickness of ≤ 2.5 mm (0.10 in.) can be cut effectively with either a power shear (straight cut) or with a steel rule die (irregular cut). The blade-to-bed clearance and alignment for the shear knife edge is an important consideration when cutting PETG sheet. Additionally, a steel rule die press must have a very accurate stroke to prevent damage to the cutting die. Saw cutting is a preferred technique for sheet thicknesses of >2.5 mm (0.10 in.).

FORMING

Hot Bending. PETG copolyester sheet can be bent around a small radius by preheating an area on both sides with an electric strip heater and then quickly bending the sheet along the heated line. Sheet thicknesses of >3.2 mm (0.13 in.) should be turned periodically during the heating cycle.

Cold Bending. Unheated PETG sheet of ≤ 2.5 mm (0.10 in.) thick can be successfully brake formed at bending rates somewhat slower than heated sheet.

Thermoforming. Several different thermoforming techniques can be used to force a PETG sheet, once heated, into the shape of a mold by mechanical force, vacuum force, or by air pressure. Both male (plug) and female (cavity) molds can be used. Low-cost plaster molds, cast aluminum molds, and/or water-cooled steel molds are commonly used. Typical forming processes include vacuum, drape, and matched mold. Thermoformed items include light fixtures, tote trays, housewares, toys, and a variety of different transparent enclosures.

PETG Sheet Assembly. Several solvents, cements, and adhesives can be used effectively with PETG copolyester sheet products. Sheet edges, once aligned, are softened by applying cement and clamping until dry.

A PETG copolyester sheet is often fabricated with mechanical fasteners. This technique is preferred if frequent disassembly of a product is required. Common mechanical fasteners include screws, rivets, bolts, clips, hinges, and dowels. This may be a concern, however, if security is a consideration.

PETG Sheet Finishing. PETG copolyester sheet is best sanded wet to avoid frictional heat buildup. An 80-grit silicon carbide could be initially used, followed by progressively finer abrasives (e.g., 280, 400, and 600).

PETG Sheet Decoration. PETG copolyester sheet can be hotdie-stamped through a film carrier that contains either

[d] UL flammability classifications are formula-specific. Spectar copolyester 14471 has the ratings shown.

metal or paint. Letters, designs, and trademarks are examples of hot-stamped processes. PETG sheet can also be printed on conventional processes such as letterpress, offset lithography, rotogravure, silk screen, and stenciling. Application of a protective lacquer is often applied over the hot-stamped and printed areas (see the Decorating articles).

PETG copolyester can be extruded in a variety of thicknesses, coextruded with or without tie layers, and formed or fabricated, to meet the needs of ever-increasing consumer and industrial markets. The price, performance, and availability of PETG copolyester make it a very important material in the plastics market today.

SHELF LIFE

Kenneth S. Marsh
Kenneth S. Marsh and
Associates, Ltd., Woodstock
Institute for Science in Service
to Humanity, Seneca, South
Carolina

DEFINITION OF SHELF LIFE

Shelf life is the time after production and packaging that a product remains acceptable under defined environmental conditions. It is a function of the product, the package, and the environment through which the product is transported, stored, and sold. Each of these influencing factors will be discussed below.

The shelf life for any given product can vary greatly, depending upon the formulation, the packaging system, and the distribution environment. In general, use of preservatives, increased barrier packaging, and colder distribution environments will extend shelf lives. These options typically also increase costs. The ideal shelf life from the company perspective is one that matches the distribution and use of the product to the company's inventory. The ideal shelf life from a consumer point of view allows them to fully use the product. Specification for overly lengthy shelf lives usually increases cost in terms of materials, whereas overly short shelf lives usually increases cost in terms of wasted or discarded product or in terms of increased liability. It is therefore prudent to define a reasonable shelf life and to assure that the shelf life specification is met.

The principles of shelf-life testing hold for virtually any product/package combination. Products that are packaged in impermeable materials, such as glass or metal, degrade primarily through mechanisms that are inherent in the chemistry of the product. Since these mechanisms are essentially product-dependent and vary with the product, evaluations of the package would be unproductive. Notable exceptions to this are situations in which the package allows or contributes to deterioration of the product. For example, glass allows light transmission that can promote oxidation reactions, but can be tinted to filter wavelengths that promote these reactions. Metal cans can react with products with either (a) the metal substrate itself (e.g., pinholes in tinplate) or (b) components of the can coating. Improvements in can and coating technology are designed to preclude these interactions. (For further discussion refer to sections of this Encyclopedia on the appropriate container.) Since the reactions of these impermeable containers are specific to the containers, further discussion of packaging influences will be directed toward semipermeable and permeable materials.

FACTORS THAT INFLUENCE SHELF LIFE

Product

Products differ greatly in their susceptibility to degradation by various agents. Some products will become unacceptable from a change in moisture content. For example, a moisture gain in ready-to-eat breakfast cereals will destroy the crisp texture; a moisture loss in an intravenous product will increase the declared dosage per unit volume. Snack items often are sensitive to oxidation of the oils absorbed during frying and can become rancid. Snacks also can be sensitive to moisture change. The mode of failure of the product will have a direct influence on the type of protection which is sought from the packaging material. The match between product susceptibilities and package protection will have an impact on the shelf life.

Once the mode of deterioration of the product is determined, acceptance criteria need to be defined. Acceptance criteria is the range of the critical component for which the product is considered acceptable. This is often done by a sensory panel. Ideally, sensory scores can be correlated to analytical data such that result of that analysis can provide the index for product quality.

The acceptability criteria for any product has a direct influence on the measurement of shelf life. Some products have a clear point of acceptability. Others have complex deteriorations that make it difficult to identify a critical point. This can be further complicated by products that have multiple or interacting modes of failure. In these cases, subjective decisions must be made to set the acceptance criteria. It deserves mention that the ultimate acceptability is that of the consumer. Concordance between a standardized definition of acceptability (as used within the company) and actual consumer acceptance is crucial to the commercial success of the product. The determination of this concordance is more properly within the domain of marketing research, but the degree of correlation determines the validity of the research effort.

The product that is tested for shelf life must be specified. This may sound trivial, but reformulations and ingredient cost reductions can alter product characteristics without changing the product name. The result is that assumptions may be made on the basis of past performance which may not hold for the present product. Therefore, the test label should include product name, formulation (or reference to specific formulation in a lab notebook), date of manufacture, date of test, conditions of test, and principal researcher. The packaging system must also be identified in terms of key factors as described below.

Package

The package offers protection for the product against an agent that degrades the product. For moisture-sensitive products, this protection is in terms of the water vapor transmission rate (WVTR); for oxygen-sensitive products it is in terms of the oxygen transmission rate (OTR); and so on. The mode of protection can change for the same product with different packaging. For example, a snack product that is sensitive to moisture gain (loses crispness) and oxygen (becomes rancid) could be called "moisture-sensitive" if the texture degrades before the rancidity becomes objectionable. This same product, if packaged in a sufficient moisture barrier, would be identified as "oxygen-sensitive" in terms of package criteria.

Permeation rates for chosen packaging materials need to be determined for the agent in question. WVTR and OTR are measurable by a variety of standard procedures (see Testing, permeation and leakage). Permeation rates for flavors and other vapors can be determined by organic permeation instruments (see Aroma barrier testing) as well as by gas chromatographic, mass spectral, infrared, and other techniques.

The size of the package also influences the shelf life. As the package size increases, the surface-to-volume ratio decreases. The result is that the amount of permeant that comes through the package increases as a square function, but the volume of product that absorbs this permeant increases as a cube function. In other words, the permeant is diluted with more product in a larger package. The barrier requirements, therefore, decrease with the package size, all other factors remaining equal.

In summary, therefore, the packaging parameters that must be specified for shelf life testing are the material designation and source, the appropriate transmission rate, the surface area, and the net weight of the enclosed product.

Environment

Product distribution causes stress on the product as a function of product sensitivities and all conditions experienced by the product as it is carried through various distribution networks. Actual conditions vary with where it is shipped, how it is shipped, the seasons, warehouse conditions, and so on. It is impossible to account for this variety of conditions by using a single storage condition. Therefore, the manufacturer of sensitive products (food, pharmaceuticals, cosmetics, tobacco, chemicals) must define the criteria that will be used for the shelf-life determinations. Pharmaceutical manufacturers must package for the worst-case situation, so packaging will be designed to survive under the most severe conditions in the distribution chain. Food products are often packaged for less-than-worst-case scenarios. Products that are not rotated on the supermarket shelf (such as if a product is replenished in front of existing stock) may fail, but this loss is considered economically preferrable to increasing packaging costs for the entire line to accommodate this situation. Conditions that allow 80% of the product to survive distribution is not uncommon. Improved distribution and product rotation can reduce the quantity of outlying product. Once the representative distribution mode is chosen, useful statistical indices can be derived which represent this mode.

The shelf life impacts greatly on the distribution system and *vice versa*. Products with short shelf lives require a more rapid distribution system. For example, Frito Lay supplies the nation's grocery stores with snack items via over 200 major distribution sites that in turn are supplied from 32 production facilities (1). This allows potato chips and other snacks, which are susceptible to both moisture and oxidative degradation, to reach the consumer in a fresh and crisp form. In contrast, Proctor and Gamble Company distributes Pringles from one production facility (Jackson, TN). A casual examination of Pringles versus Frito's potato chip packaging will describe for the reader the consequences of the product/distribution strategies. Pringles uses a multilayered composite can structure with foil barrier as compared to the simpler flexible pouch in the Frito system. But when potato chips were brought to the top of Mt. Everest, only Pringles made it intact (2).

Refrigerated or frozen distribution is costly, but provides additional protection for the products. Additional processing/packaging such as hot fill, aseptic, or retort packaging extend the shelf life and eliminate the need for refrigeration. In Europe and Asia, where typical home refrigerator and freezer space is more limited than in typical U.S. households, retort and aseptic packaging are far more important. The Brik-Pack, for example, was developed in Europe to fill the gap that the United States fills with refrigeration.

The distribution environment also impacts shelf life from a physical perspective. Lack of quality roads, suspension systems on trucks, sway potential on railcars, and so on, can influence product distribution substantiallty. Potholes, for example, can lead to crushing, bruising, and impact damage. Packaging choice can partially compensate against this damage, typically at a greater cost. But poor infrastructure will influence either packaging choice, product quality, or both. Two examples: Crates can limit weight experienced by a truckload of fresh produce on bumpy roads, and they were found to reduce crushing damage from over 20% to 5% in Sri Lanka; steel two-piece cans are used for bevereages in Africa in locales in which aluminum two-piece cans had inadequate strength to survive transport. Another factor for determining acceptability or unacceptability of products, especially food products, is attack by insects, birds, rodents, and other animals. Packaging, storage, and distribution environments all play a role in limiting this damage. Such "shelf-life" limitations from physical forces are typically addressed in distribution discussions and components such as cushioning, and biological attacks are typically addressed by materials choice and warehouse and distribution conditions. Many people in the developed world underestimate these losses (3), which become increasingly important in less developed countries in which food insecurity is a major problem. Packaging serves to protect products, but also allows products to be more competitive (4). Most of the following discussion concentrates on chemical and microbiological influences.

The measurement of shelf life is becoming increasingly more important. The competitive nature of contemporary business and increased energy costs have resulted in renewed interest in reducing packaging costs. An abundance of new packaging materials facilitates the choices, but also adds to the complexity of the choice. In addition to the above, governmental requirements for open dating, required for pharmaceuticals and some foods (5), necessitate shelf-life testing. Open dating is the addition of a date on the package which indicates by what date the product should be consumed. This can take different forms as shown below.

A brief synopsis of different types of open dating is in order. Dating of products online has been the practice of companies producing food, pharmaceutical, and other sensitive products. Each company developed its own proprietary coding system to enable identification of production dates and production facility when necessary. These codes, which were designed to be unreadable to consumers and competing producers, identify production dates when necessary. Open dating changes this.

Various types of dating are possible. A direct conversion of production codes into consumer readable form gives the date of manufacture. A freshness date (“use by”) indicates the date by which the product should be consumed to assure maximum freshness. A pull date is the date after which the product should no longer be sold. Milk and dairy products use pull dates.

It must be noted that all of the above dates assume storage under specific conditions. For example, dairy products are assumed to be refrigerated. If conditions are not held as anticipated, product quality will not be reflected as implied in the dates.

Dating of products will benefit the consumer, but also has the potential of benefiting both manufacturer and retailer. It would improve stock rotation (as mentioned above), which could ultimately reduce the packaging requirements necessitated by existence of old product.

TRADITIONAL APPROACHES TO SHELF-LIFE TESTING

Shipping Tests

One common procedure for testing shelf life is a shipping test. Shipping tests are often used as an adjunct to other shelf-life testing, but sometimes are considered a replacement. This is a mistake, because shipping is only a component of the testing environment. This type of testing is characterized by uncontrolled and often unknowable storage conditions, although recording sensors now exist to measure conditions. A product is shipped to a warehouse, stored for a specified time, and then returned to headquarters (or R&D) and examined for acceptability. Shipping tests are also used to check for product deterioration from shock and vibration during shipment. At least one company uses shipment through the Chicago post office as the ultimate test for product endurance. Shock and vibration effects are important for assessing product quality. They are abuse-dependent rather than time-dependent, however, and are discussed separately (see Testing, product fragility).

Shipping tests show product quality changes with time under real-world situations. The specific experience of a specific test may be representative of part of the distribution chain but rarely, if ever, represents all conditions that the product will experience. The test carries the illusion of being a representative real-world test. However, the changing conditions, as well as factors such as the difference in product experience between shipment in carton versus pallet quantities, will necessitate careful evaluation of the results.

Storage Tests

Storage tests consist of (a) maintaining product in a static facility and (b) evaluating product quality with time. Storage conditions can be uncontrolled or controlled. Warehouse storage is often characterized by uncontrolled conditions. Storage conditions can be controlled through the use of storage cabinets that maintain temperature (and often humidity) at specified values. This results in a test that can offer more reproducible data. Various conditions can be tested, including accelerated conditions that allow for more rapid results. A typical ambient condition (for the United States as defined by TAPPI) is 73°F(23°C)/50% relative humidity (R.H.).

Accelerated conditions vary, but a typical condition may be 39°C (95°F)/80% R.H. Accelerated storage speeds product degradation (6). However, the factor that defines this increase is related to the kinetics of the chemical reactions which define the degradation. This varies with product and with mode of degradation. Therefore, any standard multiplication factor is meaningless.

Accelerated studies are useful if an initial evaluation is performed at both ambient and accelerated conditions and then compared. This comparison can be through actual kinetic studies (such as Q_{10} analysis described below) or by shelf-life comparison. It is imperative to ensure that discontinuities do not exist between ambient conditions and accelerated conditions. If either the product or packaging passes through a transition, the results of the accelerated test will have little bearing on comparisons with ambient. Transitions that affect packaging include the glass-transition temperature (T_g). For example, permeation values for polypropylene cannot be extrapolated to frozen conditions due to a T_g at -10°C (14°F). Those for products include melting/freezing of any ingredient (usually water or fats), recrystallizations, and so on. In addition, activation energies must be considered, because certain reactions will not occur below certain temperatures. Extrapolation below these temperatures is therefore not recommended.

Q_{10} analysis involves testing products at varying temperatures, as well as defining the difference in reaction rate for a 10°C (18°F) temperature increase. A Q_{10} of 2 means that the reaction rate will double for each 10°C increase in temperature. This is based on the Arrhenius relationship, which is discussed in any text on kinetics or physical chemistry. The Arrhenius relationship is perhaps an oversimplification for the complex chemistries of most products. A straight-line relationship with a minimum of three points (over a limited temperature range) indicates that Q_{10} can provide a useful indicator for storage duration. Caution relating to transitions remains, and it also deserves mention that the Q_{10} itself is temperature-dependent. However, products are usually studied under a limited range of temperatures through which a constant Q_{10} can be assumed.

Once the Q_{10} is determined (and shown valid through a linear Arrhenius relationship), the value can be used to predict the time necessary to test a product to be equivalent to the shelf life at ambient temperature. For example, a product with a Q_{10} equal to 2.4 can be stored for 10 weeks at 33°C (91°F) to obtain results similar to 24 weeks storage at 23°C (73°F). (One can view these studies as a test in which the conditions extended to the package are exaggerated in an attempt to simulate the accelerated passage of time. The underlying assumption is not always valid, and the technique is only as good as that underlying assumption.)

An alternative type of “accelerated” test is a study in which the permeation rate of the packaging material is “accelerated.” A product that is being tested for sensitivity to moisture is packaged in a low-moisture/high-oxygen barrier material (such as polyacrylonitrile or polyacrylonitrile copolymers). With a known permeability, area, and net weight, the amount of moisture permeating the package can be determined. Product can be sampled for acceptability until failure is reached. This defines the amount of moisture transfer that can be tolerated. Calculations with higher moisture barrier materials can provide performance criteria for the additional materials. A similar study can be performed for oxygen-sensitive products by using a low-oxygen/high-moisture barrier material (such as polyolefins). In essence, this test purposefully introduces a known amount of the critical agent to accelerate the time to degradation without changing the conditions experienced by the product. A cautionary note is important. The accelerated test described above includes the inherent assumption that the changes in the product occur faster than the transmission across the package. If an accelerated test allows sufficient permeation such that product changes are slower than the influx of permeant (i.e., is diffusion dependant), the results will indicate a shelf life that is longer than the extrapolation to a reasonable barrier material. This is due to a critical permeant level being obtained faster than the evidence of product degradation.

COMPUTER MODELS FOR SHELF LIFE

The shipping and storage tests require that the choice of packaging be made before the study. Chosen materials are then submitted for evaluation with time as the test proceeds. Successful completion of the test verifies that the chosen package will last at least as long as the chosen test duration under the conditions of the test. Failure to survive the test conditions demonstrates insufficient protection. The deficiencies of this procedure are that failure is not known until demonstrated, and overprotection is not shown at all because testing usually terminates after desired time is reached.

The use of a computer to simulate a storage test provides a means to pretest materials before actual storage testing. By performing these calculations rapidly, as only a computer can do, many iterations are possible within a reasonable time, providing a powerful support tool for packaging development. The simulations are accomplished by separating the product and packaging characteristics. The product is analyzed for changes that occur on exposure to the shelf-life-limiting parameter, which is identified as the mode of failure for the product. The packaging material is analyzed for its barrier properties against that parameter. The computer is then used to combine the protective aspects of the package with the sensitive properties of the product. Since packaging, product, and storage parameters are entered independently, it is possible to test the effect of different packages or conditions simply by entering the new variables.

Computer simulation yields the most cost-effective packaging design. Later real-time storage studies serve the purposes of legal requirements and confirmation of predicted results. Differences between predicted and actual results can be used as indices to check initial assumptions. For example, poor seals will shorten actual shelf life achieved with an otherwise-adequate barrier material. In this example, the false assumption is that the material barrier value is equivalent to the package permeation (see Testing, permeation and leakage).

Simulated studies extend beyond the one-package/one-condition study. Parameters can be changed to affect another study. A survey of potential new packaging materials can be accomplished without need to retest the product. Only the changes in material parameters need be entered to test performance. This is especially important when limited amounts of product material are available, as in the product-development stage. Changing storage conditions follow a similar procedure, but the caution for passing transitions remains. Computer modeling has been used successfully for foods (7–9), over-the-counter products (10), and pharmaceuticals (11).

Product Evaluation

The mode of failure for the product must be known prior to using any simulated approach. This could be moisture gain or loss, oxidation, CO_2 loss, flavor loss, chemical degradation, and so on. Once the critical factor is known, testing is conducted to show product changes with change in the critical factor. For example, a moisture-sensitive product is evaluated for change in moisture content as the relative humidity in the storage environment is varied. This test is the moisture isotherm. The isotherm can be completed in usually one to four weeks, depending on the rapidity at which the samples equilibrate. For oxygen-sensitive products, the testing consists of evaluating product changes with oxygen uptake and can be performed by inverse gas chromatography, respirometry, Warburg, Totox, or a variety of tests for degree of oxidation. For carbonated beverages packaged in permeable bottles, the test would be to measure carbonation loss (soda), or oxidation (beer) or both.

The product testing should be performed at various temperatures if temperature effects are to be modeled. The evaluation of differences in reaction rates versus temperature supplies important information concerning the kinetics of the reaction and can be used to investigate performance for different distribution environments. A minimum of three test temperatures are recommended. The caution concerning transitions remains valid.

Package Evaluation

For computer modeling purposes, the chief packaging characteristics are barrier properties. Materials that do not change significantly with machining and flexing can be tested in flat sheet form for water vapor transmission rate (WVTR), oxygen transmission rate (OTR), or any other permeant that is critical for the product. For materials that change with handling (waxed glassine, foil, etc.,) full package testing is recommended. The computer model measures the change of permeant level in the package as a function of the transmission rate. If the flat sheet value is used in a system that is poorly sealed, or has developed fractures in handling, the predicted shelf life will be erroneously long.

The package material characteristics of sealability, printability, compatability, cost, mechanical strength, etc remain the province of the packaging engineer and are not usually incorporated into computer models. Nonbarrier parameters are not included in this discussion of shelf life. Those parameters that do affect shelf life, but are not in the model (e.g., light transmission for oxygen-sensitive products), must be considered in evaluating any computer printouts.

Model Fundamentals

The internal environment of a package changes as permeants enter or leave the package. In terms of the mathematics, components which enter the package from the outside environment, and those which permeate from the inside to the outside, are identical. Transmission will always occur from the high concentration to the lower concentration side of the material. Therefore, any discussion or examples of permeation rates are valid for either circumstance.

The transmission rate is standardized for package area, film thickness, time of measurement, and difference of partial pressure of permeant across the package. In general, the terms are amount of permeant multiplied by film thickness per package area per time per unit of partial pressure differential. The measurement is also made at a temperature that is implied but not usually stated in the units. In use, the standardized transmission rate is combined with area, thickness, and time in the model to define how much permeant can enter or leave the package. The effect on the product is a function of the net weight of the product upon which the permeant acts. The partial pressure differential across the package becomes difficult to measure, and it changes as the internal environment of the package changes.

The partial-pressure-differential change with permeation is the major reason for the use of computers in shelf-life modeling. If this change did not occur, one could simply multiply transmission rate by time and area and divide by the thickness to obtain amount of permeation for any time. This assumed straight-line relationship overestimates transmission because the permeation process itself reduces the differential of partial pressure across the film and therefore reduces the transmission. In addition to the driving-force change due to the transmission of permeant, some of the permeant is absorbed by the product and further complicates the system. In engineering terms, as the permeation process proceeds, the driving force of this process (the partial pressure differential) decreases. This change can be described by a differential equation. The computer models incorporate these effects and yield a representative manifestation of the process.

Computer models are usually based on a relatively simple mass transfer equation. Many models have been developed that have not been reported in a usable form in the literature. These include models on oxidation-sensitive products, beverages, and products in which product characteristics result in product-dependent models.

The general models are based on a standard differential equation that describes mass transfer across a permeable barrier. This is shown in the following equation (12):

$$\frac{dW}{dt} = \frac{k}{l} \times A(P_{\text{out}} - P_{\text{in}})$$

where

t = time
W = change in weight of the critical component
k = permeability coefficient for the packaging material
l = thickness of the packaging material
A = area of the package
P_{out} = partial pressure of permeant outside the package
P_{in} = partial pressure of permeant inside the package

This equation can be converted into a usable form by substituting measurable values for the W and P_{in} terms. The P_{out} term is readily obtainable: For oxygen, it is 0.21 atm (21.3 kPa); For moisture, it is the saturated vapor pressure (13) times the RH of storage; for flavors and volatile components, it is essentially zero.

The P_{in} term requires knowledge of the reaction of the permeant with the product. In the case of moisture change, this is expressed as the moisture isotherm that describes change in product moisture versus storage relative humidity. An expression that describes the water activity over the product for any moisture value can be used to define the P_{in} term. (Water activity, *Aw*, is the partial pressure of water above the product divided by the saturated vapor pressure of water at the same temperature.) First, the isotherm is determined. Second, an expression is derived which describes *Aw* as a function of moisture content. Finally, P_{in} at any moisture content can be described as the expression for *Aw* times the saturated vapor pressure. (*Note*: Water activity is traditionally used. However, this is only valid at the temperature used in the isotherm study. The preferred procedure would study moisture content as a function of vapor pressure directly, instead of as a function of *Aw*. The model converts *Aw* into pressure terms.) Models for permeants other than moisture require analogous expressions to relate internal pressure to product changes.

With a substituted expression for the P_{in} term in concentration terms rather than weight terms, the W term needs to be expressed in concentration terms. An expression is therefore needed which describes the change in concentration as a function of weight change.

The above expressions are then substituted into the equation, they are rearranged to combine variables onto one side of the equation, and the new equation is integrated to form the model. The limits of integration are (a) permeant concentration from initial to critical values and (b) time from initial to shelf life (time to reach critical amount of permeant).

The various models described in the literature use approaches related to the above procedure. Simplifying assumptions (such as linearity in the isotherm) are used to develop simpler models. These models can be used to advantage as long as the assumptions are kept in mind. The fewer the restrictions used in deriving the expressions, the more universal the model. However, the mathematics become increasingly complex.

The models do not replace the need for actual storage studies. Storage is still necessary to verify product changes, find unusual effects, and, in some cases, meet compliance criteria with government regulations. The use of the models serves to (a) reduce the time and effort necessary to identify optimal packaging protection and (b) eliminate storage studies on materials with insufficient barrier properties to be reasonable candidates for the product.

DISTRIBUTION MODELS

The above models are based on storage conditions with a single temperature and relative humidity. Computers can be used to model changing conditions, either predicted or measured, to more accurately reflect real-world conditions (14). One such model applied average environmental conditions for key cities in the United States and abroad to predict warehoused product performance in these different locations. Not surprisingly, products distributed in colder climates exhibited longer shelf lives than similar products warehoused in warmer climates. The study also showed that products manufactured in cooler seasons exhibited longer shelf life than did the same products produced during the summer months. It was found that higher temperatures experienced earlier in the distribution cycle had a more pronounced impact than did the same temperatures experienced later. Such information could be used to either modify the packaging or the distribution environment (such as storage time or warehouse conditions) or even the shelf-life requirement (shorter for warmer climates, longer for cooler ones) for economic advantage.

The development of sensors and RFID tags offers additional capabilities for shelf-life modeling. Sensors currently exist to measure real-world conditions and transmit these data to a warehouse computer. Computers could be programmed to (a) recalculate remaining shelf life for stored products based upon their actual distribution and storage experience and (b) allow product pulls based upon remaining shelf life rather than actual storage time (First In, First Out). In this manner, products experience temperature abuse could be moved out more rapidly (or pulled if unacceptable and thereby improving quality and reducing consumer complaints). At the time of this writing, RFID technology and computer programs exist to initiate this proposed program (15), but the sesnsors are currently considered too costly for general product distribution. This scenario could easily change by the time this encyclopedia is published.

OTHER MODELS

Modeling of permeation through packaging films can be extended to evaluate more complicated scenarios than storage of a product in an ambient atmosphere. As long as permeation of gases and vapors remains the key shelf-life determining parameter, modeling of mass transfer is applicable. Modified atmosphere packaging (MAP) (see Modified atmosphere packaging) utilizes a gas mixture to extend the life of the product. The gas mixtures are composed of gases with different permeation rates and different concentrations in and out of the pacakge. Computer models can predict how the concentrations will change with time. Shelf life can be directly determined if the shelf life relates directly to a gas concentration. For example, if an oxygen-sensitive product would oxidize rapidly above a critical oxygen concentration, the time required for the oxygen concentration within the package to attain that level would determine the shelf life.

Another computer model that relates to shelf life involves controlled atmosphere packaging (CAP). CAP implies that the atmosphere is controlled during the life of the product and is typically employed in warehouse situations, particularly with fresh produce. CAP can also be used for a consumer package in which a combination of permeation characteristics of a film and respiration rates of a fresh product combine to create the desirable packaging environment. As the produce respires (takes in oxygen and expels carbon dioxide), the concentration of oxygen within the package will be depleted, and that of carbon dioxide will be enhanced. An impermeable package would quickly reach conditions of low oxygen and high carbon dioxide that would asphyxiate most produce. A correctly chosen permeable film, however, can result in a packaging atmosphere that slows senescence without killing the product, thereby enhancing shelf life. Computer models in this case are used to calculate the gas concentrations that result from the dual respiration and permeation effects. The concentrations are then compared with ideal CAP conditions for the particular product and thereby used to extend the shelf life of the product.

Various models have been developed to predict shelf life of products that are limited by microbial growth. Examples of some of these models are referenced in the bibliography (16–23).

SHOCK

ROBERT M. FIEDLER, CPP
Robert Fiedler & Associates,
Minneapolis, Minnesota

The term *shock* describes a rapid change in something over a very short period of time. In the packaging field, this could relate to mechanical movements, sudden stops, or even rapid changes in environmental conditions such as thermal shock, when temperatures change rapidly with movement of products from inside to outside. We focus our discussions here only on the mechanical shocks related to the physical movement of products and packages.

The most common shocks experienced by packages and products result from handling drops. It is not the fall that hurts, but the sudden stop on impact with the solid ground. The suddenness of the shock is described as the duration of the impact. It is normally expressed in terms of milliseconds (ms) or $\frac{1}{1000}$th of seconds. Typical packaged product impact durations range from 2 to 50 ms from drops onto hard floors. The duration of the shock is dependent primarily on the amount of cushioning provided by the packaging materials used to protect the product and to some extent on the rigidity of the surface impacted.

The term *cushioning* is used to describe the effect of slowing the rate of change of the shock by increasing the time duration of the shock event. This is accomplished by allowing the product to stop over a longer period of time by beginning to stop it at a higher level above the point of final rest. Cushioning requires distance to provide the added time. Other articles in this *Encyclopedia* address the need of how to best design and shape the cushion to effectively use the available stopping distance provided by the cushion thickness to obtain maximum cushioning.

The rate of change of the speed of an item when it impacts is called the *acceleration rate* (or *deceleration rate*) of the impact. The greater the time duration of the impact, the lower the acceleration rate of the shock for impacts of the same speed. The impact acceleration rate is expressed in terms of *G* values, which are the dimensionless ratio between the acceleration in length per time squared and the acceleration of gravity in the same units—in effect, multiples of the acceleration rate of gravity (1*g*) on earth. The gravitational attraction of the earth is defined as 386 in./(s · s), 32 f^{t}/(s · s), or 9.8 m/(s · s).

Measured impact acceleration levels as discussed depend on the duration of the impact shock resulting from the cushion's effect. With no or very limited cushioning, acceleration levels can easily reach 500–1000*G*. With effective cushioning, acceleration levels can be reduced to 15–100*G*. How much cushioning is provided depends on the products' need for protection and the expected height from which the product will be dropped.

In simple terms, if an item is dropped from 30 in., it will fall at a rate of 1*G*, due to the effect of gravity. To stop the item at a rate of 1*G* would require an additional stopping distance of 30 in., assuming that you could bring it to a stop at a constant rate of 1*G* throughout the stopping distance. Fortunately, most products can be stopped at a much higher rate. In our example, if the product could withstand a stopping rate of $30G$, it could theoretically be stopped within a minimum stopping distance of 1 in. We will go on to see that by using cushions, it will actually be necessary to use much thicker cushions than the 1 in. that is the minimum stopping distance. This is due to the limited compressibility of cushions, 50–80% maximum, and to the nonconstant zero to peak–vs–constant peak deceleration rate.

Shock refers to the maximum rate of acceleration that is experienced during an impact often resulting from a free-fall drop. Obviously a packaged product may experience mechanical shocks resulting from several other events. A common event in shipping may be the impact shock received by a package when another packaged is dropped onto it. Or, it may result from being hit with a diverter on a conveyor belt during an automated sorting process. Whenever there is a sudden rate of change of velocity, an event called a shock occurs.

MEASURING IMPACT SHOCKS

Measuring shock levels requires the use of instrumentation and the understanding of what the instrumentation is presenting. Although mechanical shock recorders have been used in the past, they have been almost totally replaced with electronic instrumentation whenever accurate measurements of shocks are desired. Most shock-measuring devices rely on the use of accelerometer transducers. The accelerometers change the measured characteristics into electronic signals that can be displayed, analyzed, and recorded. Acceleration levels are presented as voltage proportional to the acceleration due to gravity. Usually this is in the range of 1–100 mV/g. The voltages are the result of the transducers converting the forces generated during an impact shock into an electronic signal. Since $F = ma$ (force = mass × acceleration), and the mass in the transducer remains constant, the measured force is directly proportional to the acceleration being experienced.

Accelerometer transducers typically are either piezoelectric or piezoresistive designs. Piezoelectric accelerometers rely on crystalline elements that generate an electronic signal when subjected to an applied force. Both accelerometer designs have their advantages and limitations, but it is sufficient to say that they are the most common means of obtaining records of acceleration levels experienced during impact shocks.

This discussion does not address the signal conditioning, power supplies, filtering, and calibration necessary to obtain records of shock acceleration levels. However, once the signals are obtained, they are often displayed as a function of time and are referred to as *shock signatures, shock pulses*, or *waveforms*.

SHOCK WAVEFORM ANALYSIS

Figure 1 shows a typical acceleration shock waveform resulting from an impact. We can discuss and characterize components of the recorded shock waveform. The first observation is that of the peak G level or the maximum acceleration experienced during the shock event. Since the entire recording is that of the acceleration levels, we must determine at what point to take a reading, and since it is usually the maximum faired acceleration that is of concern, that is what is most often used to define the shock acceleration level. Care must be taken when recording shock acceleration levels to ensure that any filtering used to clarify the shock signature does not adversely effect the peak G level recorded.

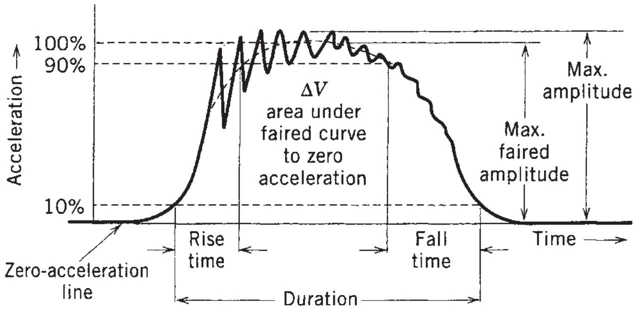

Figure 1. Standard pulse interpretation.

The second observation is that of the time over which the event occurred referred to as the shock pulse duration. By convention, the duration of a shock pulse is measured from points where the acceleration/time record is at a level of 10% of the peak G level. This is done because of the difficulty of precisely determining when the waveform actually crosses the baseline to start and stop the duration-time measurements. Shock pulse durations typically measured in package drop tests range from 2 to 50 ms.

Additional data that can be derived from an analysis of the shock waveform is the velocity change that occurs during the shock event. The velocity change is proportional to the area under the acceleration time curve. It is, in fact, the integral of the acceleration with respect to the time over the total duration of the shock pulse. The velocity change is the sum of the impact velocity from a package's fall plus the rebound velocity resulting from the impact energy stored in the cushion system being returned in the form of rebound motion.

The shape of a shock waveform can be very instructive as to the type of impact that has occurred as shaped by the cushion system's performance (see Figure 2). The waveshape of an elastic cushion acting as a linear spring will

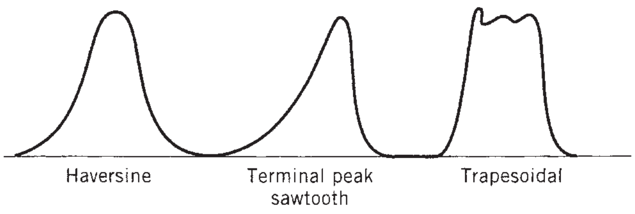

Figure 2. Typical shock waveform shapes.

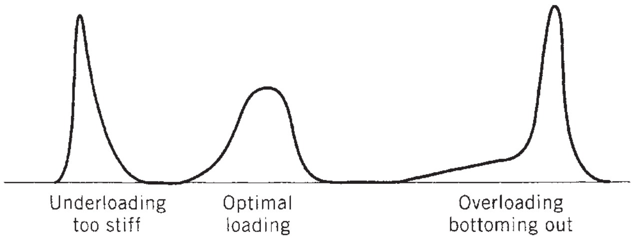

Figure 3. Cushion static stress loading concerns.

have a haversine, often referred to as a half-sine, waveshape. A nonrebounding cushion such as some corrugated pads may exhibit a waveform that can be described as a terminal peak sawtooth waveform on the basis of its visual shape. The acceleration (deceleration) reaches a peak when the object comes to rest with no rebound energy to create a rebound velocity. Another waveform shape that occurs during package testing is the trapezoidal waveform in which the acceleration reaches a peak G level that continues for a period of time as the cushion continues to crush. These trapezoidal waveforms are most often created by honeycomb or cylindrical cushion structures being crushed or in foam-in-place systems where the cushioning is provided as the material is being frangibly torn rather than compressed.

Seasoned package designers can often interpret what may be happening to a product in a cushioned package by analyzing the shock waveform observed during an impact (see Figure 3). A symmetrical half-sine waveform typically indicates that the static stress loading of the product on the cushion is in the optimum range for maximum cushioning. A waveform approaching a terminal peak sawtooth shock pulse with a sharp rise near that end compared with the beginning of the waveform may show that the product is bottoming out the cushion; the static stress loading may be too high for the cushion or the thickness of the cushion insufficient. A waveform showing a high spike at the beginning of the shock pulse may be indicating that the cushion is too stiff for the static stress loading being applied by the product. It may be like a diver making a belly flop smack on the water. The thickness of the cushion in this instance is immaterial since none of it is initially deflecting on impact.

CHARACTERIZING PROTECTIVE CUSHIONS

Cushioning materials used to protect products from shocks are normally characterized by their shock-transmitting attributes. "Cushion curve" data present the average level of the peak G level experienced on a simulated product dropped from a given height onto the given thickness of cushion (see Figure 4).

The static stress of the product on the cushion, expressed in psi, is then varied to determine the optimum loading range for the cushion. These data are derived empirically through an extensive series of drop tests during which the variables of drop height, cushion thickness, and loading (in psi) are systematically changed. The cushion-curve data thus presented can then be used as a starting point for predicting the effectiveness of a given cushioning material for a needed application.

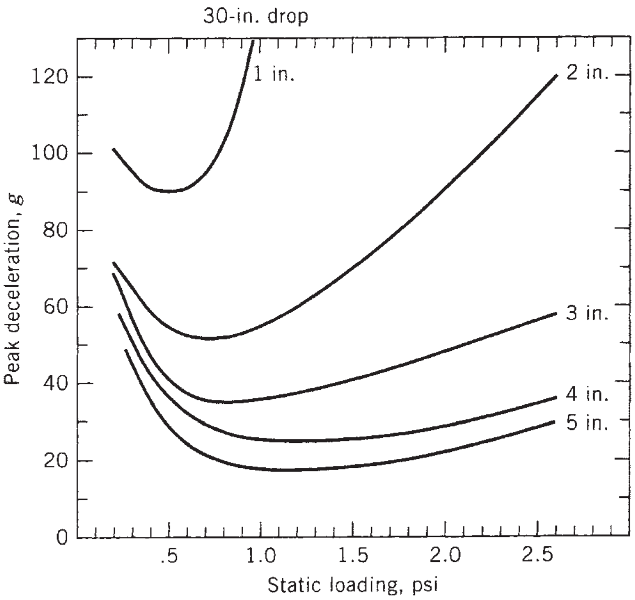

Figure 4. Dynamic cushioning curves.

From the cushion curve, the peak transmitted shock level is noted for given drop heights. When the maximum acceleration fragility of a product is compared with the cushion curves for the specified environmental drop height, both the minimum cushion thickness and optimum static stress loading can be determined. This provides the initial information for developing protective package systems for products.

THE DAMAGING EFFECT OF SHOCKS

The use of fragility testing is the most common means of determining a product's resistance to mechanical shocks. The process of fragility testing is described in much greater detail elsewhere in this *Encyclopedia* (see Testing, product fragility). The result of product fragility testing is the characterization of a product in terms of its resistance to mechanical shocks.

For a product to be damaged from mechanical shock, two conditions must occur simultaneously. The first is that the mechanical shock must have sufficient energy to cause damage. The second required condition is that the energy be imparted to the product at a rate exceeding the product's ability to absorb the energy without breaking. The first condition is expressed as the velocity-change side of the damage boundary; the second condition, as the acceleration side of the damage boundary (see Figure 5).

The velocity-change side of the damage boundary curve is an expression of how much energy is required to damage a product. This is directly related to the velocity

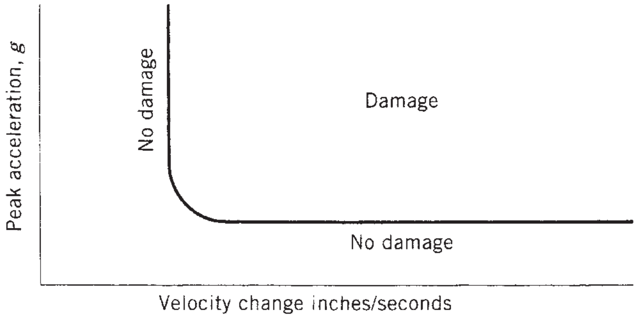

Figure 5. Typical damage boundary curve.

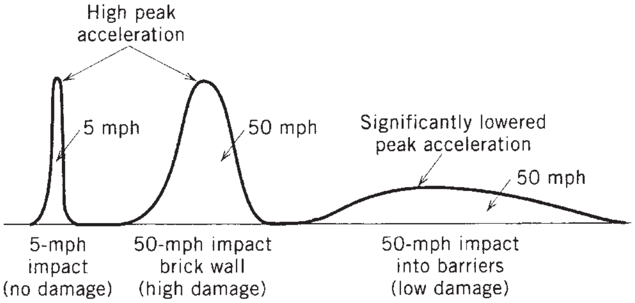

Figure 6. Effects of impact velocity and cushioning on damage in an automobile impact.

change or area under an acceleration-time shock-waveform record. Again, the predominant source of velocity in package shocks result from drops. Even if the peak acceleration level were very high, if the pulse duration were very short, the resulting velocity change might provide insufficient energy to damage a product. The product, in effect, does not respond to the high-intensity shock because the duration and energy input are too limited to cause any damage. It is similar to how the human eye can withstand the high intensity of a flash from a camera for a very short duration of time since the light does not have time to cause the eye to respond adversely.

The acceleration side of the damage boundary curve is of concern only with the prior condition, in which sufficient velocity change has been met, and is thus then a question of how fast the velocity change is being imparted to the product. A familiar analogy is that of an automobile in a crash. If the speed is slow, usually less than 5 mph (mi/h), no significant damage will occur because it is below the velocity-change damage boundary. However, if the automobile is moving much faster, say, 50 mph, sufficient energy is present and damage will certainly occur if the automobile is driven into a brick wall, causing the energy to be dissipated at a very high rate (acceleration level) when it comes to a sudden stop. If the same automobile traveling 50 mph is impacted into yellow safety barrels placed in front of the brick wall, the stop rate may be significantly less, resulting from the added stopping time, so that no significant damage occurs (see Figure 6). It should be apparent that without seat belts and airbags, people in a vehicle will continue moving at the 50-mph speed and not benefiting from the yellow barrier cushions stopping the automobile at a much lower rate.

Although both damage-boundary parameters—velocity change and acceleration—are critical in defining a product's fragility, the velocity-change side of the damage boundary is often considered to be sufficiently low for normally cushioned products, so that it will be exceeded during normal handling conditions. For that reason, often only the acceleration side of the damage boundary is referred to when one discusses the fragility of a product. This is technically insufficient; however, it is a significant improvement over working without any product fragility data.

It is next to impossible to determine the fragility of products through observations or even calculations. It is essential to conduct fragility testing to assess the fragility of any given product. However, there are certain categories of products that because of the severity of their use environments, they typically have fragility levels that reach a minimum stated acceleration fragility level. Table 1 lists the typical minimum fragility levels of products found in these categories. Stated again, without testing, one cannot know the fragility of a product. However, it may be sufficient to test only to a minimum-assurance fragility level. In other words, it may be sufficient to subject a product only to a minimum acceptable acceleration shock level to ensure that it at least withstands the minimum assurance level. This then becomes the basis for developing protective packaging.

One critical issue must be addressed when discussing the shock fragility of a product. That is the manner in which the force of a mechanical shock is imparted into a product. As an example, the acceleration portion of a damage boundary for a fresh chicken egg is 35–50*G*, depending on how it is impacted on the side or end of the egg. This is based on testing and imparting the shock

Table 1. Benchmark Fragility Levels of Products

G Factor	Classification	Examples
15–25	Extremely fragile	Precision instruments, first-generation computer hard drives
25–40	Fragile	Benchtop and floor-standing instrumentation and electronics
40–60	Stable	Cash registers, office equipment, desktop computers
60–85	Durable	Television sets, appliances, printers
85–110	Rugged	Machinery, durable appliances, power supplies, video monitors
110	Portable	Laptop computers, optical readers
150	Handheld	Calculators, telephones, microphones, radios

using a flat impact surface. If, on the other hand, the shock is imparted to the fresh egg using a surface conforming to the shape of the egg, the acceleration fragility level exceeds 150*G*. The same holds true for many products. How the cushions transmit shock into the products, on corners, edges, or flat surfaces, can significantly effect the critical fragility of the product.

Product-fragility tests must be conducted with an eye toward the final package cushion configuration that will be used. It almost makes one wonder what comes first, the cushion or the egg.

SUMMARY

In summary, shock occurs usually as the result of stopping a fall. Shocks are characterized by their duration, peak acceleration, velocity change, and waveshape. Waveshapes are the signatures of shock events that can be analyzed to characterize impacts and to analyze protective cushioning. Protective cushions are characterized as cushion curves that depict the cushion's transmitted peak acceleration levels for given drop heights and cushion thicknesses. Product-fragility testing measures the product's resistance to shocks defining in terms of both velocity sensitivity and resistance to peak acceleration shock levels. The use and analysis of shocks provide the measurements essential to engineer products and packages that can withstand their shock-generating environments.

SKIN PACKAGING

Burt Spottiswode
DuPont P&IP
Wilmington, Delaware

The innovative, technological developments in skin packaging over the past several years have opened up a whole new arena for this packaging concept. The major developments that have been made in skin packaging are better quality skin board [solid bleached sulfate (SBS) and recycled] and improved printing techniques. Now, with the new specialized printing equipment that provides higher resolution [133 dots per inch (dpi)], you can obtain beautiful-looking graphics with great sales appeal. Also, the new advances in the separation of the colors allow you to print just about anything on a skin board. Improvements in printing, along with the advancements made in skin equipment and the development of new high-performance skin packaging films, has helped to greatly expand the market opportunities for skin packaging.

As the proliferation of mass merchandising outlets and self-serve retailing continues to expand, the growth of skin packaging will continue because of its merchandising appeal to both the consumer and retailer. Today, manufacturers are striving for a cost-effective eye-appealing package that sets their product apart from competition and enhances the product. They are looking for packaging that will put new life into old products to gain additional market share. A package that offers product visibility and creates impulse sales to help make the buying decision easier. Skin packaging provides all this and in addition has the merchandising advantage of being peggable.

There are two market opportunities for skin packaging: retail and industrial. For the retail visual-carded packaging market, skin packages are typically merchandised by hanging them on a peg. This enhances space use in that the package requires less shelf space and provides better use of the space allocated by offering "more facings" and "good vertical display." Skin packaging is a cost-effective alternative to other visual carded packaging, i.e., blister packaging, clam-shells, foldover blisters, and Stretch Pak, because it requires no tooling in that the product itself becomes the mold over which the film is drawn down and around by vacuum.

Industrial skin packaging differs from visual carded packaging in that its primary purpose is to protect products in transit. Products as divergent as computer tapes, lamps, service repair kits, fans, and tabletops may be skin packaged instead of using die-cut corrugated, foam-in-place, foam peanuts, and other stabilizing or dunnage materials. Industrial skin packaging offers high throughputs and full visibility to check for tampering or missing components and allows quick identification, usually at significant cost reduction. It also considerably reduces the amount of waste that has to be disposed of and is therefore more environmentally friendly.

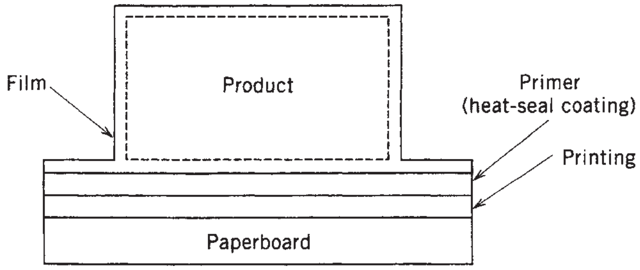

Figure 1. A typical skin package.

SKIN-PACKAGING MATERIALS AND EQUIPMENT

Skin packaging involves placing a product on a substrate material such as paperboard or corrugated board (see Figure 1). When the film is heated to the proper softening temperature, it is draped over the product and the substrate material and a vacuum draws the film down and around the product and into the pores of the board to make a secure and attractive-looking package.

A skin package has four components: the plastic film, a heat-seal coating, printing ink, and a paperboard or corrugated substrate card. The product itself becomes the mold over, which the heated plastic film is drawn down and around. This is one of the major differences between blister and skin packaging, in that in blister packaging you have to form a blister that requires a mold, for not only the thermoforming machine but also the blister packaging machine if you are buying preformed blisters.

Skin packaging begins with a sturdy card made of high-porosity paperboard or corrugated paperboard. After printing the board, which, with the developments in printing technology and the higher-quality skin board available today, you can now get beautiful four- to six-color graphics, is coated with a heat-seal dispersion coating. Today, most printers use an ethylene vinyl acetate (EVA) water-based coating. The product is placed on to the board, and then the product and board are moved onto the platen. The plastic film is held tightly in place by a clamping frame, directly below the heater, which is located above the platen.

At the beginning of the packaging cycle, the product is usually loaded onto a printed, coated skin board that is then moved onto the platen of the machine to be skinned. The plastic film that is held in the frame above the product on the skin board is heated to the proper softening temperature and is then lowered over the product and the skin board. As the frame is being lowered, the vacuum system is energized, and as the film is draped over the product and the board, the vacuum pulls the film tightly around the product and into the pores of the skin board, making a tight, attractive-looking package. The hot film instantly activates the coating on the board, and when a milky white coating is used, it becomes crystal clear when coming in contact with the hot film. The paperboard card with the product skinned to it is then moved to the die cutter, which die-cuts it into individual packages (see Figure 2).

Plastic Film. One of the least expensive components of the total package, the film is one of the most important. It is the film that holds the product on the board. The film also reinforces the board and provides a glossy surface for enhanced graphics. The film of DuPont Surlyn ionomer resin is the most widely used film in the retail visual carded packaging market with some low-density polyethylene (LDPE) and EVA coextruded films used for the low-end retail market. The film of Surlyn is a tough clear film and enhances the graphics and appearance of the package to help create impulse sales. It has excellent abrasion resistance and also has a low shrink force, which eliminates any unsightly board curl. Polyethylene (PE) is used

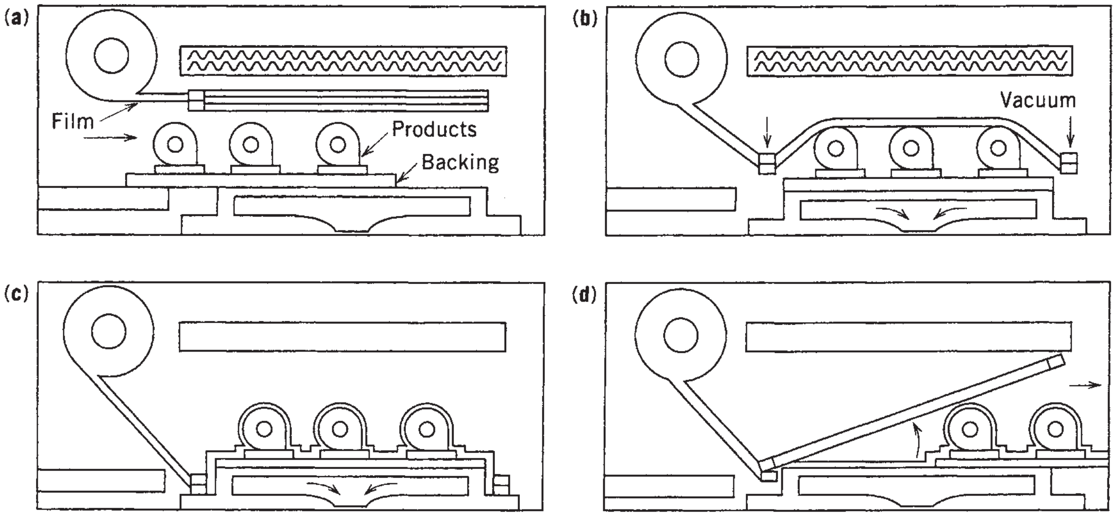

Figure 2. (**a**) Product and backing are moved onto the vacuum platen of skin-packaging machine and film is heated; (**b**) heated film is draped over product and backing; (**c**) vacuum suction draws film around product and backing, creating a skin-tight package; (**d**) finished board is moved out of the machine.

primarily for the industrial skin-packaging market where optical properties are not as important as in the retail visual carded packaging market. PE is not as clear as film of Surlyn and requires more heat and dwell time. It shrinks more of the cooling cycle and has a higher shrink force than film of Surlyn, which causes board curl. It is a tough film and adheres well to primed paperboard and corrugated. PE is less expensive but requires a heat-cycle time that is twice that of Surlyn; therefore, Surlyn can be more cost effective because of the increase in productivity.

The film gauge that is needed will depend on the weight of the product, the draw required, and the abuse that the package is likely to encounter. It is recommended that the film be corona treated to a level of 42 dyn to further improve the adhesion of the film to the board. If the film is surface-treated on one side, then the roll label should designate which side is treated. The treated side should be down to come in contact with the board.

Primer. Most skin-packaging films (Surlyn, LDPE, etc.) do not exhibit good natural adhesion to ink or board. Printed and unprinted boards are, therefore, coated with heat-sealable primers to provide strong, long-term adhesion of the film to the ink/board surface.

EVA films and coextruded films containing EVA have good initial board/ink adhesion. However, actual package failures have demonstrated that EVA to ink/board bonds will deteriorate with time. The deterioration is accelerated by high ambient temperatures (like those usually experienced during shipping).

Primers are generally aqueous EVA-based dispersions specifically formulated to provide a good bond between the film and board. The primers soak into the board fibers and porous inks. This maximizes mechanical and chemical adhesion between the film, ink, and board.

Application of Primer. The manufacturers of dispersion coatings can supply specific recommendations for applying their primers to achieve a good fiber tear bond between the film and the board. The general properties of commercially available dispersions are described in Table 1.

Dry coatings are applied commercially with a gravure cylinder. The applied coating should be of the proper weight and one that will not seal the surface of the sheet. Too light a coating will result in poor adhesion. Too heavy a coating will block the pores in the board and ink. This will cause poor evacuation and film forming.

Table 1. Properties of Aqueous Dispersions of Skin Packaging

Solids (weight %)	40–50
Viscosity	500–100 mPa
pH	9.5–10
Odor	None
Appearance unfused	Clear or milky white
Appearance fused	Colorless
Dilution	Water as required
Flammability	Nonflammable
Drying	130–230°F (55–110°C), variable

Board Priming. Board priming is usually done most economically by a company setup to print and coat the boards in one operation.

Ink. It is important to use the correct compatible heat-resistant ink to ensure good adhesion to the board (see the Inks article). Using the wrong inks or the wrong board/ink/primer combinations can interfere with the ink's adhesion to the board because of one or more of the following chemical or physical problems:

Chemical Incompatibility. A primer-to-ink bond failure can occur if the ink and primer are chemically incompatible.

Unstable Pigment, Vehicle, or Binder. An ink cohesive failure will occur if the pigment, vehicle, or binder is not stable under heat.

High Board Porosity. The ink may fail to adhere to the board if the ink has a low binder and vehicle:pigment ratio and the board is very porous. The binder and vehicle are absorbed into the board, and the poorly bound pigment remains on the surface. This phenomenon is known as "chalking."

Ink/Board Incompatibility. The ink may not bond to the board if the ink and board are incompatible. This is often caused by contaminated board.

Ink/Primer Incompatibility. A primer-to-ink bond failure will occur when the ink contains lubricants, waxes, or oils incompatible with the primer.

When starting a new job, it is important that preproduction ink evaluation tests be made before any board is printed in large quantities. This is a simple precaution to assure that the ink system is compatible with board and film. This test consists of having proofs prepared by the printer with the ink and board intended for use. Sample skin packages should be prepared with these proofs, checking for proper evacuation of air and adhesion.

Paperboard. Three types of board are used for skin packaging:

- Fourdrinier board (solid bleached sulfate)
- White lined recycled board
- Corrugated board

The board must be compatible with the ink and primer system, be porous enough to permit a vacuum to be drawn through it, and be strong enough to hold and display the product (see the Paperboard article).

By specifying board density and the weights of any coatings to be used, you can ensure acceptable porosity for your skin board, specify the nature of any coatings or treatments to ensure compatibility of the board with inks and primers, and ensure that the board is strong enough for the application by specifying board type and thickness. The strength of the board is enhanced by the skin-packaging film used. Film of Surlyn, with its superior strength, will produce a stronger package than competitive skin packaging films, so you may sometimes be able to specify a slightly thinner board gauge.

SBS Board. Solid bleached sulfate board for skin packaging is available in four calipers: 0.020, 0.024, 0.026, and 0.028. The specifications for a SBS board that will be acceptable in skin packaging are as follows:

Density. The density should be low enough to produce a board porosity that will allow a suitable vacuum to be drawn through the skin card. This porosity can be attained with a density that is equal to or less than 1.9 kg/($m^2 \cdot$ mm) (9.8 lb/1000 ft^2-point).

Finish. A soft finish is recommended for SBS board.

Brightness. The board should have a brightness of 80 or better (General Electric (GE) brightness scale). The printer may have to adjust the inks used to accommodate variations in board tint.

Sizing. Waxes, lubricants, release agents, and surface treatments are not recommended for this board and should be avoided.

Clay Coating. Clay coating is not recommended. If a clay coating is used, then the coating weight should be less than 0.49 kg/100 m^2 (1.0 lb/1000 ft^2).

Clay Binders. Clay binders must be heat stable. Protein binders are acceptable. Styrene latex binders should be avoided.

WHITE LINED RECYCLED BOARD

Density. White lined recycled board for skin packaging is available in five standard calipers: 0.028, 0.032, 0.036, 0.042, and 0.054.

The density of white lined recycled board should be low enough to produce a board porosity that will allow a suitable vacuum to be drawn through the card. This porosity can be attained with a density that is equal to or less than 2.1 kg/($m^2 \cdot$ mm) (11.1 lb/1000 ft^2-point). A denser board will require perforations.

Finish. A number 2 or number 3 finish is preferred, although number 4 may be acceptable (according to boxboard standards of the National Paperboard Association). Finish refers to density and surface; higher numbers are smoother and more dense.

Brightness. The board should have a brightness of 72 or better (GE brightness). Printers may have to adjust their inks to accommodate variations in board tint.

Gross Ink Treatment. Gross ink treatment is not recommended for white lined recycled board. If gross ink is used, then the treatment should not contain any release agents or wax-based material.

Binders. No wax or styrene binders should be used on white lined recycled board.

Clay Coating. Clay coating is not recommended for white lined recycled board. If a clay coating is used, then the coating weight should be less than 0.49 kg/100 m^2 (1.0 lb/1000 ft^2).

Clay Binders. Clay binders must be heat stable. Protein binders are acceptable. Styrene latex binders should be avoided.

CORRUGATED BOARD

Density. Nearly all common corrugated boards are porous enough to permit skin packaging. Normal bleached facing and unbleached facing made from 90-lb liner are satisfactory. The time required to permit 100 mL of air to pass through the board, as measured with a Gurley densometer (TAPPI method T460 OS75), should be less than 100 s. Laminated facings should generally be avoided. All flutings are acceptable; types B, C, and E are the most popular for skin packaging.

Finish. If a printed label is applied to the corrugated board, then all the considerations that apply to a solid bleached sulfate board should apply to the label. The adhesive used to bond the label to the board should not form a continuous film as this will destroy board porosity. Pressure-sensitive-type adhesives should be avoided. Converted starch adhesives are acceptable.

Sizing. Waxes, lubricants, release agents, and most surface treatments are not recommended for this board and should be avoided. A normal starch calender coating is acceptable.

Clay Coating. Clay coating is not recommended for corrugated board. If a clay coating is used, then the coating weight should be less than 0.49 kg/100 m^2 (1.0 lb/1000 ft^2).

Clay Binders. Clay binders must be heat-stable. Protein binders are acceptable. Styrene latex binders should be avoided.

Machinery. Skin-packaging equipment is available in a wide range of models and sizes. The most inexpensive manual models will provide only the basic requirements needed to skin package a product. A manual system will normally run at speeds of 2–3 cycles per minute. The number of packages produced per minute on these systems will depend on the skin-board size and the number of individual cards that can be cut out of the board. The standard skin-board sizes are 18 in. × 24 in., 24 in. × 30 in., 30 in. × 36 in., and 36 in. × 36 in.; however, there are skin-board sizes available up to 30 in. × 96 in. Depending on the size of the package, you can normally get 10–12 individual packages out of an 18-in. × 24-in. skin board. Semiautomatic and fully automatic systems can run at 5–12 or more cycles per minute depending on the sophistication of the machine.

The heating system on a skin machine is mounted above the platen, and a radiant-heat source is used to soften the film. The source of radiant heat is usually a series of electric resistance rods, wire coils, or quartz infrared heat lamps. A diffuse reflecting surface directs all available radiation toward the film and platen and avoids the formation of hot spots.

The vacuum system is connected to the base of the platen and is capable of drawing through the substrate board during the vacuum cycle. There are two types of vacuum systems: turbine and positive displacement. The turbine system is the least expensive and is generally used on the manual and inexpensive skin models. This system has a turbine blower (like the type used in commercial vacuum cleaning equipment) and can draw a large volume of air at a relatively low vacuum pressure. This system works most effectively with board that has good porosity.

The positive displacement vacuum system consists of a pump and a surge tank that can evacuate the air between the film and the board rapidly with a strong force. This system is used for the faster, more sophisticated skin machines. In some cases, a dual-vacuum system (turbine and positive displacement) is needed, such as for high-profile and odd-shaped products and for board with poor porosity. It is sometimes worthwhile to purchase both systems if you have a wide range of products to package.

A roller-type or hydraulic die cutter cuts the skin-packaged board into individual packages and die cuts the hanger hole used to hang the card on a hook. Stainless steel or polypropylene is an acceptable cutting surface.

High-speed fully automatic skin packaging systems can meet the packaging speed requirements of today's packaging applications while solving the concerns traditionally associated with skin packaging. They come equipped with smooth acceleration "no roll" product infeed, adjustable high/low vacuum controls, quick changeover (<5 min), automatic card feeding, ease of loading with templates, and automatic off-load boxing systems to meet industry's high-volume, just-in-time (JIT) production requirements. The new quiet hydraulic die cutters come equipped with in-press die-saver sensor systems to eliminate product damage. Automatic product placement systems are also available today for high-speed automatic packaging.

Applications. A wide variety of applications are being skin packaged today, although not all products are suitable for skin packaging. The product's shape and composition will usually determine whether it can be skin packaged successfully.

For example, flimsy products that would be crushed by the force of the vacuum or articles that would stick to the skin-packaging film should not be skin packaged. However, in the past where you could not package round or unstable ferrous metal parts, i.e., ball bearings, because of the difficulty of maintaining the product on the card prior to film contact, today you can with moving magnetic plates. You can also package parts that protrude through the back of the card.

The weight and configuration of the product will usually determine the strength of the board and the gauge of the film that is needed. Heavy, high-profile items will require stronger board and heavier-gauge film.

Skin packaging for the retail visual carded display market offers several benefits for the packager, retailer, and consumer. The packaging operation is quick and uniform, the film's clarity and sparkle enhance the product, and the display method spurs impulse buying because of product visibility and the attractive colorful graphics.

SLITTING AND REWINDING MACHINE

R. W. Young
John Dusenberry Co.
Randolph, New Jersey

Flexible plastic packaging materials generally do not have perfectly flat surfaces. The material in a parent roll contains stretch lanes and varies in gauge by about 1–5% across the web width. Slitting and rewinding such rolls requires equipment that can control the rewinding speed of each slit roll independently (1). The rewinding process is complicated even more by air entrainment into the coils of the rewinding rolls, which separates the outer convolutions and allows them to slip laterally. Winding difficulty caused by this phenomenon increases when handling high-slip films or films with smooth surfaces. The primary aim of every slitter design is to provide apparatus to deal selectively or generally with one or more of the diverse products presented to it. All designs are based on center winding (1), surface winding (2), or a combination of both.

CENTER WINDING

Center Winder (Duplex Winder). The most widely used and versatile slitter is a duplex stagger center winder or two-bar winder (see Figure 1). The web tension at the unwind of the machine is isolated from the rewind section by driven rollers in the slitting section of the machine. These rollers positively control web speed, opposing any overdraw by the rewind. For most applications, the rewinding is done on differential-rewind (slip-core) mandrels to maintain suitable rewind tension on each slit roll despite stretch lanes in the web and unequal diameter buildup caused by gauge bands commonly found in plastic webs (1). Individual riding rollers forced against each of the rewinding rolls minimize air entrainment into the rewinding roll. For winding paper products, the riding roller also has a surface-winding effect that increases roll hardness without using excessive rewind tension (3).

These machines are suitable for handling web widths up to about 80 in. (2032 mm), rewind diameters up to

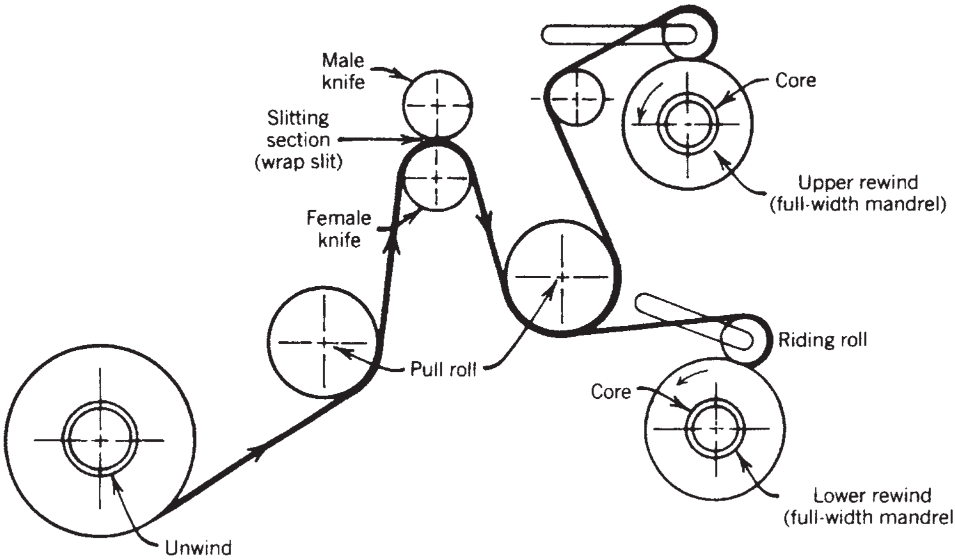

Figure 1. Center winder (duplex winder) illustrating stagger differential winding principle.

24 in. (610 mm), and web speeds of ≤1500 ft/min (~460 m/min). They are especially suited for narrow-width slitting. The productivity of machines with removable rewind mandrels can be increased by using two pairs of mandrels so that the slitting operation can continue while the alternative pair is being serviced. Removable mandrels commonly require two operators or one operator and a hoist for handling into and out of the machine. Machines equipped with nonremovable cantilevered mandrels permit one operator to remove the slit rolls, recore, and restart winding quickly without mandrel handling (see Figure 2). The choice of systems depends on the size and number of slit rolls per setup. Maximum production is achieved by mounting cantilevered mandrels into two-station turrets (see Figure 3). With automatic cutoff and restart of web around the core, these machines can slit and rewind a web emerging from an extruder on a continuous basis.

Individual-Rewind-Arm (IRA) Surface-Center Winders. IRA-winder design is based on both center- and surface-winding principles (see Figure 4). The design stresses the ability to control the surface-contact force and rewind torque of each rewinding roll individually. Each rewind core is supported by chucks (one or both driven by a torque-controlled motor) supported on pivoted arms arranged in stagger-wind fashion on each side of a winding drum. The handling of rewind mandrels is eliminated (1). The contact force between the rewind roll and the winding drum is exerted by air cylinders controlled manually or by microprocessors. For better control of roll hardness, this force can be programmed as a function of rewind diameter and web speed.

These machines are suited for processing webs in excess of 80 in. (2032 mm) in width and for winding in excess of 24-in. (610-mm) diameter. Maximum design web speed is about 2000 ft/min (610 m/min). Actual production operating speed is frequently limited to ≤1200 ft/min (365 m/min) because of web properties, vibration of the

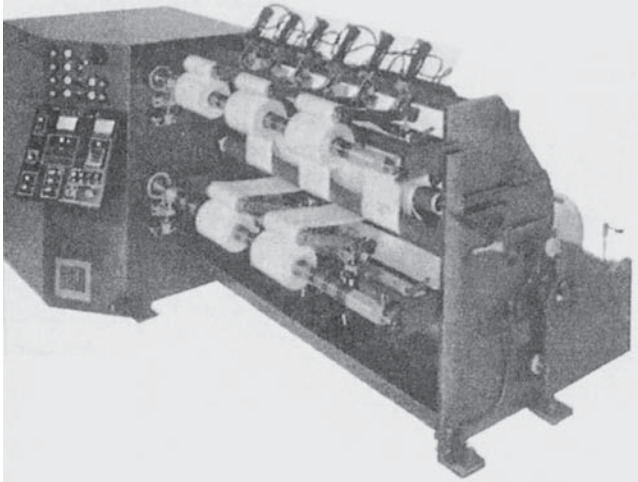

Figure 2. Center winder with cantilevered rewind mandrels and integral unwind station.

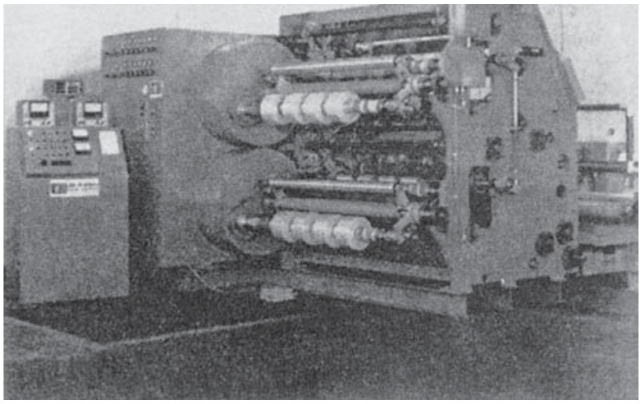

Figure 3. Center winder with cantilevered rewind mandrels mounted in turrets for continuous differential winding.

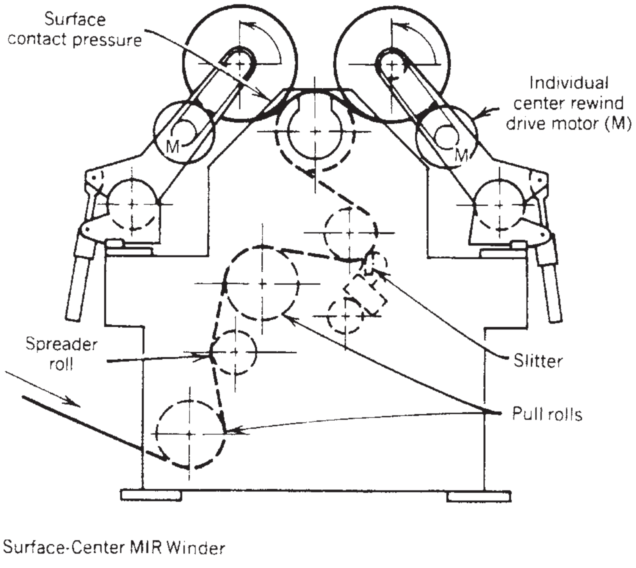

Figure 4. IRA surface-center winder.

rewound roll (4), parent-roll eccentricity, or off-machine roll-handling backup (see the Roll handling article). Doffing of the rewound rolls can be done in sets with overhead hoist and special “grabbing” devices. Recent designs feature rotating rewind arm support beams, allowing the rewound rolls to be lowered and released directly onto low-bed, wheeled dollies. This is called doffing to the floor (see Figure 5).

IRA Center Winders. This winder is similar to the IRA discussed above except that an individual contact roller, supported by a pair of pivoted arms, contacts the rewound roll in place of a full-width winding drum (see Figure 6). The contact roller is urged against the rewound roll by air cylinders. The winding tension is developed by a rewind motor driving each core. The primary function of the contact roller is to minimize air entrainment. Sensors detect the buildup of the rewind roll, which causes the rewind arms to move outward and maintain a relatively fixed position of the contact roller. This winding method is more responsive to the control of stretch lanes in the web and significantly reduces the roll vibration sometimes associated with high-speed surface winders (4). For best results, the contact force and rewind torque must be programmed by microprocessors as a function of web speed and rewind diameter, thereby giving the desired hardness and uniformity in the rewound roll at web speeds upward of 2000 ft/min (610 m/min). These machines also feature doffing to the floor.

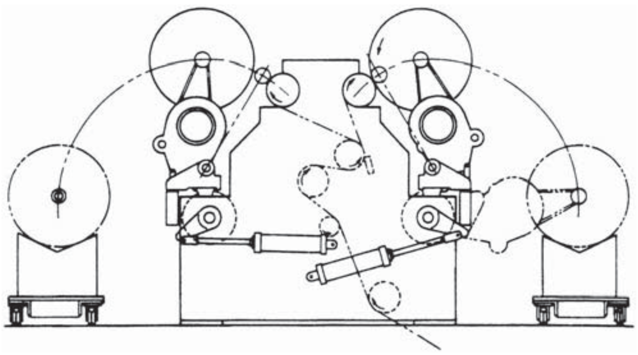

Figure 5. IRA surface-center winder with doffing to floor.

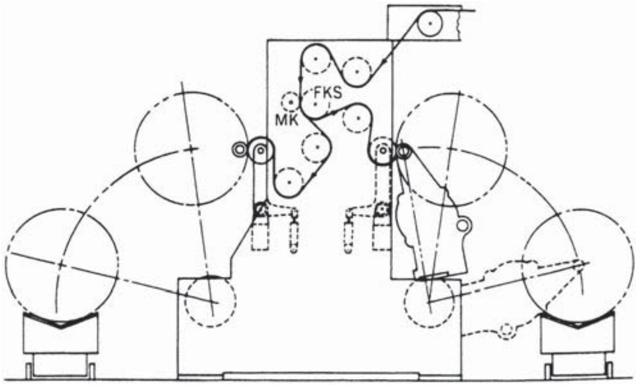

Figure 6. IRA center winder with riding roll and doffing to floor.

SURFACE WINDERS

Many versions and sizes of slitting equipment employ the surface-winding principle (2, 5). For a detailed discussion of larger-size rewinders, see Ref. (6). The machine most widely used for general converting is the two-drum winder with riding roll (see Figure 7). It is commonly used for slitting plain paper and paperboard, as well as many printed, coated, and laminated paper products.

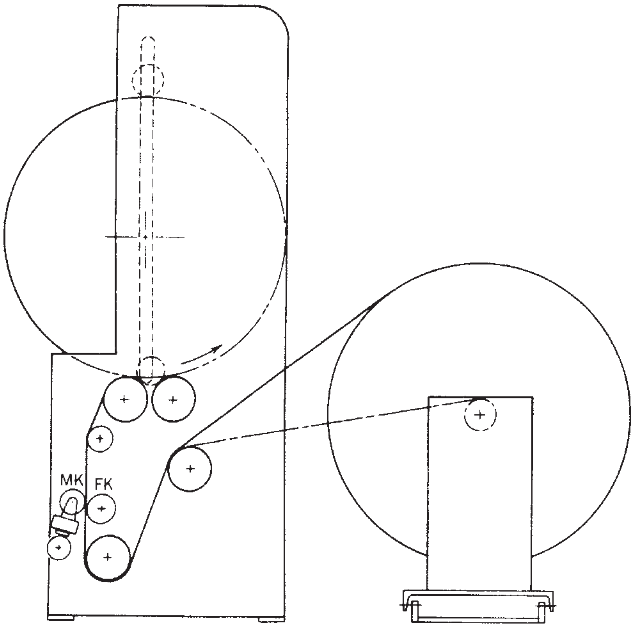

Figure 7. Two-drum surface winder with kiss-shear slitting.

Good-quality paper has the following physical properties conducive to surface winding: uniformity of gauge, freedom from bags, relatively rough surface with medium friction coefficient, high modulus of elasticity, and high degree of compressibility. The density of the finished roll is determined by a combination of constant unwind tension and down force on the riding roll (7).

The medium-size, general-purpose converting slitter has the following advantages:

1. The controls and construction are relatively simple.
2. It can wind to large-diameter buildup ratios.
3. It can wind coreless or on almost any diameter core.
4. It winds on one mandrel or without mandrel.
5. The slit-width changeover is accomplished primarily by relocation of knives.
6. It runs at relatively high web speeds, commonly ⩾2000 ft/min (610 m/min).

It also has the following disadvantages:

1. The risk of slit rolls interleaving make it difficult or impossible to separate the slit rolls. Bowed spreader rollers can alleviate roll-separation problems (8, 9).
2. It lacks versatility for winding baggy or off-caliper webs.
3. It is unsuitable for winding paper with slippery, e.g., silicone, coatings.
4. Some grades of paper develop a washboard surface on the periphery of the rewound roll during winding, thereby causing vibrations and restricting operating speed (4).
5. Operator skill is necessary to keep scrap rate low on some products.

UNWINDING

Many types of unwind stands are available, from simple shaft-type units with manual side shift to large shaftless turret unwinders (10) with automatic web guiding (11, 12). Friction brakes usually provide the holdback torque (13). Regenerative direct current (dc) drives are occasionally required for parent-roll acceleration, as well as holdback (14). The choice of automatic tension controllers for maintaining constant unwind tension during acceleration and deceleration, as well as compensating for decreasing unwind diameter, includes load-cell sensing rollers (15); dancer roller sensors, which are recommended for use with eccentric parent rolls (16); and open-loop microprocessor control based on real-time calculations of diameter and weight of parent roll. It has been common practice to use overhead hoists for loading parent rolls into operating position, but hydraulic lifts integral with the unwinder are frequently preferred (17).

TENSION CONTROL—REWIND

Tension control for surface winders simply requires constant tension control from the unwind stand and has a secondary effect on rewind roll hardness. The tension control of center winders is much more complex because tension is the primary control factor. Rewind buildup ratios of less than 5:1 may require only constant torque (decreasing tension) windup for many products. However, large buildup ratios and tension-sensitive products require either constant tension or programmed tension (18). Depending on the design of the machine, this may require automatic control of pressures to differential-rewind mandrels or air-operated slip clutches, or control of reference voltages to dc rewind motors (19). When differential winding at high speeds and large buildup ratios, it is necessary to automatically reduce the rotations per minute (rpm) of the rewind mandrels as a function of rewind diameter. The profile of the tension pattern as a function of diameter must be determined empirically. Microprocessor control is ideal for exploratory profile studies and for maintaining repeatability once the desired results are achieved.

SLITTING

Rotary shear knives can be used to slit virtually all packaging-web products. For simplicity of setup and sometimes for cleaner cutting, razor blades are used for plastics thinner than about 0.005 in. (127 μm). For better control, especially when taking narrow trim cuts, the web is wrapped around and is positively supported by a grooved roll at the point of slitting. Similarly, shear slitting is done with the web wrapped around the so-called lower or female knife shaft, known as wrap slitting. If frequent changes of slit width are required when shear cutting, it is desirable to run the web tangentially over the female knife (called "kiss slitting") (1) (see Figure 7). The prime consideration in the slitting section of the machine is ease of changing slit widths. Equipment is being introduced to accomplish this automatically, but it is not yet in widespread use on the average converter-type slitter primarily because of cost and space requirements.

OTHER CONSIDERATIONS

In addition to the basic features discussed above, many others require consideration in a slitter specification. The more common items include automatic web guiders, spreader rolls, predetermining rewind footage counters, multiple rewind and main drives, special roller coverings, static eliminators, expanding unwind and rewind mandrels, core-locking differential-rewind mandrels, roll-unloading devices, provision for web inspection, web-splicing devices, safety guards, emergency trip cables, and trim-removal equipment. Last, but not least, increasing effort is being made to automate nearly every operational and setup function associated with slitter operation. About half of all slitters sold requires some design modification or accessory to meet the special needs of the user. New models are constantly being introduced to handle new products, reduce costs, increase productivity, and enhance the quality of slit rolls (20).

The performance of a slitter depends not only on the basic physical properties of the web but also on the quality consistency of parent rolls. It is difficult to measure some of the more important characteristics, let alone predict how they will affect the slitting operations. Two supposedly identical generic products, each from a different manufacturing source, can exhibit surprising performance differences. Furthermore, problems can be expected when attempting to handle webs that deviate significantly from the norm in physical properties or when web speed and roll size exceed state-of-the-art limits. Consequently, it is always wise to check, if possible, the performance of actual parent rolls on existing demonstration equipment to be assured that performance requirements can be achieved.

Nomenclature

Bags	Undulations in a web that otherwise should be a flat surface, usually occurring in lanes of various widths in the machine direction of web. These bands frequently occur where a thickness variation is above average relative to the rest of the web (1).
Buildup ratio	The diameter of a rewound roll divided by the outside diameter of its core.
Doffing	Process of removing or unloading wound rolls from a winder.
Draw	The distance a web must travel unsupported between two web transport rollers.
Gauge	Thickness or caliper of a web. Sometimes expressed in units of points (mil, 0.001 in. or 254 µm); gauge (0.00001 in. or 0.25 μm); or micrometers (0.001 mm or 10^{-6} m).
Gauge band	A machine-direction strip or band of above-average thickness in a web evidenced by a peripheral circumferential bulge on the periphery of a web roll (1).
Guide, edge	Automatic web guide using the edge of a web as reference. Those using an air nozzle as a sensing device are sometimes called air guiders (12).
Guide, line	Automatic web guide using photocells to track a reference line on a printed web (12).
PLI	Pound force per lineal inch (1bf/in. = 175.1 N/m). Unit of measure of web tension or line contact force of riding roll against a rewinding roll.
Roll	A coiled spool of web material usually wound on a paper core.
Roll, parent	A large roll from which smaller rolls are slit and rewound. Also called mill roll, master roll, mill reel, bundle roll, unwind roll, and stock reel.
Roll, rewind	Roll resulting from a slitting or trimming operation. Also called coil, spool, and bobbin.
Roller	General term for any type of rotating cylinder serving as a web-transport device to support and guide a web through a slitter.
Roller, riding	An idler roller that maintains contact with the surface of a rewinding roll. Also called touch roller, top-riding roller, contact roller, layon roller, ironing roller, and squeeze roller. Its purpose is to minimize air entrainment into a rewinding roll.
Slitter	Short term for slitter/rewinder. It is generally understood to include an unwinder.
Winding, differential	A method of stagger winding on two-bar (duplex) center winders whereby the rewinding cores are allowed to slip with controlled torque between keyed spacer sleeves on an overrunning rewind mandrel with the aim of winding each slit strip with equal tension regardless of parent-web defects. Also called slip-core winding (1).
Winding, stagger	Winding alternate slit strips on each of two rewind mandrels so that adjacent slit strips are not wound side by side on the same axis or mandrel (1).
Winding, taper-tension	A reduction of winding tension in a controlled manner from the center of a rewinding roll outward with the aim of giving the desired hardness and uniformity in the roll (18).

SMART BLENDING TECHNOLOGY

David A. Zumbrunnen
Laboratory for Advanced
Plastic Materials and
Technology, Department of
Mechanical Engineering,
Clemson University, Clemson,
South Carolina

The development of high-performance packaging materials is often accompanied by increased complexity in manufacturing equipment. For example, multiple screw extruders and intricate dies are used to impart several functionalities to multilayer films. Because of polymer incompatibility, tie layers are frequently needed to prevent layer delamination, thereby further increasing material costs and system complexity. In contrast, *smart blenders* are machines where polymer melts that may include solid additives can be formed during blending into various finescale structural arrangements upstream of dies so multiple physical properties can be optimized simultaneously (1). Multilayer extrusions can consist of hundreds or even thousands of thin submicron-thick layers, so the technology may find special application to nanocomposite materials. Smart blenders can be used for manufacture of cast or blown film, as well as other extrusion forms. Properties of extruded film are optimized using smart blenders' ability to alter fine-scale internal structure during manufacture. A blended plastic can offer advantages over those that are coextruded. For example, one polymer type in a blend can serve as a matrix to give mechanical integrity to a film containing other plastics, chemical additives, or solids that are added to obtain other desired properties such as electrical conductivity or permeation resistance.

Smart blending denotes an ability to deliberately transform deformable material domains in response to generated flow fields in melts into fine-scale structures that may have a useful purpose. For application to packaging, a desirable outcome of blending is the formation in polymer melts of shapes having large interfacial areas such as layers, ribbons, and platelets in lieu of droplets often obtained by mixing. *Chaotic advection* (2) is an enabling recent subfield of fluid mechanics for smart blending because it provides a means to either (a) controllably stretch, fold, and redistribute melt domains and evolve a multilayer structure leading to derivative morphologies or (b) indirectly manipulate solid additives. The term *advection* denotes movement. It is now known that passive markers in a fluid can move chaotically even in response to simple, externally imposed flow fields. In Figure 1 (3), the region of space enclosing an initial minor component body becomes stretched and folded in response to the periodic motions of surfaces which can be geometrically simple. Such shape changes are fingerprints of chaotic motions and are sometimes referred to in mathematical studies of chaos as baker's transformations or horseshoe mappings. In the inset photograph, developed and incipient folds in a continuous polyethylene layer are evident in a polystyrene matrix (4). The circular hole corresponds to the location of a stir rod of a batch device that was rotated to generate chaotic advection. With more prolonged chaotic advection, stretching and folding would continue such that the polystyrene and polyethylene become converted to layers folded about each other in a type of encapsulated, interlocking blend structure (5). A variety of blend morphologies are obtainable by *progressive structure development* (6), defined as the formation of structured materials via sequential insitu transitions from one structure type to another. This feature is shown in Figure 1, where ruptures transform multilayers to a dual phase continuous (i.e., sponge-like) structure that can fragment to yield platelet shapes and droplets in the minor component. Other blend morphology types are also producible (7, 8).

DESCRIPTION OF A SMART BLENDER

Smart blenders are scalable and are available for various products including cast film or tubular extrusion forms, such as blown film and piping (9). The technology makes possible the manufacture of blown film with a wide variety of microscopic internal structures in polymer components and additives in lieu of only a few layers obtained from coextrusion. Common elements of smart blenders are stir

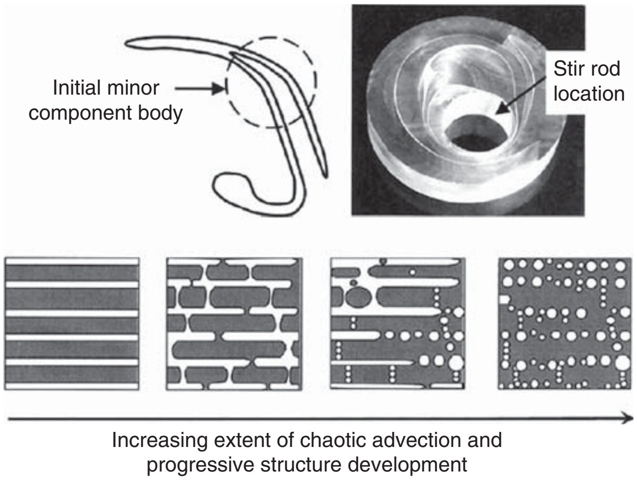

Figure 1. Stretching and folding of polymer melts by chaotic advection and transformation of resulting multilayers to derivative blend morphologies by layer rupture (4).

rods that undergo simple motions leading to chaotic advection of melt contained in them and features to promote progressive structure development. An example of a smart blender for producing cast film is shown schematically in Figure 2 (3). This smart blender consists of a barrel with an oval crosssection and circular stir rods. Separate melt flows of polymer A and polymer B are supplied by screw extruders where the relative mass flow rates of each polymer define the prescribed overall composition of an extrusion. (Additional polymer types or additives can be similarly provided.) When desired, one or more melts can be a precompounded masterbatch that consists of a polymer and a solid additive. The stir rods are rotated by computer-controlled variable speed motors following specific algorithms. As an example of one algorithm, the stir rods are rotated alternately and periodically by three rotations to generate time-varying velocity fields within the smart blender (8). Mechanistically, the path followed by a fluid particle becomes sensitive to its precise location as velocity fields change, thereby resulting in chaotic motion and the characteristics associated with chaos.

The extent of melt structuring by progressive structure development is selectable via a number *N* of periodic rod speed alterations while the melt is resident in the smart blender (3). The insitu layering and progressive structure development are represented in Figure 2 by the alternating black and white stripes adjacent to the stir rods as the combined melts flow toward an attached die. A lesser amount of chaotic advection is specified to extrude fewer and thicker layers, whereas thin and numerous layers or derivative blend morphologies result from longer specified durations of chaotic advection during the melt transit to the extrusion point. Details of such in situ structural transitions have been described in experimental and computational studies (8, 10, 11). Computationally generated results are also shown in Figure 2. In these simulations, a minor component polymer is represented by discrete particles so that layers have a granular appearance. In the leftmost inset figure, duration of progressive structure development is short, so partial blending occurs. By continuing the periodic rod rotations, chaotic advection leads to larger numbers of layers and improved compositional uniformity at smaller length scales. In effect, both polymers are folded about each other, although layering is most visually apparent in the minor component as in the polyethylene layer in Figure 1.

Process parameters that are needed to produce particular types of blend morphologies can be compiled in morphology maps. Such maps can be based on batch or online monitoring of extrusions, theoretical models, and rheology characteristics of polymer resins. If maps are

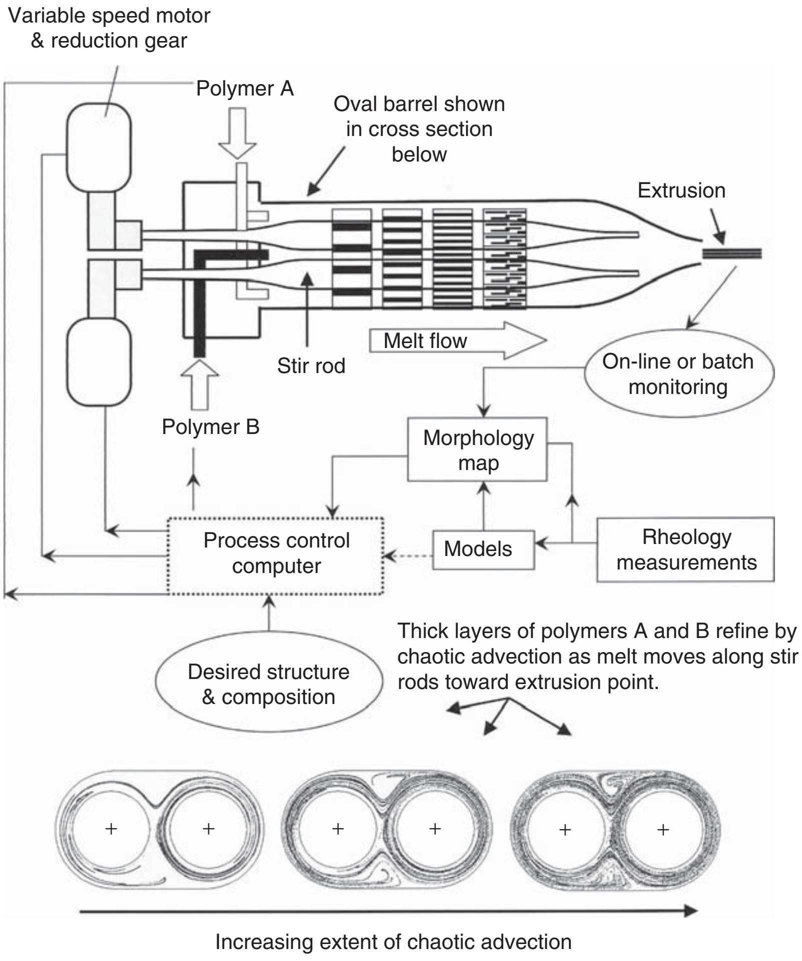

Figure 2. Schematic of a smart blender system used to produce cast film and computational simulations of layer formation for increasing extents of chaotic advection (3).

available, machine operators with the assistance of a process control computer can set up a smart blender for manufacturing extrusions with particular properties. In their absence, such as when new polymer types are being considered, structure–property studies can be done by producing extrusions with differing extents of chaotic advection.

APPLICATIONS

The intrinsic characteristic of chaotic advection to transform melt domains into layers (Figure 1) underpins applicability to packaging. However, to instill a spectrum of physical properties in a minimum of layer types, other blend morphologies can also be desirable. A few varied applications are described below. Because smart blending is a new technology, additional applications can be anticipated.

Barrier Films

Permeability results are given in Figure 3 in terms of the smart blending parameter *N* for extruded films composed of ethylene vinyl alcohol (EVOH) copolymer and linear LDPE (LLDPE) (12). For $N < 4$, EVOH and LLDPE melts are converted to few, thick and localized layers such as in the photograph inset in Figure 1. With further chaotic advection, the fine multilayer structure in the scanning electron micrograph in Figure 3 arose. Layers are parallel to the film surface. Oxygen permeability is reduced for $N \approx 5$ by factors of about 240 and 400 in blends containing 20% or 30% by volume EVOH. The extruded films have a layer-ribbon blend morphology where components are folded about each other (Figure 1). Due to continuity in the LLDPE component, delamination between the layers is less problematic than in coextruded films even though tie layers are not included. The polymer components are mechanically interlocked by virtue of the blend morphology. For more extensive chaotic advection and correspondingly larger *N* in Figure 3, the multilayers transform to EVOH fibers and droplets. Notably, droplet morphologies such as at $N \approx 14$ typically result from mixing and are associated with little or no measurable improvements in barrier properties.

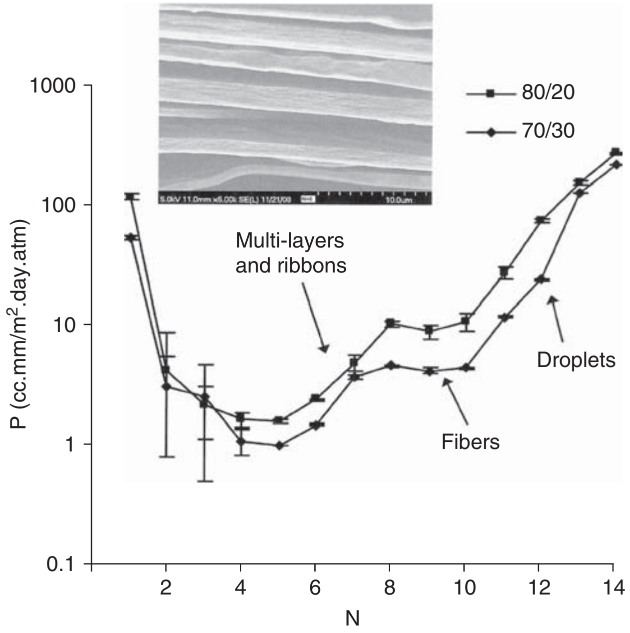

Figure 3. Reductions in permeability of EVOH-LLDPE film with 80/20 and 70/30% by volume EVOH for differing extents of chaotic advection imposed by smart blender in terms of the process parameter *N* (12).

Nanocomposites

Clay particles consist of very thin (~1 nm) platelets having high frontal area ($0.01\,\mu m^2$) and very low mass diffusivity (13). When platelets are liberated from particles in a process known as exfoliation and blended with a plastic, molecular diffusion can be impeded. Smart blenders can be especially effective when applied to such materials because platelets can be localized and oriented within numerous layers also of nanoscale thicknesses (14). An example of a novel clay nanocomposite film is shown in Figure 4 (3, 15). To produce this nanocomposite, a masterbatch of polyamide-6 and 4%-by-weight exfoliated nanoclay and polyamide are supplied to the smart blender as polymers A and B (Figure 2) in a 1:1 ratio to obtain extruded films of 150-μm thickness with an overall 2% nanoclay loading. The nanocomposite has a hierarchical structure consisting of oriented platelets localized within multiple layers separated by matrix polyamide layers. Internal dimensions of the hierarchical structure (i.e., adjacent distances between oriented platelets and layer thicknesses) can be adjusted via the online control features of smart blenders for property optimization. In the example in Figure 4, the extruded film contained about 350 discrete polyamide and platelet-rich layers. Platelets are oriented such that their frontal areas are parallel to the film surface. Due to orientation and localization within multiple layers, platelets can induce changes to polymer crystal morphology and crystallinity (16). Orientation of thin or oblong particles such as platelets results from the alternating shear flows caused by stir rod rotations. Orientation can occur more volumetrically because chaotic advection effectively shuffles melt to different locations in the smart blender (Figure 1). In effect, platelets, carbon black agglomerates, nanotubes, or oblong particle clusters orient in response to stretching and folding to reside with the layers containing them. Excellent platelet dispersions such as also shown in Figure 4 can be obtained by increasing the extent of chaotic advection in the smart blender such that the thicknesses of the polyamide layers become vanishingly small. Physical properties of nanocomposites are not solely an outcome of the nanoscale dimensions of solid additives but may also be derived from the physical arrangements of the nanoscale additive.

Toughened and Electrically Conducting Plastics

Because smart blenders can form polymer melts into various microscopic structural types even at a fixed

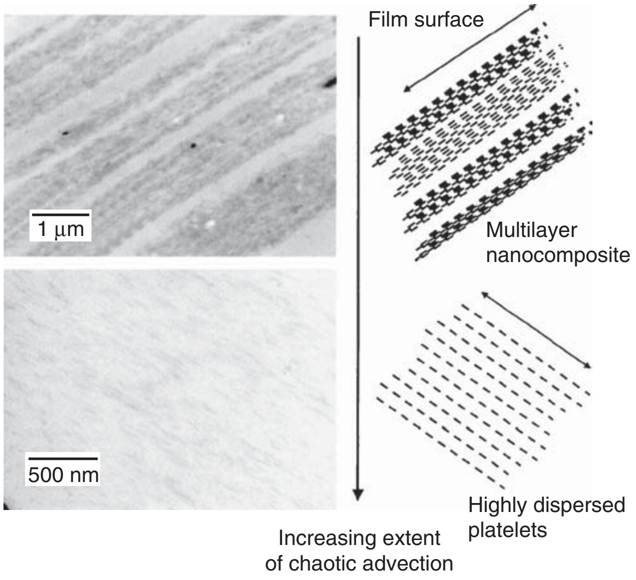

Figure 4. Examples of clay nanocomposite films with oriented and localized platelets within multilayers or well-dispersed platelets (3, 15). (Structural arrangements are clarified by graphical representations.)

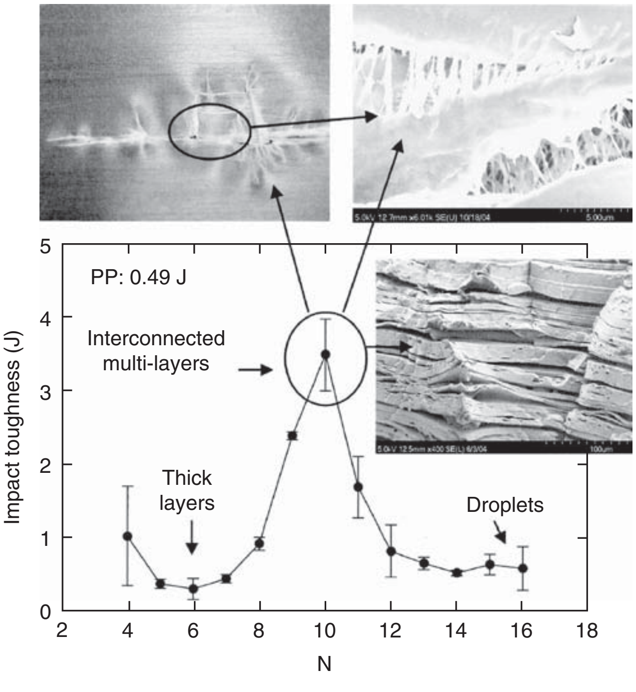

Figure 5. Improvements in the toughness of PP film by adding 20% by volume EPDM and forming EPDM into multilayers corresponding to $N \approx 10$ [3]. Films with thick layers (such as produced by coextrusion) or with droplets (resulting typically from mixing) failed by fracturing in contrast to the film shown where dart impact energy was effectively absorbed by forming interconnecting EPDM tendons. In the scanning electron micrograph, the EPDM layers were removed with a selective solvent to discern film structure.

composition, the physical properties of a film or other extrusion type can be optimized. An example is given in Figure 5, where the impact toughness by the dart drop method (ASTM D-882) of polypropylene (PP) film is enhanced by adding 20% by volume ethylene–propylene–diene monomer (EPDM) (3). Injected PP and EDPM melts are first converted in the smart blender to layers. The layers decrease in thickness and become more numerous for a larger amount of chaotic advection (i.e., for higher N). Due to their small thicknesses, the PP layers deform readily upon impact. Toughness increases for $N = 10$ are due to the formation of abundant, submicron ligaments between layers. Toughness of the blend increases by 760% in comparison to PP. A predominant fiber morphology at $N = 12$ and a droplet morphology at $N = 16$ have comparatively much smaller increases.

Smart blenders can also be used to form networks among particles. If conducting particles are used such as carbon black, electrically conducting plastics result (17, 18). Particle interactions are more likely when particles are arranged into striations or localized within multilayers such as in Figure 4. The extent of interconnectivity among networks is selectable via process control, so a variety of conductivity properties can be obtained.

SMART PACKAGING

PAUL BUTLER
Smart Packaging Consultant,
Packaging Materials &
Technologies Ltd, Henley-on-
Thames, Oxon, United Kingdom

INTRODUCTION

Smart packaging is generally defined as packaging that provides additional levels of useful functionality beyond protecting, containing and providing information about the product (1). This new type of packaging has been classified in many other ways—“active,” “intelligent,” “diagnostic,” “functional,” and “enhanced” are all terms that have been used over the last few years—but a simpler view, and the one used here, is to collect these subsets together under the all-embracing term “smart packaging.” This definition of smart packaging therefore encompasses aspects of packaging design, the use of smart materials in packaging, and the incorporation of mechanical, chemical, electrical, and electronic forces, or combination of these, within the package. It includes packaging that is active in some way with or without communication to the user. And it also includes the most common form of electronic smart packaging, RFID-enabled packaging.

The approach and technologies involved in making packaging smarter depend to some extent on the ultimate beneficiary, whether the supply chain, the brand owner, or the consumer. Table 1 shows the three main beneficiaries plus some generic smart packaging approaches applicable to each. Clearly, there are significant overlaps, particularly between the brand owner and the consumer.

In this chapter we concentrate on smart packaging for the consumer (2) and look at the various ways in which it can provide new beneficial functionality and new levels of convenience. Established brands are most likely to benefit from developing and introducing innovative smart packaging features since in doing so they can grow and sustain their position and prevent the erosion of brand value. But first we look briefly at societal and other factors driving these developments.

Table 1. Main Beneficiaries and Smart Packaging Approaches

Main Beneficiary	Smart Packaging Approaches
Supply chain	Helping to prevent errors
	Providing full track and trace
	Helping retain/monitor product quality/safety
Brand owner	Making counterfeiting more difficult
	Helping retain/monitor product quality/safety
	Providing shelf appeal and differentiation
	Creating new and unique products
Consumer	More convenient packaging
	Making products more effective in use and preventing waste
	Providing new and unique products
	Helping monitor product quality/safety

MORE DEMANDING CONSUMERS AND THE CONSUMER/PACKAGING INTERFACE

We live in a rapidly changing world where yesterday’s status quo is no longer good enough. For consumers, the existing packaging functions of bringing the product safely to the shelves and then being part of the buying decision are largely taken for granted. Now in addition, consumers expect packaging to be easier to open and use, to be more convenient, and to deliver more functionality in support of busy lifestyles. To offer convenience, consumers want first and foremost packaging improvements that save time, are easy to use, and reduce stress on an already busy life.

The problem starts at the retail store or supermarket, where typically a sea of colored packaging noise greets shoppers: row upon row of near identical packaged products that fail to engage the senses, lift the spirits, educate, inspire, or entertain. With a few exceptions, desperation appears to be the major driver in new product/package introductions, underpinned by an apparent strategy of just throwing new products at consumers and seeing what happens. Real innovation appears hard to find, a view supported by the “Build a Better Mousetrap” New Product Innovations of the Year data, provided by Productscan® (3). Genuine packaging innovation needs to move up marketing and advertising budgets in terms of importance, and there is evidence that this is happening for many of the major global brands, who recognize the importance of the first moment of truth interaction with consumers at point of sale.

Unfortunately, the current consumer/package interface does not always impress post-purchase, and there are opportunities for significant improvements to this interface. Consumers are weary of those packs that make demands on their time and attention, are difficult to open or dispose of properly, and contain instructions in font sizes that cannot easily be read. Openability, or lack of it, can cause a high level of frustration with today's consumers, so much so that it has its own media tag: "wrap rage" (4). The problem is particularly acute for people in the 50+ age population (5), who will demographically be a growing proportion of tomorrow's consuming generation.

Readability is another issue for packaging as increasing demands for more product information drive more and more printed text onto packaging to be deciphered by a population with increasing numbers of elderly consumers many with reduced visual acuity. Better means of communication at the consumer/packaging interface are essential, and this suggests that future trends will involve the use of sound and visual imaging to augment the printed text on packaging.

A further growing demand on packaging revolves around the search by consumers for packaging/product offerings with new functional benefits. On-the-go lifestyles are creating new consumer demands that rely heavily on packaging that is lightweight, portable, and easy-to-open without the aid of tools, but also resealable. Future packaging must become smarter and offer and deliver a more compelling value proposition to the consumer, particularly in terms of convenience and on-the-go support to increasingly active lifestyles.

IMPROVING CONVENIENCE IN PRODUCT USE

User convenience is a major driver in the development of smart consumer packaging. The simplest smart packaging innovations are those involving elements of packaging design and the appropriate use of materials to create packaging that, without complex functionality, fulfills a very real need for consumers. Yet examples of this type are not that commonplace despite the fact that there is generally little, if any, added cost required to achieve the design functionality. The common feature of smart packaging by design is that there has been an element of insight into how the consumer uses or operates the packaging, and this core value has remained central to the package designer's brief.

A collection of some designs that meet consumer needs for convenience is shown in Figure 1. The shaped lightweight 600-mL paint container is easy to open and easy to hold in one hand; the shaped spout dispenser makes it easy to direct toilet cleaner where it is needed; the smart straw on the aerosol can does the same thing for an oil-based water dispersive spray, and the single-serve PET white wine bottle has the convenience of an integral glass that also acts as the bottle closure.

Unique products, tailored to a consumer's requirements, are possible where the packaging allows variable ratio dispensing of two different products. An innovative dispensing pack that allows dual dispensing in variable proportions from 0% to 100% has been developed by German company Variotec. Termed Dialpack, the packaging requires a simple twisting of a dial to adjust the pump dispensers in each chamber to allow different ratio mixes of two components with high mixing accuracy. The two substances are drawn from their two separate cartridges by the pumps, mixed by a static mixer, and then dispensed from a pump- or spray-style closure. Cartridges can be purchased and replaced according to need. By rotating the dispenser head, the consumer can then dispense the required proportions of the two products. Sunscreen and sun-tanning preparations are available in this type of packaging, as is Dave's Adjustable Heat Hot Sauce (Figure 2). Very hot sauce is contained in one compartment while milder sauce is in the other, allowing consumers to adjust the ratio to their own personal taste.

Figure 1. Some examples of smart packaging by design.

The convenience of microwave heating and cooking has led to a number of smart packaging innovations. Simplest is the addition of a thermochromic label to indicate when a product like pancake syrup is at the right temperature for serving (Figure 3).

More sophisticated packaging with data matrix bar coding permits a microwaveable-ready meal to be precisely heated and browned for the table. The packaging code is scanned into the smart microwave oven (Figure 4), which then automates the optimum mix of convection oven and microwave heating to deliver a perfectly cooked meal.

Figure 2. Dual dispensing packaging allows the consumer to "dial in" their preferred ratio of product—in this example, hot sauce. The Dialpack cartridge technology allows two components to be delivered and mixed at source in varying ratios.

Figure 3. Thermochromic labels add convenience as in this plastic container of pancake syrup. The label indicates the correct temperature via the word "HOT" following microwave heating.

IMPROVING OPENABILITY CONVENIENCE

Frustration can occur when packaging is difficult to open and can lead to consumers suffering injury as they resort to the use of knives and other sharp implements. Hard-to-open packaging discriminates against the weak and is a real barrier to consumer choice, negatively affecting repeat purchasing.

The American publication *Consumer Reports* looks annually at the most difficult to open packages and awards the dubious honor of "Oyster Awards" for the worse culprits, generally won each year by the ubiquitous welded hard-plastic clamshell packaging for consumer goods. In the UK, the consumer magazine *Health Which?* asked 1000 readers if they had experienced any problems with food and drink packaging (6). Of the 235 respondents, the noteworthy finding was that 45% reported avoiding particular types of packaging because they found them difficult or impossible to open.

Designing easier-to-open packaging is generally not rocket science and frequently is one of good design which adds little, if any, to the package costs. What is needed is an underlying packaging "design-for-all" philosophy where changes are made to the designs of consumer products so that the greatest number of members of society can use them. A focus on better design (size, shape, etc.), along with the optimum use of materials, can produce easy-opened packages consistent with the opening strength capabilities of an aging population. These small design changes, made with consumer openability in mind, fit into the broad definition category of smarter packaging.

An example is the packaging industry's recent introduction of a new range of easy to drink from closures for beverage and water bottles, carried by athletes and cyclists. With one hand, a sportsperson can open these tops by pulling them with his/her teeth, squeeze a shot of drink into their mouths, and close the bottle again by pushing the tops against the chin. There has been a significant adoption of this type of drink container by the elderly and disabled because of this mode of operation. This example illustrates the wider opportunities that are available for introducing minor design changes to provide significant

Figure 4. Smart appliance meets smart packaging, resulting in the convenience of a perfectly prepared ready meal. The consumer uses the microwave to scan the smart code on the packaging, and the Samsung smart oven does the rest.

gains for consumers, in the application of the "design-for-all principle."

Simple designs tend to be the best, and the packaging for Nestlé Maggi bouillon cubes is a good example of easy openability design at zero on-cost. The flat cardboard pack is perforated across one of the flat sides and down the corresponding two edges. A sharp tap along the back of this line hinges open the pack, allowing individual cubes to be easily removed and allowing the pack to be reclosed (Figure 5).

The message is that small design changes can make large differences to openability, resulting in far more senior-friendly packaging that all consumers benefit from. Rigid containers are sometimes difficult to grip and nearly all package closures are round, so they are difficult to grip without resorting to the variety of opening aids presently available on the market. Some packages have "non-round" tops on products such as paper-whitener so that able-bodied people can get a better grip when the top sticks to its base. The German company Gerresheimer has developed a cap that is designed to improve handling for elderly or infirm users. Viewed from above, the cap looks like a plus sign with arms reaching out from the center of the cap. This design greatly reduces the force required to open the container. Bottles can also be stood cap side down, allowing the user to more effectively empty viscous materials.

Squeezeopen™ (7) is an innovative design solution to many of the problems of openability. The closure consists of a lid that is a press snap fit onto a base that serves as the container and opening is performed by simply gently squeezing the lid's sides and releasing the pressure. A multipurpose inner symmetrical ramp system guides and joins the components together (creating an effective seal) when the lid is pressed onto the base and helps to force the components apart when the lid sides are compressed.

The metal can has made great strides in openability with ring-pull easy-open ends appearing on more and more products. Simple design changes, such as increasing the clearance between end and tab to allow easier finger access as in Crown's EasyLift™ end, contribute to improving the convenience for consumers. Metal closures on vacuum-packaged products in glass jars, however, remain an openability obstacle to many consumers, but technology is available to solve even this problem, developed by Metalgrafica Rojek SA based in Sao Paulo, Brazil. The innovative Rojek closure fits both cans and glass jars and has a peelable elastomer seal over a small aperture in the top of the closure. Pulling the seal releases the vacuum and the container can then easily be opened, without the requirement of great manual strength or any opening devices like can openers or knives.

Other developments in smart packaging are looking at the use of smart adhesives to create electrically assisted self-opening structures that are still tamper-proof. Such adhesives have been developed—for example, the electrically debonding epoxy system, ElectRelease™ (8). The incorporation of these smart adhesives in bonded, rather than mechanically seamed, metal ends might offer an easier way of opening via debonding of the adhesive on application of current from a small battery pack.

Stora Enso have recently applied this technology to difficult-to-open blister or clamshell packaging containing items of high value that can easily be stolen. The commercial laminate "CDM Sinuate," is designed to make shoplifting more difficult for small but valuable products such as mobile phones, portable media players, computer supplies, and other consumer electronics. The material provides a strong seal that is difficult to open for a shoplifter but easy to access for a consumer once the package is electrically unlocked at the checkout (Figure 6).

Other convenience-driven smart packaging concepts that improve ease of use are being considered, such as the development of "dial-a-dose" smart caps and closures that allow the safe dispensing of exact controlled quantities of product—for example, pharmaceuticals,

Figure 5. A package can be easy to open through smart design. Tapping this soup bouillon pack on a hard surface breaks the pack in half so it can easily be hinged open to remove a single portion.

Figure 6. Electrical debonding at point of sale of a hard-to-open clamshell package via a hand-held power source. (Reproduced with permission from Stora Enso.)

cleaners, and other potentially hazardous materials. Alternatively, we might envisage a shape memory material acting as a metal rubber band to retain an end or closure that vents or opens automatically with change in temperature—for example, on microwave heating. As always however, there is a fine line between “easy-to-open” and “easy-to-tamper with.”

ADDING NEW FUNCTIONALITY—SELF-HEATING AND SELF-COOLING PACKAGING

Self-Heating—Technologies and Applications

The only viable form of heat engine for self-heating packaging is an exothermic chemical reaction. A number of options are available with varying degrees of heat output, but the most reactive are also the most dangerous, using potentially toxic chemicals and producing undesirable gaseous byproducts. The exothermic chemical reaction of choice for consumer packaging is lime reacted with water because lime is cheap and readily available, and it generates substantial heat output with environmentally acceptable byproducts. An alternative reaction is the hydration of anhydrous calcium chloride, which has the advantage of no reaction byproducts but generates a lower heat output.

Beverages, and particularly coffee, have been the most active application area for self-heating packaging. One of the most successful self-heating containers was launched in test markets in the UK in 2001 as a joint venture between Crown Cork and Seal, Thermotics Development, and Nestlé. The product “Hot When You Want” Nescafé canned coffee heated ~200 mL of hot coffee to around 40°C above ambient in about 3 minutes. More recently, there has been a major launch of self-heating gourmet lattes in the USA, with a range of 10-ounce Wolfgang Puck gourmet lattes being available through Kroger grocery stores in 32 states. Based on the lime/water reaction, the plastic container is portable, fits into a cup holder, and heats the coffee to around 60°C in 6 minutes—and stays hot for 30 minutes.

In many Mediterranean countries, traditionally a small quantity of strong espresso coffee is the beverage of choice, drunk at medium warm temperatures. With these parameters, less energetic exothermic reactions can be used. Caldo Caldo, an Italian development, uses the exothermic reaction between anhydrous calcium chloride and water. A cross section of the package is shown in Figure 7. When the substances are mixed, heat swirls around the aluminium cup and is conducted into the beverage. The consumer shakes the container for 40 seconds before peeling off the lid and a temperature rise of around 23°C is achieved. Hot drink variants are coffee, cappuccino, chocolate, coffee with grappa, and tea with lemon. This beverage is sold across Europe in sports venues, motorway rest areas, and many other outlets.

Self-Heating—Other Products

The increasingly convenience-orientated domestic market requires a means to heat all types of food and beverages,

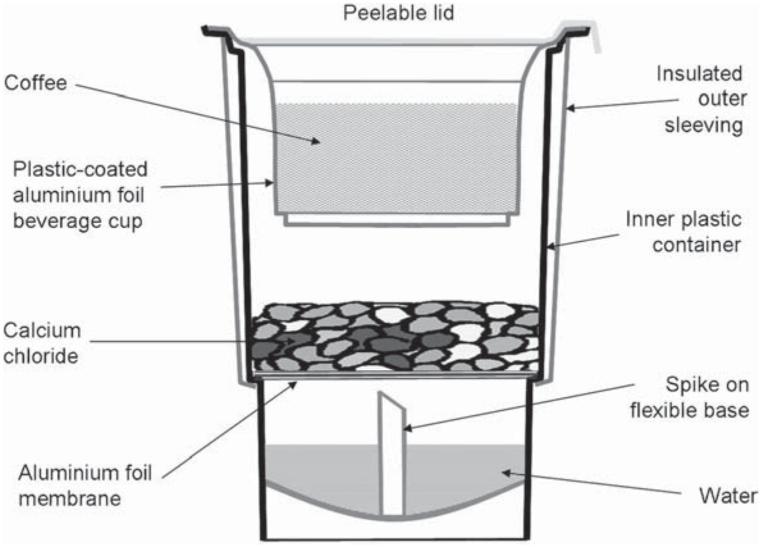

Figure 7. Cross section of “Caldo Caldo” self-heating coffee container. Depressing the flexible plastic base pierces an aluminium foil membrane allowing the water and calcium chloride to mix. When shaken, the resulting exothermic reaction transfers heat via the foil cup to the beverage.

including high-viscosity liquids and solid products—that is, thick soups, snacks including wraps, fajitas, stuffed pita bread, ready meals, pasta, rice and stews. To date, the technologies for self-heating have been confined to lime/water reactions, where heat output is lower but the reaction is safer. But heating times can be long for solid food products since heat is transferred from the heating source to the product solely by conduction.

By ensuring excess water is present with the lime/water reaction, a new heat transfer process is being developed by Thermotic Developments—that of direct steam heating (9). This highly efficient system transfers heat to the product by injecting steam directly into and through the food. Steam is a very effective medium for transferring energy, with 1 g of steam providing 2.2 kJ of energy.

Spin-off technology from the military MRE programs using highly reactive exothermic reactions based on magnesium oxidation or the reaction between potassium permanganate and glycerine provides rapid heating even for solid food meals. This has created a niche but growing market for self-heating food products for emergency services and the outdoors sector.

A number of non-food commercial products are available that use the lime/water reaction for heating. SC Johnson's Raid® Fumigator is designed to fumigate a room or dwelling area. It consists of a metal can containing insecticide in pellet form in an upper cup and lime below in a separate container. Supplied with the can is a separate plastic container that is part-filled with water and into which the can is placed, activating the reaction. The room is then evacuated and the heat generated evaporates the insecticide through a filter in the top of the can. A self-heating cleansing body wipe, Redi+Wash, for use in hospitals and by consumers looking for hygiene on the move, such as campers, travelers, and government field officers has been developed by U.S.-based Donovan Industries. After activation, the wipes in packets of five or eight heat up in 1–2 minutes and then keep warm for a further 20–30 minutes.

Self-Cooling—Technologies and Applications

Self-cooling is technically more challenging than self-heating, and current developments are focused on the two most cost-effective and safe technologies: endothermic chemical reactions and heat pump technology using water vapor as the heat transfer fluid.

Endothermic chemical reactions tend to be weak, producing cool but not cold products. The sister product of Caldo Caldo, Freddo Freddo, is a commercial coffee beverage product that employs the endothermic reaction between sodium thiosulfate pentahydrate and water.

By contrast, water evaporation can be a powerful cooling process, as stepping out of the shower on a cold day demonstrates. The evaporation of 10 mL of water can theoretically cool 330 mL of water by 18°C. Heat pump technology has not yet become commercial for single-serve containers, with high cost and lack of reliability appearing to be the key factors. But the technology is finding commercial success in party keg sizes of beer. The German CS-Metallbau Company has developed the world's first self-chilling refillable stainless steel keg using zeolite heat pump technology. The technology is licensed to Cool-System Bev. GmbH (10); and it is being used by Germany's Tucher Bräu brewery, as well as other breweries throughout Europe, Asia, and the United States, for take home-beer in 5- to 20-L sizes.

Self-Heating and Self-Cooling Smart Packaging—Future Outlook

For self-heating packaging, technical developments are expected to continue with the focus being on lime/water and calcium chloride/water chemical reactions with the provision of a temperature control feedback system so the devices create a maximum temperature for the drink regardless of the ambient temperature. Thermochromic temperature labels will be incorporated to indicate when a product is hot. Costs will come down and product quality will go up, so the future is promising, particularly for direct steam heating.

If individual self-cooling beverage cans are to become commonplace, this will likely require the development of cost-effective miniaturized "drop-in" modules using heat pump technology where the heat produced inside the beverage container can be absorbed by phase change materials, as in the concept sketch of Figure 8.

MORE EFFECTIVE USE OF PRODUCTS

Food waste is a major problem for the developed world and one that smart packaging can help reduce. Food

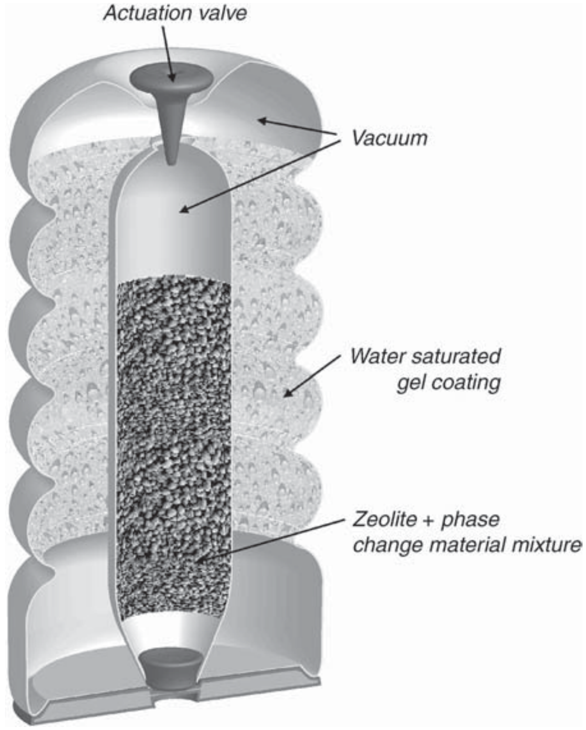

Figure 8. Self-cooling packaging in the future might utilize drop-in modules that rely on water evaporation/heat pump technology for their cooling effect.

degradation kinetics are overwhelmingly determined by the storage temperature, not by the storage time. Since the majority of perishable packed food has a "best before" or "use-by" date, indicating storage time and not temperature, the result is that much perfectly edible and safe-to-eat food is thrown away by consumers because it has reached its printed "use-by" date, regardless of actual condition.

Accurate shelf-life data can be provided to the consumer by smarter food packaging having color change labels that integrate the passage of time and the various storage temperature excursions, changing color when a composite sum of exposure has been reached. Up to now, with one exception, these time-temperature indicators (TTIs) have met with significant retailer resistance but are now close to wider commercialization according to many developers: Vitsab in Sweden, Avery Dennison in the USA, OnVu in Europe, Cryolog in France, and TEMPTIME in France and the USA.

The most successful and longest-running application is for the Fresh-Check® label from TEMPTIME, which has been in use for at least 15 years by the French supermarket Monoprix, and now can be found on more than 400 different products. An example on a minced beef patty is shown in Figure 9. When the central bull's eye of the "Puce Fraîcheur" label turns darker than the outer layer, the product is no longer safe to eat. Details of TTIs and other freshness color change indicators for foods such as fish, seafood, and poultry are discussed and reviewed in reference 1.

Figure 9. The French supermarket group Monoprix has used time–temperature indicator (TTI) labels on perishable foods in their stores for more than 15 years.

Some smart packaging developments have taken inspiration from Nature, where there are many color-change chemical reactions at work associated with food degradation and ripening that can be borrowed and applied to consumer packaging. As an example, the ripening of many fruit is accompanied by the emission of ethylene gas—easily detected by animals but not by humans, who therefore have real difficulty in deciding whether certain types of fruit are ripe in the absence of a color change. So ripe bananas are easy to spot, but fruit like winter pears, avocados, and melons are not.

Using a color change label that is responsive chemically to ethylene inside the pack creates a smart package that informs the consumer when pears are ready to eat and at a certain level of ripeness (Figure 10). Since fruit and vegetables are a major source of post-consumer food waste (11), this innovation ought not only to help consumers enjoy fruit more but also reduce the tendency for consumers to throw away unripe or overripe fruit.

The drive to use smarter packaging to reduce environmental impact by ensuring a more complete utilization of food products by consumers has been extended to "hard-to-get-out" packaging. High-shouldered containers and packaging with sharp internal angles are typically difficult to empty completely, and the last 5–10% of product is generally discarded with the packaging as consumers "give up" on getting the last of the product out. Packaging containing viscous food products is also difficult to empty completely, and this has triggered the development of non-stick superhydrophobic internal surfaces based on the "Lotus Effect" (12), which allow containers to be more completely evacuated (Figure 11).

Figure 10. A pack of four Concorde pears with active ripeness indicator. The label inside the pack changes color from dark red to yellow as the pears ripen.

Figure 11. Smarter packaging can contribute to reducing post-consumer food waste—in this example by ensuring less residual food is left in the package when it is empty.

Figure 12. Smart packaging in aerosol form. Improved insecticide performance and less environmental impact results from packaging that electrostatically charges the insecticide particles.

Metal aerosol cans are smart packaging innovation leaders in the household and cleaning market. The Mortein "SmartSeeker™" insecticide aerosol can provides improved effectiveness over conventional aerosol spray cans since the spray is electrostatically charged through a specially engineered nozzle each time the insecticide is used, improving insect "kill" by electrostatic attraction (Figure 12). Not only is the product more effective and lasts longer, but the packaging contributes to reducing the environmental impact associated with insecticide use within the home.

PROVIDING CLEARER, MORE EFFECTIVE COMMUNICATION

Smart packaging offers the opportunity to dramatically improve the communication aspects of the human/packaging interface. For brands this offers the opportunity to strengthen the emotion connection with the consumer—via, for example, story-telling related to the provenance or history and traditions of the product. But to communicate more effectively, there needs to be a movement away from text-based communication toward the greater use of visual and audio information on packaging. Both at point of sale and during subsequent use and disposal, there are opportunities for packaging to inform about the utility and characteristics of the product, such as

- the product, ingredients, and attributes,
- the way the product works or is best used,
- for pharmaceuticals, when and how to take the product.

It is expected that these communication packaging innovations will be strongly driven by advances in technologies such as nanotechnology, biomimetics (learning from Nature), electroluminescent, and other display technologies and printed electronics.

Advances in package communication that provide sound and vision is possible using conventional silicon device circuitry with LED or electroluminescent (EL) illumination and sound chip technology driven by button cell battery power. This exists today but is going to add a dollar or two to the cost of a package, depending on complexity, putting it out of bounds for all but high value products. As an example, sound and EL label illumination effects, stressing the history and tradition of rum making in Barbados, can be found on the bottle of the 10-year old Barbadian rum *Coyopa*, which retails for around $50.

But real communication opportunities need not wait for the commercialization of cost-effective printed electronics on packaging, although these will come. Advances in nonelectronic technologies such as color-change chemistry, lenticular graphics, and data matrix bar codes can today offer a conduit to better story-telling about a brand product's attributes, provenance, and how the product can be used or can provide useful product information in an easily understandable communication format for the consumer.

As already discussed, the current ubiquitous printed date coding system on perishable food is fatally flawed and there is currently a move toward more accurate time-temperature colour change labeling. Eventually color-change chemistry will give way to low-cost printed electronics on labels, leading to electronic self-adjusting "use-by" dates and displays providing the important technical breakthrough for smart packaging, leading to a dramatically improved user interface with food packaging of the future (13).

Simple communication about the benefits of using a product can be visually and effectively represented through lenticular graphics. As an example, the no-spill medication for children sold across the United States under the ElixSure brand features a lenticular label on the outer paperboard carton that shows two images of spoons that flip back and forth, signaling "spill-proof" to the consumer (Figure 13).

Combining lenticular graphics with conventional silicon sound chip technology can augment printed instructions and improve communication effectiveness about product use in a powerful way. "Smokey Eye—the Talking Palette" eye makeup from Stila Cosmetics (Figure 14) comes in a kit that not only visually shows the eye before and after application by means of a lenticular graphic but also instructs consumers in a step-by-step audio process at the press of a button.

Compliance packaging for pharmaceuticals is an active development area for electronic smart packaging, and several devices are commercial and have recently been discussed (14). As an example, the Med-ic™ Smart Package uses an onboard CPU embedded in a blister package to record each time a pill or capsule is removed. The RFID tag records the time for later analysis, such as at repeat prescription time or on a follow-up visit to a health center, when the information can be downloaded through a 13.56-MHz RF wireless reader and displayed graphically. When used for clinical trials, at the end of the trial period the patient returns the blister package and the information is downloaded to a database (Figure 15). A second variant is a smart medication bottle termed eCAP™. It reminds the patient when the next dose is due and records the time the patient opens the bottle to remove the tablet or capsule, without active patient input.

CLOSING REMARKS

Smart packaging need not use new technologies or be complex to offer real customer benefits and improved levels of convenience in today's crowded marketplace—considerable scope exists for using today's technologies in more imaginative ways. The more extensive use of

Figure 13. Increased ease-of-use and accuracy of dosing is provided by this spill-resistant medicine for children. The outer packaging communicates the non-spill characteristics of the formulation by lenticular graphics.

Figure 14. Electronic smart packaging plus lenticular graphics provides full sound and visual instructions to consumers with this cosmetic eye make-up palette.

lenticular graphics and data matrix bar codes are just two possibilities. But it is expected that new technologies, many becoming available for the first time in the next few years such as nanotechnology, printed electronic displays, and batteries, will hugely boost the capabilities of smart packaging.

For some market sectors, such as pharmaceuticals and healthcare, smart packaging will be as much about improving the human interface as about providing new functionality. The growing demands for information about the product will force an abandonment of printed text on packaging as the principal means of communication. Packaging will be capable of sensing, speaking, and displaying, and hence of warning the consumer of, for example, problem ingredients. No longer will seniors struggle to open pharmaceutical packaging or forget to take their medication. All age groups will benefit from these future packaging advances, many of which will be electronic in nature.

Consumer benefits will ultimately drive smart packaging developments and must be clearly communicated to

Figure 15. Electronic smart packaging from Information Mediary helps and assists patients to be compliant in their pharmaceutical regimes. [Reproduced with permission from Information Mediary Corp (IMC).]

the consumer. On-the-go as a way of life seems to show no signs of abating and in all likelihood consumers will become even more mobile and time pressured. In this brave new world, untapped opportunities exist for smart packaging to offer new and improved levels of benefits and convenience.

Cost-effective smart materials and systems development will perhaps one day realize the truly interactive package that greets the consumer at supermarket aisles, plays music, or even flashes the brand logo of the product in bright lights as an inducement to purchase. Once purchased and back in the home, the labelling and communication devices on the package will additionally provide an interaction with smart inventory systems, smart storage/disposal and smart cooking equipment in the kitchen—as is happening already, for example, with microwaveable convenience meals.

Smart packaging can be considered as a natural progression in package innovation for many fast moving consumer goods (FMCGs). After all, competition for shelf space has never been more intense, and the competition arena is increasingly moving from media to the point-of-purchase making packaging more important than ever before.

SMART PACKAGING TECHNOLOGIES FOR BEVERAGE PRODUCTS

Joseph P. Kerry
Department of Food and
Nutritional Sciences, University
College Cork, Ireland

INTRODUCTION

The beverage industry constitutes one of largest sectors within the global consumer packaging market and has been at the forefront in pioneering the development of novel packaging concepts or through the adoption of new technologies as they relate to innovative packaging solutions. Today, some of the leading global product brands in consumer goods are beverages. Beverages are now no longer seen as merely thirst-quenching products but as vehicles for delivering functional nutrition that promotes health and well-being through the incorporation of "wellness" components such as vitamins, minerals, phytochemical extracts, pre- and pro-biotics, and so on, into beverages. Water-based, milk-based, and juice-based beverages, which continue to grow in popularity, are seen as natural and ideal carriers of such components. Equally, the development of beverage product lines where flavor, among other organoleptic properties, need to be created or controlled is another key area in beverage product development. In the future, nanotechnology promises to yield new solutions to key challenges for the beverage industry, just as it is likely to impact the food industry. Research and development currently underway to improve the beverage product itself includes the development of functional beverages, in-pack nutrient delivery systems, and methods for optimizing beverage appearance, such as color, flavor, and consistency (1). Additionally, nanotechnology will also be used to affect the beverage pack as well—For example, by enhancing barrier properties, lightweighting plastic bottles but improving mechanical strengths and heat resistances, providing mechanisms to help packaging to degrade or biodegrade in the environment, and producing packaging materials that have an enhanced and associated hygiene status (2).

The use of smart packaging as a novel marketing tool is another means by which this technology can be effectively harnessed. For example, the development and use of fragrances as packaging components in an attempt to attract the consumers' attention to high-value food and beverage products is one such approach (3). Additionally, as consumers are confronted by a barrage of ever increasing advertising mechanisms, the consequence is that the traditional use of television, radio, and print advertising as a means of commercializing products is losing effectiveness; consequently, novel marketing techniques are developing to explore new advertising mechanisms in an attempt to get brand and product noticed. One such approach appears to be targeting as many of the five senses as possible, all of which are delivered directly through the product packaging (4). Issues pertaining to tradition, luxury, and high-end beverage products such as reinforcement of consumer appeal, tamper evidence, counterfeiting, and brand protection are also highly topical areas of interest within the beverage industry.

Many of the issues described above are being addressed through the use of smart packaging technologies, and these are discussed subsequently and in greater detail.

GAS-RELEASE PACKAGING

One of the most common and widely adopted forms of innovative packaging is the gas-releasing "widget" developed originally for canned and bottled beer products, one of the best known being Guinness stout (Figure 1). This technology was developed to provide a draught beer for the consumer, so that pub-quality beer (having more body, more effervescence, and a thicker and creamier head) could be experienced by the consumer in the comfort of their own home. The widget functions by releasing CO_2 from some of the beer in order to create the head. The widget that is used in canned beer consists of a hollow nitrogen-gas-containing plastic sphere which is 3 cm in diameter and has a tiny hole in it, while that used in bottled product is cylindrical in shape and approximately 7 cm long with winged appendages to prevent the widget from exiting through the neck of the bottle. In the case of

Figure 1. Bottled draught Guiness containing widget technology.

canned product, the widget sphere is added to the can before the can is sealed, where it floats on the surface of the beer with the hole just slightly below the surface (5). Prior to sealing the can, a small shot of liquid nitrogen is added to the beer; this evaporates during the rest of the canning process and pressurizes the can. As pressure increases in the can, beer is slowly forced into the sphere through the hole, compressing the nitrogen inside the sphere. When the can is opened, the pressure inside the can immediately drops and the compressed gas inside the sphere forces beer out through the tiny hole into the additional surrounding beer. This agitation causes a chain reaction of bubble formation throughout the beer; the CO_2 that is dissolved in the beer forms tiny bubbles that rise to the surface which form the head. The presence of dissolved nitrogen allows for smaller bubbles to be formed, which consequently produces the creaminess associated with the head of the product (5). This result can be explained because the smaller bubbles in the product need a higher internal pressure to balance the greater surface tension which is inversely proportional to the radius of the bubbles. Achieving this higher pressure is not possible by merely using dissolved carbon dioxide because the much greater solubility of this gas compared to nitrogen would create an unacceptably large head. The result, when the can is then poured out, is a surging mixture in the glass of very small gas bubbles and liquid, just as is the case with certain types of draught beer. Not only does the nitrogen make the beer creamier and produce a better head, it also protects against oxidation. Consequently, the brewer can permit the beer to be less carbonated (5). The "canned draught" products have levels of carbonation similar to those in cask-conditioned ales, and they have less than half those in some bottled beers.

Apart from Guinness, other breweries have since come up with their own widget designs, which were introduced to draught beer in 1992, lager in 1994, and cider in 1997. In 2002, the Kenco Ice Cappio coffee drink from Kraft Foods, which contained a widget, was launched in the United Kingdom. When the can was opened, the widget produced a creamy head of froth on the beverage (6). As has been shown, this technology has proven itself but yet has enormous potential because it also lends itself to application in other segments such as mixed milk drinks and milk shakes, yogurt drinks, fruit juice-based drinks and smoothies, and coffees. For Kenco Ice Cappio, Ball Packaging Europe also inserted plastic capsules in 0.25-L cans. A relatively new cappuccino cocktail is focused on the Ball Packaging Europe can: "Cafe Kiss," which is a cappuccino drink containing vodka, was launched on the UK market in a 200-mL Slimline can in 2006. A capsule-style widget inside the can ensures that the typical cappuccino froth head is produced when the can is opened. The coffee cocktail can be primarily sourced from British retail chains Tesco and Spar (7).

Future developments of the widget may incorporate elements of nanotechnology; for example, the external surface of the widget could be expected to provide a site for nucleation, or a liquid or active agent could be encapsulated within the widget. The widget could also offer prolonged bubble release and create other "theater effects" during opening and consumption (2).

FLAVOR RELEASE PACKAGING

Other smart packaging devices may be used to release flavors and aromas into beverage products at the point of consumption so as to create or maintain product intensity and quality. Companies have already incorporated scents directly into plastic-based containers so that consumers can smell, for example, the aroma of freshly ground coffee without opening the product. Newly developed scented ink, meanwhile, is allowing ads and catalogues to capture a consumer's attention with an unsuspecting whiff, using a technology beyond your father's scratch-'n-sniff (4). Fragrances and deodorants for plastics are used in a variety of applications and are playing a growing role in marketing food and beverage packaging and in consumer products for the home (3). Olfactory scientists say that using scent is smart marketing. Of all the human senses, smell has the most direct pathway to the emotional center of the brain (4).

The incorporation of aromas into the polymer material can be used to attract consumers when the package is opened, and also to balance any detrimental effects of aroma loss (8). AddMaster recently developed a chocolate fragrance for use in polyethylene packaging of chocolate-flavored milk-based drinks that is intended to create an "in-store awareness" of the product (3). Also, a new aroma and flavor-releasing technology for packaging is being tested in consumer trials in bottled water and nutritional food packaging applications in the United States (9). A U.S. company, ScentSational Technologies, is behind the product, which is also known as ScentSational (Figure 2).

This patented flavor and brand-enhancing packaging incorporates aromatic qualities directly into closures (10). Pasteurization generally burns off what is known as top notes, or the aroma notes in beverages traditionally associated with freshness (10). Additionally, aromas strongly associated with certain packaged foods and beverages are not statically stable; consequently, they become altered chemically over time, resulting in the generation of different and sometimes undesirable odors. The aromas that ScentSational uses remain stable because the molecules are, essentially, encased in plastic (4). ScentSational essentially replaces the top notes lost from products during processing, handling, and storage through the insertion of food grade flavors that are FDA-approved and generally recognized as safe (GRAS). These flavors are mixed with polymers during the injection molding of closures or during the manufacture of plastic-based liners and seals for metal closures (10). The plastic used gradually emits volatiles that are responsible for the specific aromas produced. It has been reported that these aromas persist for approximately a month and actively scent whatever food or liquid product is in close proximity to the packaging material (4).

ScentSational's technology is based on the premise that foods and beverages contained in packaging that smells better will taste better. The technology works using the

Figure 2. Aroma Water, LLC, licenses the technology from ScentSational Technologies to produce Aroma Water™. The cap emits an aroma (lemon-lime or mandarin orange scent) that tricks the taste buds into believing the water is flavored.

science of taste. With the exception of sweet, sour, bitter, salt, and Umami, all other taste is a result of the sense of smell. When someone drinks a beverage, the liquid creates vapors inside the mouth that travel up the retro-nasal canal where it eventually hits the olfactory bulb. It is here that these flavor vapors are interpreted as taste by the brain (10).

NutriSystem, a leading marketer of weight management products, recommends that users of its products drink at last eight 8-ounce glasses of water daily to help flush out toxins produced when body chemistry changes as weight is lost (11). To make the challenge a little easier, the company sells a water bottle fitted with a closure infused with another product also produced by ScentSational Technologies called CompelAroma®. This product encapsulates substances within the structure of a plastic package that emits an aroma during heating and after opening. This gives the water contained in the bottle a specific taste, even though no flavorants have been added to the product (11).

A Pensylvania-based beverage firm, Aroma Water, LLC, licenses the technology from ScentSational Technologies to produce Aroma Water™ in either a lemon–lime or mandarin orange scent. Both "flavors" are approved by the Food and Drug Administration (Figure 2). The aroma of a particular flavor can affect the sense of taste. For NutriSystem, CompelAroma® is added to the closure of the water bottle as it is injection molded. The closure emits an aroma (currently lemon, peach, or berry) that in effect deceives the taste buds into believing that the water is flavored, enhancing the consumer's enjoyment of water without adding calories, sweeteners, or preservatives (11).

A recent innovation to make milk more popular with children has been developed by Unistraw Intl. Pty. Ltd., Australia. This company has been engaged for the last seven years in perfecting a milk-flavoring solution that is mess-free, convenient, wholesome, and tasty (12). The patented Unistraw™ system enables flavor "beads" to be dissolved in a beverage as the liquid passes through the straw. The system has three elements; a straw, filters, and flavor beads. The system's first component, the straw, is made from transparent polypropylene (PP), mixed with a food-grade plasticizer/toughener that prevents the straw from cracking or splitting. The straw measures approximately 0.26 in. diameter and is 7.08 in. long. Filters are heat-welded into both ends of the straw and use a patented cone shape that allows an optimal flow of liquid through the straw while keeping the company's UniBeads inside (Figure 3). Each straw holds approximately 4 g of UniBeads, which are 0.08-in.-diameter round beads that can be dissolved into a beverage to add flavor, vitamins, or other ingredients. The UniBeads are manufactured at Unstraw's facility in New South Wales, using processes and equipment developed by the company (12). In Australia, the straw is sold under the brand name "Sipahh™." These milk-flavoring straws were designed for the 5- to 15-year-old target market. The original launch flavors of Chocolate, Banana, Caramel, and Strawberry have already been joined by Toffee Apple, Cookies & Cream, and Choc-Mint. Other applications envisioned for the Unistraw™ system include the delivery of vitamins and other nutrients, nutraceuticals, and bioactive ingredients or pharmaceuticals into beverages (12). Sipahh™ fits perfectly into the global trend toward healthier and convenient products that deliver nutritional benefits in a fun and novel way (13).

Choice-enabled packaging (patent pending) is now being marketed by IPIFINI Inc., a Boston-based

Figure 3. Defense$^{(\text{TM})}$ citrus flavored vitamin and mineral supplement beverage line from New York-based Brain Twist, Inc. which is formulated to promote consumer "wellness."

innovative consumer technology company that provides a unique approach for flavor and aroma additions into liquid-based products. Ipifini's technology allows consumers the opportunity to personalize their products at the point of use, as well as delivering products that are susceptible to degradation when blended with other product materials or stored in bulk containers. Depression of a button on the side of the pack that contains the additive allows the flavor to be wholly released into the product. Previous innovations have suffered from being susceptible to tampering on the supermarket shelf, but this range of products has a method for overcoming this problem (14). This flavoring technology works with carbonated drinks, but only when the pressure is released by opening the closure. Alternatively, the buttons can be camouflaged as part of the packaging design. Some advantages of these products could be the provision of multiple flavor choices for the consumer and the possibility of creating multiple flavor combinations in beverage products, not dissimilar to what has already been achieved by Jelly Belly for jelly beans.

NUTRIENT-RELEASE PACKAGING

As well as adding flavors directly to beverages, products have been developed that add a segregated nutrient that otherwise cannot be preserved in liquid solutions. In effect they are added just prior to consumption. The Ball packaging group has developed "FreshCan®," which is geared toward the health, wellness, and sports drink markets. Developed jointly by Ball Packaging Europe (BPE) and Degussa FreshTech Beverages LLC. FreshCan® Wedge technology is a patented delivery system that enables dry sensitive ingredients, such as vitamins, to be dispensed into a canned beverage only when the can is opened (12). With FreshCan®, sensitive substances such as vitamins, pro-biotic additives, or trace elements can be stored in a can in a dry state and remain unmixed with the beverage until the can is opened (15). This technology is a patented beverage can that was specifically developed to contain an air- and water-tight plastic container called a "wedge." When opened, pressure decreases in the can, causing the wedge end to spring open. Consequently, sensitive substances are not dissolved in the beverage until it is destined to be consumed. Additionally, nutritional additives that the consumer could previously only take in powder or tablet form can now also be sold as a drink, making it a more convenient form of ingestion for specific consumer categories, like the sport and fitness sector for example (15).

The first commercial application of the wedge became available with the launch of the new Defense$^{(\text{TM})}$ vitamin and mineral supplement beverage line from New York-based Brain Twist, Inc. Offered in orange and lemon–lime flavors, Defense combines zinc, pectin, calcium, and vitamins C, and A, B2, and E in a beverage formulated to combat germs that cause common colds and flu (Figure 3). Defense is packaged in a traditional, two-piece aluminum can holding 14.5 oz of the beverage. Inside resides the FreshCan® Wedge, a two-compartment, polypropylene device containing 10 mL of dry ingredient cylindrical in shape and having a total volume of 25 mL.

Other commercial applications of the wedge-style applicator exist. Atlantic Multipower Germany, Europe's leading supplier in the sports food sector, is introducing a ready-to-drink creatine product in Germany, United Kingdom, and Austria. With wedge support, the creatine is freshly mixed with the drink when the can is opened. The Swiss company Emmi is using this packaging device to overcome stability issues with a nutrient known as CoQ10. Its "LactoTab" performance drink, based on milk serum, has CoQ10, vitamins, and minerals contained within a tablet sealed in the lid of the bottle (16). Further specific details relating to these products have been reviewed by O'Sullivan and Kerry (17).

Alternative technologies to the wedge applicator exist. A company called Portola has introduced the Fusion cap, which again facilitates the product user to add a flavor or vitamin to a bottled beverage by simply twisting the cap. This two-piece, resealable cap is designed to keep a flavor or vitamin powder, tablet, or liquid separate from the beverage until the consumer is ready to drink it (18). Similarly, the New Zealand-based company Alto has designed the Technology cap, which was commercialized by Rio beverages for its IKon energy drink, and has also developed the Freshmix cap, which contains the feature of a fizzing tablet dispenser. This feature allows the active ingredient to remain fresh and inactive within an aluminum foil compartment in the closure until the point of consumption, when the tablet is released into the beverage to provide a fresh and fizzy drink on demand.

PRO-BIOTIC RELEASE PACKAGING

Orchard Maid is the first drinkable yogurt to be equipped with the pro-biotic Life Top Straw™ (19). This product first appeared in the United Kingdom and was developed by BioGaia and marketed by Tetra Pak, both located in Skåne, Sweden. Orchard Maid fruit yogurt drinks are packaged in regular single-serve cartons with straws (20). The pro-biotic bacteria are only released when the liquid portion of the product passes through the straw at the point of consumption, thereby ensuring bacterial viability and effective dosage. These pro-biotic straws, containing the lactic acid bacterium *Lactobacillus Reuteri* (Reuteri™), which has been reported to reduce gastrointestinal disorders and enhance the immune system, can be attached to the outside of the primary packaging (19). Aseptically processed and packaged, the drinkable yogurts have an ambient shelf-life of 12 months. Additionally, the product provides further convenience for manufacturers in that it facilitates the continued usage of existing packaging materials and formats. Using this approach, pro-biotics can be added to virtually any beverage, without compromising on ingredient usage or taste. The straw eliminates production concerns relating specifically to accurate product blending, controlled dosage, and heat damage (19).

ENZYME-RELEASE PACKAGING

Several categories of antimicrobials have been tested for antimicrobial packaging applications: organic acids, fungicides, bacteriocins, proteins, inorganic gases, species, silver substitute zeolite, and enzymes (21–23). One form of active packaging utilizes the incorporation of enzymes to facilitate in-package processing (24). Active packaging technologies that employ bioactive compounds such as enzymes and peptides typically immobilize the moiety via entrapment or physical adsorption. However, there are advantages to covalently attaching the compound to the packaging film. From a regulatory standpoint, if it can be established that a compound is highly unlikely to migrate from the polymer to the food, it may not need to be considered a food additive (25). Researchers at Cornell University have successfully impregnated packaging films with enzymes posessing specific functions. Soares and Hotchkiss (26) displayed that the bitterness associated with certain citrus juices could be significantly reduced using CA (cellulose acetate) films containing immobilized naringinase. These films reduced bitterness by hydrolysis of naringin and sorption of limonin, thereby increasing perceived product sweetness using sensory evaluation panels. In order to be practical, an improvement in enzyme activity per unit area may be required so that a lower film area to product volume ratio can be used. This work also demonstrates that an active packaging system based on immobilization of enzymes to product contact layers of packaging may be feasible. Unlike the current situation where most foods deteriorate in quality during storage, products exposed to package-bound enzymes might improve during storage (27). Appendini and Hotchkiss (28) investigated the efficiency of lysozyme immobilized on different polymers and determined that the combination of cellulose triacetate (CTA) containing lysozyme produced the greatest antimicrobial activities. Goddard et al. (29) also demonstrated that this concept similarly operates in removing lactose from milk. Instead of adding lactase to milk or using an immobilized enzyme reactor that can foul or clog, lactase can be incorporated into the packing container's wall (Figure 4). A British patent assigned to Tetra Pak International AB describes incorporation of lactase into pasteurized or sterilized milk prior to packaging to split the lactose after packaging (24). With sufficient activity, you could reduce the lactose concentration of the milk during shipment (29, 30). Lactose intolerance, or mal-digestion, is the reduced ability to hydrolyze lactose and affects individuals with insufficient lactase activity in the small intestine. It is a dietary problem affecting a minor, but nevertheless substantial, proportion of the population (24). Intolerance results in varying degrees of abdominal cramps, gas production, and nausea (31). Goddard et al. (29) used a yeast-derived β-galactosidase which was covalently attached to a surface-modified polyethylene film to produce sustained enzyme activity over a range of temperature and pH values (29). These data suggest that enzymes that may have applications in foods can be covalently attached to inert polymer surfaces, retain significant activity, and thus have potential as nonmigratory active packaging materials.

Similarly, enzymes that metabolize cholesterol could be used in a manner similar to lactase in order to reduce the cholesterol in a product like milk (30). Brody and Budny (24) suggested a system whereby active packaging combined with PharmaCal Ltd. technology would allow the incorporation of the enzyme, cholesterol reductase, within the primary packaging structure containing the product in question. For example, untreated milk could be packaged; and in the time taken to transport the package to the consumer, it could conceivably become free of cholesterol.

ODOR REMOVAL PACKAGING

Flavor scalping, or permeation of aroma components, may result in loss of flavor and taste intensities and/or change

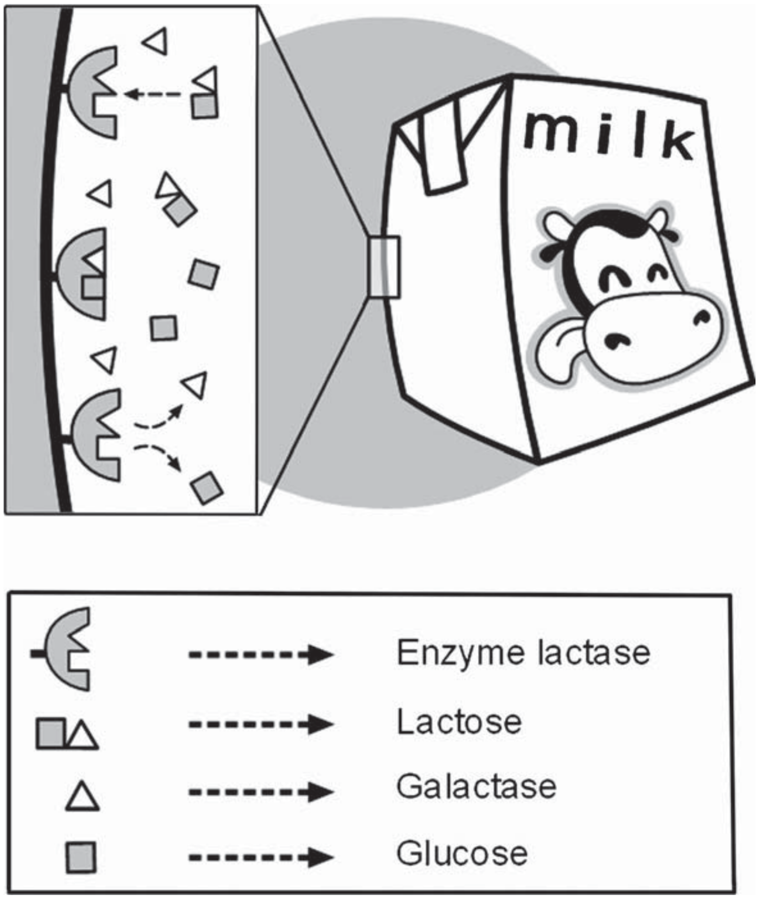

Figure 4. Enzymatically active pack of milk: Lactase enzymes are attached in the inner part of the pack transforming lactose. (Reproduced with permission of Alberto Bertolín Terrádez.)

in the organoleptical profile of a beverage product (32). The development of unpleasant flavors as a consequence of processing can be the result of either (a) thermal degradation of components, such as proteins, or (b) the manufacture of chemical components via Maillard reactions (33). Equally, the oxidation of fats and oils is also accelerated during processing and especially when elevated processing temperatures are required. Apart from these more common and relatively fast chemical reactions, there can also occur the slow generation of chemicals which can result in the creation of unpleasant flavors—for example, when fruit components are disturbed from their structural components in the fruit. The bitter principal, limonin, builds up in orange or grapefruit juice after pasteurization, and it renders juice from some cultivars undrinkable. Chandler and Johnson (34) showed that substantial quantities of limonin could be removed or scavenged through the use of acetylated paper (35). The concept of odor removal using chemical affinity was further developed by Brodie and Visioli (36), who used the reaction of aldehydes with amino polymers.

Odors that result from aldehydes such as hexanal and heptanal, which are formed from the breakdown of peroxides created during the initial stages of auto-oxidation of fats and oils, can be removed from package headspaces by active packaging (37). Synthetic aluminosilicate zeolites, which have a highly porous structure, have been incorporated into packaging materials to adsorb odorless aldehydes (38). Such compounds formed in dairy-based and beer-based beverage products could be removed, resulting in improved sensory quality.

In the case of beer, a number of commercial oxygen scavenging technologies have been developed to be incorporated into PET bottles. The Oxbar system (Constar International, USA) consists of an aromatic polyamide (MXD-6) with reducing properties that can be blended in any proportion. By inclusion of a layer of MXD-6 within two layers of PET and using a cobalt salt as a catalyst, structures suitable for the manufacturing of bottles for beer, wine, or sauces can be designed (39).

Sulfites have also been proposed as active substances for use in plastic gasket liners for bottle closures, as liquid trapped between sheets of flexible packaging material, or as compounds that are directly incorporated into plastic film structures to pack products such as wine or ketchup. Other, more recent developments of integrated systems include oxygen-scavenging labels such as Freshmax (Multisorb Technologies, Inc., USA) and incorporation of O_2 scavengers in closure seal liners for beer and soft drink bottles such as Smartcap (a development of Advanced Oxygen Technologies Inc., USA) or Oxbar™ (Carnaud Metal Box, UK), which is specifically designed to be incorporated into PET bottles. A typical oxygen-scavenging structure used in beer bottles is presented (Figure 5).

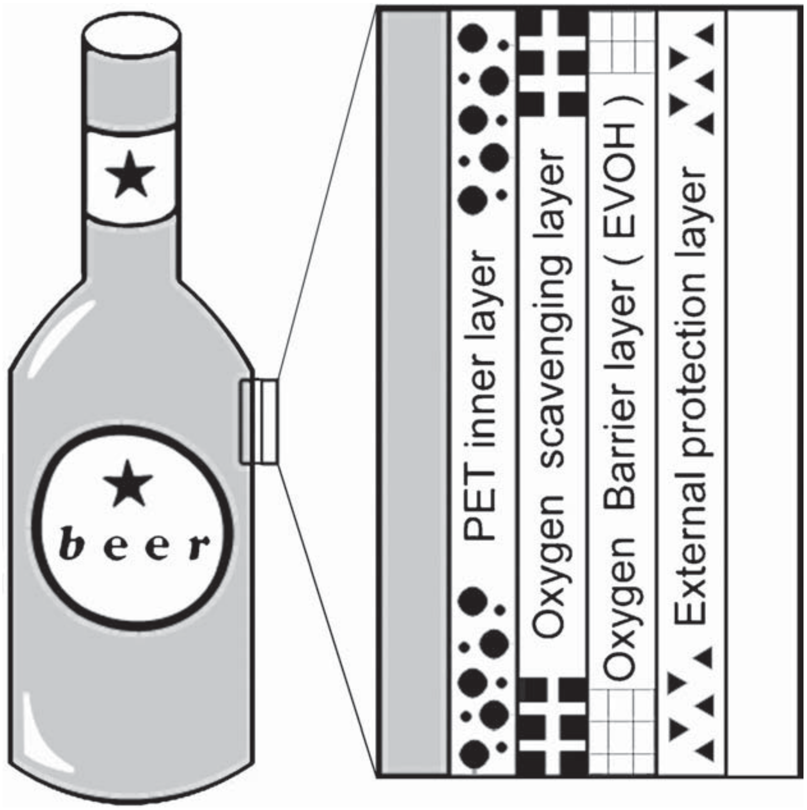

Figure 5. Typical oxygen-scavenging multilayer structure used in PET bottles for beer. (Reproduced with permission of Alberto Bertolín Terrádez).

CONVENIENCE OR USER-FRIENDLY CONSUMER PACKAGING

Consumer smart packaging has the potential to meet future aspirations in improved packaging by placing the packaging user interface and consumer experience at the heart of both product purchase and product utility. This in turn will provide new levels of consumer convenience in areas such as efficient and effective product usage, in storage and disposal, and in bringing new forms of useful functionality to help support consumers in their day-to-day lifestyles (40). While often overlooked in technical reviews and in basic packaging design, the area of consumer smart packaging is pivotal in its capability to directly satisfy consumer needs and requirements associated with a vast array of commodity products, with food and beverages being paramount among them. Several really good examples of consumer smart packaging used for beverage products are in existence today and are found distributed from retail outlets through to vending machines.

Self-heating and self-cooling packaging are two very good examples of consumer convenience smart packaging which have been applied to beverage products. For self-heating packaging to function as required, an exothermic chemical reaction must be employed in order to generate enough heat to warm/heat the product to the consumer's expectation and satisfaction. While there are numerous chemical reactions that can produce heat, relatively few can be used due to safety issues, toxicity issues, and cost impediments relating to practical usage. The exothermic chemical reaction of choice for consumer packaging is lime reacting with water because it generates substantial heat output and is inexpensive and the byproducts of the reaction are environmentally acceptable (40). The exothermic reaction is initiated by the consumer at the desired time of product consumption through some physical action that results in the mixing of the water with the lime at some strategic point in the product container (usually the base). This initiates the exothermic reaction, which is usually maximized through product agitation or shaking, by the end-user, for a certain period of time.

One of the most successful self-heating beverage containers was launched in the United Kingdom, in 2001, in test markets as a joint venture between Crown Cork and Seal, Thermotics Development, and Nestlé. The product "Hot When You Want" Nescafé canned coffee heated about 200 mL of hot coffee, with an occasional shake, to around 40°C above ambient in about three minutes. More recently, there has been a major launch of self-heating gourmet lattes in the United States, with a range of 10-oz Wolfgang Puck gourmet lattes being available through Kroger grocery stores in 32 states (40). Other examples of coffee products sold using self-heating packaging are Caldo Caldo,, Café Caliente, and Rocket Fuel (Figure 6). Additionally, self-heating packaging has been developed for drinking chocolate, and tea and is currently being explored for use with soup.

Self-cooling packaging technology is not as developed as is its self-heating counterpart primarily because of issues to do with cost, safety, environmental concerns, reaction times, and current limitations in technological

Figure 6. Examples of self-heating coffee products.

approaches. The technology choices at present boil down to two endothermic chemical reactions and heat pump technology using water vapor as the heat transfer fluid. Forms of gaseous high-pressure expansion can provide effective and rapid cooling but can quickly be ruled out on environmental and safety grounds (40). Nevertheless, commercial application of self-cooling packaging has been undertaken commercially.

The Italian self-cooling coffee product “Freddo Freddo” employs an endothermic reaction between sodium thiosulfate pentahydrate and water. Another example of an endothermic reaction that has found commercial uptake has been the self-chilling refillable beer keg. This technology, which is based on zeolite heat pump technology, has been developed by the German CS-Metallbau Company, licensed to Cool-System Bev. GmbH and used by Tucher Bräu brewery for 20-L refillable stainless steel kegs to cater for the “take home” market.

Other examples of consumer-friendly smart packaging used by the beverage industry to deliver or enhance consumer satisfaction during product usage can be seen in the development of closure systems. The diversity in closure systems described here also nicely demonstrates the simplicity and complexity that can be associated with smart packaging systems.

A very simple closure that can be described as consumer-friendly smart packaging is the simple embossed aluminum foil cap found on the top of all 500-mL aluminum cans of all Kiss ciders and parries. The foil caps have been specifically provided for hygienic protection of the product; once opened, however, they also form a physical barrier to product tampering.

A more sophisticated form of closure device is that associated with Sheridan’s liqueur by Diageo. Sheridan’s liqueur is a two-component drink where a white vanilla crème liqueur is floated on the surface of a dark coffee-chocolate liqueur, resulting in a drink similar in appearance to an Irish coffee (40). Strategic to meeting consumer satisfaction is the requirement that the correct ratios of white to black liqueurs are dispensed into a glass to provide the desired Irish coffee appearance of white on black. This has been achieved through the development of the Perfect Pour closure system by the consulting group, PA (Figure 7). The closure had to be designed by PA to account for product dispensing, product viscosity, return air flow, and the fitting of the closure unit on two joined bottles, resulting in the perfect pour. The Perfect Pour closure enabled IDV/Diageo to build a brand around the smart packaging closure concept (40).

THERMOCHROMIC LABELING

The technology to make thermochromic inks (change color when exposed to heat) and photochromic inks (change color when exposed to light) has been in existence since the mid- 1970s (41). Thermochromic inks can be printed on labels or containers that are to be heated or cooled prior to consumption to indicate the ideal drinking temperature of the product (37). The use of such technology for beverages first became popular with wine labeling (37). Label color changes, whole or in part, that respond to temperature has been made possible through the development of temperature-sensitive inks formulated by B&H Colour Change Ltd. and Chromatic Technologies, Inc.

Today, this form of labeling is also found on many beer products. For example, commercially available Coors Fine Light Beer has a temperature-sensitive mountain logo (Figure 8) that turns from white to blue when the bottled product is cold enough to imbibe (17).

Similar examples of beer products sold from retail outlets which possess labels incorporating thermochromic-based designs include Wolf beer from the United States and Hite beer from Korea. Depending on their composition, thermochromic inks will change color at specific temperatures; and if appropriate colors are

Figure 7. Example of a smart closure on Sheridan's coffee layered liqueur.

chosen, then hidden messages such as "drink now" or "too hot" become visible (37). A Colour Changing Disposable Lid from Smart Lid Systems™ provides consumers with a visual indicator of product temperature for beverages in paper or polystyrene coffee cups. Infused with a color-changing additive, the Smart Lid™ coffee-cup lid goes from "coffee-bean brown" to glowing red after being placed on a cup containing a hot beverage (12). A further visual indicator ensures that the lid has been placed securely on the cup and serves as a safety feature. When the lid changes color, a dark ring forms around its edge, but only if the lid is attached to the cup properly. The lid is made from virgin high-impact PS, which is mixed in the cold-pellet state with a color-changing additive from Matsui International and which has been approved for food contact by the U.S. FDA. Another aspect being promoted by Smart Lid Systems™ is the lid's potential as a marketing tool, whereby an advertising message can be printed on the lid and would only appear once the lid changes color. For example, text printed in brown ink on the lid or on a

Figure 8. Example of thermochromic ink usage on Coors light beer bottle labels.

clear sticker applied to the lid would only be visible when the lid was in a hot, or red, state (12). Huhtamaki, a Finnish packaging company, uses what it calls “Heat and Reveal” temperature-responsive labels. This approach uses thermochromic technology to reveal a hidden message or strap line incorporated into the cups design. The temperature of the beverage determines when the ink is made visible. Such messages could provide instant win opportunities for vending operators and branders. This technology allows the competition and winning message to be kept secret until the moment a beverage is dispensed. Similarly, the device can also reveal a surprise slogan or message that will only become visible once a drink is poured (42).

SMART BRANDING

The competition for the consumers’ attention on-shelf has never been more intense, and innovative beverage packaging companies are interested in packaging that captures the attention of the consumer (12). Manufacturers are spending more to design packages that blink, beep, yell, and waft scents at shoppers (4). U.K.-based Cognifex Ltd., has developed a miniature electronic unit with an LED and silicon chip and posessing a self-contained button-cell power source that illuminates plastic and glass beverage bottles for marketing and promotional purposes (12). The Cognifex unit is designed to fit on the bottom of a standard-sized beverage bottle and can be triggered in a number of ways. These activation methods could include manual depression of a switch, pulling of a tab, removal of the cap or lid with a special opener, an infrared (IR) signal, magnetic switching, or an external radio-frequency (RF) signal. Once triggered, the LED will illuminate the bottle and its contents for a predetermined period of time. Depending on what the brand owner is trying to achieve with the illumination effect, the device can be designed to function for anywhere from a few minutes to several months. Another possible application envisioned is for sweepstakes or promotional campaigns, where bottles could be illuminated remotely to indicate a winning package, or winning bottles could emit a different color than regular bottles.

As people increasingly ignore commercials and spread their attention across many types of media, traditional television, radio, and print advertising is losing effectiveness, and marketers are looking for new ways to get noticed (4). Under development are computer chips embedded in packaging that can communicate with a shopper’s PDA or cell phone to give additional product information. Miniature sound systems on boxes and bottles will give people spoken tips and ideas. The German electronics giant Siemens AG has developed a flat electronic display that can be applied to boxes like a label, allowing for tiny lights, miniature games, or flashing messages (4).

Finally, in what might be the first instance of naming a wine for its packaging, Don Sebastiani & Sons released Plungerhead in March 2006. The Dry Creek Valley Zinfandel derives its commercial name after the "zork" closure from Australia (www.zork.com.au) composed of a polyethylene cap and plunger that "pops" when opened (42). The closure is favoured not only because it eliminates corking taint, but because it retains a sense of celebration in opening a bottle of wine (42).

ANTI-COUNTERFEIT BEVERAGE PACKAGING

A concern among packagers and their customers worldwide is the growing incidence of counterfeit products making their way into global markets. Experts estimate that in Europe alone, as much as 7% of the branded consumer products market is lost to counterfeit products (43). The amount of fake food and drinks entering the EU grew by 200% in 2004, with the higher quality of counterfeits making detection more difficult (44). Counterfeiters are shifting their attention into mass market goods categories. Packaging is to the forefront in fighting counterfeiting (43). Lipton, Coca Cola, and Nestlé products topped the list of counterfeit food and beverage items seized at EU's borders, the European Commission said when announcing new measures to crack down on the problem (44). In many Western nations, such as the United Kingdom or the United States, the quota of counterfeit products is about 10%. China accounted for most of the total counterfeit goods seized in 2004. The massive increase in counterfeit food and beverage production occurred following the collapse of the Russian economy in 1998. This single event offered food fraud the opportunity to fill empty retail shelves with cheap and counterfeit goods (45). In Russia, products like condensed milk and mineral water are targeted by counterfeiters. In fact, it is estimated that three-quarters of the mineral water sold in Russia is thought to be fake, with counterfeit bottled water accounting for half of the Moscow market (45). Counterfeiting and tampering can undermine consumers trust in the quality and safety of a branded food product, leading to a loss in market share. In response, companies have turned to new forms of smart packaging and labeling to ensure that consumers and custom officials can check for product authenticity (44).

Protection against theft and counterfeiting is a highly developed area for high-value goods such as electronics and clothes. However, it has not found widespread application in the beverage industry because of the comparatively low unit value of packaged foods (37). Many anti-counterfeiting devices did not work in the past because they were too costly to duplicate. Now the emphasis is on technology, including the use of radio-frequency identification (RFID) tags, security-smart printing techniques, and use of special inks (46). To date, RFID technology has primarily been used to increase convenience and efficiency in supply chain management and traceability, being normally applied to secondary and tertiary packaging (37). However, RFID technology may play an increasingly important role as a security countermeasure to counterfeiting, theft, and tampering of beverage products.

Hi-resolution printed intertwining lines known as guilloches, already used successfully on banknotes, can be printed on primary packaging and/or labels. Microtag particles can be printed using multiple ink layers that combine to form a unique code or holograms that can be integrated into primary or secondary packaging (46, 47).

Microtrace offers a variety of identification and authentication labeling in the form of compounded plastic resins, films, adhesives, paper, security labels, and now security inks (48). A new series of microtaggant security inks will allow any printer to apply the anti-counterfeit technology to packaging using flexographic or screen printing processes. In basic form, microtaggants are a unique numeric code sequence in a multiple-colored layer format. In more complex forms, microtaggants deliver multiple layers of security through the incorporation of several taggant technologies (49). The ink gives products and packages a unique numeric code sequence in a multiple-colored layer format. The codes will be unique for each manufacturer. Once a formulation is produced for a customer, it becomes their exclusive "fingerprint" (48). The acetate films containing microtaggants can be used to produce authenticated, finished holograms.

Thermosensitive inks change color when a packaged product has been exposed to predetermined temperatures, often a sign that it has been counterfeited and introduced into the supply chain. UV inks fluoresce under ultraviolet light and infrared inks can only be detected using a special camera, offering security that does not interfere with the graphic appeal of the package. Metameric inks look identical, but are revealed to be different under a special filter. Scented inks offer both a shelf appeal and security protection (46).

Biowell Technology, a Taiwan-based biotechnology company, has perfected the world's first DNA-tagged anti-counterfeit label. By using bioengineered DNA as an invisible and highly specific identification tag, forensic-level authentication of a tagged item is possible. DNA tagging has the ability to protect brand name products, documents, artworks, ID cards, and so on, from counterfeiting trade tools: precision computer scanning and printing equipment. DNA tagging provides an extremely high counterfeit barrier, because the unique DNA sequence that identifies a tagged object can never be replicated by a counterfeiter (50). This DNA anti-counterfeit label has been applied in luxury brand protection to wine, tobacco, and pharmaceutical industries (50).

Kodak is using new high-tech, anti-counterfeiting technology to help several Napa Valley vineyards in the fight against wine fraud (51). Kodak's Web site describes the company's Traceless system; marketed as an anti-counterfeit solution to the drug industry, it could also be used to protect premium or high-value wines. It uses invisible markers that can be mixed with printing inks or paper and are detectable only with proprietary portable readers. These readers can be leased to clients and cannot be opened without being damaged (52). Industry experts estimate that the problem of wine counterfeiting alone could affect up to 5% of wines sold in secondary markets (51).

TAMPER-EVIDENT PACKAGING

From a consumer safety concern perspective, evidence that a packaged product has been interfered with or tampered with is crucial, especially for retail-ready commodity products such as foods and beverages, some of which have gone through elaborate handling and transport systems. The main purposes in lowering tampering risks are to (a) eliminate tampering and (b) locate the already tampered products on the shelf by integrated identification (53). Tamper evidence technologies that cannot easily be replicated—for example based on optically variable films or gas-sensing dyes, involving irreversible color changes—will become more widespread and cost-effective for disposable packaging of commodity items (54). Piezoelectric polymeric materials might be incorporated into package construction so that the package changes color at a certain stress threshold. In this way, a "self–bruising" closure on a bottle or jar might indicate that attempts had been made to open it. The new packaging is a natural red to light-pink color (54). When punctured, the light and air react with the packaging in a process called photochemical oxidation, which forms a type of bruising (55). This is a form of smart packaging that indicates when the integrity of the barrier has been breached. This breach may result from a malicious individual, an insect, or an inadvertent rupture of the package by poor handling. Packaging protection is an increasingly important part of packaging design. Consumers are now far more aware of product safety, and they require assurances from the manufacturer that the food or beverage products that they purchase are fit for usage and/or consumption. Additionally, aluminum and plastic closures can help customers identify if the package has been opened. The tamper-proof band will split when the package is opened, which provides tamper evidence to the consumers (53). Risks include what the industry terms malicious and nonmalicious tampering. The former is an increasing threat, particularly in the light of increasing terrorist activities and the potential for sabotage or bioterrorism attacks using packaged food and beverage goods as vehicles of delivery (55).

In conclusion, the use of smart packaging technologies by the beverage industry is a vibrant and rapidly developing field. Much has been offered by the use of these technologies in the beverage industry already and also in related product areas. Some leading global beverage brands, like Guinness for example, have used such technology to demonstrate innovation, offer unique product selling points, enhance the product brand, provide consumer convenience, and, of course, sell more product. However, many of the smart packaging technologies relevant to the beverage industry are fledgling in nature, or are still under development, and it will take some time for them to reach their full potential through commercial uptake.

SOCIOECONOMIC DRIVING FORCES OF FOOD PACKAGING

KIT L. YAM
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

The food packaging industry is largely driven by market pull to satisfy the needs of the society and economy. Hence, the viability of any new packaging technology depends on its ability to fill these socioeconomic needs. Below are some major socioeconomic forces driving the food packaging industry.

- *Consumer lifestyle.* This lifestyle is the need that drives innovations in conveniently packaged foods. In recent years, consumer lifestyle has been influenced greatly by the aging population, increasing number of smaller families, single-person households, and dual-income families. As a result, the consumer is increasingly demanding food products that are convenient, good tasting, safe, wholesome, and nutritious. This change has also created opportunities for innovative food packaging to satisfy target consumers of diverse demographics. For instance, packaging has played an important role in the development of convenient food products, such as on-the-go snacks, microwavable foods, and refrigerated meals (also known as meal solutions).
- *Value.* This need, defined as benefits/cost ratio, is driven by the consumer. Higher benefits may be achieved by enhancing the functions of packaging to satisfy the unmet needs of the consumer. Lower cost may be achieved by using less expensive packaging materials, using high-speed machines to increase productivity, and using more compact package designs to reduce distribution cost. For instance, material cost may be reduced by replacing a thicker monolayer material with a thinner, multilayer material, production speed may be increased by replacing double-seamed containers with heat sealed containers, and distribution cost may be reduced by replacing heavy glass containers with plastic containers. In the efforts of reducing cost, it is important that product quality and safety are not significantly compromised.
- *Profits.* This need is driven by food companies to maintain or grow their businesses. To earn profits, food companies frequently rely on packaging innovations to meet the ever-changing market needs. Profits also spark intense competition in the packaging industry to fill the market needs. For example, beverages may be packaged in different forms, which include glass bottles, plastic bottles, aluminium cans, and stand-up pouches—and this diversity provides a battleground for packaging materials suppliers to capture the market through optimization or innovation.
- *Food safety and biosecurity.* This food security is the need that drives innovations in protective food packaging. Each year in the United States alone, food-borne diseases cause approximately 76 million illnesses, 325,000 hospitalizations, and 5000 deaths. Microbial contamination is a major cause of food-borne illness that can occur during harvesting, processing, distributing, handling, store display, and food preparation. After the tragic event of September 11, food bioterrorism (e.g., deliberate contamination of commercial food products) has become a serious public threat. Packaging can effectively protect against microbial contamination and product tampering. Innovative food packaging, such as antimicrobial packaging, advanced package integrity inspection systems, tamper-evident packaging, and biochemical sensors are increasingly sought to provide enhanced food safety and biosecurity.
- *Food packaging regulations.* These regulations are the needs that drive research and development that relate to food packaging safety issues, such as the migration of unwanted compounds from package to food (especially during situations such as microwaving) and the use of recycled materials in food packages. The purpose of food packaging regulations is to protect the consumer against unacceptable levels of food contamination by packaging components. This concept also has led to a continued interest in studying the migration of packaging components under various conditions and in developing sophisticated analytical methods to detect volatile compounds at lower concentrations.
- *Environmental concerns.* These concerns drive innovations in environmentally friendly packaging. As landfill sites are diminishing, packaging waste disposal has become a major public concern in many developed countries. A growing pressure exists for the society to favor food packages that use less material and are easy to reuse, recycle, or incinerate. Also, a continued quest is underway for bio-based and biodegradable packaging materials that have good mechanical and barrier properties.

SOUS VIDE OR COOK/CHILL FOOD PRODUCTS

Dong Sun Lee
Department of Food Science
and Biotechnology, Kyungnam
University, Masan, Gyeongnam,
Republic of Korea

The principle of conventional cook/chill processing is to cook, chill, and hold the prepared food for later use, providing time buffer in food service establishments or at home. *Sous vide* processing and packaging is an improved variant of the cook/chill process in which the prepared foods or meals are vacuum-packed in a heat-resistant barrier plastic pouches or trays, pasteurized in hot water, and cooled rapidly. The products are stored by the producer and distrbuted under chilled temperature until mealtime. At the point of consumption, the sealed package may be reheated in a hot-water bath or a combination steam oven; the food contents may be transferred to another container to be heated on stovetop or inside a microwave or conventional oven. Figure 1 presents typical procedures of *sous vide* and cook/chill processing. The

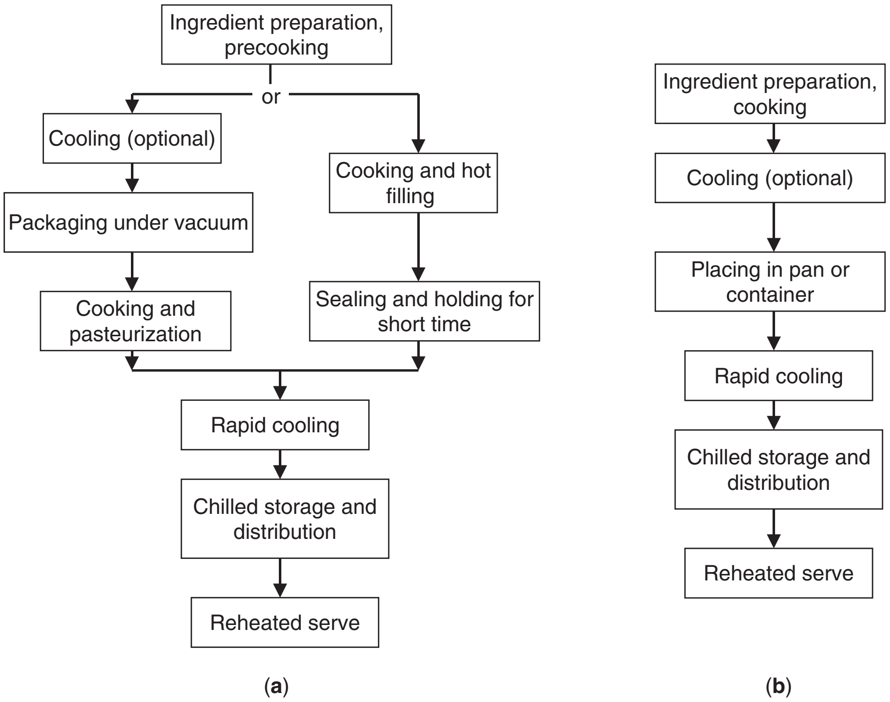

Figure 1. Typical procedures for manufacturing (a) *sous vide* products and (b) cook/chill food products.

term *sous vide* emphasizes the vacuumed packaging conditions of the cook/chilled products. There are wide variations of processes in application of this technology, and thus in actual practice there are often no clear distinctions between *sous vide* and cook/chill.

Sous vide (orignated from the term 'under vaccum' in French) or cook/chill process has been used extensively to produce pre-packaged refrigerated foods for both the retail and institutional markets. The combination of mild heat treatment and refrigeration can produce high-quality ready-to-eat meals with extended shelf life. The *sous vide* and cook/chill products in foodservice systems ensure a time buffer providing the flexibility of meal provision. Increased demand for high-quality prepared foods and productive food service operation from consumers and catering industry has led to the rapid commercial development of these new processes and packaging technologies. Particularly, the *sous vide* and cook/chill technology enabled multiunit restaurant operators to develop a centralized kitchen system that prepares the foods centrally and serves satellite food service locations with effective inventroy control.

PROCESS AND PRODUCTS

Sous vide with Pasteurization

This method is basically a heat-cook of the product that has been filled into a heat-resistant pack and hermetically sealed under vacuum. The heat-cook achieves also pasteurization effect to inactivate vegetative microorganisms and some spore formers. This process prevents postprocessing contamination and retains product quality attributes. Foods such as meat, fish, poultry products, pasta, legumes, or diced vegetables are prepared by this technique. This technique has been most often employed for high-volume uses of hotel, restaurant, and institutional foods, and expanded to retail sector.

The initial preparation includes blanching, grilling, searing, or mixing of meat, seafood, pasta, and/or vegetables. The prepared items or mix is assembled or packaged in a pouch or tray, which is then vacuumized and sealed hermetically. The products may be precooled prior to the packaging step for controlling the vacuumization operation and attaining consistent temperature and quality. The pasteurization or cooking step employs heating under hot water, air/steam combination, or microwave. Hot water may be used for immersing medium or spraying. Usually the pasteurization process is determined based on the product core temperature reaching 75–93°C. Cooking time and temperature depend on the product and shelf life desired (see below). After cooking, the products must be quickly chilled to $<3^{\circ}$C before distribution. The chilling can be attained by agitated ice water bath or air-blast chiller.

Resistance to high temperature (mostly up to 100°C) is the primary requirement of the materials for *sous vide* packaging. High-density polyethylene (HDPE), polypropylene (PP), nylon, and ployethyelene tetrephthalate (PET) are used in single-layer and/or laminated structures. For long-shelf-life products, a high oxygen barrier layer of polyvinylidene chloride (PVDC) or ethylene vinyl alcohol (EVOH) may be placed inside the multilayered structures. For some meat products, a slight adhesion of film to the product to retain moisture and reduce purge is desirable. Good abrasion resistance to withstand possible abuses during distribution is also important. Depending on the packaging equipment, bags, trays, casings, and roll stock are available.

Sous Vide with Hot Fill

Hot fill is most often used for pumpable foods such as soups, sauces, stews condiments, fruit-based beverages, and toppings. The products are usually prepared in large, steam-jacketed kettles and heated to a minimum temperature of 85°C. Products are then transferred via pump/fill stations into preformed clipped casings, or through a vertical form/fill/seal (VF/F/S) machine that uses roll stock to create a flexible pouch. Heating and filling while maintaining that temperature helps to remove air and attain pasteurization effect for the required shelf life. Controlling the temperature of filling is critical for ensuring the required pasteurization and safety of the foods. The proper choice of cooking and packaging equipment depends on the product and the volume requirements. Pump/fill stations and clipped casings work best with low to moderate volumes of production. Sustained, high-volume production of a single product is done most efficiently with VF/F/S equipment and roll stock film.

For maximum shelf life, air inside the casings or pouches must be removed during the packaging process, and rapid chilling is needed to preserve the flavor and nutritional characteristics of the food. For food safety, the product temperature is recommded to be reduced to 3°C in less than 2 h. Tumble chillers are generally most effective in cooling products placed in casings; blast chillers are most often used on VF/F/S packages.

Pouch packaging can be sized to fit the commercial need. Pouches can be produced containing as little as an ounce of product to more than two gallons. Custom size to fit specific requirements (a package containing the exact amount of filling for one pie, for instance) can be easily made, thereby improving sanitation and inventory management and reducing storage requirements.

While *sous vide* packages with hot fill require the same heat resistance and barrier properies as those of *sous vide* with pasteurization, more abuse resistance is particularly required to endure the shock of tumble chilling and to withstand the rigors of distribution.

Cook/Chill with Other Hurdles

Packaging after cooking and chilling in conventional cook/chill process has postprocess contamination risks. Microorganisms present in the environment, packaging materials, and cooking and packaging equipment can transfer to the product after it has been cooked (pasteurized) and can cause spoilage. Sanitation during production and strict temperature control afterward are critical for delivery of safe food products to consumers. The products are preferably cooked and chilled in near-cleanroom conditions to reduce the chance of postprocess contamination.

Other preservation hurdles such as modified atmosphere packaging, irradiation, preservative, and high-pressure treatment can be used in combination to provide longer shelf life. Modified atmosphere packaging is the technique most often used for baked goods, fresh pastas, precooked vegetables, and multicomponent meal items. After preparation, foods are immediately packaged in a gas-flushed environment using a high-barrier material. The gas mixture is selected to fit the particular requirements of the product (see Modified Atmosphere Packaging).

EQUIPMENT

Any cook/chill or *sous vide* methods require specialized kitchen layouts to achieve optimum output. Conventional cook/chill production can be accomplished with standard cooking equipment found in most commercial kitchens. A method to quickly cool the just-cooked products may need to be added, however, if cold storage space or ice baths are not able to handle the volume. Product can be placed in holding pans for chilling in cold storage or immediate use.

The *sous vide* process incorporating pasteurization or hot fillling uses a variety of high-volume production equipment. Steam-jacketed kettles with vertical sweep-and-fold tilting mixers are used for soups, sauces, taco meats, and puddings. The same kinds of kettles equipped with horizontal stationary mixers are used for thicker foods such as mashed potatoes and batters.

Tilting skillets are used for searing, browning, frying, poaching, and boiling. Ground and stew meats, fried foods, and poached fish are generally prepared with this equipment. After cubed meats are seared or browned, they are often transferred to kettles for further preparation as ingredients in soups or stews.

Metered filling stations (pump/fill equipment) are used to pump premeasured amounts of cooked product into clipped casings or premade pouches. After filling, the containers are closed with a metal clip. Moderate volume production of low- and high-viscosity foods with small particulates (less than 1 in. in diameter) are packaged with this kind of equipment.

For larger volumes of pumpable products, VF/F/S equipment is used, creating pouches from roll stock in a continuous operation. These packages are heat-sealed as part of the filling process.

Blast chillers or tumble chillers are used to quickly reduce the temperature of these products. The choice is based on product, package style, and cooling temperature. Blast chillers are most often used for chilling prechilled product to a desired state or moderate speed cooling without mechanical stress. Tumble chillers are the most effective method of reducing cooked food temperatures from pasteurization levels to 3°C. They can be aggressive, however, and are generally used with foods that have little or no particulates.

Continuous-belt chillers operate by transferring the packaged product through a cold-water bath, chilled brine, or spray. They are less abusive and thus a preferred cooling method for pouches vertically form/fill/sealed. The chiller length and way of product pass are designed to ensure proper dwell time to reach the desired temperature. For applications such as meat prepared in cook-in casings, cook/chill tanks are used. This specialized piece of equipment cooks the product in a hot-water bath, and then it drains the water and replaces it with cold water for quicker and more efficient cooling.

SAFETY AND SHELF LIFE

Safety and quality of *sous vide* or cook/chill products rely on the pasteurization and low temperature if the production has been preformed under hygienic process control. The pasteurization process destructs most of pathogenic and spoilage microorganisms, but not all of them. The chilled storage delays the growth of any surviving microorganisms for limited time period, but not forever. The organisms able to survive the pasteurization and grow at refrigerated conditions are of the most concerns to cook/chill products. Psychrotrophic bacteria able to grow below 5°C are of major concerns. Mesophilic organisms cannot grow at temperature below 10°C and is of little concern for properly chill-stored products (typically below 3°C).

Storage even at properly chilled temperature is not sufficient to prevent growth of psychrotrophic organisms. Therefore pasteurization conditions should be selected for required degree of microbial inactivation or shelf life of the products should be limited. For acid foods with pH less than 5.0, any psychrotophic, heat-resistant pathogenic bacteria cannot survive mild pasteurization process. When these products are properly pasteurized, they can be stored without any concerns on public health as long as the storage temperature is controlled below 8°C. However, in the pasteurized foods having pH ≥ 5.0, some heat-resistant pathogenic bacteria can survive and grow to produce toxin, which can be a health hazard. The most noted organisms are vegetative *Listeria monocytogenes* and spore-forming nonproteolytic *Clostridium botulinum*. *L. monocytogenes* is a typical vegetative heat-resistant organism and can be destroyed with milder heat treatment (typically 2 min at 70°C based on product center temperature), providing shelf life less than 10–14 days at below 8°C. Inactivation of nonproteolytic *C. botulinum* requires severe condition (typically 10 min at 90°C based on product center temperature) and can provide longer shelf life up to 40 days at storage below 8°C. The product shelf life is dependent on product's intrinsic characteristics, heat treatment condition, additional hurdles applied, and storage temperature. For maximum shelf life of the products and food safety, storage temperatures between 0 and 3°C are desired.

As an aid to control the quality and safety of *sous vide* or cook/chill products, norms or guidelines are sometimes given for their microbial state (Table 1).

SPECIFICATIONS AND QUALITY ASSURANCE

Claire Koelsch Sand
Ameripak, Inc., Stillwater, Minnesota

Dannette Fay Casper
Minnetonka, Minnesota

Specifications have evolved to customer-driven platforms that define in detail how the package fits the product, enable environmental chain of custody tracking, detail environmental characteristics, provide essential measurements, and ensure compliance with international regulations and the final relationship to the final consumer. This is a major switch from specifications that defined solely manufacturing requirements and provided internal documentation. This evolution has provided the impetus of change for quality assurance procedures. Now, quality programs have evolved from the standard ISO certifications to Six-Sigma and data-linked quality value chain-driven programs. This article explains basic elements of specifications and quality assurance. General packaging and component specific packaging specification and quality procedures are addressed.

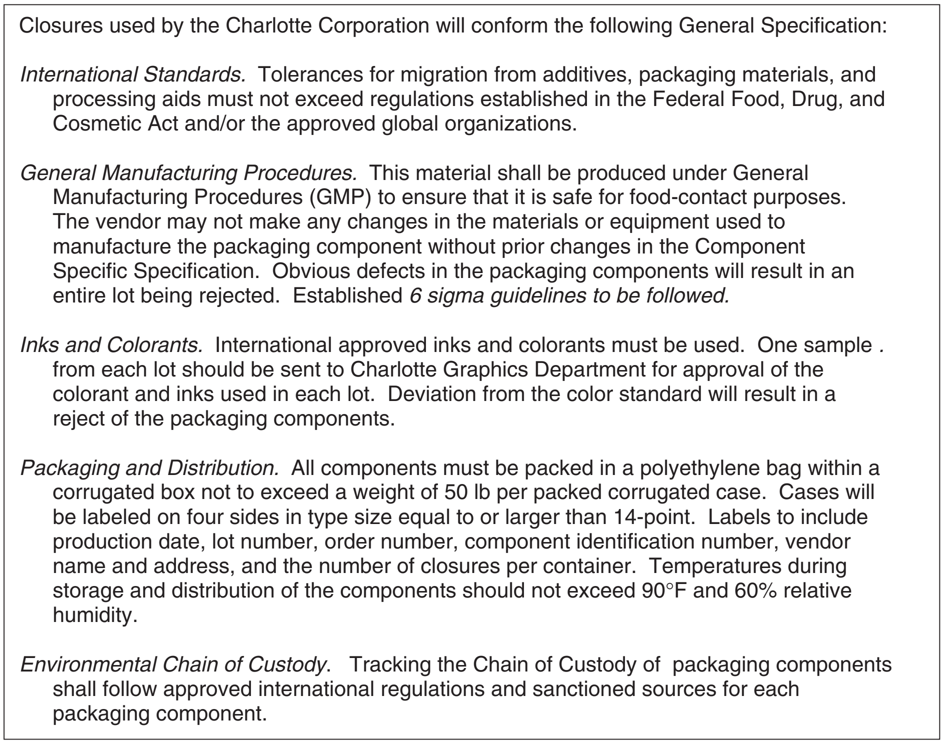
Specifications are, in the simplest sense, the means of communicating information critical to purchasing, production, and distribution functions between the vendor, product manufacturer, customer, and postconsumer disposal, through the entire value chain. Each of these functions requires the assurance that the correct packaging components are purchased and will be appropriately used and distributed to the end consumer and beyond. For this reason, specifications are clear, have extreme detail, and are the focal point for discussions on packaging.

Specifications also reflect the capability of manufacturing methods to attain certain tolerances and parameters. This ability has evolved as the technology to attain and measure specific package component attributes has improved. One example is the use of digital technology as a means of measuring finish and closure threads versus the human eye. In this case, digitized images enable measurements to the nanometer level and we could define measurements to the nanometer in all closures and threads. But, defining all measurements in a specification to the nanometer level is not always appropriate for all packages. This is because tolerances and parameters that are too tight foster unwarranted manufacturing challenges, higher costs, and environmental damage. And, likewise, specifications that are too loose often result in damaged products. Higher costs and slower manufacturing speeds may be justified in one industry (for example, in medical device packaging) and not another (sporting goods). Achieving the optimal tolerances and parameters makes for an efficient operation and allows for the specification to be accepted within the entire value chain.

Today, packaging specification tolerances and parameters are designed appropriately with the entire packaging value chain in mind and enable the incorporation of environmentally friendly practices, use of high-speed manufacturing, and flexible shipping to protect products efficiently for customers.

GENERAL PACKAGING SPECIFICATIONS AND QUALITY PROCEDURES

General packaging specifications are developed with the needs of the end user in mind and relate expectations independent of the supplier of the packaging materials. General packaging specifications are employed to outline characteristics common to all packaging components of the same component type. For example, rigid injection-molded components such as jars, tubs, and closures are within one component type. The purpose of the general specification is to specify general and broad standards and expectations for components that may include items mentioned in Figure 1. Included in the general packaging specification is the expectation that the packaging will be within quality limits such as the now common Six Sigma procedure. Use of Six Sigma defines acceptable ranges and



Closures used by the Charlotte Corporation will conform the following General Specification:

International Standards. Tolerances for migration from additives, packaging materials, and processing aids must not exceed regulations established in the Federal Food, Drug, and Cosmetic Act and/or the approved global organizations.

General Manufacturing Procedures. This material shall be produced under General Manufacturing Procedures (GMP) to ensure that it is safe for food-contact purposes. The vendor may not make any changes in the materials or equipment used to manufacture the packaging component without prior changes in the Component Specific Specification. Obvious defects in the packaging components will result in an entire lot being rejected. Established *6 sigma guidelines to be followed.*

Inks and Colorants. International approved inks and colorants must be used. One sample . from each lot should be sent to Charlotte Graphics Department for approval of the colorant and inks used in each lot. Deviation from the color standard will result in a reject of the packaging components.

Packaging and Distribution. All components must be packed in a polyethylene bag within a corrugated box not to exceed a weight of 50 lb per packed corrugated case. Cases will be labeled on four sides in type size equal to or larger than 14-point. Labels to include production date, lot number, order number, component identification number, vendor name and address, and the number of closures per container. Temperatures during storage and distribution of the components should not exceed 90°F and 60% relative humidity.

Environmental Chain of Custody. Tracking the Chain of Custody of packaging components shall follow approved international regulations and sanctioned sources for each packaging component.

Figure 1. General packaging specifications for injection-molded components.

the use of appropriate standardizations. Concepts such as Six Sigma establish appropriate procedures in order maximize efficiencies, define opportunities for cost reduction, and comply with General Manufacturing Practices (GMP). As shown in Figure 1, the general specification is very vague and further refinement to a component-specific specification is required before the packaging components can be of known dimensions and consistency.

COMPONENT-SPECIFIC SPECIFICATIONS

Component-specific packaging specifications for each package component are developed jointly with the parties involved to ensure both an understanding of compliance to specifications. As a case study, if the incoming packaging is an injection-molded closure (see Figure 2), specifications are developed jointly with the resin, tool molding, closure and liner, capping machine manufacturers, and the end user of the closure. All phases of manufacturing the packaging component leading up to the end user contribute to constructing the specification. In addition, all functions throughout the process are connected to other manufacturers by a quality umbrella that ensures the manufacturers and end user what was specified. All internal quality procedures become part of the specification.

Manufacturing specifications are developed jointly between the suppliers of the packaging component, technology functions, and the production facility. The team identifies critical control points throughout the process where a specification is required. Then a test protocol and a specification range are developed to ensure that the production facility operates within the required range. For example, if a closure needs to have a defined removal torque at 2–6 months to meet guidelines of “openability,” specific removal torque values are written into the specification. Furthermore, the relationship between removal torque at 2–6 months and application torque must be known. So, controlling application torque at the manufacturing level is a critical control point. A correlation between removal torque can be made. For example, an

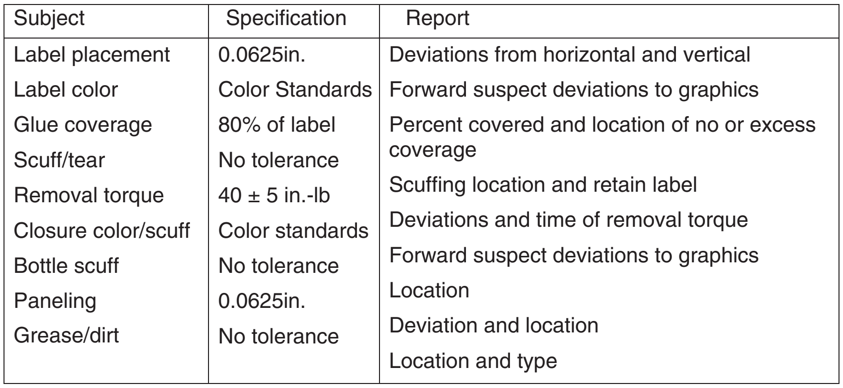
application torque range of 45–50 in.-lb results in a removal torque of 28–30 in.-lb at 2–6 months shelf life. Thus, on-line checks to verify machine settings of 45–50 in.-lb on each chuck are necessary. Sampling frequency is established.

An example of how specifications are derived using a closure specification follows. Let us suppose that the consumers of the end product require that the removal torque on the closure be 28–30 in. lb. between 2 and 6 months of shelf life for “openability.” Quality protocol will define the acceptable variability. This requires the following working relationships within the value chain:

- The approved resin supplier works with resin suppliers to identify a resin that will have low variability of closure thread dimensions. This will translate into less torque variability.
- The mold maker and closure supplier design the tool to accommodate this resin and provide low thread tolerances.
- Quality specifications detailing defects, Six Sigma, and actions to be taken regarding defects are established jointly by the closure manufacture and the end user.
- Closure supplier and capping manufacturer ensure that the capping equipment is designed for the closure and establishes the application torque range to attain the required 28- to 30-in.-lb removal torque.
- Manufacturer of product verifies that the specification is followed via uniform quality checks on retained samples.
- Disposal companies, retailers, and manufacturer facilitate redefined closure disposal, recycling, or reuse.

Achieving the proper the removal torque is accomplished through specifying the optimal resin, tool design, tolerance within the closure and liner material, and ensuring that the capping manufacturer can produce capping equipment to sufficient tolerances. Figures 2 and 3 illustrate a representative component-specific specification for a closure. Figure 2 expands on the general specification shown in Figure 1 and adds details specific to a closure. Each area from the resin selection to the capping is subject to internal quality procedures to verify that the product specified is the product produced.

Finished package specifications provide the final check in the process to verify that the packaging components



Subject	Specification	Report
Label placement	0.0625in.	Deviations from horizontal and vertical
Label color	Color Standards	Forward suspect deviations to graphics
Glue coverage	80% of label	Percent covered and location of no or excess coverage
Scuff/tear	No tolerance	Scuffing location and retain label
Removal torque	40 ± 5 in.-lb	Deviations and time of removal torque
Closure color/scuff	Color standards	Forward suspect deviations to graphics
Bottle scuff	No tolerance	Location
Paneling	0.0625in.	Deviation and location
Grease/dirt	No tolerance	Location and type

Figure 4. Representative finished-goods specification.

were received, were used, and will arrive to the consumer packaged as intended. This is also established using a standard Bill of Materials or similar document. Finished package specifications are developed by the manufacturing facility, marketing, technology, operations functions, and international environmental concerns. Often visual verifications of package compliance are acceptable, but quantifiable scales of acceptance provide a clear image of shift, manufacturing, and location variability. They also ensure a solid data-based framework for decision making. An example of a finished package specification for a package system using the closure specification discussed previously is shown in Figure 4.

CONCLUSION

Packaging specifications and quality procedures extend throughout the value chain to:

- Communicate expectations of quality and consistency.
- Translate specific needs and features of packaging components.
- Provide internal parameters for the appropriate manufacturing of packaging components.
- Convey consumer needs into clear quantifiable specifications.
- Facilitate tracking of components throughout the chain of custody.
- Define appropriate disposal of packaging components.

STANDUP FLEXIBLE POUCHES

Michael J. Greely
Totani America, Inc., Green Bay, Wisconsin

Conventional standup pouches are those with bottom "horizontal" panel gussets, more commonly known as *bottom gussets*. The gussets are heat-sealed to produce flexible bases on which the pouches may stand without support. This base permits the two sidewalls or facewalls to spread at the bottom when the pouch is filled. In effect, standup flexible pouches are three-panel flexible pouches that are self-standing when full or partially full of product heavy enough to bear down on the bottom panel. In most instances, the bottom panel is a separate sheet of flexible material, but some structures fold a single web sheet into a "W" shape and heat-seal a base from this configuration. Standup flexible pouches with separate bottom gussets have been in existence for several decades.

These pouches are very adaptable for packaging of dry products and liquids. In many applications, they are a suitable replacement for other types of packaging, including plastic or glass bottles, cans, and boxes. The advantages of standup pouches for packaging are numerous. They are environmentally sound, offering source reduction of solid waste ranging from 70% to 90% by both weight and volume. The use of pouches reduces the need for recycling, landfill, and/or incineration. Another advantage of standup pouches is that they offer the use of four- to six-color graphics, for improved shelf appeal and acceptance. Standup pouches offer cost savings, with reduced transportation costs. Unlike the shipping of traditional large plastic empty containers, there is no shipping of "air." There is further savings with reduced inventory space and storage costs for containers. Standup flexible pouches take up only one-eightieth of the cubic feet compared to storing an equal quantity of rigid containers (see Figure 1).

Other standup flexible pouch structures employ sidewall folds or side gussets and overlapping flat sheet bases. Because they do not have the bottom gusset, these pouches do not stand up quite as well, and they have been used more successfully for dry products than for liquids. Both types of standup flexible pouches are currently being used and/or considered for dry products packaging.

Conventional flexible pouches can be fabricated with four face-to-face seals, with three face-to-face/one overlap, or with fin seals with a vertical form/fill/seal machine. In any case, they are generally not able to stand independently because they have a single bottom fin seal or fold that brings the face and back panels together. In the standup flexible pouch, rather than a single seal or fold,

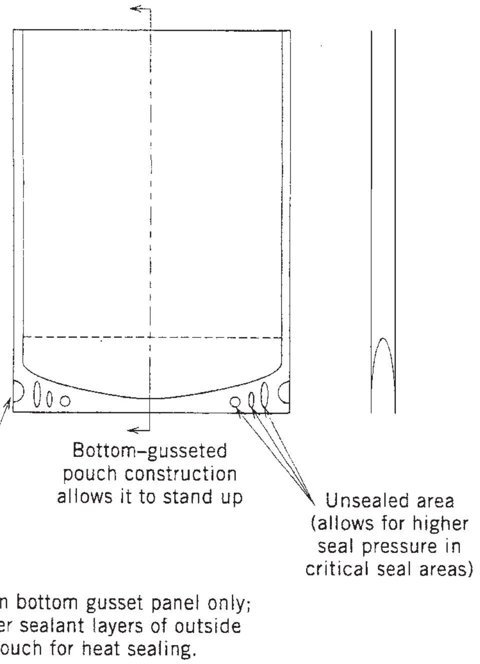


Figure 1. Section view of standup pouch. Unsealed area (allows for higher seal pressure in critical seal areas).

there are two seals: one of the bottom-to-face panel, and the other of the bottom-to-back panel. In unopened form, the bottom gusset panel is generally folded in and hidden. When opened, the bottom panel (or the bottom fins of the expanded face panels) functions as a base on which the pouch stands (see Figure 2).

Standup flexible pouches generally employ two face-to-face fusion side seals and a single face-to-face across-the-top seal in addition to the bottom seals. When viewed from the side, it looks like a distorted triangle with the base of the triangle at the bottom. The across-the-top seals may be interrupted by a spout insert, zipper closure, or other structural devices to facilitate opening, dispensing of contents, and reclosing. The application of spouts and closure devices adds versatility and ease of use to the standup flexible pouches (see Figures 3, 4a,b).

Other flexible pouches that have self-standing capabilities include (a) pouches with side gussets that permit the bottom to fold into a flat position, like a paper grocery sack, and (b) those with four-corner side seals to actually form a rectangular solid shape from several webs of flexible materials. In such pouches, the product itself and not the package provides the rigidity to impart the standup feature (see Figure 5).

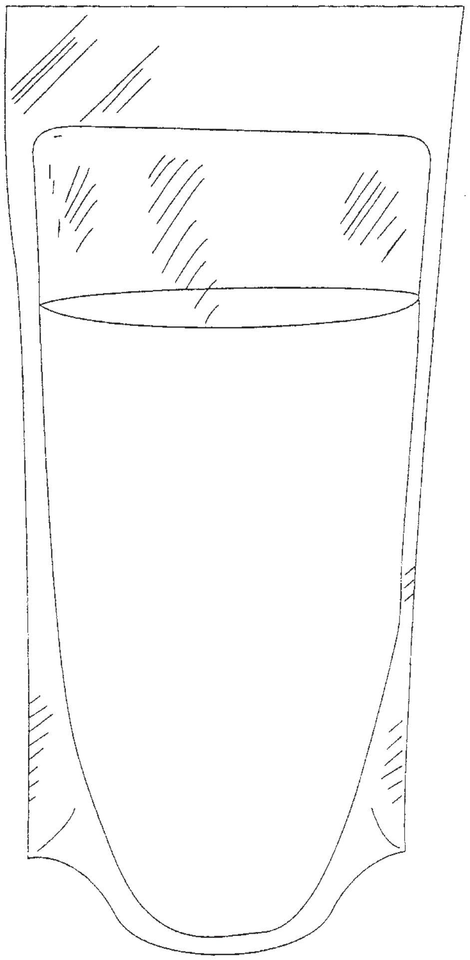

Figure 2. When standup pouch is filled, the bottom gusset opens or expands. Bottom of side panels function as base of pouch.

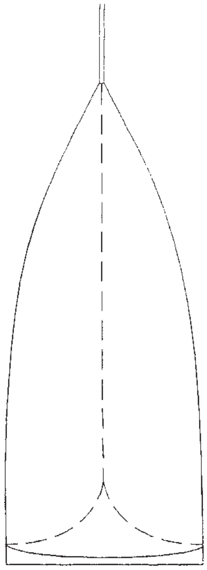

Figure 3. Section view of unopened and filled standup pouch.

HISTORY

Historically, standup flexible pouches have been in existence commercially for about 50 years. The first pouches were developed by French machine maker Thimonnier. In fact, standup flexible pouches are often generically (and erroneously) called Doy Packs after their inventor, M. Louis Doyen, majority shareholder of Thimonnier.

By the end of the 1960s, preformed standup flexible pouches were being used in the United States for sugar candies and in Europe for olives in brine and for wine, among the earlier applications of such pouches for liquid contents. During the early to mid-1970s, the standup flexible-pouch concept was applied to the European-initiated Capri Sun, a shelf-stable fruit-flavored beverage. Capri Sun marked the first major application of standup flexible pouches for liquid product contents.

Relatively few new applications appeared until the mid- to late 1980s, with the reemergence of environmentalist pressures for package source reduction. German liquid detergent manufacturers converted polyethylene bottles into standup flexible pouches. By this time, Thimonnier had developed machines that could produce and fill standup pouches directly from rollstock. Other manufacturers had also developed horizontal form/fill/seal machines for standup pouches, although the majority of liquids were still packaged in premade standup pouches (see “ 2” section). The detergent packaging was reasonably successful in Germany, where strict environmental regulations were already in effect. The same concept, although offering environmental and economic benefits, has not been as successful in North American markets.

Actually, standup flexible pouches found greater commercial success in Japan than in Europe during the 1980s, spear-headed by Fujimori.

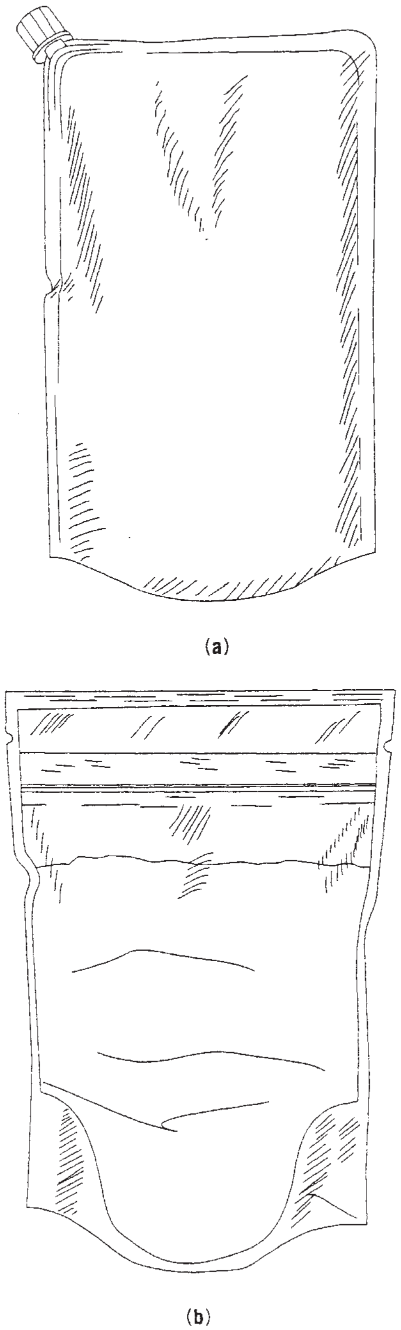

Figure 4. Standup pouches with (**a**) reclosable pour spout and (**b**) reclosable zipper.

TECHNOLOGY

All standup flexible pouches are not alike. In general, they may be classified as one of the following types:

1. *Preformed Pouches.* Pouches are made on a separate converting machine and delivered to a packager in ready-to-open, fill-and-seal form); often with dispensing spouts and zippers already built in.
2. *Horizontal Form/Fill/Seal Pouches.* Pouches fabricated in-line by the packager from flexible roll stock materials on machines that fold the sidewalls and die-cut openings for heat-sealing into the bottom section (see Form/fill/seal, horizontal).

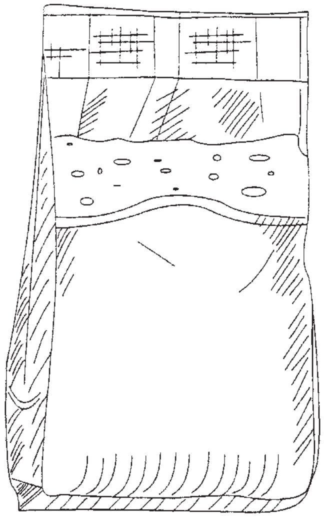

Figure 5. Side-gusseted pouch.

The most widely used standup flexible pouches for liquids are made from preformed pouches produced by flexible package converters using laminated film structures. Most standup pouch flexible-material constructions are relatively simple webs, such as trap-printed polyester film plus an interior stiffener/sealant of low-density or linear low-density polyethylene (LDPE or LLDPE). Effecting a seal in the pouch requires polyethylene-to-polyethylene or analogous fusion heat sealing. The sealing of the bottom-web material to the two face webs requires that the heat sealants face each other, which dictates die cutting large openings in the bottom material (see Figure 1).

Positive sealing is essential for liquid containment because liquid is pressing against the base heat seals. Of significance is the hydraulic pressure exerted by the liquid against the bottom seals, particularly when there is an impact or a drop, and the liquid exerts a sudden high force against the heat-seal area. Thus, although the thick gauges of polyethylene sealant serve to enhance the standup feature, an important reason for their presence in such quantities is to provide sufficient strength to resist hydraulic shock. This problem also justifies the preferred use of LLDPE, which has greater stress resistance than does low-density polyethylene. Many pouches use a nylon cast or biaxially oriented film/polyethylene lamination as the bottom gusset.

In earlier years, the materials employed included nylon film as well as, or in place of, polyester film, plus exterior coatings. The materials for consumer-size pouches now are largely polyester/polyethylene combinations that have proved satisfactory in commercial practice. Output speeds of intermittent motion preformed pouchmaking machines today are always faster than those on form/fill/seal machines because of multilane possibilities as well as the limiting factors of filling and sealing on the filling machines. Furthermore, it is easier to incorporate dispensing and other fitments on separate converting equipment than on in-line form/fill/seal equipment. Preformed pouches, to date, have tended to be more reliable in distribution performance than in-line-made form/fill/seal pouches. Because of this reliability factor, most liquid-containing standup flexible packages to date have used preformed pouches. Since many different fill/seal machines beginning with preformed pouches are commercially available, preformed pouches have commonly been used.

STANDUP FLEXIBLE-POUCH MACHINERY

In general, there are two types of machines for producing standup pouches: preformed pouchmaking machines and horizontal form/fill/seal machines.

Preformed pouch machines are used by converters to make standup pouches that are supplied to a packaging company that will fill the pouch through the open top. These machines utilize single-wound laminated (nonextensible) rollstock. They make pouches in either (a) two lanes of production, for pouches smaller than approximately 7 in. × 11 in, or (b) one lane of production, for pouches larger than 7 in. × 11 in. The same pouch machines can add zipper reclosures and easy-open features, or can be used to make conventional three-side-seal pouches. Some pouch machines use a separate bottom gusset web and can then easily manufacture in two lanes ("2-up" or two pouches at one time). Other machines use one web and plow the bottom gusset into the center-folded material, but are limited to one lane of production.

The advantages of using the preformed pouch are its superior seal integrity and the ease of adding a reclosure feature, such as the reclosable pour spout. Preformed pouch equipment is used more often for packaging liquids and for small-market-niche products.

Packagers utilize form/fill/seal machinery to fabricate and fill the standup pouch. Again, single-wound laminated sheeting is used on the machine to form the pouch and then fill and seal it in-line. This is known as a *one-step operation*, while the preformed pouches must be shipped from the converter to the packager for filling and sealing in a second operation.

The form/fill/seal (one-step) operation offers economies to the packager. Even though the speeds of the pouch-forming operation are typically much slower than those using preformed pouches, the fact that all operations are done in-line saves on storage and labor costs. Standup pouch form/fill/seal machinery is more typically used for the packaging of large-volume, dry granular products such as nuts and snacks (see Form/fill, seal horizontal and vertical).

USE OF STANDUP FLEXIBLE POUCHES WORLDWIDE

The worldwide use of flexible standup pouches, exclusive of Capri Sun, was about 700–900 million in 1993, with the largest fraction being in Japan, with the grand total in the 3–3.5 billion range. There was limited but steady growth during the mid- to late 1990. During recent years, 2005 to 2007, Standup pouches have been growing at a steady rate.

The introduction of the flat bottom standup pouches began in late 2005. The flat-bottom pouch can be made as a relacement for rigid and semirigid packages. The year 2007 has seen the format grow in human and pet food applications. This format is expected to grow steadily into the future.

The following is a discussion of the use of standup flexible pouches throughout the world, broken down by area.

North America

Package material source reduction was a major factor behind the development of product packaging in standup flexible pouches in the United States and Canada. Although there is really no practical way to recycle the standup flexible pouch itself, the initial package reduces material use and results in less material going to the landfill. Standup flexible pouches offer the potential for up to 80% package mass reduction for liquid products such as household laundry products, window cleaners, chemicals, detergents, fabric softeners, lotions and creams, and shampoos. Packagers with environmental concerns began to investigate and test standup flexible pouches that had been commercialized in Germany in the mid-1980s. Using structures of polyester film and sometimes nylon film plus LLDPE and a variety of European packaging equipment, packages were introduced as environmentally "friendlier." A popular application was as a refill for high-density polyethylene (HDPE) bottles.

The first use of a large-size standup flexible pouch in the United States was for evaporated milk. It was retorted to achieve ambient temperature shelf stability.

Standup flexible pouches appear to have effected a more successful entry into the Canadian market for liquid laundry products under the umbrella of being environmentally more "friendly." Some of these laundry products are packaged in the United States. Other products being marketed in standup flexible pouches in Canada include hair shampoo/conditioner, motor oil, and liquid household cleaner.

Europe

Among the products being packaged in standup flexible pouches in Europe are liquid detergents, fabric softeners, shampoos, hand creams, windshield-washer fluids, and latex paint in $\leqslant$5-L sizes. Standup flexible pouches represent a rather large usage for liquid packaging in Europe.

Most European standup flexible pouches for liquids are premade and appear to be three-piece, using 12-μm (0.00048-in.) PET film/0.004- to 0.006-in. LLDPE for the two major faces and the softer, stronger nylon film/LLDPE or PET/LLDPE for the bottom panel. Thus, the flexible structures for standup flexible pouches are not especially unique or difficult to fabricate.

Latin America

In Latin America, standup flexible pouches have been well-received. One reason is the apparent low cost of flexible materials versus their semirigid plastic package counterparts. The pouches have become established in a number of food markets, including mayonnaise, mustard, ketchup, salad dressings, and hot-filled jams and jellies in the fluid category, as well as for dry (powdered) gelatin desserts, syrups, toppings, rice, and analogous flowable dry products. In the nonfood category, several companies pack liquid fabric softeners and detergents in standup flexible pouches. Capri Sun is also present in the Latin American market. The number of standup flexible pouches in Latin America is estimated to be in the 200-million-unit range.

Japan

Almost all are preformed pouches fabricated from polyester film/aluminum foil/cast polypropylene film, with some in glass-coated polyesters as the barrier, packaged on several different types of equipment. A few of the aluminum foil laminated standup flexible retort pouches are distributed in the United States.

In Japan, several supply companies developed both equipment and materials that allowed for a relatively healthy market niche for liquid food products. The concept was so well engineered that it could be applied for retort pouches of low-acid fluid foods and beverages such as milk.

India

Prominent uses include dry rice, motor oil, and related automotive fluids. Environmental factors once again play a role in the choice of pouch packaging. Motor oil represents a significant environmental solid-waste problem, since the conventional extrusion blow-molded HDPE bottles are not recyclable. Large numbers of semirigid bottles become part of the municipal solid-waste stream. The incorporation of motor oil into flexible packages helps reduce this package mass.

ECONOMIC ISSUES

Historically, the standup flexible pouches have not offered lower packaging costs, although this has now begun to change. The actual costs of the standup flexible pouches with liquid dispensing spouts have been more than double the cost of extrusion blow-molded plastic bottles with labels and closures. Another added cost is importing from Europe, Israel, and even Japan. Thus the expected cost savings initially did not materialize, and, in fact, they were negative or at best even. In late 1993, however, a significant change in the costing situation emerged as domestic sources for both preformed and form/fill/seal standup flexible pouches began to develop. In the United States, the costs have come down considerably and are now competitive with the costs for more traditional packaging, such as an extrusion blow-molded HDPE bottle. On the horizon, however, is the ability of plastic bottle blowers to reduce the wall thicknesses and hence the package mass and the economics even more—and, of course, their increasing use of postconsumer scrap plastic for nonfood/cosmetic contents.

Yet another major problem is that all automatic standup pouch flexible-packaging equipment is much slower than bottle-packaging equipment, some down to 25–30 one-liter units per minute. Maximum output speed for any standup pouch flexible packager is in the range of 120 per minute. Most bottling lines for liquid household products begin at 100 and go up to 400 bottles per minute, with some even higher.

Some pouch equipment manufacturers are developing higher-speed machines, with speeds of $\geqslant 400$ per minute. This new equipment will generate greater attention for standup flexible pouches for liquid packaging.

Standup flexible pouches have almost zero vertical compression strength and thus must be totally protected by higher-cost and higher-package-mass secondary and tertiary packaging in distribution. Furthermore, standup flexible pouches are much more difficult to handle than their bag-in-box equivalents.

Another key to the use of standup flexible pouches is a lack of equipment to handle and unitize the pouches into secondary and tertiary packages. Much of the North American output is actually hand-packed into corrugated fiberboard cases. On the other hand, equipment for utilizing flexible pouches is commercially available.

The standup flexible liquid-content pouch market is relatively small, representing only about 1% of the total of all flexible pouches.

STAPLES

J. R. Charters
Paslode Corporation

INTRODUCTION

In packaging, staples are used to assembly wooden pallets, skids, and boxes and crates (see Boxes, Wood). In

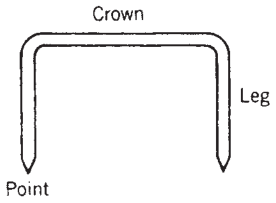

Figure 1. Three basic parts of the staple.

fastening wood to wood, the relatively heavy shank of a nail provides greater shear strength, but staples provide greater holding power because their two legs provide more wood-to-metal contact surface area. Staples are used as a replacement for nails in many applications including furniture, housing, fencing, etc, but the following discussion focuses on packaging applications only.

The staple has three basic parts: the crown, two legs, and two points (see Figure 1). In selecting the proper staple, four factors must be considered: wire size (gauge), crown width, leg length, and type of point.

WIRE SIZE

Heavy-duty staples are designated by the gauge (ga) of the wire prior to manufacturing the staples.

$$16\,\text{ga} = 0.062\,\text{in.} = 1.587\,\text{mm}$$
$$15\,\text{ga} = 0.072\,\text{in.} = 1.829\,\text{mm}$$
$$14\,\text{ga} = 0.080\,\text{in.} = 2.032\,\text{mm}$$

In packaging applications, 16-gauge is the most common. Heavier-gauge staples are used if a particularly strong combination of holding power and shear strength is required, as in the assembling of some heavy-duty skids. Lightwire staples are designated by the width of the wire after manufacturing; for example, “30” is equivalent to 0.030 in. (0.762 mm) finished width; “50” is equivalent to 0.050 in. (1.270 mm) finished width. A “50” staple is heavier and more power is required to drive it.

CROWN WIDTH

The widths most common in packaging are shown in Figure 2.

The staple used most frequently for packaging applications is the heavy-duty 1/2 -in. (1.3-cm) crown. The wide-crown 15/16-in. (2.4-cm) heavy-duty staple is used to prevent pull-through on attachment of porous materials—for example, fastening a corrugated box to a wooden skid. The wide-crown staple is also used over steel strapping to secure it in place. Lightwire staples are used to attach identification tags to the outside of wooden boxes. Plastic liners are attached to boxes with lightwire staples as well. These are just a few of the numerous applications for heavy-duty and lightwire staples in packaging.

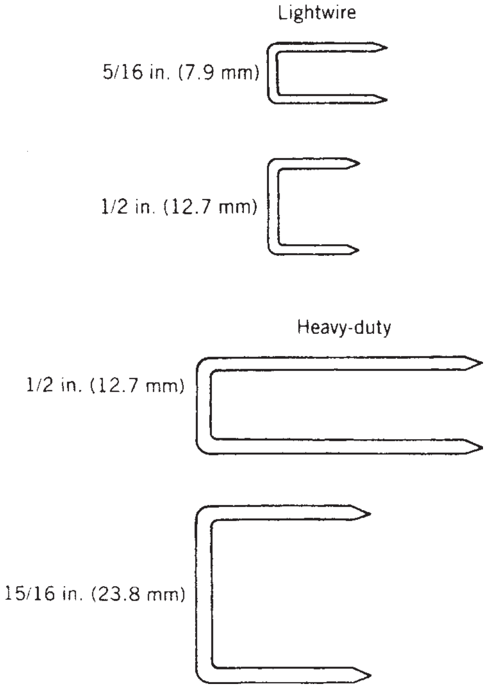

Figure 2. Common crown widths.

LEGS

A staple has two legs of equal length. The staple must be long enough to penetrate the receiving member with sufficient length to adequately hold two pieces of material together. The stress of the application must be considered in order to determine the minimum allowable penetration of the staple in order to do the job.

POINTS

Staple points are cut at different angles to meet various application requirements (see Figure 3). A divergent point causes the staple legs to divert in opposite directions when it is driven into the wood. This type of point is advantageous when clinching is required. Clinching is the process of bending the staple points over the opposite side of the work piece. The staple legs penetrate the wood members then strike a steel plate diverting the points back into the wood. The chisel point, which is designed to cut through the wood without diverging, is the most common in the industry.

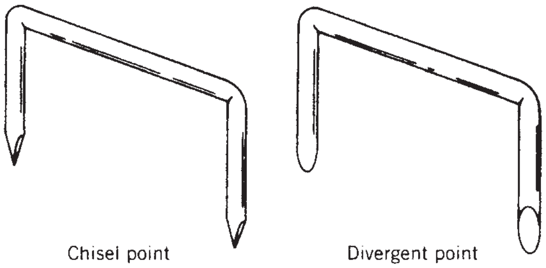

Figure 3. Staple points.

STATIC CONTROL

H. Sean Fremon
Cole Static Control, Inc., Akron,
Ohio

Since its inception in the packaging industry approximately 80 years ago, static control has become an integral part of packaging processing. As machinery speeds have increased and materials have changed from paper to plastics and combination laminates and coatings, the need for static control has rapidly expanded.

As a result, the last 10 years have seen the greatest increase in the use and development of static control products to enhance manufacturing processes.

Static is the excess or deficit of electrons on a material. A regular nonpolar atom has a nucleus with a positive charge and negatively charged electrons orbiting it. When one atom comes in close proximity to another, electrons from the orbit draw or tear away electrons, leaving one atom with an excess of electrons and the other with a deficit. This process, called ionization, leaves the atom with the excess carrying a negative charge, while the one with the deficit carries a positive charge.

CAUSES OF STATIC

Static in packaging manufacturing is caused by friction, separation, heat change and improper grounding. Packaging and material handling equipment often incorporate a combination of these to accomplish its function.

Friction

Static is most commonly caused by friction, the rubbing of two materials during packaging processing. When a plastic substrate in web form rubs over a steel roller, or when a pouch is shaped around a forming collar on a vertical form fill seal machine, for example, the plastic picks up the negative charge while the steel roller carries the positive charge. Because metal is such a good conductor, however, the positive charge is bled off. The charge on the plastic is not.

Table 1 shows the likely relative polarity a material will exhibit if it is rubbed with another. The material higher on the chart will hold a positive charge, while those in the lower positions will hold the negative charge.

Separation

When material separation occurs, such as the unwinding of packaging material on a form–fill–seal machine, static charges are produced at the tangent of the unwind. This can result in very high charges that attract dust and contaminants and can cause operator shock hazards. Anyone who has handled Scotch tape may recognize this phenomena. As a piece of tape is pulled off its roll and the tape wraps around itself, it becomes difficult to handle because static has occurred from the separation.

Heat Change

The change in heat during the thermoforming, injection and blow molding of packaging products can cause static charges. As plastic is melted to shape and removed from its appropriate tooling, it undergoes a cooling process that can add more static to existing products. As a part cools, its charge increases and can draw existing dust from the plant atmosphere. In extreme situations, the dust can draw to the product surface and adhere to the hot part, making it nearly impossible to remove later. If the parts undergo additional manual operations, such as bottle printing or container sealing, operators are susceptible to shock (see also Thermoforming).

Improper Grounding

One of the common misconceptions in static control is that if a machine is grounded, no static can be present. However, despite grounding efforts from the material to ground, there can be blocked passages in the form of greased bearings, poor metal-to-metal connections and charges too high to be properly grounded. Because many packaging products are insulators, partial static reduction can be attained, but full grounding is impossible.

Results of Untreated Static Electricity

The development of static-related problems are often inevitable in the manufacturing environment and can lead to a variety of different problems.

Production Problems and Slow Downs

A static charge generates an electrical field that acts like a magnet, repelling similar charges and attracting opposite or neutral charges. This accounts for the attraction between charged materials and machine frames or rollers causing machine jams. In many cases, the machine operator will be forced to run at slow speeds to avoid the problems caused by static.

Dust Attraction

Many products, such as plastic molding materials and film, develop high static charges on their surfaces. This highly charged surface will attract airborne dust, sometimes from more than three feet away, and hold it tightly to the surface. This can lead to high scrap rates. Subsequent operations (such as molding, printing, or laminating) and their end products can be seriously affected by such difficult-to-remove contamination.

Shocks to Personnel

When handling highly charged material, people receive unpleasant shocks either directly from material or indirectly. This can become a safety issue if the operator, after being shocked, recoils into other moving machinery in the plant.

Fires and Explosions

Static is usually found on nonconductive materials where high resistivity prevents the movement of the charge. There are at least two situations where the static charge an move quickly and be dangerous in a combustible atmosphere. The first is where a grounded object intensifies the static field until it overcomes the dielectric strength of the air and allows current to flow in the form of a spark. The second case is where the charge is on a floating conductor such as an isolated metal plate. Here the charge is very mobile and will flash to a proximity ground at the first opportunity.

Damage and Interference in Electronic Components

Strong static fields and static discharges can cause interference with electronic equipment. This can cause metal detectors to malfunction, ink-jet printer boards to burn out, and weighing equipment to give false readings.

TYPES OF STATIC CONTROL DEVICES

Active/Electrical Ionizers

Active electrical ionizing equipment, one of the most effective ways of eliminating static charges, is seen in nearly every large packaging plant that processes plastic or paper at high speeds. These units create ionization by forcing high voltage to ground and breaking down air molecules in between into low levels of ozone. This makes available millions of free positively and negatively charged ions and effectively “feeds” away the static charge by “matching up” ions of opposite charges. Active ionizing equipment comes in many shapes and sizes, including alternating current (ac) bars or rods, blowers, nozzles, and air curtains, steady-state direct current (dc), and pulsed dc units.

Electrical ionizers are driven by power supplies, which transform 110 V or 220 V into voltage ranging from 4500 V to 14,000 V while lowering amperages to a safe level. This equipment is normally custom manufactured and retrofit to the machine it serves. If this equipment is not employed properly, it is useless in packaging applications.

Many bar- or rod-type units are used in web and sheet-based applications, while air-driven units are used for static control on asymmetrical parts such as closures, jars, or thermoformed packages. Most electrical ionizers cannot be used in hazardous areas.

Static Bars. Static bars are most often used in web-based applications in the packaging industry. This equipment is necessary on many form–fill–seal, overwrapping, tamper evident sealing, and stretch wrapping machines. Bars are normally placed within close proximity to the web and do not require any air to operate. Most bar-type ionizers must be within three in. of the substrate as it passes beneath the bar(s).

Air Ionizers. Air ionizers, driven by small fans, compressed air or large blowers for large parts, are used for static control on asymmetrical products. In conveying, unscrambling, filling, denesting, and sorting operations, air ionizers may be necessary to prevent parts from sticking together, prevent operator shock, or eliminate dust attraction.

Nozzles, Guns, and Pinpoint Ionizers. *Nozzles* are used in packaging to clean packaging products and to eliminate static and dust. An example of this is during composite can cleaning. Ionizing *guns* are used in more manual environments where cycle times afford the luxury of cleaning each unit. *Pinpoint ionizers* are used in powder filling, for example, when a small area must be ionized with a small piece of equipment. Powder filling operations often use pinpoint ionizers to discharge materials.

Steady-State DC. Steady-state DC generators allow the production of a desired polarity, positive or negative or both, which makes them ideal for high-speed webs where the polarity of the material is known. This allows control of static with higher voltage where conventional lower-voltage AC static control is less effective.

Pulsed DC. Pulsed DC controllers allow adjustment of positive and negative ions and control of the frequency of ions, in hertz, that the unit produces. This type of equipment is used in clean room and benchtop applications where the use of air is not allowed or where large areas need to be ionized. A “cloud” of ions is produced, making it ideal for hand packaging of medical devices, for example.

Passive

Passive static control incorporates grounding and conductive materials. Gold and silver are excellent conductors but cost-prohibitive. Carbon fiber, stainless steel, and phosphor bronze are more commonly used passive static control devices in the packaging industry. However, tinsel remains most commonly seen because of its low cost and availability. It is recognized by its similarity to Christmas garland. Tinsel is usually loosely tied to the frame of a machine’s ground. Its effectiveness is considered mixed, but if it reduces static to an acceptable level, it does away with the need for more expensive electrical ionizers.

Nuclear Ionizers

Nuclear ionizers, radioactive ionizing devices, incorporate polonium-210, an alpha-emitting isotope. When the alpha particles collide with an air molecule, it creates thousands of positive and negative ions without the use of electricity.

This makes nuclear ionizers ideal for explosion-proof environments where electricity cannot be used and the possibility of an electrically related spark can exist. Coating and chemical packaging are examples of plants where nuclear ionizers must be used for static control. Most nuclear ionizing units have an active life of approximately one year, after which they must be returned and refilled.

The Nuclear Regulatory Commission requires yearly registration of these devices, which must be continually leased instead of owned. The cost of leasing nuclear static control devices versus buying electrical ones is much higher and can make them cost-prohibitive. If a nuclear unit is damaged, the site can be susceptible to strict clean-up requirements by the NRC.

Static Generators

Static generators are used to temporarily bond materials together, generally in web handling processes. Static generators work the same way as static eliminators, except that a ground is not present locally. It is placed on the opposite side of the materials passing between forcing two substrates to accept the ionization, thereby pinning them. Static generators operate on DC, allowing polarity control in packaging operations. Examples of static generator use in the packaging industry include air bubble removal, overwrapping, laminating, in-mold decorating, and heatshrink packaging.

Static control devices, when used properly, can make a great deal of difference in production efficiency and overall costs. It is important that you meet face-to-face with your static eliminator supplier or know your application well when you are specifying or purchasing to assure the equipment is necessary and correct for the application intended. When ionizers results are minimal, it is usually because equipment is improperly placed or the wrong equipment is being used.

In the packaging industry, static “problems” are relative. In one plant, such as a plastic bag converting plant, charges of 10,000 V may be barely noticed. In another plant, such as a medical device packager, charges as low as 1000 V may be attracting airborne dust and foreign matter. It is important to know what actions can be taken to remove existing problems relating to static and to what extent they will enhance the packaging manufacturing and material handling operations.

STRUCTURE/PROPERTY RELATIONSHIPS OF PACKAGING MATERIALS

Kit L. Yam
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

The properties of materials are closely related to their structures. This article provides an introductory understanding of the structure/property relationships of packaging materials. Four levels of atomic and molecular structures are discussed: (a) *chemical constituents*, what atoms are composed in the material; (b) *chemical bonding*, what forces hold the atoms together to form a molecule; (c) *intermolecular forces*, what forces attract molecules together to form a material; and (d) *spatial arrangements*, how molecules are arranged in three-dimensional space. Although each level has distinct characteristics, the four levels are closely related, with each level affecting the sequential levels in determining the observed material properties.

In a large sense, the first two levels of structures—chemical constituents and chemical bonding—are responsible for the chemical properties of the materials. Chemical properties determine the sensitivity of a material to chemical changes, which involve breaking chemical bonds to transform part or all of the original material into new substances. Examples of chemical changes important to packaging include oxidation, corrosion of metal containers, and incineration of packaging wastes. However, the last two levels of structures—intermolecular forces and spatial arrangement—are responsible for the physical properties of materials. Physical properties determine the physical behavior of a material under conditions, such as heat, pressure, and concentration gradient, which do not involve breaking chemical bonds and forming new substances. Examples of physical properties important to packaging include gas permeation through package walls, migration of volatile compounds from package to food, and shock and vibration during distribution.

Table 1. Chemical constituents, chemical bonds, and intermolecular forces in packaging materials

Material	Commonly found atoms	Chemical bond	Intermolecular forces
Plastics	Major: C, H Minor: O, N, Cl, etc.	C–C backbone, ionic	van der Waals forces
Paper	C, H, O	Covalent	van der Waals forces
Glass	Major: Si, O Minor: Na, K, Ca, Al, etc.	Covalent, ionic	Ionic solid
Metals	Major: Fe, Al Minor: Cr, Sn, etc.	Metallic	Coulombic forces

CHEMICAL CONSTITUENTS

The first level of structure considers the chemical constituents, which are the atoms composed in the packaging material. These atoms determine what type of chemical bonds can be formed and what chemical properties can be expected. In general, consumer packages are constructed of four basic types of materials (plastics, paper, glass, and metals) with chemical constituents shown in Table 1. It is important to note that plastics and paper are carbon-based organic materials, whereas glass and metal are inorganic materials, because this categorization has profound implications on their properties, sources of raw material, manufacturing technologies, and economic value. Like most organic materials, plastics and paper are inherently lighter, weaker, and more susceptible to chemical reactions than inorganic materials such as glass and metals.

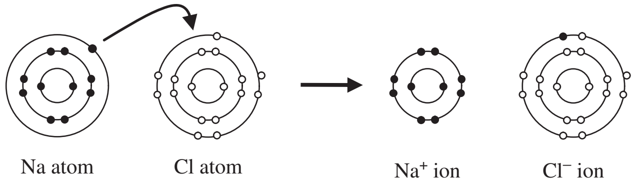
Although most packages are made of single materials, some packages are made of two or more different materials to provide the necessary functionalities for certain applications. For example, aseptic cartons for milk and juices are made of a laminate consisting of 70% paper, 6% aluminum (Al), and 24% polyethylene (PE). The typical structure of the laminate is PE/paper/PE/Al/PE, in which the paper layer provides strength and stiffness, the thin aluminum foil layer provides gas and light barrier; the polyethylene layers provide inner and outer protection, heat sealing, and binding between paper and aluminum.

CHEMICAL BONDING

The second level of structure is chemical bonding that determines how atoms are bound together to form a molecule. A chemical bond is formed when the outermost electrons from two atoms interact with each other to achieve a lower and more stable energy state. These interactions involve sometimes the transferring of electrons to form ionic bonds and sometimes the sharing of electrons to form covalent bonds or metallic bonds, depending on the electronegativities of the atoms (i.e., their abilities to attract electrons). Ionic, covalent, and metallic bonds are known as primary bonds, which are characterized by strong bond strengths as shown in Table 2.

Some properties of materials generally associated with the different types of chemical bonding are shown in Table 3.

Ionic Bonding. An ionic bond is formed when two atoms come together to transfer one or more electrons between each other. For example, a sodium atom will transfer an electron to a chloride atom to yield a Na^+ ion and a Cl^- ion:



The electrostatic attraction binding the oppositely charged ions together is known as the ionic bond.

Formation of an ionic bond occurs between two atoms of greatly different electronegativities. Typically, one atom is a metal (such as Li, Na, Al, or Fe) because of its tendency to donate electrons, and the other atom is a nonmetal (such as O, F, S, or Cl) because of its tendency to accept electrons. Ionic materials are strong, hard, brittle, and resistant to aggressive chemicals, and they also have a high melting point.

Compared with covalent and metallic bonds, ionic bonds are found less commonly in packaging materials. Nevertheless, ionic compounds are found in protective layers for packaging applications, such as alumina (Al_2O_3) on foil and tin oxide (SnO_x) on tin plate. Ionic bonds are also found in ionomers, which are copolymers that contain both ionic and nonionic repeat units. Shown below is the chemical structure of Surlyn (DuPont, Wilmington, DE), which is an ionomer polymer (see the Inomer article) that contains a small portion of

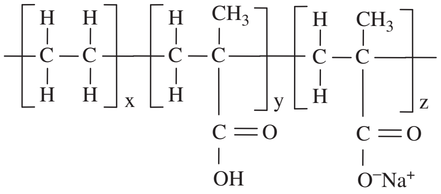
Table 2. Typical bond strengths of chemical bonding and intermolecular forces

	Interaction type	Bond energy ($kJ\,mol^{-1}$)
Chemical bonding	Covalent bonds	200–800
	Metallic bonds	100–400
	Ionic bonds	40–500
Intermolecular forces	Hydrogen bonds	4–40
	Dipole–dipole forces	0.15–15
	Ion–dipole	5–60
	Dispersion forces	0.4–4

Table 3. Properties associated with chemical bonding

Property	Ionic bond materials	Covalent bond materials	Metallic bond materials
Melting and boiling points	High melting and boiling points because of strong attractions between atoms (ions)	Relatively low thermal transition temperatures caused by weak attractive forces between molecules	High melting and boiling points caused by attraction of metal ions with the delocalized electrons
Electrical and thermal conductivity	No electric conductivity and poor thermal conductivity because of the absence of mobile charged particles	The electron sharing makes the electrons tightly bound to atoms, thus no charge available for conductivity	High conductivity because of easy transmission of vibration energy through the "electron cloud"; metallic luster coming from free electrons
Mechanical properties (hardness and brittleness)	Generally hard because the ions are strongly bound to the lattice; also often brittle because of strong repulsion between equal charges at close proximity at the distortion	Generally soft because the intermolecular bonds are weak and easily displaced	Dense, hard, and strong with tightly packed atoms in the lattice; malleable and ductile as the distortion is possible without disrupting the interatomic bond

methacrylic acid partially substituted with Na in its carboxyl group:



$$-\!\left[\mathrm{CH_2{-}CH_2}\right]_x\!-\!\left[\mathrm{CH_2{-}C(CH_3)(C{=}O)OH}\right]_y\!-\!\left[\mathrm{CH_2{-}C(CH_3)(C{=}O)O^-Na^+}\right]_z\!-$$

The ionic groups in an ionomer may interact each other to form a cluster with ionic bonds as shown in Figure 1. This type of bonding may be considered partly as intramolecular bonding and partly as intermolecular interaction. The ionomer is used as sealant between a plastic layer and a foil in packaging applications where excellent heat sealability and hot tack are required.

Metallic Bonds. Metallic bonds are found in aluminum foil, metal containers, and other metal-containing packaging materials. Atoms in metal typically have low electronegativities and are willing to share electrons freely, not only with neighbor atoms but also with all other atoms in the lattice. For example, Figure 2 shows the formation of metallic bonding, when aluminum atoms lose their outer electrons, become positively charged Al^{+3} ions, and those electrons in turn form a "sea of electrons" to surround the regularly spaced Al^{+3} ions. It is important to note that the electrons in metallic bonds are "delocalized" or free, which means that they are nondirectional and free to move in all directions in the lattice, unlike the electrons in covalent bonds that are bound to specific atoms and locations.

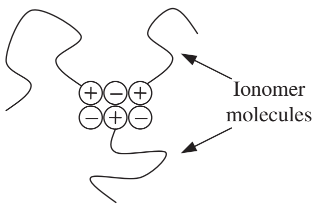


Figure 1. Ionic interactions in ionomer molecules.

Metallic bonds are largely responsible for the strength, malleability, and ductility of metals. Malleability is the ability to be hammered into various shapes; and ductility is the ability to be drawn out into thin wires, whereas the shape of the material is changed without cracking or breaking in both cases. Therefore, a metallic material such as an aluminum sheet may be rolled into a thin aluminum foil, or an aluminum disk may be hammered into cups used for the popular soda cans.

To explain why metallic bonded materials are malleable and ductile, Figure 3 shows several layers of metal ions held closely together.

Although strong, metallic bonds are not bound to specific metal ions. Hence, forces from hammering or stretching can cause layers of metal ions to slide over each another. As the metal ions move, they also attract the delocalized electrons to their new locations, whereas the sea of electrons is not broken and still holds the metal ions together.

Metallic bonds are also responsible for high electrical and thermal conductivities of metals. The high electrical conductivity may be explained by the ability of the delocalized electrons to flow freely in the lattice of positive metal ions when a voltage is applied. The high thermal conductivity may be explained by the ability of metal ions to absorb heat energy by vibrating faster. Because the metal ions are closely packed in the lattice, the faster vibrating ions can collide with their neighboring ions to transfer the heat energy.

Covalent Bond Model. Covalent bonds are the most abundant chemical bond found in plastics, paper, and glass. A covalent bond is formed when two atoms come together to share their outermost electrons. Typically, these atoms have high and similar electronegativities, which means that they have strong affinity to electrons and are willing to share them with their partner atoms. These atoms are from nonmetal elements (such as C, O, N, and Cl) located on the right side of the periodic table. As an example, shown below are two oxygen atoms sharing

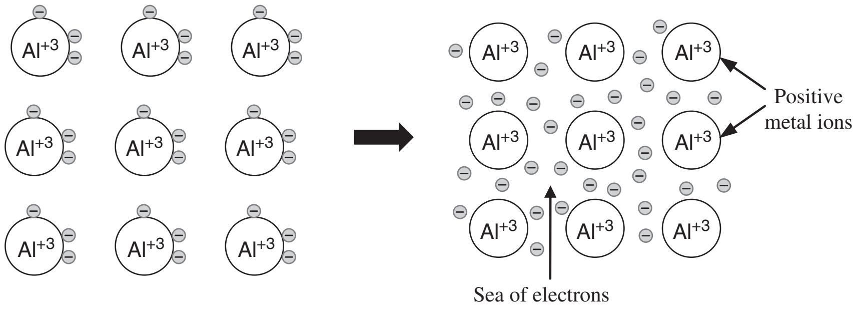

Figure 2. Formation of metallic bonding.

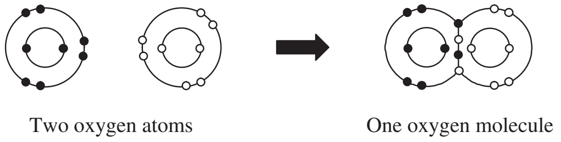
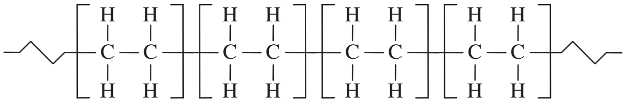
two pairs of outermost electron to form an oxygen molecule joined by a double covalent bond:



Although small molecules such as O_2 and H_2O are important to products such as food, the molecules in packaging materials are much larger and more complex. For example, polyethylene (PE), which is the most frequently used packaging polymer shown below, is a molecule consisting of thousands of C–C and C–H covalent bonds:

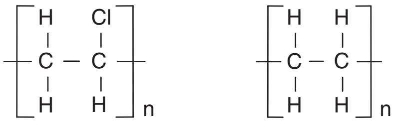


$$\sim\left[\overset{\displaystyle H}{\underset{\displaystyle H}{C}}-\overset{\displaystyle H}{\underset{\displaystyle H}{C}}\right]\left[\overset{\displaystyle H}{\underset{\displaystyle H}{C}}-\overset{\displaystyle H}{\underset{\displaystyle H}{C}}\right]\left[\overset{\displaystyle H}{\underset{\displaystyle H}{C}}-\overset{\displaystyle H}{\underset{\displaystyle H}{C}}\right]\left[\overset{\displaystyle H}{\underset{\displaystyle H}{C}}-\overset{\displaystyle H}{\underset{\displaystyle H}{C}}\right]\sim$$

For a polymer molecule, the degree of polymerization determines the number of covalent bonds and thus molecular weight, which affects the property and performance of the material. Although C–C and C–H bonds are the most common, C═C, C═O, O–H, and other covalent bonds are also frequently found in plastics and paper. The most common covalent bond in glass is Si–O.

An important attribute of a covalent bond is bond polarity, which is determined by the difference in electronegativities between the atoms joined by the bond. When the difference is zero or negligible, the electrons are shared equally between atoms, and a nonpolar covalent bond such as C–C is formed. When the difference is small but significant, the electrons are no longer shared equally between atoms, and a polar covalent bond such as C═O is formed. When the difference is large, the electrons are no longer shared but are transferred from one atom to another, and an ionic bond is formed.

Bond polarity can greatly affect the polarity of the molecule and thus the properties of the material. If all its bonds are nonpolar, the molecule is also nonpolar. If some of its bonds are polar, the molecule could be polar or nonpolar, depending on the symmetry of the molecule. This concept is illustrated by considering the covalent bonds in two common packaging polymers, polyvinyl chloride (PVC) and PE:



$$\left[\overset{\displaystyle H}{\underset{\displaystyle H}{C}}-\overset{\displaystyle Cl}{\underset{\displaystyle H}{C}}\right]_n \qquad \left[\overset{\displaystyle H}{\underset{\displaystyle H}{C}}-\overset{\displaystyle H}{\underset{\displaystyle H}{C}}\right]_n$$

PVC (polar)   PE (nonpolar)

Because C–H and C–Cl are both polar bonds, PVC is a polar molecule. But PE is a nonpolar molecule, because its C-H bonds are arranged symmetrically in such a manner that the dipoles cancel out, which results in no net dipole. The more polar the molecule, the stronger are the intermolecular forces, and the stronger intermolecular forces accounts for the reason why PVC has higher mechanical and barrier properties than PE.

Covalent bonds may be broken when packaging materials such as plastics and paper are exposed to severe conditions, such as aggressive chemicals, high temperature, and high shear. High temperature, for example, is encountered during heating of food packages in the microwave oven (especially when a heating device known as susceptor is used in the package) or in the conventional oven. High temperature and high shear are frequently encountered during the processing of polymers such as extruding polymer resins to form plastic films or containers. A major concern associated with the breakage of chemical bonds is possible formation of undesirable oligomer compounds, which can migrate from package to food.

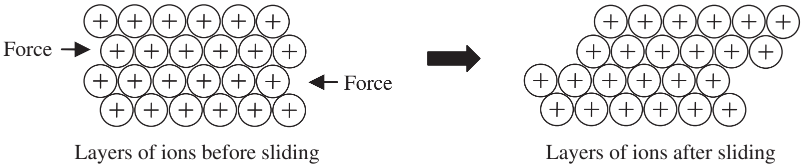


Figure 3. Sliding between layers of metal ions.

Table 4. The strength of some selected covalent chemical bonds at 25°C

Bond	Bond energy (kJ mol^{-1})	Bond	Bond energy (kJ mol^{-1})
C–Cl	338	O–H	463
C–F	565	C–C	348
O–O	146	C=C	612
Si–O	466	C–N	305
C–H	412	C–O	360
N–H	388	C=O	743

Covalent bonds are typically stronger than metallic and ionic bonds. The amount of energy required to break a covalent bond between two linked atoms is known as bond dissociation energy. Some covalent bond energies relating to packaging materials are shown in Table 4.

It needs to be mentioned that a molecule may have more than one type of chemical bond. For example, ionomer is a packaging polymer that consists of mostly of covalent bonds and a small but significant number of ionic bonds (Na^+ or Zn^+ ions) to its side chains. Its covalent-ionic nature provides ionomer with unique properties (heat seal strength, abrasion resistance, and melt elasticity) not found in polymers with only covalent bonds.

INTERMOLECULAR FORCES

The third level of structure considers the intermolecular forces that attract molecules together. Although atoms are bond together tightly by strong covalent bonds to form a molecule, a group of molecules are held together loosely by weak intermolecular forces. Typically covalent bonds are 10–100 times stronger than intermolecular forces. Intermolecular forces can be cohesive between like molecules in surface tension or adhesive between unlike molecules.

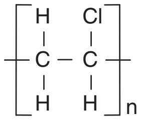
Plastics and paper are composed of polymer molecules, and their physical properties are greatly influenced by the intermolecular forces between these molecules. When a PE film is punctured or melted, what are broken are only the intermolecular forces that hold the PE molecules, whereas the much stronger covalent bonds holding the C and H atoms remain unaffected. The weak intermolecular forces are largely responsible for the low strength and low melting point of these materials.

However, glass and metal are not composed of a collection of molecules. A glass or metal material is composed of a single giant molecule, in which all the atoms are bound together by primary bonds to form a network. Glass is a network of Si-O bonds extending throughout the lattice, and metal is a network of metallic ions held in the sea of electrons. Hence, cutting a metal container involves breaking metallic bonds, and shattering a glass bottle involves breaking covalent bonds. Metal and glass are inherently stronger and stiffer than plastics and paper, because metallic bonds and covalent bonds are much stronger than intermolecular forces.

Intermolecular forces, which are often called van der Waals forces, correspond to a combination of different ways of attraction among molecules according to their dipole moment (dipole–dipole, dipole-induced dipole, and dispersion forces). Dispersion forces are the weakest intermolecular force (one hundredth-one thousandth the strength of a covalent bond), hydrogen bonds are the strongest intermolecular force (about one-tenth the strength of a covalent bond): dispersion forces < dipole-dipole interactions < hydrogen bonds.

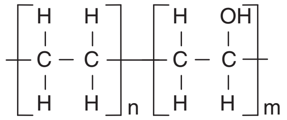
Dipole–Dipole Forces. Dipole–dipole forces are intermolecular forces between polar molecules: There are attractive forces between the positive end of one polar molecule and the negative end of another polar molecule. They have a significant effect only when the molecules involved are close together (touching or almost touching). Dipole–dipole forces have strengths that range from 0.15 to 15 kJ mol^{-1}, being much weaker than ionic or covalent bonds.

Consider the chemical structures of two polar molecules, PVC and ethylene vinyl alcohol copolymer (EVOH):



$$-\!\left[\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{Cl}}{\underset{\mathrm{H}}{\mathrm{C}}}\right]_n\!-$$

PVC



$$-\!\left[\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}\right]_n\!\!-\!\!\left[\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{OH}}{\underset{\mathrm{H}}{\mathrm{C}}}\right]_m\!-$$

EVOH

For PVC, each C–H bond is polar because carbon is more electronegative than hydrogen, and the C–Cl bond is polar because chlorine is more electronegative than either carbon or hydrogen. Each hydrogen atom will take on a partial positive charge, and the chlorine atom will take on a partial negative charge resulting in a net dipole because the dipoles will not cancel out because of the difference in electronegativities of carbon, hydrogen, and chlorine. For EVOH, vinyl alcohol part is polar because the OH group is more electronegative than hydrogen. When these molecular chains are in close proximity, dipole–dipole attractions are formed.

Hydrogen Bonding. This is a special type of dipole–dipole interaction. It occurs when a hydrogen atom is covalently bonded to a small highly electronegative atom such as nitrogen or oxygen. The result is a dipolar molecule. The hydrogen atom has a partial positive charge and can interact with another highly electronegative atom in an adjacent molecule (again N, O, or F). This results in a stabilizing interaction that binds the two molecules together. Hydrogen bonds vary in their bond strength from about 4 to 40 kJ mol^{-1} being much weaker than typical covalent bonds, but are stronger than dipole–dipole or dispersion forces.

Hydrogen bonding is important for some paper and plastic packaging materials. For example, the high oxygen barrier of EVOH is largely caused by the formation of hydrogen bonding between the EVOH molecular chains.

Dispersion Forces. These intermolecular forces exist between nonpolar molecules. They are forces between temporary dipole molecules as a result of positive nuclei of one molecule attracting the electrons of another molecule. Although dispersion force is the weakest intermolecular force, it plays an important role in many nonpolar packaging polymers because of their long molecular chains. For example, the molecular weight of PE is typically larger than 100,000; along the chain of this large molecule many dispersion forces exist, and the summation of these many forces can significantly affect the properties of the polymer.

SPATIAL ARRANGEMENTS

The fourth level is to consider spatial arrangements, which includes how molecules are arranged in the material. In addition to chemical bonds, the spatial arrangement of atoms in the molecule and the molecular weight are also important factors determining the chemical and physical properties, particularly for polymeric materials including plastics and paper. The fine structure of material observed by microscopy resulting from chemical composition, molecular arrangement, and crystalline degree is sometimes referred to as morphology.

Tacticity. The atomic arrangement in three-dimensional molecular configuration is called stereochemistry or tacticity. The way the molecular or ionic units are geometrically organized distinguishes between crystalline and amorphous solids: the former has symmetric, periodical, and well-ordered structural organization, and the latter is asymmetric, not periodical, and unsettled (Figure 4).

For example, methyl groups in polypropylene (PP) may be positioned in three different ways: Isotactic PP has all the methyl groups on the same side of the chain; syndiotactic PP has the substitute group alternately above and below the chain plane, and atactic PP is with random sequence (Figure 5). The tacticity or steroregularity is important in determining the ability of the solid material to crystallize: Regular atomic arrangement in the molecular structure makes the molecules easily pack together into rigid crystals. Therefore, isotactic and syndiotactic PPs are crystalline, whereas atactic is amorphous.

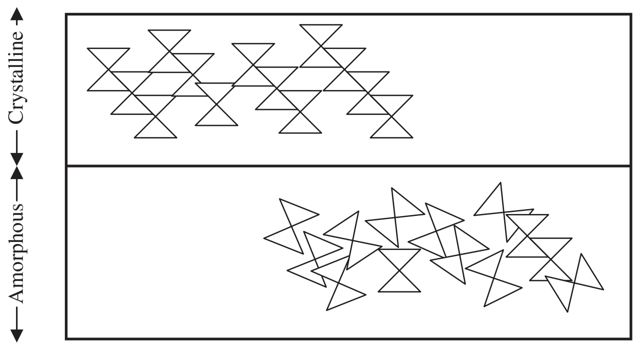


Figure 4. A schematic representation of the crystalline and amorphous spatial configuration of solid constituents.

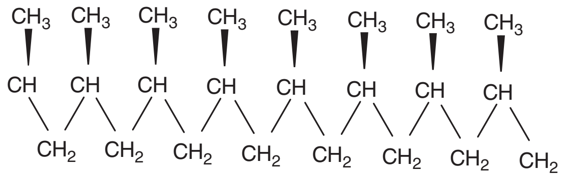
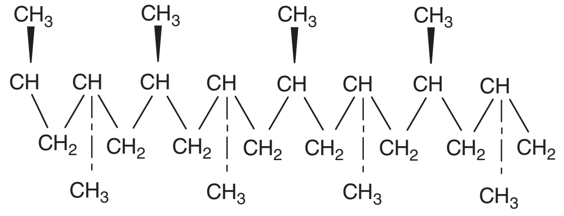
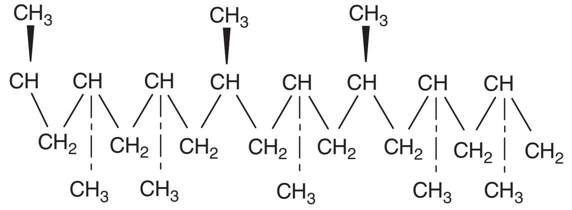


(1) Isotactic



(2) Syndiotactic



(3) Atactic

Figure 5. Different tacticities in polypropylene.

Crystalline Versus Amorphous State. The crystalline structural organization of solids applies to structures composed of repeating identical units that orderly disposed with a fixed geometric relation between each other. The framework derived from such a symmetric organization of units may be more or less complete and homogeneous (with vacancy or impurities), but it always has the lowest energy, and therefore is the most favored one. Stereochemistry, kinetics of solidification from a liquid state, and presence of crystallization promoters are factors that determine the degree of crystallinity. The performances of the packaging materials are greatly affected by the crystalline or amorphous structure (Table 5). Glass is typically a noncrystalline, amorphous material. Ceramic material may be in different degrees of crystallinity

Table 5. The crystalline and amorphous state for general categories of materials used for packaging

Material	Spatial organization
Glassy	Amorphous
Ceramic	Crystalline/amorphous
Cellulosic	Crystalline (pure cellulose)
Metallic	Crystalline
Plastic	Amorphous/crystalline

depending on the chemical composition and manufacturing conditions. Most plastic materials are composed of crystalline and amorphous regions. It is possible to modulate their degree of crystallinity by processing of the packaging materials.

Important consequences of the crystalline state are high density, good mechanical properties, reduced free volume, and low gas transmission throughout. Some solids can crystallize in different forms (this behavior is called polymorphism), and each form has its definite set of chemical and physical properties. This, for instance, is an important point in understanding different resistance to corrosion or mechanical strength of different types of stainless steel or aluminum alloys. The potential of the crystalline structural organization, in establishing several and even unusual properties, is well exemplified by the fullurenes, discovered in the mid-mid-1980s, which show carbon atoms arranged in hollow spheres (that can be possibly filled with functional molecules) or in the recent “nanotubes” or “nanogears,” which appeared in the most advanced metallic nanotechnologies.

Solid structure that lacks orderly arrangement is of an amorphous state. Amorphous materials like glass do not have a definite melting point as crystalline materials do. The structural organization of amorphous materials can be explained well by that of liquids, which are deprived of any order or symmetric organization. Amorphous solids also behave like solidified liquids, which have properties of flowing, ductility, and transparency. An amorphous solid is formed when the molecular chains have little orientation and regularity throughout the bulk structure.

Most plastic materials are semicrystalline, and the controlled combination of crystalline and amorphous structures can attain a material with advantageous properties of strength and stiffness. Generally, an increase in crystallinity causes increased density, increased tensile and compression strength, increased gas and moisture barrier, increased sealing temperature, decreased transparency, decreased tearing resistance, decreased impact strength, decreased toughness, and decreased elongation.

Molecular Orientation. As shown in Figure 6, this involves stretching an unoriented thermoplastic below T_m (melting temperature) but above T_g (glass transition temperature) either uniaxially (in machine direction only) or biaxially (in both machine and transverse directions), to induce alignment of polymer chains and then retain the acquired molecular structure thereafter, for the purpose of achieving better optical, mechanical, barrier, or other properties. The oriented films have a tendency to shrink with heating and are used for shrink packaging. When dimensional stability is required, the oriented film is heated even more to relax or set the structure.

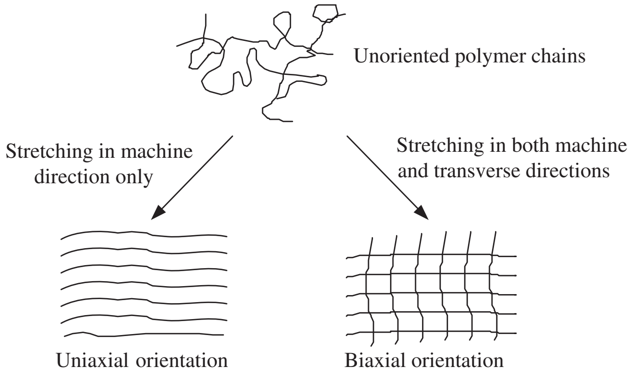


Figure 6. Stretching polymer chains to induce molecular orientation.

Stretching of thermoplastics to induce molecular orientation typically occurs in processes such as blown film extrusion, injection stretch blow molding, and cast film extrusion (when a tenter frame is used). Molecular orientation is achieved with proper control of temperature and rate of stretching to develop and retain the desirable molecular orientation.

STYRENE–BUTADIENE COPOLYMERS

D. L. Hartsock
Phillips 66 Company,
Houston, Texas
Updated by Staff

INTRODUCTION

The styrene–butadiene copolymers (SB) that are suitable for packaging applications are those resinous block copolymers that typically contain a greater proportion of styrene than butadiene and that are predominantly polymodal with respect to molecular weight distribution. These copolymers, produced by solution polymerization processes using sequential multiple additions of an organolithium initiator, styrene, and butadiene (1, 2), are amorphous in nature and transparent. Compared to other transparent styrenic polymers (e.g., general-purpose polystyrene and styrene–acrylonitrile copolymers), the styrene–butadiene copolymers offer outstanding shatter resistance (3). Physical properties are dependent on molecular weight distribution, styrene:butadiene ratio, and the nature of the block structure. Since all three of these parameters are a function of the polymerization recipe, grades having different properties can be produced: Grades tailored for injection molding (see Injection molding) and for extrusion. (see Extrusion) are commercially available (see Table 1). Current producers are listed in Table 2.

APPLICATIONS

One of the major applications for SB is single-service cups and lids, but a combination of good mechanical and visual properties, low density compared to other transparent

Table 1. Styrene–Butadiene Copolymer Physical Properties

Process	Injection Molding and Extrusion	Injection Molding
Specific gravity	1.01	1.01
Flow rate, condition G, g/10 min	7.5	8.0
Tensile yield strength, psi (MPa)	3700 (26)	4400 (30)
Elongation, %	160	20
Flexural yield strength, psi (MPa)	4900 (34)	6400 (44)
Flexural modulus, psi (MPa)	205,000 (1413)	215,000 (1483)
Hardness, shore D	75	75
Heat-deflection temperature, 264 psi (1.8 MPa), °F(°C)	163 (73)	170 (77)
Vicat softening point, °F(°C)	188 (87)	200 (93)
Light transmission, %	90	90

polymers, and ease of fabrication by the typical molding and extrusion techniques make styrene–butadiene copolymers a good choice for many packaging applications. These include bottles and jars, hinge boxes (ball-and-socket or integral-living hinges) (see Boxes, rigid plastic), tubs and lids, blisters, medical devices, packaging, and many film applications (see Carded packaging; Films, plastic).

Styrene–butadiene copolymers are often blended with other polymers. If transparency is a requirement, the blending polymer must have a refractive index very near that of the styrene–butadiene copolymer. This includes styrenic polymers such as general-purpose polystyrene (GPPS) (see Polystyrene), styrene–acrylonitrile copolymers (SAN) (see Nitrile polymers), and styrene–methyl methacrylate copolymers (SMMA). GPPS is used extensively as a blending polymer for applications requiring sheet extrusion and thermoforming (see Thermoforming) (e.g., carded packaging). Blends with SAN or SMMA are mainly used for injection molded applications (e.g., hinged boxes, videocassette cases). The impact strength of SBR can be either enhanced or reduced when blended with other styrenic polymers. For example, a significant loss of impact strength occurs with the addition of even low levels of GPPS. In contrast, certain blends of SBR and SMMA have synergistic impact strength. Therefore, the suitable blend ratio for a given application depends on the required combination of stiffness, toughness, and economics. Blend ratios typically range from 40:60 to 80:20 SB: styrenic polymer. If clarity is not a requirement, blends with polymers such as high-impact polystyrene (HIPS), polypropylene (PP), and polycarbonate (PC) can provide synergistic enhancement of certain physical properties, unusual aesthetics such as gloss and pearlescence, or reduced cost. Bottles and jars can be produced from nonblended SB by extrusion or injection blow molding (see Blow molding). Blown and cast films can be produced from nonblended SBR or blends of SBR/GPPS.

Table 2. Producers of Styrene–Butadiene Resinous Copolymers

Company	Location	Tradename
Chevron Phillips	United States	K-Resin
BASF	Germany	Styrolux
Denka-Kaguku	Japan	Clearene
Total Petrochemicals	Belgium	Finaclear

SPECIFICATIONS

Some U.S.-produced styrene–butadiene resinous copolymers meet FDA specifications (CFR 177.1640). Finaclear complies with European 89/109/EC and FDA requirements (4) Styroflex also has FDA food clearance. Certain grades are fully documented to qualify for U.S. Pharmacopoeia Class VI-50 medical applications and blood contact uses, and they have been shown to be nonmutagenic, nonirritants to sensitive tissues, and nondestructive to living cells. In view of these qualifications and because they can be sterilized by both gamma irradiation and ethylene oxide (ETO) procedures, these copolymers are widely used in medical packaging applications.

TOXICITY

Most significant environmental issues with respect to styrene–butadiene copolymers relate to the manufactuirng process, taste and odor issues in end-use, and solid waste in final disposal of these polymers. Manufacturing process issues relate to industrial hygiene, exposure, and volatile organic emissions. In end-use, block copolyer/polystyrene blends tend to have taste and odor issues, especially sensitive in food packaging applications (5). As with most hydrocarbon-based polymers, SBs burn under the right conditions of heat and oxygen supply. Combustion products of any hydrocarbon based material should be considered toxic.

SUPPLY CHAIN ENGINEERING

H. H. SCHUENEMAN
San Jose State University,
San Jose, California

The globalization of the world economy started in earnest in the last half of the 20th Century and has had profound effects on the distribution of the world's goods. In particular, most manufacturing has exited technologically advanced countries, largely in the West, and has relocated to countries with large pools of inexpensive labor. Most of these countries were physically removed up to half a world away from the primary markets for the goods they were now producing. To make this situation viable, efficient logistics, distribution, shipment, and supply chain management are absolutely essential.

To understand the situation better, it is helpful to define the primary terms, including packaging, logistics, and supply chain management.

Packaging, in the context used here, implies a protective device designed and tested to provide physical protection, containment, identification of the contents, and utility during the distribution and storage process. Physical protection is provided primarily by cushion materials to prevent damage from impact and vibration, which are common during distribution, and polymeric films for moisture and dust protection. For containment, corrugated containers provide an inexpensive method to contain the product and its associated pieces and parts. The same container or box easily can be printed to provide the identification of the contents in both readable format and scannable or machine-read format. The same shipping container also provides utility primarily in the means to stack the product on pallets or in warehouses without product damage.

It must also be recognized that the product and package system must work together to survive the often harsh and harmful elements of the physical distribution environment. This cooperation is a natural outcome of the systems approach for efficient and safe product protection during delivery. The concept holds that it may be much more feasible, from a cost standpoint, to ruggedize a product than to design and purchase an overly expensive package system to protect a physically weak product. Often, the cost trade-off of these two options favors product ruggedization over expensive protective packaging. Remember also that packaging is an expense and rarely adds to the value of the product as it is normally discarded after safe product delivery. When the product/package systems approach is used effectively, delivered cost is normally minimized and customer satisfaction is normally maximized.

Logistics defines the entire process of materials and products moving into, through, and out of the firm. This process is often broken down into inbound logistics, materials management, and physical distribution

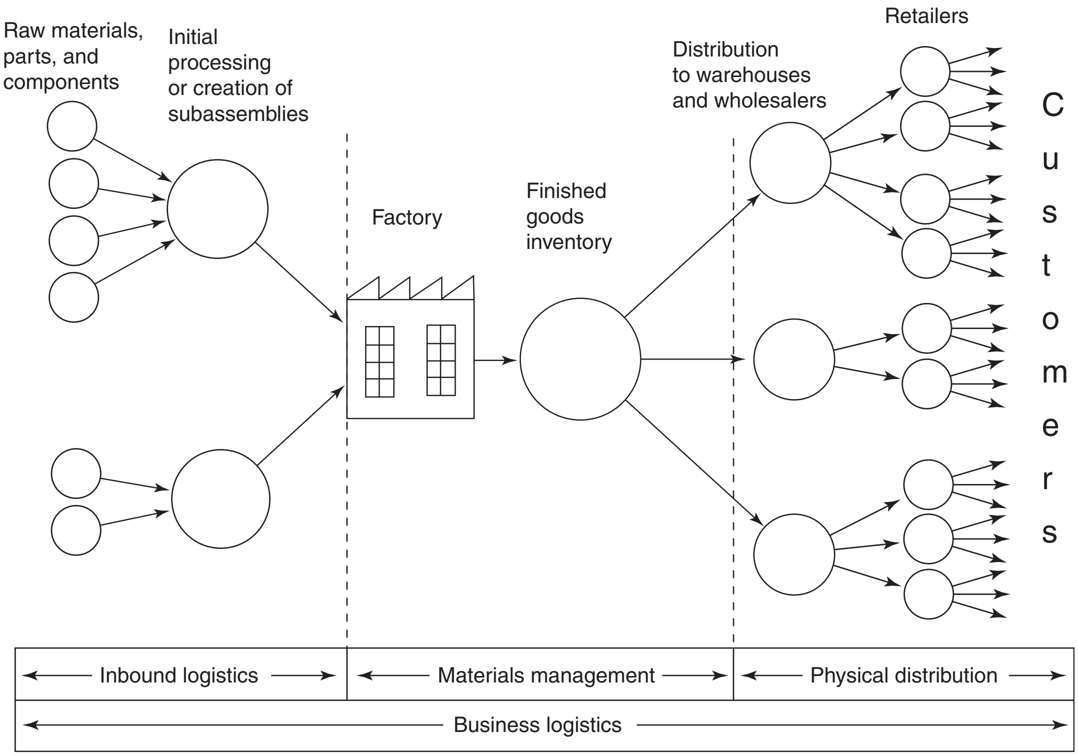

Figure 1. Typical logistics concept diagram. Source: (1) *Contemporary Logistics*.

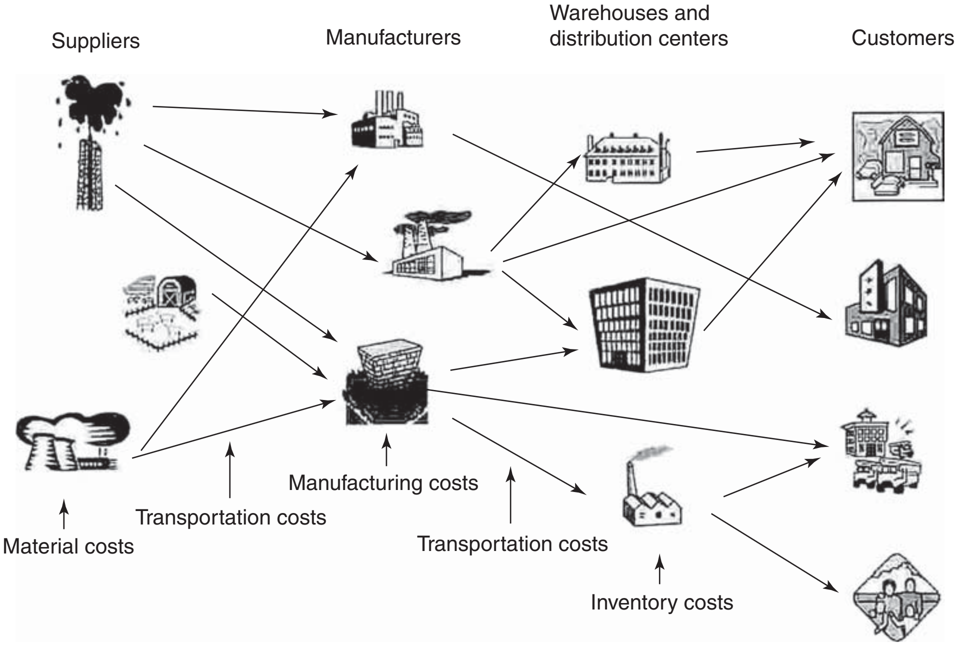

Figure 2. Typical SCM concept diagram. Source: (2): *Designing & Managing the Supply Chain*.

(see Figure 1). The Council of Logistics Management (CLM) defines logistics as "a process of planning, implementing, and controlling the efficient, effective flow and storage of goods, services, and related information from the point of origin to the point of consumption for the purpose of conforming to customer requirements." The word *logistics* was first associated with the military and is attributed to Major Chauncey B. Baker, who described it as "the art of war pertaining to the movement and supply of armies."

Most authors today believe that logistics is a much broader concept that includes functions such as demand forecasting, documentation flow, interplant movements, inventory management, order management and processing, packaging, production scheduling, purchasing, traffic management, and recycling. A popular concept in logistics management occurred in the 1980s with the introduction of just-in-time (JIT) delivery. This concept held that total cost could be minimized by reducing the size of component inventory at the manufacturing location to the absolute minimum, which is typically enough for one shift. Although other costs such as transportation likely would increase because of this concept, total cost could be minimized. Although some manufacturing operations still use this concept, most firms agree that a balanced approach of cost-effective delivery combined with prudent warehousing provides the best overall balance and the least overall costs.

Supply Chain Management (SCM) is a somewhat larger concept than logistics in that it deals with managing both the flow of materials and the relationships among the channel intermediaries from the point of origin of raw materials through to the final customer. In this context, supply chain management is essentially an integration of suppliers, manufacturers, storage facilities, and retail outlets in such a fashion that products are produced and distributed in the right quantities, in the proper locations, at the correct time, to minimize costs while providing maximum customer satisfaction (illustrated in Figure 2).

The concept of supply chain management reached maturity at a rapid rate when the global distribution of goods demanded an efficient system to handle all of the various processes necessary for supplying worldwide markets from distant production sources. The systems approach was the concept that made the whole process work. In times past, the transportation manager would try to minimize transportation costs while the packaging engineer would try to minimize packaging costs and the warehouse supervisor would try to minimize costs by stacking containers higher, for example. The systems approach, by contrast, attempted to look at the total cost of the finished product safely delivered to the customer. Thus, it could be possible for higher transportation costs to result in even greater savings in packaging, which would result in net cost savings to the firm.

WELL-DESIGNED PACKAGING IS THE KEY TO EFFECTIVE LOGISTICS

For both incoming raw materials and outgoing finished products, the key to effective logistics is always efficient cube use during transportation and warehousing. In the globalized economy, long-distance shipping is commonplace. This shipping often uses ocean-going containers or similar structures with defined interior dimensions. Whether or not the distribution cycle uses ships on the ocean, it is very likely that the most efficient manner for shipment is to use as much of the interior cube of the container as possible. For most products and shipping situations, the cube of the container is maximized long before the allowable weight limits are reached. With few exceptions, the cost for shipping a loaded container is normally fixed up to its maximum weight limit. Thus, if 10% more raw materials or finished goods can be placed into a shipping container, the cost for those additional items is essentially free, and thus, the overall transportation efficiency is greatly increased.

Historically, most of the elements of logistics have been well optimized in most distribution cycles. That is to say, if demand forecasting, purchasing, packaging, or production scheduling were improved by 10%, then the results may be gratifying but probably not overly significant cost wise. If, however, delivered transportation costs were lowered by 10% because of more compact product design and packaging, then the results would be both gratifying and significant cost wise.

Recently, the manufacturer of computer peripheral equipment started removing products from pallets and placing them on slip sheets prior to loading them into ocean-going containers. Those customers who demanded products on pallets at the receiving end then would have their products re-palletized at the end of the distribution cycle. This process resulted in an increase of approximately 12% in cube use on ocean-going containers. The cost savings were in the multimillion-dollar range.

For many consumer products distributed globally, the cost of delivery can exceed the cost of the product, sometimes by a factor of two or more. This expense indicates that cost reducing the product by 10%, for example, would not result in substantial savings, whereas increasing distribution efficiency by 10% would result in much more significant cost reductions. A study conducted by a well-known electronics firm concluded that packaging materials made up less than 20% of the total delivery cost for their products. Logistics made up 80% or more (illustrated in Figure 3). It doesn't take a genius to figure out where they spent most of their cost-reduction efforts.

Commercially available software often is used to determine the exact shape and configuration of product/package systems that fit most efficiently and maximize cube use during distribution. Information from these programs can be best used by close cooperation between product design and package design functions. For example, tradeoffs between product ruggedness and package cushion thickness can be easily quantified in terms of delivery cost and, thus, can be weighed against the anticipated cost of the necessary product ruggedization to achieve this efficiency level. Sadly, this type of close cooperation between product and package design functions is the exception rather than the rule.

The bottom line is that smart product/package system design is the key element to cost effective logistics through efficient cube use during storage and distribution.

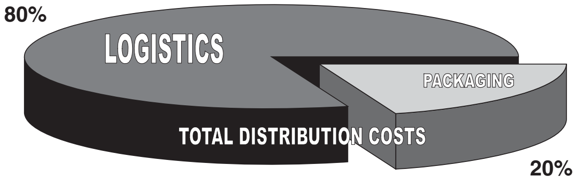

Figure 3. Total distribution cost.

LOGISTICS IS THE KEY ELEMENT IN SUPPLY CHAIN MANAGEMENT

Supply chain management, in all its various forms, always requires the smooth and efficient flow of goods, materials, and information throughout a normally complex network. Goods and materials will always move more efficiently and effectively throughout this process if they are packaged and unitized in a fashion that makes them easy to handle, identify, store, and ship. Unitization by means of pallets is the most popular method, although other unitization methods such as slip sheets and clamp loads are gaining popularity.

The important point is that good logistics will enhance supply chain management, and some authors even suggest that good logistics makes supply chain management actually work. However, poor logistics or even insufficient attention to logistic requirements in the supply chain will cause disruptions and inefficiencies that may lead to total abandonment of the supply chain concept. The more globalized companies' operations are, the more dependent they are on efficient logistics to make supply chain management a viable concept. All of these factors are a recognition of the fact that transportation and distribution costs are a very high percentage of the total cost of producing a product. This issue was not the case a generation ago but is certainly very true today. The near future promises more of the same as companies strive to take advantage of cost-effective production in more remote parts of the world. As these production sites become more and more remote, the critical value of good packaging, logistics, and supply chain management becomes more apparent.

PRODUCT/PACKAGE SYNERGY

At this point, it is clear that logistics is the key element in good supply chain management and that packaging is the key element in good logistics. Thus, it would seem that the global distribution of goods is highly dependent on efficient and effective (smart) packaging. As is often the case, packaging is one of the last elements to be recognized as important or crucial in this area. But the simple fact remains that, without smart packaging, the global distribution of goods, and therefore, our current lifestyle would be impossible.

Typical elements that go into a product design focus would include things like product aesthetics, safety, functionality, weight, dimensions, materials, and many other considerations. Rarely, if ever, is the idea upheld that efficient distribution is one of the key elements in a successful design for globally distributed products. However, the lessons of global logistics tell us that the transportation and storage costs may be the largest cost item in the entire product. What product designer in his or her right mind would ever consider designing a product without paying close attention to the largest cost item in the product? Yet, that is almost exactly what happens over and over again when the cost of distribution is ignored.

Several forward-thinking companies have examined this topic and have determined that efficient product distribution is one of the primary determinants of the actual product dimensions. If changing the dimensions of a product by a relatively small amount will yield a potentially large savings in distribution costs, then smart companies change product dimensions and use the savings to help increase their competitive advantage. The companies that ignore this—simple, but vital—principle are doomed to higher costs and competitive disadvantage throughout the entire lifecycle of the product. In addition, this spiral will only increase in intensity as fuel costs increase because of scarcity, and distribution cycles get longer because of more remote production facilities. It is important for companies to determine the most optimal and efficient dimensions of the product and package system together before the product is even conceived.

In conclusion, it has been shown that product and package synergy is the best possible method to enhance logistics in the distribution of goods and materials, primarily through optimum cube utilization. This process, in turn, results in the greatest efficiency available through focus on supply chain management throughout the distribution cycle. Because distribution costs can constitute a major overall cost of the product itself, this approach will result in the minimization of cost and in the maximization of efficiency simultaneously. Anyone responsible for efficient product distribution should pay close attention to this relatively simple message; optimize packaging and product/package synergy first. Efficient logistics and effective supply chain management will result.

SUPPLY/DEMAND CHAIN MANAGEMENT

Chris Dominic
STFI-Packforsk AB, Lund
University, Packaging Logistics,
Stockholm, Sweden

SUPPLY/DEMAND CHAIN MANAGEMENT

Emergent structures in Supply/Demand Chain Management (SDCM) are the interaction of logistics activities leading to material flow, thereby satisfying the consumer's demand. The logistics area is rapidly developing to create individualized value for the consumer as well as a sustainable growth for the actors involved in the Supply/Demand Chain. Ericsson in Waters (1) maintains that creating customer value has been discussed ever since the 1940s, but distribution channels are often organized by supply activities that have resulted in supply push rather then demand pull. Development in this area has improved with the implantation of new technologies that have provided the actors with real-time information that has resulted in enhanced competitiveness. The use of the information and communication technology (ICT) has increased the awareness of the need to satisfy the consumers' specific requirements. This development can be also seen in the packaging area. Packaging is assumed to have a major influence on logistics in general and on physical distribution in particular. The packaging plays an active role in protecting and creating value from when it is filled at the packer/filler* until the product is emptied by the end-user. This in logistics terms means that the actors involved in packaging must play an important and proactive part in maintaining efficiency in logistics.

The key elements applied in Supply/Demand Chain (2) are Packaging Logistics and e-logistics. For each of these constitutive elements, the current theoretical foundation is described below.

The work is done to bridge the theoretical gaps in Supply/Demand Chain Management. The theories discussed here are based on the material flow in the distribution channels as well as on the actor's point of view.

CONCEPTS APPLIED IN LOGISTICS

Logistics can be an array of activities generating a physical flow of supplies from the refiners of material through to the packaging supplier, the packer/filler, and distributor and all the way to the end-users (i.e., consumers). Postconsumption and reverse logistics activities are also considered. The logistics activities are driven by aggregated demands generated by the consumers. The demands (end-user information) flow in a direction opposite to the physical flow. Frohlich and Westbrook (3) have divided the concept of integration into the integration of supply and demand. The demand data from the consumer is the driving force for planning, production, packing/filling, distribution, storing, and sales. Also, post-sales activities regarding packaging are also included here.

DISTRIBUTION CHANNEL

The distribution channel is undergoing changes; new techniques (e.g., e-business) have an influence on the design of packaging (4). The development toward controlling the customers' inventory solutions are growing. The concept of Vendor Managed Inventory (VMI) is used to integrate a cross-functional process by allowing, for

---

* A company that takes empty packaging and then packs or fills it with products.

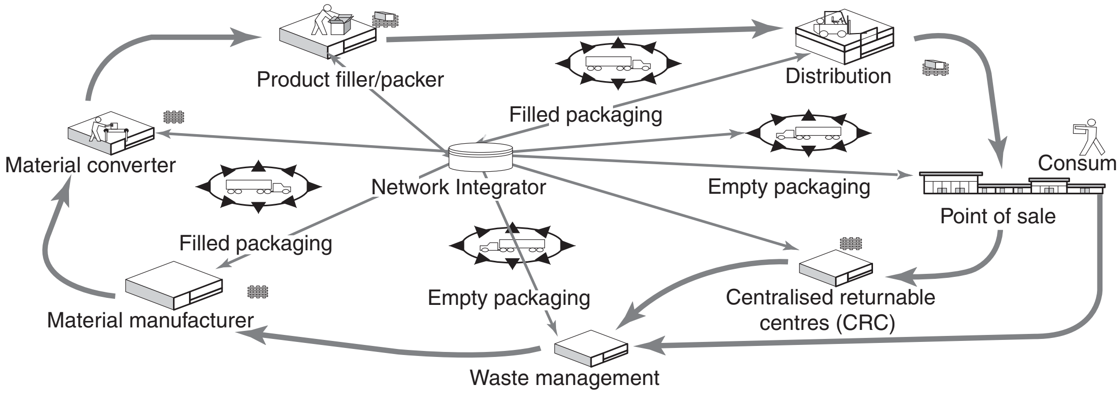

Figure 1. Activities in packaging logistics.

example, the packaging suppliers to own that part of the process that has traditionally belonged to the customer. Many authors [e.g., Waller et al. ((5), p. 186)] stress that VMI can lead to better planning and help to bridge the information gaps and contribute to forward integration with the actors in the distribution channels. These developments can also be seen in the packaging area where the packaging actor is using, for example, Shelf-Ready Packaging (SRP) and Retail-Ready Packaging (RRP) concepts presented by ECR Europe (6). According to Greaver (7), there is an increasing amount of subcontractors who deliver certain functions, services, or parts of the production process externally, instead of the company carrying out these tasks internally. Dominic (8) has identified packing services, storage, and distribution as examples of services with which some major packaging suppliers are familiar and that have served as natural links in the distribution channel.

For backward integration, many actors have started to look into the theories of reverse logistics (9), which is a physical flow moving in the most efficient and cost-effective way possible. In an ideal world, the logistics flow goes in the direction towards the consumer. However, as the world we work in is not ideal, packages often have to move against the stream in the flow.

Processes related to these activities, which companies have contracted to carry out, are often regarded as unwanted and resource demanding. Here the greatest problem is the lack of good information systems capable of handling the reverse logistics functions.

PACKAGING LOGISTICS

The subject of Packaging Logistics is defined as an approach with the purpose of developing packaging and packaging systems[†] that support the logistics process and meet customer demands. In logistics, a well-functioning packaging system creates time, place, form, and ownership benefits in the product in relation to the customer—that is, an undamaged product in an easy-to-handle package which is easily disposed of. Figure 1 illustrates packaging logistics activities and the actors involved. Dominic (8) has identified the actor Network Integrator (plotted in the middle), who plays the role in integrating the supply flow and with the demand flow.

Packaging systems can be either one-way or reusable. Reusable packaging is collected at a centralized return handling central (CRC), where it is cleaned, stocked, and distributed for refilling. The used packaging is shipped for waste management.

THE PACKAGING AND THE ACTOR

A package should be designed to provide optimal efficiency in storage, sales, and subsequent waste management. Good packaging affects material, handling in terms of load stability, stackability, and compatibility with different forms of mechanization and automation. The choice of a packaging system is a complicated task, and it should be based on market considerations, actors involved in the process logistics, and environmental requirements. Small changes in a packaging system affect the distribution channel in many different ways. In general, the following factors are involved (10, 11): product protection, available packaging technology and functionality, economics and costs, marketing considerations, product properties, environmental considerations, legal constraints, and information transfer. Normally, the package properties are adapted to the product, but sometimes the product properties are modified in order to facilitate more practical packing/filling. Packaging is also important for shippers and for materials managers who are closely tied to functions dealing with warehouse and transportation efficiency. Good packaging can have a positive impact on layout and design and overall warehouse productivity. With the need for a holistic approach and a trend toward longer and more complex Supply/Demand Chain, a method called Packaging Scorecard (PSC) (12) is introduced in Packaging Logistics. PSC helps to evaluate the performance of the packaging system in the SDC and to reduce packaging waste. Lately, the concepts of PSC are widely used by the distributor and in retail.

The role of a packaging supplier in logistics is often limited to interaction with the packer/filler in the distribution channel. The nearest interface for the packaging

---

[†] The packaging system is based on four identified levels: primary, secondary, tertiary, and load carrier.

supplier in the distribution channel is with the packer/filler. Today, packaging suppliers are challenged to develop solutions aimed at both commercial and logistical upgrading throughout the flow. The packaging suppliers should aim at looking beyond the immediate users of packaging (8). They have to anticipate and integrate the specific demands of subsequent distribution phases such as retail and logistics management through to the consumer. They also have to minimize the use of hazardous substances and ensure the environment-friendly disposal of the packaging after use.

e-LOGISTICS

According to Ericsson (13) e-logistics has been the natural development in the subject of logistics in the past few years. Information and Communication Technology (ICT) is one of the legs of e-logistics which bridges the interorganizational gaps. The second leg is traditional logistics comprising material management, warehousing, transport, and Just-In-Time theories. Business processes is the third leg, where the actors in logistics play an important part in creating efficiency in the distribution channel.

Together with ICT, packaging can play an active part in e-logistics by integrating the three legs. By increasing knowledge in packaging logistics and adapting to new technologies, the actors in packaging can increase logistics efficiency and add value for their customers.

DISCUSSIONS

During the 1990s the Supply Chain Management concept noticeably started to spread broadly. The physical flow in a Supply Chain (SC) composed of a number of companies, buyers, and sellers, who communicate directly with the nearest actor is forward for sales and backward for purchases. The relations often consist of finding a partner who can offer the right product price and, in an established cooperation, share information about logistics issues including stock levels, delivery, and product development issues. The relations are based on the creation of contact between two individuals, namely, a seller and a buyer.

Information about consumer requirements passes from the point of sale via the distribution to the packer/filler and then to the packaging supplier. This puts an emphasis on relevant information being brought from the packer/filler to the packaging producers. The process is further complicated when several enterprises are involved in the flow. Betts and Heinrich (14) give an example of how "ICT-fication" can be used to create adaptations. ICT-fication means that electronic aids give access to the customer's and sometimes the flow's database and consumer demands.

The development in ICT-fication has reorganized the distribution channels, which are becoming increasingly nonstatic in order for companies to gain a competitive edge. Instead of developing specialized departments in companies, one could outsource the value-creating activities and focus on the core business. The basis of Supply Chain Management is to command and have control over value-creating activities. According to Ericsson (13), Supply Chain (SC) is a supply push construction rather than a construction driven by demand-pull conditions. In traditional SC, the focus is on the physical flow resources. ICT is used as a tool for the individual companies to help them fulfill their tasks, and non-interorganizational functions will lead to inefficiencies. For example, a package moving from the supplier of packaging to the packer/filler and then to the point of sale involves arms-length transactions, leaving gaps between the actors involved in the distribution channel. When there are many competing, parallel distribution channels, the system will become demand-driven, which should not be mistaken for a demand chain (DC). A DC is largely about managing the information flow. The driving force is information rather than the actual physical flow. The goal is to substitute the information for inventory among the actors involved in the flow. Here, as mentioned above, a new actor called Network Integrator (8) enters the marketplace with the function of integrating the information flow and the physical flow. This development can be adapted to packaging theory by introducing packaging integration, and the actor involved is the Packaging Integrator.

BRIDGING THE GAPS IN LOGISTICS THEORIES

In this article, the concepts of packaging logistics and e-logistics create an interesting logical element for creating efficiency in logistics. The theory of Supply/Demand Chain Management is supporting the concept of demand-pull. There is relatively modest research supporting the packaging suppliers' roles in the logistics. But the work done in the field of Supply/Demand Chain Management adds the theory of Packaging Logistics as an important element that will create efficiency in logistics.

In conclusion, this work looks for answers in the literature to the questions of how the packaging suppliers can contribute in logistics to create efficiency and how the theoretical discussion about Network Integration can contribute to develop the logistics theory.

SUSTAINABLE PACKAGING

ANNE JOHNSON
Sustainable Packaging
Coalition, Charlottesville,
Virginia

INTRODUCTION TO SUSTAINABILITY

Sustainability is a systems concept that is simple common sense. We need a healthy planet to provide resources for our basic needs and to support the needs of our economies. People need robust commerce for employment and require a healthy and productive environment in which to live. Effective economies need healthy employees to work and stable societies in which to operate.

For millennia, our planet has provided the material resources that both societies and business require. We are entering an unprecedented era where the demands of humanity exceed the biocapacity of the planet, and in a short hundred years we have depleted finite geological oil resources on which we have grown to depend. Through the mounting evidence in the form of global changes like climate change, we are receiving clear signals that the cumulative impacts of mankind are leaving a swath of unintended environmental consequences. Our current industrial and consumptive practices are leaving a tragic legacy of degraded and limited resources for future generations.

In 1987, the UN World Commission on Environment and Development issued a report entitled *Our Common Future* that established a definition for sustainable development. This definition is commonly used for what is now referred to as simply sustainability: “Development that meets the needs of the present without compromising the ability of future generations to meet their own needs.” (1) The principles elucidated in this statement strive to balance the demands of society and the production of goods and services with consideration for the environment.

In 2007, it is clear that sustainability is hitting the mainstream. For 15 years or more, a handful of leading CEOs and companies have recognized the leading indicators of a shifting business climate and started to consider how the future might impact their businesses. To these companies, many of whom are global brands, the concepts implicit in the term “sustainable development” have taken on greater meaning and bottom-line significance as sustainability has attracted widespread consideration.

Globalization, demand for accountability and transparency, rising energy prices, and escalating environmental degradation are just some of the issues driving interest in sustainability on the part of business and advocacy groups. With the entrance of Wal-Mart into the arena in 2005, along with the announcement of the company’s sustainable packaging initiative, sustainability is currently impacting almost all businesses in the packaging value chain.

While packaging is often not the overwhelming contributor to an environmental footprint compared to a product, it does have a uniquely personal relationship to consumers. When the product is gone, consumers are often left with the packaging and need to figure out what to do with it. For this reason, along with the fact that it represents a significant use of materials and resources, places a burden on communities, and is a very visible source of waste or litter, packaging ranks high on corporate sustainability agendas.

It is clear that careful stewardship of the planet and its resources are essential for a sustainable future for society and business. Sustainability represents a tremendous design opportunity—that is, to design chemicals, materials, products, buildings, cities, transportation, and packaging systems that contribute meaningfully to a positive, sustainable future.

One of the sustainability frameworks that has proved valuable for envisioning sustainable material systems is the language of cradle to cradle design found in the book *Cradle to Cradle: Remaking the Way We Make Things* by William McDonough and Michael Braungart (2). In *Cradle to Cradle*, McDonough and Braungart ask us to imagine industrial systems modeled on the effectiveness of natural ecosystems. Cradle-to-cradle design envisions a world powered by the sun where growth is good, waste is nutritious, and productive diversity enriches human and natural communities.

The application of cradle-to-cradle design creates an opportunity to cycle industrial materials in a sustainable way. Each material in a product is designed to be safe and effective, as well as to provide quality resources for subsequent generations of products. Like the earth's nutrient cycles, the flow of materials eliminates the concept of waste.

THE DEFINITION OF SUSTAINABLE PACKAGING

A formal definition of sustainable packaging is needed to provide a common platform of understanding against which the packaging supply chain can measure their efforts. This was the objective of articulating the "Definition of Sustainable Packaging," released in October 2005 by the Sustainable Packaging Coalition. The Sustainable Packaging Coalition, a project of GreenBlue, is an industry working group dedicated to creating a more robust environmental vision of packaging. Drawing on fundamental eco-efficiency concepts and sustainability principles articulated by cradle to cradle, the definition outlines a framework for sustainability in the context of packaging and its related materials systems.

Encompassing the entire life cycle of packaging and more, the definition presents a vision for the packaging industry in eight criteria—all of which must be addressed if sustainable packaging is to become a reality. The definition is ambitious and comprehensive. It presents a challenge to the *status quo* while offering guidance to identify opportunities and strategies to move forward.

Sustainable packaging (3) has the following characteristics:

A. It is beneficial, safe, and healthy for individuals and communities throughout its life cycle.
B. It meets market criteria for performance and cost.
C. It is sourced, manufactured, transported, and recycled using renewable energy.
D. It maximizes the use of renewable or recycled source materials.
E. It is manufactured using clean production technologies and best practices.
F. It is made from materials healthy in all probable end-of-life scenarios.
G. It is physically designed to optimize materials and energy.
H. It is effectively recovered and utilized in biological and/or industrial cradle to cradle cycles.

A. Beneficial, Safe, and Healthy for Individuals and Communities Throughout Its Life Cycle

In addition to profitability, social equity and the environment are growing areas of corporate focus. As part of globalization, companies are expanding operations and increasingly are held accountable for actions resulting in negative social or environmental consequences. The emergence of the corporate social responsibility reporting reflects the growing focus on corporate citizenship, accountability, and transparency.

The global packaging industry is conservatively estimated at $417 billion and employs more than five million people all over the world (4). The benefits of packaging to individuals and communities vary from (a) the creation of meaningful, stable employment to (b) the protection, preservation, safety, and transport of products and foodstuffs. Packaging allows key marketing and product differentiation and educates and informs the consumer. At the same time, the procurement, production, transport, and disposal of packaging can have negative consequences for both the environment and societies around the globe. Through intelligent packaging and system design, it is possible to "design out" the potential negative impact of packaging on the environment and societies.

Cradle-to-cradle principles offer strategies to improve the material health of packaging and close the loop on packaging materials, including the creation of economically viable recovery systems that effectively eliminate waste. These strategies support communities through the creation of gainful employment and improvements to the environment. Corporate social responsibility, accountability, and equitable wages are all part of creating a sustainable system.

B. Meets Market Criteria for Performance and Cost

Economic growth and prosperity are essential components of sustainable development. The United Nations estimates that the population of the planet will grow from 6.4 billion in 2005 to 9.0 billion by 2050, roughly a 40% increase in global population (5). An efficient and productive industry engaged in truly sustainable practices is essential to meet the increasing demand for goods and resources that this growth implies. Historically, increased packaging use has accompanied economic growth. A goal of sustainable packaging is to facilitate economic growth by delivering benefits of packaging without the negative impacts associated with traditional packaging designs.

Ongoing profitability is a fundamental element of sustainable business practice. Managing the cost of packaging procurement, production, and product delivery with the desired functionality and appearance is fundamental to a profitable business. The true cost of packaging is becoming more complicated as costs that have traditionally been borne by society (e.g., disposal) are being redirected to producers through legislation and levies. Sustainable packaging design considers the full life cycle of the package, recognizes the principle of Shared Product Responsibility (6), and consequently seeks to minimize the total packaging system cost through efficient and safe package life cycle design.

Sustainable packaging initiatives offer multiple strategies to meet and even exceed market criteria for performance and cost, including improved package design, resource optimization, enhanced material selection, and source reduction (7). Education of business colleagues, suppliers, consumers, and regulators is also an important vehicle to connect a sustainable packaging strategy to existing market needs.

Collaboration across the packaging supply chain facilitates understanding, helps identify opportunities to improve materials and packaging systems, and enables sustainable alternatives to be developed with zero or little additional cost. Experience from other sectors that are beginning to embrace the principles of sustainable business indicates that improvements in product quality and profitability are often realized. Other benefits of sustainable packaging include (a) brand enhancement and new sources of materials made available through reuse and (b) mechanical and chemical recycling.

Innovative new packaging materials from renewable resources and advances in recovery/recycling systems, while still on the horizon for many materials, are actively being used in other parts of the world. While there may be costs associated with the transition to new packaging materials or recovery strategies, there also will be savings. Experience has shown that some of these direct savings could include reduced regulatory and tipping fees and reduced environmental management costs.

C. Sourced, Manufactured, Transported, and Recycled Using Renewable Energy

The wide-scale use of fossil fuels as the primary source of energy is the principal factor contributing to many local, regional, and global pollution issues including climate change, acidification, ozone depletion, mercury buildup, photochemical ozone, and particulates. Renewable energy potentially offers a solution to many of the environmental, social, and economic issues central to the development of a sustainable world. The most common types of renewable energy include solar energy (passive and active), wind power, hydroelectric energy, biomass (biofuels and biopower) energy, tidal energy, and geothermal energy.

Today most packaging materials and conversion processes rely on fossil fuel-based energy to a greater or lesser extent. The transition from fossil fuels to renewable energy throughout the packaging supply chain will require changes at many levels over a significant timeline. It is not possible, in the short to medium term, to migrate all materials and processes to renewable energy sources; the limiting step will be the availability of an economic and sustainable supply of renewable energy.

Companies are beginning to address the need to shift to renewable energy through a variety of strategies. In the near term, making fossil fuel-based systems as efficient as possible is an effective strategy for moving toward sustainability with very real economic and environmental return. At the same time, there must be a dedicated effort to diversify the energy mix and build momentum behind the transition to renewable energy sources. This transition is being encouraged through the direct investment or purchase of renewable energy, through carbon credits, or through tradable renewable allowances (RECS).

Transportation is a significant source of fossil fuel consumption associated with packaging. Companies experience direct cost benefit from improving fleet performance through optimized distribution or better fuel efficiency. Companies are also encouraging the use of bio-based fuels, hybrid vehicles, and other innovative technologies through internal measures or by acknowledging the efforts of suppliers. These types of activities help develop markets for renewable energy and offer alternatives to fossil fuel as strategies toward a more sustainable energy future.

D. Maximizes the Use of Renewable or Recycled Source Materials

The use of renewable or recycled materials can contribute to the creation of sustainable material flows and thus provide materials for future generations. Using recycled materials (renewable or nonrenewable) encourages waste reduction and the conservation of resources. The use of renewable materials reduces dependence on nonrenewable resources, uses current solar income to create raw materials (greenhouse gas neutral), and encourages sustainable management of resources.

The use of renewable or recycled materials supports the development of sustainable packaging by improving its environmental profile and providing a source of future packaging materials. Yet the physical deterioration of some materials through mechanical reprocessing (i.e., recycling) currently poses a limit to effective and economic reutilization of some packaging materials. Under cradle-to-cradle principles, materials should be recovered through either biological or industrial cycles or both. Many renewable or bio-based materials are suitable for recovery through either mechanism. Materials from nonrenewable resources should be recycled. Since the value of these materials cannot be recovered by natural processes, it requires a high degree of stewardship throughout their life cycle to ensure that they are recovered and reused.

Specifiers and designers striving for sustainable packaging should ensure the recyclability of materials, especially if they are made from nonrenewable resources. Environmentally preferable procurement and prescriptive regulations regarding the environmental characteristics of packaging are expanding and often incorporate recyclability (8) and recycled content requirements.

A key strategy for improving the sustainability of packaging is maximizing the use of renewable and recycled materials. The availability, performance, and price of some renewable or recycled materials affect the feasibility of incorporating them into new packaging designs. Material and technological advances that positively influence these factors for renewable and recycled materials can substantially improve the practicality of their use.

The sourcing of recycled materials is closely linked to end-of-life issues. From experience to date, it is clear that demand for recycled materials and the creation of market pull is a key driver for strengthening the recovery and recycling industry needed to provide them.

Encouraging the use of sustainable management practices through credible certification systems is an essential component of specifying renewable materials and an increasingly common strategy to address concerns associated with the production of virgin bio-based packaging materials. This tactic is used currently to address forestry and agricultural practices. While there is some focus on the sourcing of nonrenewable resources through clean production, there is not a comparable set of well-accepted sustainability practices or certifications directed toward sourcing nonrenewable resources. Because the extraction of both petroleum and mineral resources has great impact, steps need to be taken to address the sourcing of these materials.

E. Manufactured Using Clean Production Technologies and Best Practices

Clean production refers to the continuous application of an integrated environmental strategy to increase overall efficiency and reduce risks to human health and the environment. This includes conserving raw materials, water, and energy, eliminating toxic and dangerous raw materials, and reducing the quantity and toxicity of all emissions and waste at source during production processes (9).

Clean production represents environmentally responsible practice and applies to any industrial activity, including the production of packaging. Packaging uses significant quantities of energy, water, and materials in manufacturing and production processes. Clean production seeks to reduce and ultimately eliminate the environmental impact of any emissions and toxins emerging from these production processes.

Eco-efficiency strategies are currently pursued to minimize emissions, energy use, and waste. Some examples include voluntary emission reduction or elimination programs and the use of cleaner technologies.

Encouraging companies and suppliers to ensure that their production processes meet clean production best practice standards and support responsible manufacturing, worker safety, and sustainable packaging can ultimately reduce costs, thereby improving quality and long-term profitability.

New approaches and technologies are on the horizon. Advances are being made on closed-loop systems and beneficial reuse to eliminate wastes. Green Chemistry (10) and Green Engineering (11, 12) represent encouraging signs that the technical and scientific intelligence that created the technological transformation of the 20th century is now being directed toward solutions to unintended consequences.

F. Made from Materials Healthy in All Probable End-of-Life Scenarios

Human and ecological health is a basic requirement of sustainable development. Material health is a cradle-to-cradle principle that addresses the use, presence, and release of harmful substances to the environment. The accumulation of problematic substances in the biosphere and in our bodies is the subject of increasing concern for consumers, health professionals, and governments.

Packaging may contain certain chemicals that result in the unintended release of harmful substances during the life cycle of the package, particularly at the end of life. While these chemicals are typically utilized in small amounts, the scale and quantity of packaging waste can render them significant. Ensuring all ingredients—including additives, inks, adhesives, and coatings—are safe for human and environmental health throughout their life cycle is a vital aspect of sustainable packaging design.

Careful selection and specification of the safest materials available to meet the package performance requirements is the preferred strategy. Currently, companies continuously monitor materials bans, restricted substances lists, and legislation prohibiting the use of certain substances within packaging. There is also a need for an ongoing dialogue to examine what is in packaging materials and to encourage the optimization of material formulations for human and environmental health. The development of tools and methodologies to assess material health is underway and will allow more transparent communication of material characteristics throughout the value chain.

G. Physically Designed to Optimize Materials and Energy

Seventy percent of the overall impact of a product is determined in the design phase (13). By thinking about the entire life cycle of a product during the design phase and identifying critical aspects, it is possible to anticipate impacts and eliminate problems and waste up front. For this reason, anticipatory design is a fundamental best practice for sustainable products and packaging.

Typically companies design packaging to meet critical cost, performance, and marketing requirements. Sustainable packaging design adds consideration of life cycle impacts including: energy use over the life of the package, impact of materials in end-of-life scenarios, and appropriateness of the design/materials to facilitate material recovery. Other factors that should be considered in the design phase are consumer behavior and the variation of established recovery systems by market.

Several methodologies are currently used to support sustainable design including Design for Environment, Design for Disassembly, and Source Reduction. Corporate strategies to address packaging design include developing sustainable design guidelines and embedding them within product development processes. It is important to note that sometimes the adoption of one design strategy over another may result in tradeoffs. One design may focus on minimizing energy impacts over the life of the package and another may focus on the use of recycled content. Internal corporate sustainability objectives may influence the weighting of specific life cycle impacts and thus influence ultimate internal design strategies. In general, sustainable packaging design calls on designers to weigh these factors against each other and optimize their use as a whole. Standardization and communication of sustainable design strategies and their adoption by the packaging industry will create significant advances toward more sustainable packaging.

H. Effectively Recovered and Utilized in Biological and/or Industrial Cradle-to-Cradle Cycles

Currently, economic expansion and the related growth in resource use are considered to be inconsistent with sustainable development. Creating sustainable flows of materials will reduce the overall use of finite natural resources and minimize waste. Effective recovery means creating the collection and recycling infrastructure necessary to close the loop on materials in order to provide valuable resources for the next generation of production.

The greatest challenge to the development of sustainable packaging is the creation of economically viable and effective systems to collect and recover value from materials. The recovery phase of the packaging life cycle is the recipient of the cumulative impacts of all upstream decisions.

Effective recovery implies the significant collection and recovery of material at the highest value that is economically feasible. As suggested by the discussion under previous criteria, effective recovery can be achieved through supply chain collaboration, by the coordinated efforts of the packaging system to create healthy and recyclable materials, by packaging designed for recovery, and by establishing appropriate collection and recovery infrastructure with the combined support of end users—brand owners, retailers, and consumers.

There are many methods of collecting and recycling packaging materials to recover their intrinsic value to society. In reality, the established recovery infrastructure in the country in which the product is sold/used, together with market dynamics, will ultimately determine the method through which a package will be recovered. Some of the more common recovery methods are discussed below.

Biological Recovery (Managed Composting). The earth's biosphere effectively recovers the nutritive value of basic biological materials. The conditions for effective biological degradation do not exist in landfills and the release of problematic substances is a further concern. It is necessary to engineer and manage biological recovery systems to ensure safe and effective recovery of value from biological materials. Managed composting and anaerobic digestion with energy recovery are examples of managed biological recovery systems; landfills are not.

Technical Recovery (Recycling). Because nature cannot effectively recover many man-made packaging materials, engineered recovery systems are necessary to avoid their accumulation in the environment and to recapture their value. Some examples of technical recovery include mechanical and chemical recycling of plastics and thermal recycling of metals and glass. It is also possible to recover biological materials in technical systems (e.g., paper recycling). The ability to economically recover value varies by material, regional variations in infrastructure and technology, and consumer behavior.

Energy Recovery (14) (Waste to Energy). Energy recovery increasingly is used as a method to recover value from packaging materials. Safe incineration with energy recovery, waste to energy facilities, and the use of plastic and paper as an alternative fuel are all energy recovery methods. These technologies represent conversion of material to energy.

While energy recovery does not represent a sustainable use of nonrenewable packaging materials (e.g., fossil fuel based plastics), it is a preferable interim alternative to landfills, litter, or uncontrolled burning.

For bio-based materials, energy recovery has different implications. Bio-based materials are a preferred alternative to fossil fuels because they are renewable and are considered carbon neutral with respect to climate change. However, they are not without other pollution impacts like particulate or nitrous oxides. The best efforts to meet many of the criteria outlined in this definition (e.g., performance and cost, renewable energy, safe materials, optimally designed packaging) will only result in sustainable packaging if it is collected and recovered. Ideally, materials and recovery options should be introduced at the same time, which requires coordination along the entire value chain.

IMPLEMENTING THE VISION

As they stand now, conventional definitions of design quality are typically limited to cost, technical performance, appearance, and, in certain cases, regulatory compliance. When sustainability is added to the mix, it introduces an expanded set of criteria that may include optimizing resources, responsible sourcing, material health, and resource recovery. This means the ability to design packaging that strives for total life cycle quality. A survey of Sustainable Packaging Coalition members showed that several companies have started to make steps toward sustainability through innovative redesign.

Origins Natural Resources, Inc. (Origins), a subsidiary of The Estée Lauder Companies, Inc., recently created a new line of products in collaboration with integrative health specialist Dr. Andrew Weil. Origins wanted to use this product launch to strengthen the environmental ethic embedded in its mission. The new line consists of 50% post-consumer-recycled-content paperboard, and it is manufactured, printed, and folded using 100% renewable wind energy. Environmental savings include reductions in greenhouse gases and other pollutants associated with coal-powered electrical generation.

Michelman, Inc., a leading coatings manufacturer, developed a polymeric emulsion coating for corrugated boxes that allows them to replace nonrecyclable expanded polystyrene (EPS) boxes typically used for long-term grape storage. These coated boxes are priced comparably to EPS boxes. They offer an end-of-life revenue opportunity for end users through recycling and eliminate the cost associated with the disposal of EPS. In addition, the polymeric emulsion coated boxes replace the use of styrene, the monomer used to make EPS and a known respiratory irritant and possible human carcinogen.

Starbucks Coffee Company set out to redesign its packaging boxes for its line of bite-sized chocolate-covered nuts, espresso beans, dried fruit, and grahams. Although the redesign had aesthetic goals, the Starbucks design team set out to mitigate environmental impacts as well. The company reduced the number of layers and thinned the paperboard used in the packaging. By critically analyzing the package's weaknesses including size, weight, recyclability, number of component parts, and sourcing locations, Starbucks has produced a more effective product. In addition to reducing materials and environmental impact, the new smaller design resulted in costs savings through reduced material input and labor and more efficient transport and storage.

While these and many other companies have taken significant steps to improve their packaging, according to the criteria outlined by the Sustainable Packaging Coalition, currently no packaging can be defined as sustainable. Yet each of these sustainability objectives opens up numerous opportunities for a solutions that improve on existing packaging approaches. This is the challenge for packaging professionals: to continue to innovate, meet, and exceed performance in the new categories of excellence introduced by sustainability. In the new world of sustainable packaging, design is a critically important leverage point.

14. These comments are only valid for incinerators that do not emit dioxins and other pollutants into the atmosphere (i.e., they are equipped with appropriate waste air scrubbing and cleaning processes. The latter is referred to “safe incineration with energy recovery”).

SUSTAINABLE PACKAGING: CONCEPTUAL FRAMEWORK

Kit L. Yam
Department of Food Science,
Rutgers University, New
Brunswick, New Jersey

In 1987, the World Commission on Environment and Development defined the term “sustainable development” as the guiding principles for meeting the needs of the present without compromising the ability of future generations to meet their own needs. Similarly, the European Union defined sustainable development as a vision of progress that integrates immediate and longer term needs, local and global needs, as well as regards social, economic, and environmental needs as inseparable and interdependent components of human progress. In these definitions, the general terms, guiding principles, and vision of progress are used, because sustainable development is a complex process with no specific steps applicable to every situation.

Today interest is growing from organizations, governments, and companies around the world to give sustainable development useful and practical meanings. Although the concept of sustainable development is important to virtually all industries, this article is focused on sustainable packaging.

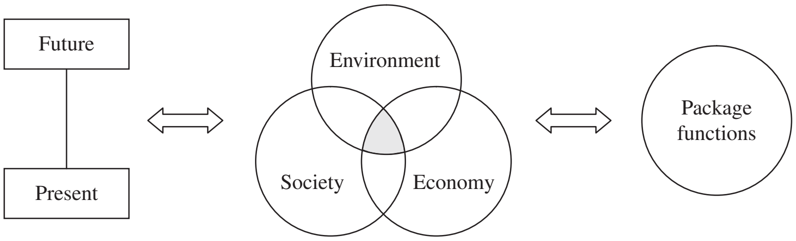

Figure 1. Conceptual framework of sustainable packaging.

The Sustainable Packaging Coalition, a leading organization for sustainable packaging, defines sustainable packaging as a target vision for creating "a world where all packaging is sourced responsibly, designed to be effective and safe throughout its life cycle, meets market criteria for performance and cost, is made entirely using renewable energy, and once used is recycled efficiently to provide a valuable resource for subsequent generations" (see also Sustainable Packaging).

CONCEPTUAL FRAMEWORK

The framework below describes substance packaging as a holistic concept that consists of three interrelated components.

The first component is related to time and perpetuality. Sustainable packaging is aimed at not only meeting the needs of the present generation, but also meeting the needs of future generations. It requires a cradle-to-cradle flow of packaging materials in which the materials can be used repeatedly without depleting resources.

The second component is related to striking a healthy balance to meet the needs of the environment, society, and economy—a packaging system is not truly sustainable until all these elements are addressed in an equitable manner. For example, a packaging system with the sole purpose of maximizing profits is irresponsible if it fails to address the needs of the environment and society. Similarly, a packaging system with the sole purpose of minimizing the negative impacts to the environment is unrealistic if it fails to address the needs of the society and economy. In Figure 1, sustainability occurs only in the shaded area where the circles of environment, society, and economy meet.

The third component is related to the packaging functions, which are as follows: containment, protection, convenience, communication [see Packaging Functions and Environments; Intelligent Packaging]. Unless a package can perform some useful functions, the justification of its existence is questionable. For example, a package may be considered environmentally friendly because it is biodegradable; however, if it fails to protect the product, the product will likely be discarded and not used by the consumer. The packaging functions, unfortunately, are largely overlooked in the literature when sustainable packaging is discussed.

Many articles in this encyclopedia fit under and support the conceptual framework in Figure 1. For example, the impacts on the environment are addressed in articles such as Biobased Materials, Environment, and Life Cycle Assessment. The socioeconomic factors are addressed in articles such as Economic of Packaging, Laws and Regulations, and Tamper-Evident Packaging. The packaging functions are addressed in articles such as Packaging Functions and Environment, Food Packaging Development, and Packaging of Food. In fact, many articles in this encyclopedia describe packaging materials, processes, products, or technologies for achieving certain desirable packaging functions.

GUIDELINES FOR DEVELOPING SUSTAINABLE PACKAGING

How best to develop sustainable packaging to meet the needs of the present without compromising the ability of future generations to meet their own needs? Although no straightforward answer exists to this complex question, below are some useful guidelines:

- Consider the conceptual framework in Figure 1 and strike a healthy balance to meet the needs of the packaging functions, environment, society, and economy (see Packaging Functions and Environment).
- Avoid over-packaging by using minimal, but adequate, amount of materials to meet safety, quality, and market needs.
- Avoid toxic constituents and use energy efficient technologies whenever possible for manufacture and distribution of product.
- Whenever feasible, use packages that are made of renewable, environmentally friendly, or recycled materials, without compromising product safety and quality or greatly increasing cost.
- When developing packaging system or technologies, it is important to strike a healthy balance to meet the needs of the environment, society, and economy.
- Use methodologies such as life cycle assessment (LCA) to aid the development of sustainable packaging.

Association

INTRODUCTION

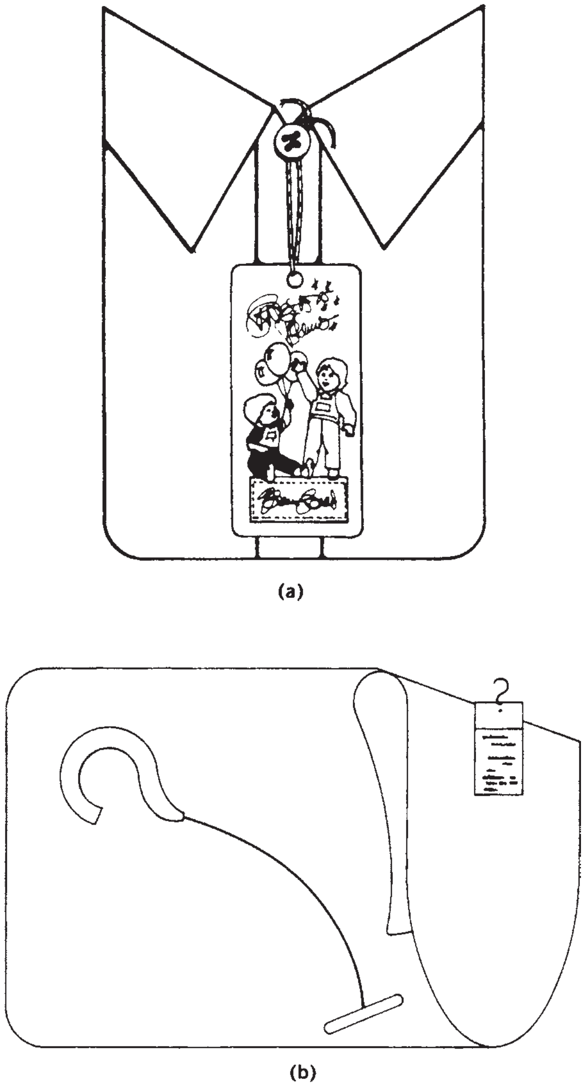
Tags have been used in all areas of business and industry for centuries. The more progressive merchants of the 1800s used tags in the same manner and for the same reasons as merchants today: to inform, instruct, identify, and inventory (see Figure 1). Traditional cloth and paper materials have been joined by nonwoven and film-based synthetics (see Nonwovens; Plastic Paper).

Tags used in retail environments are generally produced from cast-coated paperboard stocks ranging in thickness from 8 to 10 points (0.008–0.010 in., 203–254 μm). Type stands out and colors are brilliant on the smooth surface of cast-coated stocks. Cloth tags are frequently called “law labels.” This term describes labels generally sewn onto mattresses and furniture to comply with government regulations regarding the identification of stuffing materials. Tags manufactured of synthetics such as nonwoven Tyvek (DuPont Company) are gradually replacing cloth tags because they exhibit an extremely high tear strength, are insensitive to moisture, and have a smoother, more uniform printing surface than cloth. Plastic tags are generally used for advertising or instructional purposes in the retail industry.

Figure 1. Price marking tags from the 1800s.

Many fastening methods are available, but the most common in the retail industry for product identification is a knotted string (see Figure 2**a**). Plastic barbs are generally used for price marking in retail garment applications. Manufactured from an ultrathin plastic, these barbs affix price tags to ready-to-wear merchandise to prevent price-tag switching. Plastic barbs can also be combined with a hook (see Figure 2**b**) to hang merchandise such as socks.

In manufacturing, processors, converters, and fabricators have a variety of uses for tags. Tags play an important part in tracking serially numbered goods such as electronic components. The simple tag shown in Figure 3**a** uses transfer tape on two of the three stubs to enable the tag to



(a)

(b)

Figure 2. (**a**) Knotted-string fastener. (**b**) Plastic barb with hook.

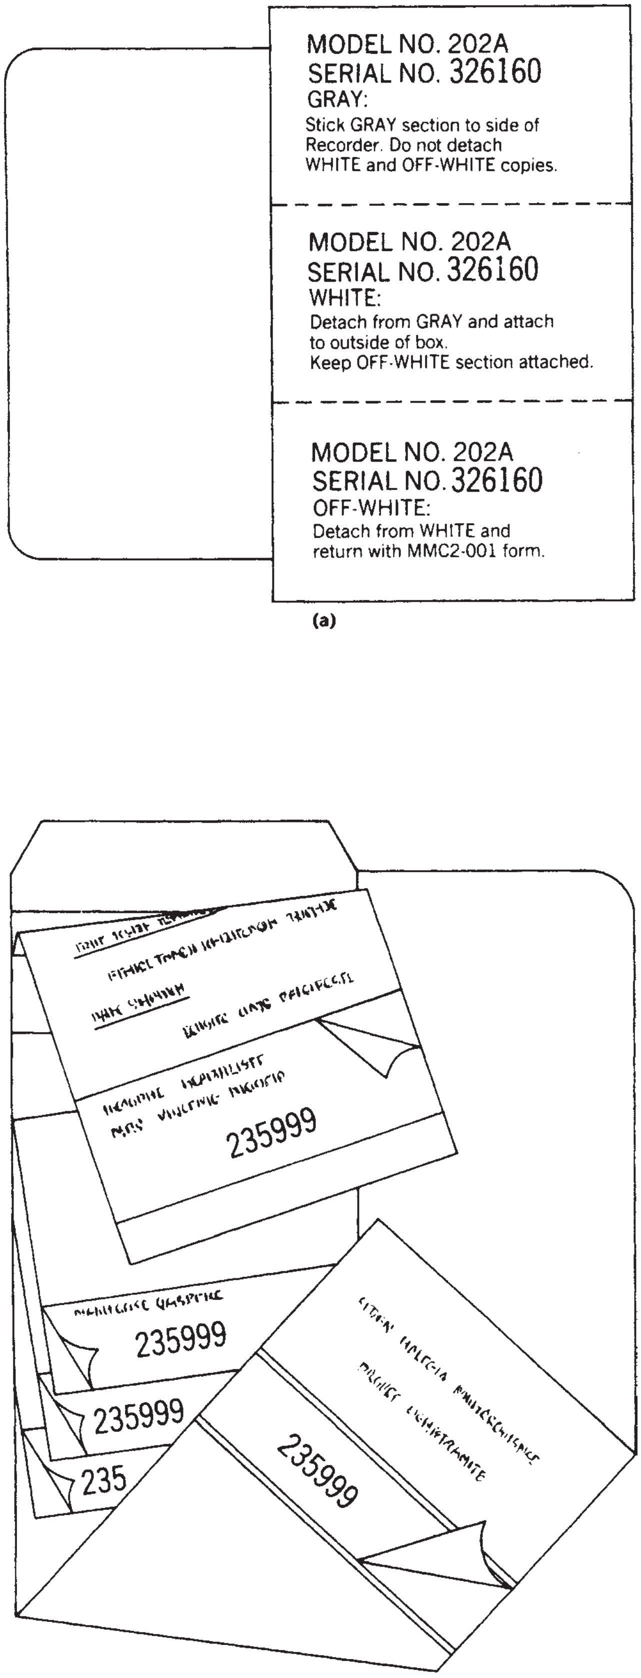


Figure 3. (**a**) A three-stat tag. (**b**) Tag-and-label combination.

travel with the component throughout the entire packaging cycle without losing track of the serial numbers. Color coding minimizes the need for processing instructions. The entire tag is affixed to the component at the end of the assembly line, using the transfer tape on the gray stub first. Prior to boxing the product, stubs two and three (white and off-white) are detached and affixed to the outside of the box. On receipt of shipping instructions, the off-white portion is detached and forwarded with a copy of the shipping document to inventory control.

Tags and pressure-sensitive labels are frequently combined to create unusual tag products. The tag in Figure 3**b** includes four pressure-sensitive labels, each carrying the serial number of the component, in addition to the nameplate, which in this case is affixed to the product after delivery by the installer. The tag is attached to the component with string or transfer tape, depending on the surface or characteristics of the component. The shipping department lifts up part 1 to reveal part 2 of the set, which consists of a small-face slit label containing the serial number of the component and the instructions "put on shipping document." Part 2 is torn at the perforation along the top and reveals three additional labels with instructions for distribution (warehouse copy, distributor copy, installer copy). This unusual tag and label combination provides a simple solution to the often difficult task of tracking serially numbered products and components from assembly through shipping to their ultimate destination.

Tag applications in the retail packaging industry include, but are not limited to, product description, content identification (i.e., materials used in production), care and use instructions (i.e., operating and care directions, identification of potential hazards), guarantee and warranty information, decoration and promotion, inventory control, and price marking (frequently combined with inventory control when using magnetic stripes, OCR, or bar codes) (see Bar Code; Code Marking and Imprinting).

Product marking tags, also called "hang tags," are printed in up to eight colors on a variety of stocks and include many features designed to get the attention of the potential consumer. Sizes range from small jewelry marking tags (see Figure 4**a**) to oversized tags used to identify major appliances.

Hang tags are generally shear-cut, die-cut, or continuous, and they offer maximum versatility for product identification, sales promotion, and advertising. The three basic tag styles found in retail tagging applications are shear-cut, die-cut, and continuous tags.

SHEAR-CUT TAGS

Shear-cut tags, also called "shipping tags," are the oldest and most common of all tag styles. Shear-cut tags are simply sheared off the end of the web from the bindery section of the press after all manufacturing processes are completed. These tags may be simple, printed on one side with black ink, with a standard 3/16-in. (4.8-mm) punched hole. They may also be very complex, with such features as multicolor printing on both sides. Eyelets in tags used

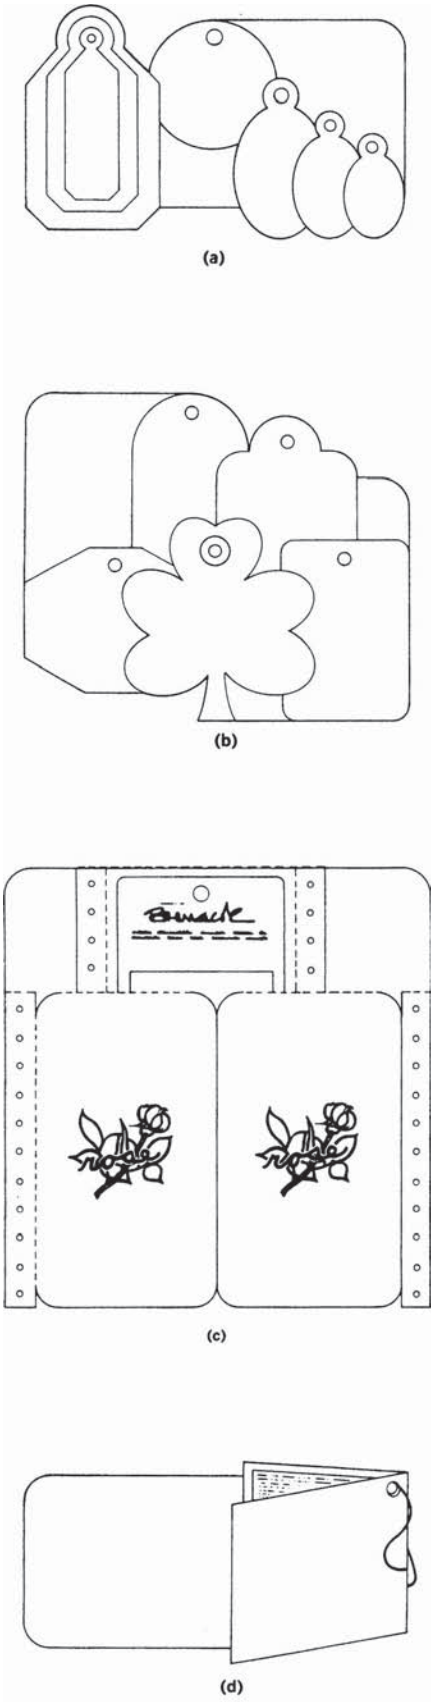

Figure 4. (**a**) Jewelry tags. (**b**) Die-cut tags. (**c**) Continuous tags. (**d**) Booklet tag.

for product identification are rarely reinforced because the life expectancy of the tag is short.

DIE-CUT TAGS

Die-cut tags are cut out of the web at the end of the bindery section of the printing press using either stock or custom-manufactured dies. Die cutting produces tags that are round, have rounded or scalloped corners, or have unusual shapes as shown (see Figure 4**b**). Die-cut tags may have all or most of the features of shear-cut tags, but usually do not require features such as large patches or jumbo numbers. They are used primarily as promotional pieces or to convey information regarding a specific product, and they are usually not subjected to a great deal of rough handling.

CONTINUOUS TAGS

These are used in applications where variable information is imprinted by a computer printer. Many possibilities exist for the number of perforations and form depths since stop-and-go presses are used in their manufacture. Continuous tags are generally used for retail price marking (see Figure 4**c**). Special features are frequently incorporated to create hang tags that are used effectively as promotional pieces.

Booklet tags are shear-cut tags, scored vertically to form a fold, providing four surfaces for copy instead of two (Figure 4**d**). Special effects can be added to further enhance the image of these versatile tags. Die cuts on one of the pages, generally the first, can be used to highlight the company logo or trademark or provide a representation of the product (Figure 5**a**). Die cuts are also used on the front cover to create a window on the cover panel or to create a three-dimensional effect. The die cut is generally backed up with a solid color block or printed design which shows through the die cut (Figure 5**b**). *Gatefold tags* are a special variety of booklet tag featuring two vertical scores to form three separate double-sided surfaces for a total of six surfaces available for printing (Figure 5**c**). *Accordion-fold tags* have three vertical scores that create a total of four “pages” with eight surfaces for printing. Accordion-fold tags also may be produced with additional scores to add pages and sides (Figure 5**d**).

Many applications require that tags not only carry a message regarding the product but also serve as a carrier for the product itself. In instances where merchandise (e.g., jewelry) is hung on racks for display or when merchandise is seasonal and only temporarily displayed, this type of tag is very effective. Figure 6**a** shows a tag with die cuts and additional punches to hold stick pins in a retail jewelry application. The center punch is used to hang the merchandise on a display rack. The tag shown in Figure 6**b** uses two die-cut triangles to hang gloves on display racks in order to conserve space because of the product’s seasonal nature. The tag is folded at the score over the cuff and stapled to fasten it to the merchandise. The die-cut triangle is then used to hang the gloves on the display rack. Figure 6**c**

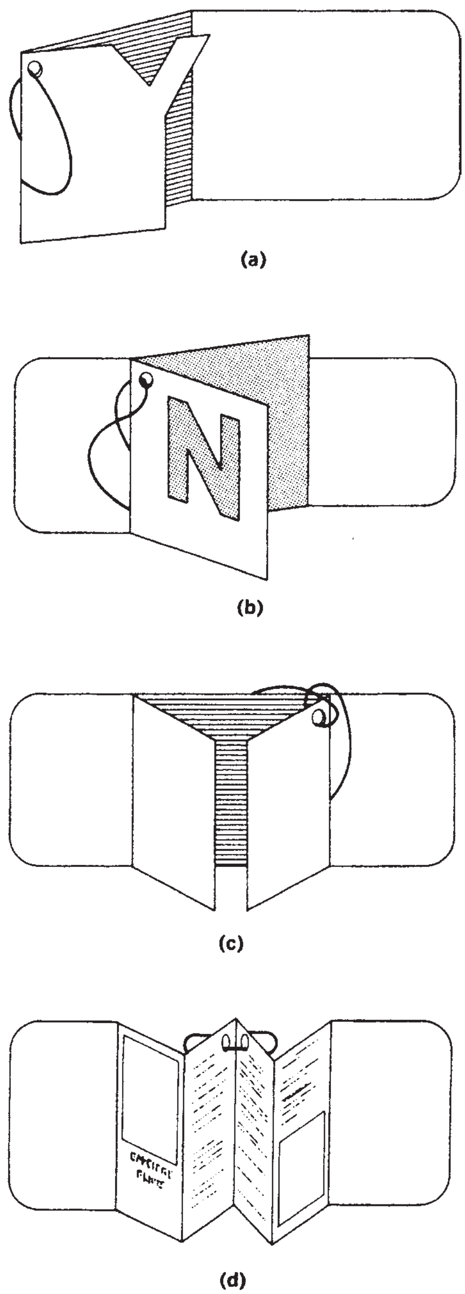

Figure 5. (**a**) Die-cut outline. (**b**) Three-dimensional die-cut tag. (**c**) Gatefold tag. (**d**) Accordion-fold tags.

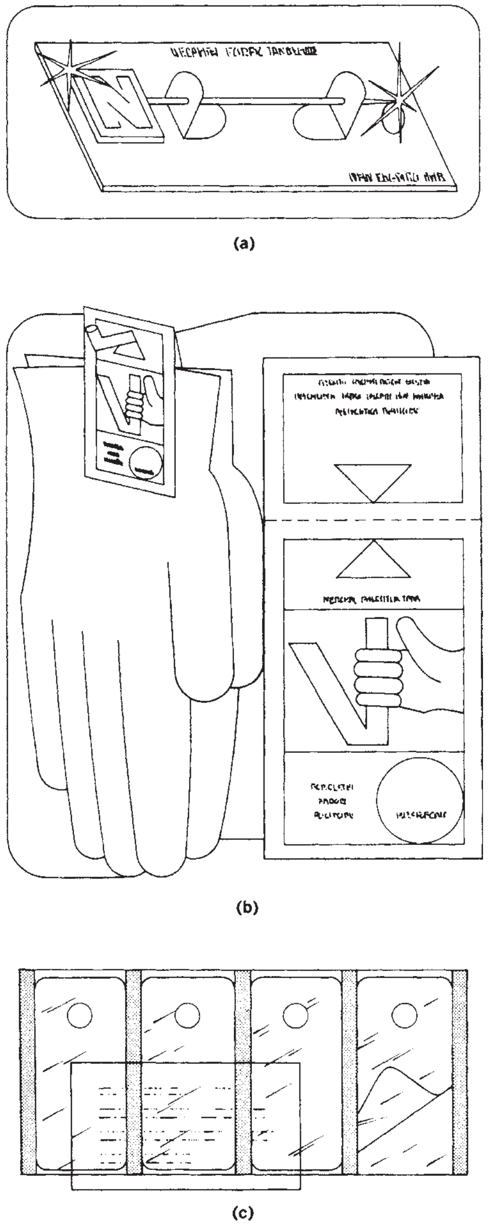

Figure 6. (**a**) Jewelry display tag. (**b**) Display-rack tag. (**c**) Transparent hang tag.

shows a hang tag of clear plastic partially coated with a pressure-sensitive adhesive. The coated portion of the tag is applied to the merchandise, and the die-cut hole is used to hang the merchandise on the rack.

Tags used for price marking are generally produced as continuous tags. These tags satisfy the special needs of large retail organizations by affording them the opportunity to ship preprinted price tags along with stock shipments to their various distribution locations. The tags come in a variety of sizes and shapes are generally affixed with plastic barbs by tagging guns to prevent price switching. The accelerated use of computers in the retail industry has had a dramatic effect on the appearance and use of tags. Price-marking tags are now being produced with magnetic stripes (Figure 7**a**), which can contain information such as style, lot number, and manufacturer. In addition, bar code and OCR (optical character recognition) technologies have gained acceptance in the retail tag market.

Tags can also aid in theft prevention, which is one of the biggest concerns in the retail industry. Hard plastic tags such as those shown in Figure 7**b** are affixed to articles of clothing in many large retail stores. The tags must be removed at the time of sale to prevent triggering an alarm as the garment passes through a special gate that contains a scanner that is sensitive to the tag. Because of their bulk, these tags are used primarily for clothing. Recent innovations in miniaturization have

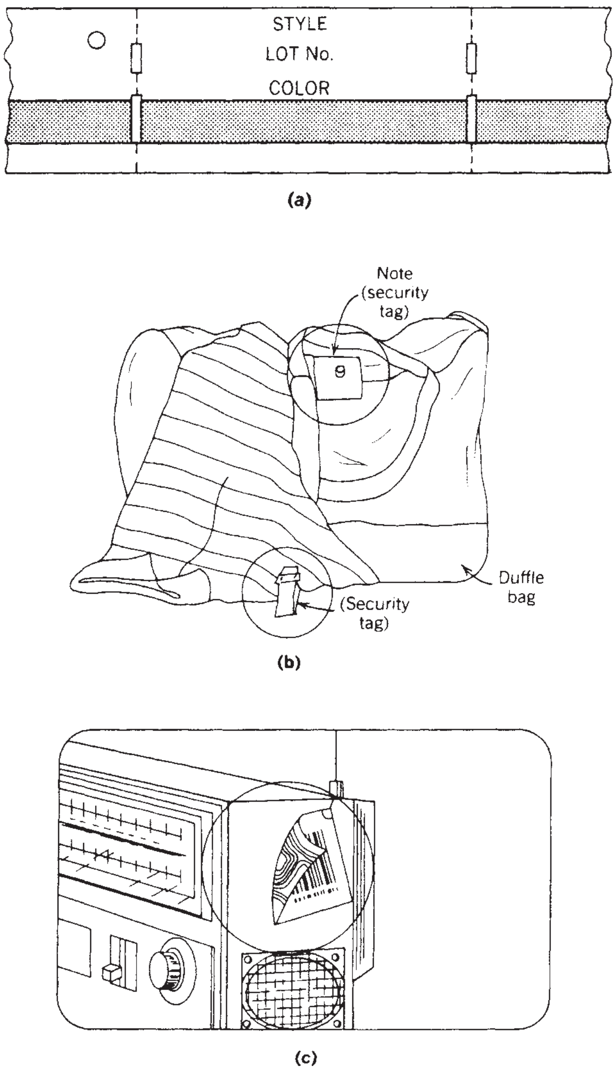

Figure 7. (**a**) Marking tag with magnetic stripe. (**b**) Plastic electronic security tags. (**c**) Security tag with miniaturized radio circuit.

produced tags with what appears to be a strip of aluminum foil (Figure 7**c**), but which is actually a built-in security device. If not deactivated by another strip of foil affixed at the time of sale, these circuits interrupt radiowaves being transmitted from the exit gate and set off an alarm. These tagging systems are currently marketed by companies that sell retail-security systems.

Industry indicators predict that the future of the tag industry in retail operations will not be adversely affected by advances in computer technology. As long as there are products to be identified, inventoried, and priced, there will be a market for tags of all kinds in the retail industry.

TAMPER-EVIDENT PACKAGING

Jack L. Rosette
Forensic Packaging Concepts,
Inc., Jefferson City, Tennessee

HISTORY OF THE PROBLEM

Since 1982 the entire industry, including the consumer, has become aware of tamper-evident packaging. This awareness has benefited the consumer by a reduction in loss of life due to consumption to adulterated products from tampering. Never before has an industry reacted so swiftly to resolve a problem that could be the ruination of most manufacturers.

In 1982, seven people in the Chicago area died from consuming cyanide-laced Tylenol capsules. The incident resulted in a total product recall, massive negative publicity for the product, new requirements for safe packaging, and a federal statute making product tampering a crime. Since that time, the packaging industry has become visible to most consumers.

HISTORY OF INCIDENTS

Although there were incidents prior to 1982, product tampering became highly visible after the Chicago incidents. The exact number of incidents per year is unknown because of various methods of reporting. Beginning with the 1982 deaths, there have been deaths from product tampering that are widely known such as those in 1982, 1986, and early 1991. All deaths due to targeted tampering are not included, because we are discussing random tampering, not tampering with a specific person in mind. It is probably a coincidence on the timing as the various incidents are unrelated, and in some instances the violator in earlier cases was incarcerated at the time of the ensuing incidents.

According to government figures, the problem peaked in the United States in 1986, when there were almost 1800 claims of possible product tampering. The number has decreased to around 500 per year now. Is the decrease due to better packaging or less interest on the part of potential violators, due to the penalties for violating product-tampering laws? Considering the experience in assisting law-enforcement agencies, the decrease appears to be caused by a change in the way claims are recorded as well as a reluctance on the part of manufacturers to report all claims of possible product tampering.

If the experience of other developed nations is an indication of the future, it is expected that the problem of product tampering will escalate in this country in the future. Every developed nation has experienced product-tampering incidents. The main difference between domestic incidents and what is happening elsewhere is the motive of the tamperers: extortion prior to injury, with money appearing to be the primary motive, versus apparently random tampering without prior threat in this country. Most developed nations are either implementing or modifying their rules on the use of tamper-evident packaging. Some features as they are used in the United States would have to be modified, or the use of a secondary feature would be required to meet the standards of various countries.

The problem of state-sponsored terrorism is so serious that a series of meetings were held in the late 1970s were the problem was addressed in great detail. Participating in the meetings were representatives of the FBI, Commerce Department, Defense Department, State Department, and CIA. One of the chief concerns at the time was the threat of retail-product tampering by a state-sponsored organization. The term “state-sponsored terrorism” refers to any group of terrorists that is supported financially, logistically, or in intelligence by a government body of any country. It has been documented that training in ways to tamper with retail products and how to use such acts to further their agenda is being conducted in certain countries that sponsor terrorist groups. Picture, if you will, the potential for disaster that exists if a potential tamperer has the financial and human resources available to build a complete packaging line and can print duplicate labels. It sounds far-fetched, but a similar incident occurred in South America when a drug organization bought a beverage plant to smuggle cocaine into the United States. In that case at least one bottle in a specially marked case contained the drug in a liquid form. When the contents of the bottle was distilled in the United States, it would yield a powder that could then be cut in strength and distributed to the dealers. Unfortunately, one bottle was overlooked and sold to a consumer who died from a massive cocaine overdose.

While most incidents of retail product tampering in the United States have been perpetrated by individuals, the potential exists for even greater harm from the same acts committed by a state sponsored terrorist group.

THE FDA RULE

In 1982 the FDA passed a rule (21 *CFR* 211.132) requiring the use of tamper-evident packaging on all over-the-counter (OTC) drugs and some cosmetics, while ignoring other products they regulate. The fact that your product is not required to use tamper-evident (TE) packaging does not protect you in the event of a claim of product tampering.

According to attorneys specializing in packaging and product liability, product tampering is a foreseeable possibility, and manufacturers have a responsibility to protect consumers against such possible acts. If your product in an adulterated form could harm a consumer, you have a responsibility to protect the product and consumer against such acts. This means that the use of tamper-evident packaging transcends FDA regulations.

The Rule specifies which packaging features are acceptable for use in providing resistance to tampering, and the list was modified in 1988. At the current time there is a proposal to modify the Rule again and to make the acceptability of a feature based on performance.

What if the feature you want to use is not on the approved list of the FDA? The FDA has a procedure by which methods of providing protection that are not on the approved list may obtain approval on a case-specific basis. To obtain approval, samples of the complete package must be submitted to the FDA along with a written request for a waiver. Contact the local FDA compliance officer to find out the current procedure to obtain approval.

The inclusion of a specific form of protection does not warrant that the feature will deter violation, nor does it prevent legal action in the event of a claim of injury related to product tampering. There are variances in designs, and even tooling of the same design that affect the effectiveness of each feature. Any evaluation of a package relates to the exact components used in the tests, and material from a different manufacturer will usually result in a different level of effectiveness, much the same as using a different resin or closure liner will affect a stability study.

CONSUMER PREFERENCES

Studies into consumer preferences for tamper-evident packaging have consistently revealed that the consumer prefers products that are resistant to tampering and prefer the features to be shelf-visible. The same studies indicated a willingness to pay slightly more than a competing brand that is not TE. The exact amount is inconsistent among the studies, but the consistent replies of concern indicate consumer awareness of packaging. This awareness increases with publicity of tampering incidents, and it decreases with time until the next publicized incident.

COST OF CLAIM OF PRODUCT TAMPERING

The cost of responding to a claim of possible product tampering would boggle the mind of the average person. The cost begins when the complaint is received by company personnel, and it includes the following:

- *Meetings that Will Be Held to Determine How to Respond to the Claim.* A complaint of possible product tampering requires participation of top management in all phases of meeting the problem.
- *Expenses Related to High-Level Managers Visiting the Locale Affected.* Top management or their representative will usually visit the location involved to get a better feel for the situation.
- *Cost of Picking Up All Stock and Possible Restocking of Retail Displays.* . If the brand is to remain viable, fresh supplies must replace all product that may have been vulnerable to violation.
- *Cost of Complete Inspection of Targeted Stocks or Destruction of Those Not Capable of Inspection.* Since it is unlikely that the entire supply of product on the shelves at the time of the incident was affected, inspection of the stock may prevent destruction of the entire inventory.
- *Lost Sales When Consumers Changed to Other Products.* Many consumers will switch to other brands until they regain confidence in the brand affected.

- *Rewards for Information on Incident*. Rewards usually lead to information as to the identity of the violator and result in ending further incidents.
- *Fees for Packaging Consultants*. Since it is impossible for every company to have employees who are experts on every contingency, outside consultants will be required to assist in meeting the challenge.
- *Cost of Legal Counsel to Respond to Litigation*. Self-explanatory.
- *Damage Awards Where Determined in Court*. See above.

The list can go on. Many of these costs will be incurred even in false claims of possible product tampering.

When compared to the potential expense for defending a single claim of tampering, the cost of effective tamper-evident packaging becomes insignificant. Some in the industry will take the moral position that we have an obligation to protect the consumer and they are right. Beyond the moral position is the reality that many firms simply cannot afford the cost of responding to product tampering claims, especially if the firm is a small, with a very limited product line where the reputation of the entire product line can be affected by adverse publicity on one item in the product line. Liability insurance cannot restore lost-customer confidence.

A recent incident, later determined to be suicide, almost caused a household name brand to go out of business because of the high cost of produced recall and package redesign, even though the product and company were linked to the incident only by circumstance.

In considering cost, the cost associated with responding to one claim of product tampering far exceeds the cost of incorporating tamper-evident features in the package design. Would you want to explain to your boss how your company could not afford the penny or two for making each package tamper-evident, and how you can afford the 10 million dollars or more your company is spending on defending a claim of possible product tampering? Who can put a value on human life that would justify not using effective tamper-evident packaging? The reality is, tamper-evident packaging should be utilized if it will provide any protection for your product, regardless of government regulation.

SELECTING WHICH FEATURE TO USE

Everyone has a preference for one type of package over another. This preference has been developed by either the products we manufacture or our experience with various types of packaging in our everyday living. Selecting which feature to use should not be affected by these preferences, but by objective testing during the package development stage.

During the design stage, the package engineer should consider the function of the product and how the consumer intends to use it. Next, each TE feature that is usable on the package should be tested to determine which feature will offer the greatest protection to the consumer. The test used should be objective, consistent, and replicable. Records of the test results should be retained indefinitely. If a feature selected for use achieves a lower value than others that were rejected, reasons for the selection should be recorded and retained with the test results. Remember, cost cannot be a factor in selecting which feature to use. You would not want to be questioned by attorneys for the other side as to why you were willing to accept less effectiveness to save a few pennies and to compare those few cents to the value of injury to a consumer.

One form of testing the effectiveness of tamper-evident packaging is the *Rosette Protocol*, which measures the degree of difficulty in violating a specific package and restoring it to a nearly original condition. The Protocol also measures increases in effectiveness through the use of multiple features. The value for a specific combination of features is not equal to the sum of each feature. Some factors cover the combination, rather than each feature separately. For example, the knowledge factor is applied once, regardless of the number of features in the combined package, and only one knowledge level was required. Time is cumulative; if it takes 20 min to violate each feature, the time required is not the value for 20 min multiplied by the number of features used on the package. In this example the time factor is the value for 1 h. Only one category of equipment may be required if all tools or equipment required to violate the different features in the combination are in the same class. The feature visibility values for all used on multiple feature packages are multiplied; even the use of multiple features that are not shelf-visible increases the effectiveness of the package. The feature material is added for each feature replaced or reused to determine the feature material value. The value of the feature, used with the specific package components, on the specific product and form of product tested, is the sum of all the factors.

The FDA and the Non-prescription Drug Manufacturers Association have expressed concern that the industry would gravitate to the feature achieving the highest score in any testing procedure. In reality, the value for a specific feature will vary, depending on the exact product and all other packaging components used in a specific package. The same feature from different manufacturers may achieve different values, because there are slight variations in design and manufacture, even though the features may appear to be identical. If a value were to be established at 20 on a scale of 0–50 for a single feature, the value of 20 could be attained through the use of multiple features if necessary. This would preclude any single feature from becoming the industry mandated method to provide protection. The above value of 20 is for illustration purposes only; prior testing has shown the minimum design for FDA acceptance to be around 11, with some minimum values for approved features scoring much higher. A standard requiring 20 as the minimum value would require most packages to be improved before the package would meet the standard. The use of multiple features can result in a value higher than 50. While the Rosette Protocol has been tested and in use for several years, there are others that may be as objective and in use by other companies.

Certain tamper-evident features in use today, and approved for use by the FDA, are at best window dressing. Such features can be violated without the use of tools of any type, the feature removed and replaced after violation of the package, and all without leaving any indication of possible violation. Some very effective alternatives to the features are not being used because of a slightly higher per unit cost. Other features used to provide resistance to violation are being used in a form that does not meet the FDA standards and can be duplicated very easily—all to save a penny per unit. It is time for the packaging industry—the producers and the users—to accept their responsibility and provide effective packaging to their customers. The best way to do this is through the use of an objective approval process that disregards minor costs or inconveniences.

WHAT IS THE BEST TE FEATURE?

A lot of people ask "What is the best TE feature?" No single TE feature is best for all products! There are variations in effectiveness of similar features from different manufacturers as well as variations in effectiveness where the product contributes to the effectiveness. An example is a metal can which is much more effective for a carbonated product than for a noncarbonated product. The product can determine which feature provides the most protection; for instance, a product that can be adulterated effectively by penetration would require a more rigid outer container than one that degrades visibly on violation by penetration. The best feature for your product is the one that provides the greatest resistance to violation for that product in its current form and size. All features can be violated in some manner; effective TE features provide greater difficulty in violating the product than do ineffective features. In some cases the packaging was violated by being opened, just as any consumer would do, and then the tamperer replaced the original product with a toxic substance, not making any attempt to restore the package to its original appearance. The package worked as intended—it showed that it had been opened, but still resulted in injury to the consumer. The violation does not have to be exotic to harm the consumer. Tamperproofness does not exist!

DOES TAMPER-EVIDENT PACKAGING WORK?

Since the implementation of the FDA rule (21 *CFR* 211.132) in 1982, the consumer has increased awareness of packaging. This awareness has led to an increase in the number of complaints of possible product tampering, although most incidents are later dismissed as unfounded. Tamper-evident packaging prevents tasting in stores, prevents in-store violation, and, if the feature is intact, ensures the consumer that the product is safe. Effective tamper-evident packaging acts as a deterrent to most persons who would commit such acts of violation and makes it difficult for others to violate the package and restore it to its original appearance. Yes, effective tamper-evident packaging works, provided that consumers are aware of the feature and pay attention to what they are about to use.

Most experts agree that the consumer should be more aware of what to look for in tamper-evident packaging. Educating the consumer could include pictures of the feature and product on the label and in media ads. One recent case resulted in loss of life where the package met this test with two indicators: The product was pictured on the label and the actual product consumed did not resemble the picture on the label in two different ways, as well as numerous other indications of violation. The consumer used the product anyway and died from consuming the substituted item. If the consumer had examined the product and package, it should have been obvious that the product was not to be used. Better consumer awareness may have prevented this incident.

The consumer today is different from those in previous generations. You may remember as a child that if a can was dented, it would be passed over by shoppers until it was the last package on the shelf. Most dented cans were sold at a discount in a special bin. Today consumers are so confident of the quality of the product, and accustomed to manufacturing defects, transporation damage, and other variations in the package, that they accept without question packages their parents and grandparents would have rejected. This demonstrates the confidence the consumers have in our products, which we can be proud of, but insulates them from taking responsibility for their own safety.

Both the products themselves and their manufacturers have taken the entire blame for past incidents of product tampering. Another weak link in the chain of package security is the retailer. In prior cases, the retailer has not been held accountable for the violation of any package, or the sale of packages with obvious indication of prior opening. During research, many stores were visited to observe what products are converting to the use of tamper-evident packaging and to determine which features are used on what types of products. During those visits, many packages were observed where the tamper-evident feature indicated possible prior opening. In every case the package was taken to the store manager, with an explanation of what was observed. Their statements have ranged from "I will put it aside for the salesman to pick up" to "there's nothing wrong with it, it happens all the time" to "put it back on the shelf and I will have the company pick it up." What if the package had been violated and a consumer died from using the product? How does the manager know that another consumer will not buy the package before the company picks up the product? Retailers need to participate more in making tamper-evident packaging work as intended, rather than being a weak link in the chain of package security.

PRODUCT TAMPERING AS AN INTERNATIONAL TERRORISTS TOOL

The compalcency of the world was shattered on 9/11. When the World Trade Center collapsed, so did the feelings of sereness and security of most Americans. On 9/11 all potential acts of terrorism— biological and others— became real-world and increased our awareness of our surroundings and actions by others that may indicate a potential threat to our safety and wellbeing. The risk of retail product tampering being used by international or domestic terrorists has existed for decades, and 9/11 did not change the potential threat for its use as a terroristic tool. The author proposed a means for identifying potential large—scale product tamperers to Federal law enforcement agencies in 1991. The laws at the time precluded their ability to implement such a domestic threat identification program. Perhaps someday we will be able to take a proactive position and reduce the potential use of product tampering as a terroristic tool.

MAKING TAMPER-EVIDENT PACKAGING WORK

Making tamper-evident packaging work as it should requires the efforts of all involved: The manufacturers of packaging components should promote effective packaging for use in providing protection, product manufacturers should use the most effective feature for their product, retailers should be aware of the potential for violated products being in their display, the consumer should maintain an awareness of what to look for in a secure package and refuse to buy packages that look suspicious, law-enforcement agencies should conduct professional investigations and prosecute all violations, government agencies should provide for legal relief to companies meeting or exceeding government standards, and the media should report only those incidents that are verified as representing a threat to the health and welfare of the public without causing hysteria through false alarms. It all begins with you as packaging professionals.

Product tampering will not disappear. We as an industry must remain committed to providing the consumer with quality products in packages that provide protection to the consumer. Since 1982, we have come a long way, but we must continue to research and develop improvements in packaging to ensure the availability of safe products for the next generation.

TAPE, GUMMED

R. W. Mc Kellar
The Gummed Industries
Association

INTRODUCTION

Gummed paper tape and reinforced gummed paper tape have always been very effective carton sealing materials. Technological advancements in paper, laminates, adhesives, reinforcements, and dispensing and application equipment provide today's user with a scientifically produced high-quality product. Gummed tapes are environmentally friendly because they are made from natural raw materials and are 100% recyclable. Depending on the packager's need, gummed tape can be obtained with a wide range of tailor-made special features. Advantages of using gummed paper tape include the following: (a) It is tamper-proof, that is, the tape cannot be removed from a carton without leaving traces; (b) water-activated adhesives in gummed paper tape penetrate right into the liner of the carton, creating a total bond; and (c) extreme temperatures do not change the characteristics of gummed tape. The closure is resistant to aging (1).

TYPES

There are two basic forms of gummed tapes: single-ply nonreinforced "paper" sealing tape and double-ply fiberglass "reinforced" sealing tape. Both varieties begin with what is commercially known as "gumming kraft," which differs from ordinary kraft paper in that it is sized to prevent the adhesive from penetrating too deeply into the paper. Following application of a vegetable-based remoistenable adhesive (see Adhesives), single-ply paper-sealing tape is slit into roll lengths of 375–6000 ft (114–1829 m).

Depending on the basis weight of the paper (35#, 60#, or 90#) (see Paper), the product is categorized for light-, medium-, and heavy-duty application.

PRODUCTION

Double-ply reinforced gummed sealing tapes are produced by sandwiching fiberglass yarns between two sheets of kraft paper with either a hot melt of water-based adhesive. The use of recycled pulp in the paper is encouraged (2). Fiberglass yarns generally run in three directions (machine direction and both transverse directions), forming a diamond or "three-way" pattern. As in single-ply paper tapes, a water-remoistenable adhesive of vegetable and/or animal glue formulation is applied to the bottom sheet before or after lamination. Depending on the user's needs, paper basis weight, yarn spacing and denier, and laminate- and adhesive-coating, weight can be varied to produce products for light-, medium-, and heavy-duty application. Finally, the parent or "jumbo" roll is slit into smaller rolls ranging in size from 360 to 4500 ft(110–1372 m).

Both paper and reinforced sealing tapes are usually wound gummed-side-in on a cardboard core. Most manufacturers also supply coreless rolls. Tape widths generally range from 1 to 3 in. (25 to 76 mm) in 1/2-in. (13-mm) increments. Gummed tapes are available in a range of colors, widths, and lengths. They can also be custom-printed and can be obtained in strippable grades or with special antitheft, tamper-evident, or inventory-control features.

USES

When properly purchased and applied, both paper and reinforced sealing tape fully meet the requirements and specifications for rail (UCC Rule 41), truck (NCB Rule 222), plane, parcel post, UPS, and other parcel delivery-service shipments. General Services Administration Commercial Descriptions (CIDs) A-A-1492A, A-A-1671A, and A-A-1672A govern the purchase of gummed tapes by the federal government.

Gummed tape sticks well to a wide range of products, but will not adhere to plastic products. Tapes are strong and can be used for very heavy cartons. They are odorless, so they can be used in the food industry. They are hygienic, which is ideal for pharmaceutical products. The tapes will hold firm and do not stretch, making them ideal for bar-code readability. Gummed paper tapes' strength and tamper-evident qualities are important for packaging high value products, such as alcohol and jewelry. The tape's printability adds to safety by enabling batch and transport information to be printed onto the tape at the very moment of closing the box. Last-minute printability allows for savings because fewer preprinted boxes are needed (1).

Gummed tape dispensing and application equipment fall within several categories: (1) hand-operated dispensers; (2) electrically operated dispensers; (3) automatic taping machinery for fixed-size boxes, and (4) automatic taping machinery for random-size boxes.

TAPE, PRESSURE SENSITIVE

R. L. Sheehan
3M Corporation,
Minnesota
Updated by Staff

INTRODUCTION

Pressure-sensitive tape (PSA) can be defined as a continuous flexible strip of cloth, paper, metal, plastic, or foam coated on one side or both with a permanently tacky adhesive at room temperature which will adhere to a variety of surfaces with light pressure (finger pressure) with no phase change and usually available on a roll (1). PSA is used for closing boxes, combining packages, attaching packaging lists, color coding, pallet unitizing, adding carrying handles, splicing, providing ease of package opening, protecting labels, reinforcing critical package components, holding documents, and a variety of other jobs.

The first pressure-sensitive tape was developed in 1925 for paint masking; it had a paper backing and a glue–glycerol adhesive. Today, there are hundreds of specialty tapes available for specific applications in packaging.

TAPE TESTING

As with all package components, tape testing must be focused on the function of that component on the package. An engineering analysis of the package followed by package testing are excellent beginnings. The critical physical properties of the tape can then be chosen, in conjunction with technical input from a reputable tape supplier (2).

One of the most important tape properties is often the strength of the backing. ASTM D3759 is the standard laboratory method for measuring the tensile strength and elongation of pressure-sensitive tapes. Some packages require a tape with very little stretch; others require a relatively high elongation to achieve the desired breaking energy. For many narrow tapes, only the machine-direction

strength is of importance. For wider tapes, however, the cross-direction strength can be more critical.

Peel adhesion, ASTM D3330, is perhaps the most often quoted adhesive measurement. It measures the force in ounces per inch of width (N/100 mm) required to peel a strip of tape back onto itself (180°) from a stainless-steel surface. Test conditions and rubdown are closely controlled. The relationship of this test to tape functioning correctly on a package is often questionable; the angle of pull for the test is not seen on most packages, and the stainless-steel substrate does not represent package surfaces well. However, for a given adhesive type, the test may be useful as a quality-assurance procedure.

A packaging tape adhesive must have good tack to allow it to adhere to a variety of package surfaces with only a light rubdown. The literature on pressure-sensitive tape includes several methods of measuring the initial tack or "wet grab" of an adhesive. These can be valuable research test methods, but, because most of them use glass or steel as a test surface, it can be difficult to correlate tack test results with the performance of tape on a package.

Tapes are often used on packages where the tape must hold in shear: The Force on the tape acts in parallel with the package surface. One test that can relate to this is ASTM D3654-A, holding power of pressure-sensitive tapes to fiber-board. A $\frac{1}{2}$-in. × $\frac{1}{2}$-in. area of tape is applied to a fiberboard surface (NIST Standard Reference Material). A 1-kg mass is attached to an end of the tape. The test measures the time it takes for the mass to pull the tape from the surface.

ASTM test methods and other standards relating to pressure-sensitive tape are listed in Table 1. Other test methods are published by the Pressure Sensitive Tape Council (PSTC). Tape test methods are workable in both the inch-pound system of units and the SI metric system; physical properties are convertible from one system to the other. The standard widths of tape are a little different in the two systems. The metric replacement widths are based on uniform slitting increments, resulting in standard widths shown in Table 2; these are based on PSTC-71, *Guide for Width and Length of Pressure Sensitive Tape*. Most packaging uses of pressure-sensitive tape will readily allow these metric sizes.

PRESSURE-SENSITIVE ADHESIVES

Pressure-sensitive adhesives are unusual materials because they are are somewhere between the viscous and rubber states at room temperature. They show sufficient liquid-like behavior to deform or flow into contact with a smooth surface under light contact. Yet they must show appreciable resistance to flow duing a separation or debonding process. The main advantage of pressure-sensitive adhesives compared with other types of adhesives is convenience of use. There is no storage, activation, or waiting involved. Often the bond is reversible. The disadvantages of pressure-

sensitive adhesives are as follows: The adhesive strength is low, and they are unsuitable for rough surfaces. They are also expensive in terms of cost per unit bond area. The most well-known type of adhesive consists of natural rubber blended with a tackifier resins and a small amount of antioxidant. Rigid PVC and polypropylene are used exrtensively as backing materials for general-purpose tapes. Plastic films are used in specialized products. Polyacrylates are generally used in high-quality tapes for their better technical properties. The most recent development in pressure-tape manufacture is the hot-melt coating process. Almost all of melt adhesives are based on SIS thermoplastic rubber, mixed with hydrocarbon tackifier resins and oils in substantial amounts and an antioxidant in minor amounts (3).

BOX-SEALING TAPE

The largest use of pressure-sensitive tape in packaging is the closure of regular slotted containers. Figure 1 depicts a typical construction of a box-sealing tape; a plastic film is coated on one side with a pressure-sensitive adhesive. The film may have a release treatment on one side to allow easy removal of the tape from the roll during dispensing. Some film backings also are treated or coated on the adhesive side to increase the bond of the adhesive to the backing; although for a box sealing tape, this is not a critical factor.

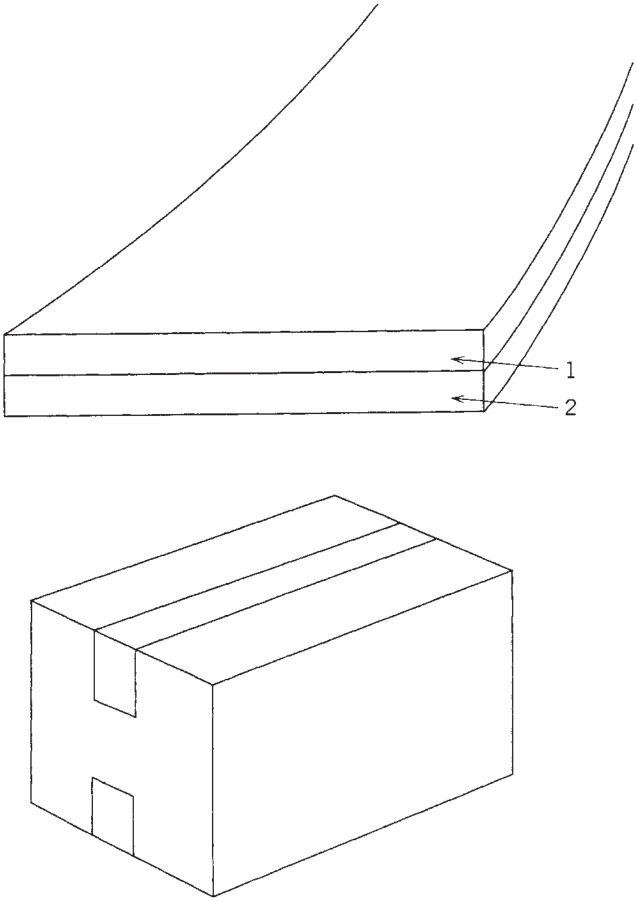

Figure 1. A typical box-sealing tape consists of a backing film (1) and a layer of pressure-sensitive adhesive (2). It is used most often as a closure for regular slotted containers.

The standard application of a box sealing tape is described in ASTM D1974, *Standard Practice for Closing and Sealing Fiber Boxes*. A 2-in. (48-mm)-wide tape is applied over the center seams of a regular slotted container (RSC) and extends about $2\frac{1}{2}$ in. (65 mm) onto the end panels of the box. This seals the center seam and helps keep dust and dirt out of the box. If a total seal is needed, cross-strips of tape can be added at the end edges of the box. This "six-strip seal" or "H-seal" is specified for some military and export packages but is seldom used for domestic shipments.

The choice of tape for box closure is very important and affects the performance of the entire package during storage and distribution. The most common backing material is biaxially oriented polypropylene. Some tape backing is made of a relatively "square" film with the machine-direction and cross-direction properties about the same. Most heavier-duty tapes are made of a tentered film with the cross-direction strength higher than the machine-direction strength; this usually results in better performance on boxes. Polyester, unplasticized PVC, and saturated papers are also used as backings.

A proper backing for a box-sealing tape is a good start, but the tape must have an aggressive adhesive if the backing strength is to be realized. Many box-sealing tapes use an adhesive based on rubber and a tackifying resin, but acrylics and other synthetic adhesive systems are also used. Critical adhesive properties are tack (for production efficiency) and shear-holding power (for package warehousing and shipping).

Tape is applied by handheld dispensers (Figure 2) or with box-sealing equipment. A range of equipment is available for both semiautomatic (operator feeds the boxes into the box sealer) or fully automatic operation. Box sealers are either adjustable to boxes of a single size or random, able to take a mixture of boxes of varying sizes.

Most pressure-sensitive box-sealing tapes hold well in damp and humid conditions. Water resistance (ASTM D5570) is required by the United Nations (UN) and the U.S. Department of Transportation (DOT) for tapes used on boxes containing hazardous materials.

Standard Specification ASTM D5486, *Pressure Sensitive Tape for Packaging, Box Closure, and Sealing*, replaced Federal Specifications PPP-T-60 and PPP-T-76. Type I is a polyester-backed tape used in H-type closure. Type II is a polyester-backed tape used in single-strip closures. Type III is a polypropylene-backed tape used in single-strip closures. Type IV is a cloth-backed tape, and Type V is a paper-backed tape.

FILAMENT TAPES

A second broad category of packaging tape is pressure-sensitive filament tape, sometimes known as "strapping tape." Figure 3 shows that this is typically made of

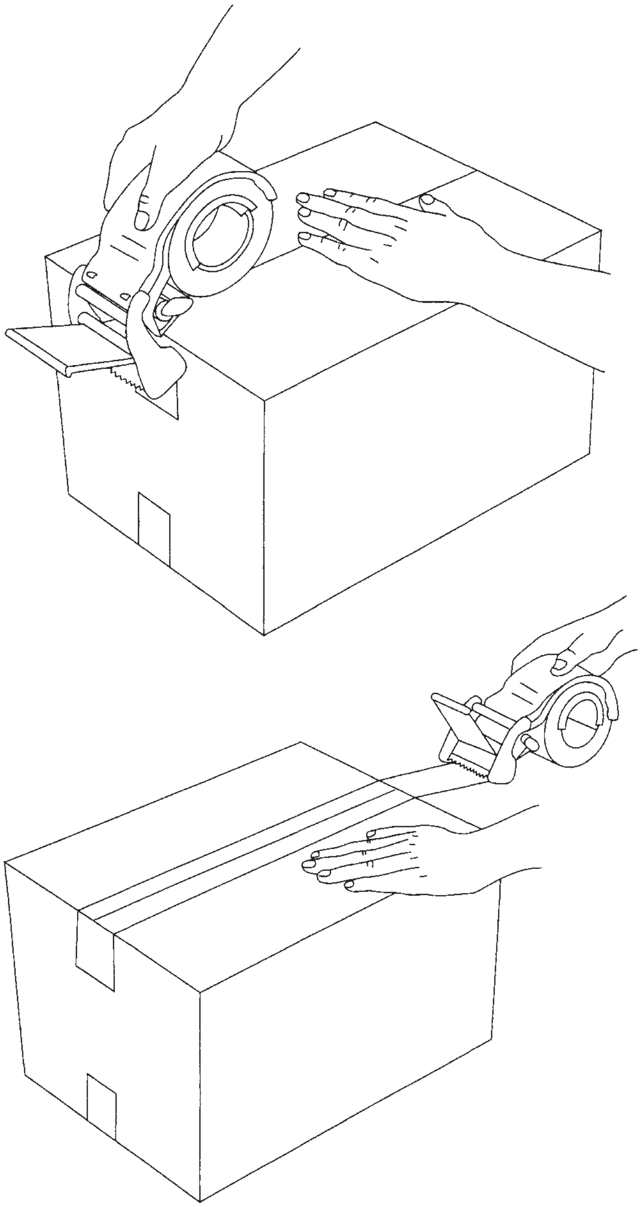

Figure 2. Use of a handheld dispenser for applying box-sealing tape to close RSC.

a film backing (polyester or polypropylene) with reinforcing filaments embedded in the pressure-sensitive adhesive. The most common filament is fiberglass, which provides a high tensile strength with very little elongation. A few tapes have polyester or rayon filaments for extra impact or cut resistance. Tapes are also available with integral polymeric filaments. The adhesive requirements for filament tapes are at least as critical as those of box-sealing tapes. Care should be taken to choose a tape with a balance of tack (initial adhesion) and shear-holding power.

Box closure can be accomplished with filament tape on a variety of box styles. In ASTM D1974, filament tape is recommended for use with boxes with fully overlapping flaps such as a five-panel folder, full-telescope box, or full-overlap box. A high-performance filament tape may be applied in L-shaped strips as small as $\frac{1}{2}$ in (12 mm) wide by $4\frac{1}{4}$ in. (105 mm): two in (50 mm) on each side of the L-clip. A tape with lower tensile and adhesive properties may have to be used in $\frac{3}{4}$-in. × $6\frac{1}{4}$-in. (18-mm × 155-mm) L-clips for equivalent performance on a box.

Filament tape is used in dozens of other packaging applications where high strength is required. These include reinforcing boxes, combining boxes for shipment, bundling, recooperage, and pallet unitizing. Special filament tapes are available for use directly on appliance surfaces to hold doors and drawers in place during shipment.

Standard Specification ASTM D5330, *Pressure Sensitive Tape for Packaging, Filament Reinforced*, replaced Federal Specification PPP-T-97. It includes four classes of filament tape: Type I—cut-resistant, Type II—medium-tensile-strength, Type III—high-tensile-strength, and Type IV—high-tensile-strength, weather-resistant. Other grades of filament tape are also available for industry, institution, and home use.

SPECIALTY TAPES

With a full choice of films, papers, and foils for backings, along with a wide range of adhesives available, it has been

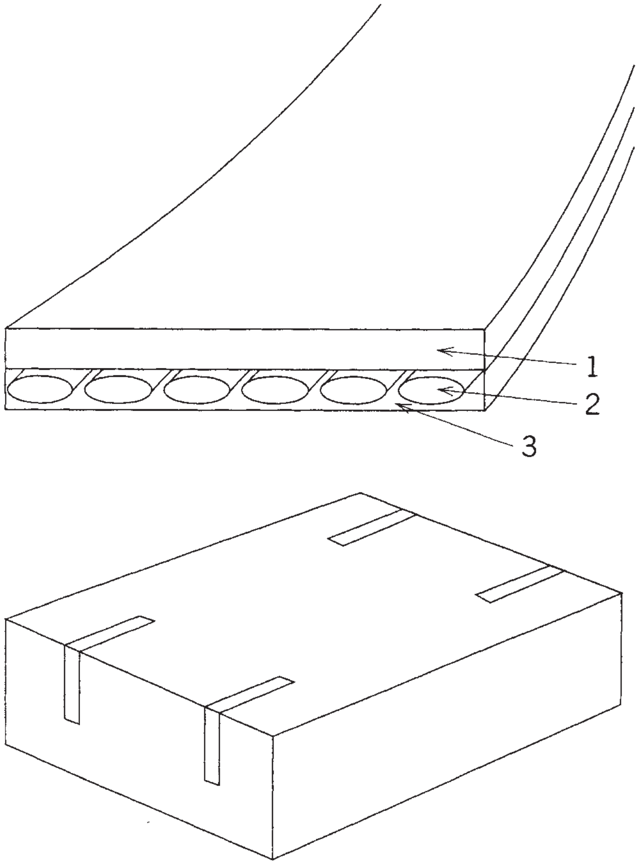

Figure 3. A typical filament tape has a backing film (1) and filaments (2) embedded in a pressure-sensitive adhesive (3). One of the uses is the L-clip closure of full-overlap boxes.

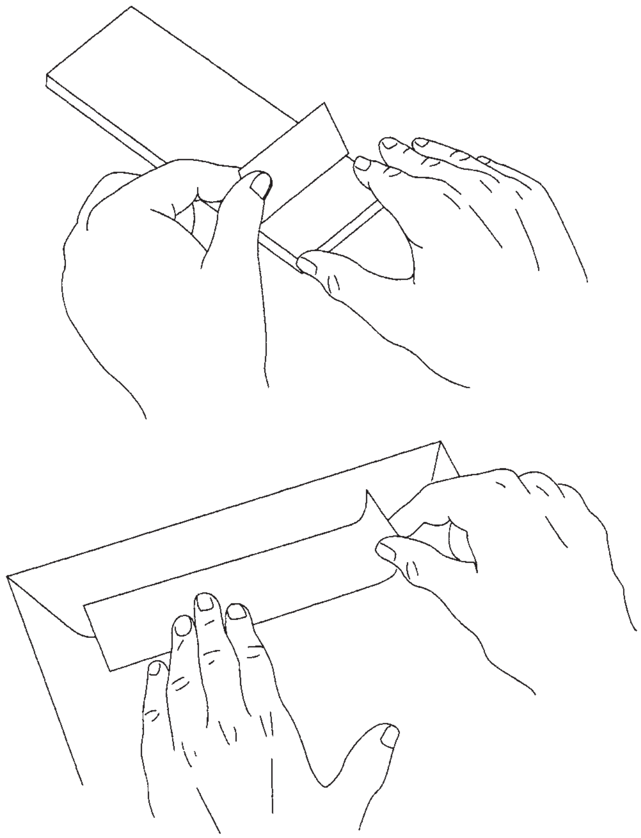

Figure 4. Use of a pressure-sensitive tape from a pad to close a mailing envelope.

possible to develop special pressure-sensitive tapes for many packaging uses, including combining and tamper evidence. Tapes are used to attach and protect labels on packages. Tape pouches often enclose packing lists and documents for shipment (see also Tape, gummed).

Several tapes are available not only on traditional rolls but also in precut pads (Figure 4). These pads provide for the use of presized pieces of tape for covering labels, attaching documents, and closing packages. They do not require a dispenser and offer the advantage of portability.

ENVIRONMENTAL CONSIDERATIONS

The environmental considerations for tapes applied to boxes are given in ASTM D1974. Pressure-sensitive tapes are often a good method of source reduction, considered to be a primary objective in reducing the contribution of packaging to municipal solid waste. Box-closure tapes often use less materials than alternative closures. Small L-clips of tape can close folding cartons, replacing a shrink overwrap and reducing material usage.

Compatibility with recycling operations for larger package components is important. For box recycling, pressure-sensitive tapes do not have to be removed from corrugated boxes prior to recycling operations. When a tape has a water-resistant tape backing, the adhesive stays with the backing in the hydropulper. The tape is easily removed intact by normal pulp-cleaning processes; neither the recycling paper nor recycling water is contaminated by the tape. When corrugated boxes are recycled, film-backed box sealing tapes do not hinder box recycling: The PSA tape stays with backing and is easily removed (4).

Stretchable LLDPE tapes are available for pallet unitizing, offering source reduction from full stretch wraps. When the tape is used in conjunction with stretch wrap, it is compatible with the stretch-wrap recycling operations (see also Recycling; Environmental laws, International and North America).

Pressure-sensitive tape is a versatile packaging material that can offer cost savings, productivity improvements, and source reductions. Innovations beneficial to packagers will continue.

TESTING CONSUMER PACKAGES FOR MARKETING EFFECTIVENESS

Lorna Opatow
Opatow Associates, New York,
New York

Primary and secondary packaging techniques are the key to marketing success in bringing brands from production, through distribution and selection by end users, and in generating the levels of satisfaction that warrant repeat purchase. Survey research is used to help those involved in package development make the informed choices that result in a marketing success.

Many package-performance dimensions can be measured in the laboratory. Characteristics related to marketing effectiveness need to be evaluated by users and potential users of a brand—preferably before the package is put into production. A variety of marketing research methods is used for this evaluation.

MARKETING RESEARCH OPTIONS

Most research options fall into three broad categories:

Analysis of existing information
Original qualitative research
Original quantitative research

Analysis of Existing Information. An analysis of existing information is often undertaken at the start of a package development program. It can be an important first step because it assures that subsequent surveys will add to, rather than duplicate, information.

The information is drawn from public sources such as government, trade groups, and publications; from past studies completed within the organization (especially tracking studies which reveal changes in consumer behavior); from syndicated surveys (sponsored and conducted by a research company that sells the results to any company willing to pay for the information); and from customer- and consumer-contact records. (In large packaged-goods companies, consumer-contact information is available daily, and it is often the first clue to product and packaging problems, changing consumer concerns, deficiencies in instructions for use, etc.).

The information obtained is summarized and analyzed in a report that contains conclusions about the nature of the market and recommended packaging objectives—criteria or goals that the package must satisfy. The objectives guide the development program and are used as standards for judging packaging effectiveness.

Qualitative Research. When people talk about "qualitative research," they are referring to studies among small samples of current and/or prospective users of the brand. These people are interviewed in depth, either individually or in a group. The research is diagnostic, that is, exploratory or directional, and its purpose is to obtain early indications of packaging problems and opportunities.

In the individual interviews, one person is questioned at a time using a predetermined question guide (list of subjects to be covered), or a questionnaire that includes mostly open-ended, rather than closed-ended, questions. ("How do you feel about the New York subway system?" is an open-ended question. An example of a closed-ended question is "Compared with other forms of public transportation, do you think the New York subway system is better, about the same or not as good?").

The group interview is called a "focus-group session" and is conducted with 8 to 10 people. Questioning is in the form of a discussion that is led by a trained leader or moderator who covers subjects listed in a predetermined discussion guide. Each of these qualitative research techniques has certain advantages:

During individual-depth interviews, information is obtained, and feelings are explored in detail. Each person expresses his/her opinions and interpretations without reference to the ideas of others so there are clear indications of individual preferences and understanding.

Participant interaction in focus group interviews provides a rich, multilayered accumulation of information and feelings about the subject being discussed. Comments made by one person may remind others of points they had not thought of. Each idea expressed suggests other ideas. Normally, the discussion results in a group consensus.

Both approaches are helpful in the early stages of an investigation, or as an aid to informed judgment. Individual-depth interviews are recommended for early trial, or where there are questions about consumer understanding of how a package works, packaging copy, or communication of ideas. Group interviews are recommended to gain insights about a broad range of feelings and opinions, as well as to identify the language or terminology consumers use to talk about the package and product.

Qualitative research is usually used to develop instructions for use, create hypotheses and questionnaires for larger studies, or get initial indications of opinions and ideas about products, packages, or product/package combinations.

Quantitative Research. "Quantitative studies" are conducted to obtain definitive information for decisionmaking. This type of research can take many forms but is characterized by sample sizes where enough people are interviewed, so results can be analyzed using statistical techniques. The interviews may be conducted in person, by mail, online, by computer, or via video. Certain kinds of packaging studies are conducted by telephone, for example, surveys to determine how and where products are stored and used, or to define the target market (the intended buyer/user).

Questionnaires for quantitative studies usually include more closed-ended, than open-ended, questions. The questions are structured to permit various kinds of statistical analyses that will aid in interpreting the results.

PACKAGING EVALUATION

In considering its marketing effectiveness, management is most likely to question the degree to which a package meets three types of goals, and these are the ones most often subjected to some kind of survey research evaluation: functional effectiveness, visual impact (visibility and shelf attention), and communications effectiveness (brand and product identification, and imagery).

Testing Functional Effectiveness. Functional effectiveness is easier to evaluate than the other marketing dimensions. Some aspects can be handled in the laboratory; others, through product-testing techniques such as one-time or multiple-use tests; others, through individual-depth or focus-group sessions, depending on the nature of the product and the package.

With few exceptions, product users can be questioned directly about whether a package is easy to handle, open, close, store, and use, and whether it might protect the contents over a period of time. The sample of potential brand users interviewed should include people who use the product in different ways, those in a mix of age groups (from children through seniors depending on use), people of various ethnic backgrounds, as well as those with a variety of physical characteristics (left or right handed, have smaller or larger hands, etc.).

It is a given that packages must protect the contents. But it is also true that the user must *believe* that the package really does this. The inner, outer and overwrap for many over-the-counter (OTC) remedies, as well as premium food and beauty-aids products are technically unnecessary. However, proposed substitutes intended to reduce packaging costs are often rejected by consumers, primarily because of perceived differences in product protection.

Depending on the nature of the product and package involved, an in-home or at-work trial study may be conducted among people in several geographic areas. Where a totally new packaging concept is being tested, such as the early versions of aseptic containers for foods, the study may be restricted to people in areas closest to manufacturing facilities because the samples have a short storage life.

Those people who agree to try the product are interviewed to obtain their initial reactions about its appearance, anticipated benefits and drawbacks, and general expectations. The product may be tried at that time, or left for use later, with an evaluation sheet to be completed immediately after trial. If needed, follow-up interviews can be conducted by telephone the next day.

Testing the Effectiveness of Graphic Design. Although, the physical package can be evaluated using product-testing techniques such as the ones described above, different approaches are needed to determine the effectiveness of packaging graphics.

Extensive evidence suggests that overall surface designs including words are primary contributors to the marketing effectiveness of a package. If you think of packaging as the environment for a product, it is easier to understand its effect. The tray used for a frozen entrée, the baking pan included in a mix, a plastic or glass bottle, a composite or metal can, a see-through or foil pack; words, colors, illustrations and over-all design of the container or label; all of these factors influence consumer expectations of, and satisfaction with a brand.

In all studies that involve packaging graphics, the physical appearance of the test and competitive packages must be equal. An apparently unfinished mockup or one that is custom finished should not be shown with printed competitive packages. The difference flags the package in a way that biases results. In addition, if the test versions are potential alternatives for an existing package, the sample of people interviewed should include enough current users of the brand to analyze their reactions separately.

In general, graphic design can be evaluated in regard to the following three aspects: visual or shelf impact, communications effectiveness, and aesthetic appeal.

Visual or Shelf Impact. The most elusive and difficult packaging aspect to measure is visual or shelf impact. The questions to be answered include the following:

1. When people shop the product category, does the package call attention to the brand?
2. As people shop for other types of product, is the package creating an in-store presence that will enhance familiarity with the brand?
3. When the buying decision has been made *before* the store visit, does the package make the brand easy to find?

To date, there are no research techniques that fully answer these questions, primarily because visual perception involves a complex relationship between the structure of the eye and the functioning of the mind. For example, seeing is selective. Regardless of where or how the eye moves, people "screen out" elements they consider irrelevant and focus on the familiar. In a visibility test, this familiarity bias usually produces a higher score for the current package than for a new package, and for an established brand than for a new one.

In addition, the effects of demonstrated visual "enhancers" such as high contrast, size, and color density are predictable. This makes it possible to design for the test, which produces an apparent "winner." The most commonly used methods for testing some aspects of visual impact are a shopping test, a T-scope (tachistoscope) or controlled-exposure test, and an eye-movement test of single or multiple packages in a competitive environment. To some degree, all of these techniques are deficient, but the shopping test comes closest to indicating what might happen in a store.

In a shopping test, a rough approximation of the in-store environment is reproduced with actual packages on shelves in a central interviewing facility, on a videotape, or on a computer screen. The product arrangement is deliberately structured to give all the test brands an equal opportunity to be noticed, and study participants are free to look at what interests them and to ignore what does not.

Where an actual product display is used, people can "shop" the shelves and view the packages in motion at their own pace. They can pick up and examine packages to gain more information about the brand. Whereas shopping tests using videotape and computer simulations are easier to administer, they have some drawbacks: people are seated in a quiet room and concentrating, there may be color and copy distortion due to the limitations of photography, and the product display is "framed" so that some of the normal in-store confusion is reduced.

In the controlled-exposure test, the length of time people can view a picture of a package or shelf display is limited. A device called a tachistoscope or T-scope is attached to the lens of a projector. Operating like the shutter of a camera, it controls the amount of time that a picture is shown (in fractions of a second). Each exposure is shown at an increasing amount of time. After each one, people are asked what they saw.

The controlled-exposure method of testing visual aspects of packaging is a speed test. It measures how quickly something is seen, and it has several drawbacks: People are concentrating on a stationary picture that organizes the display, and there may be photographic distortion. For new brands, the interpretation of results is strictly limited to how easily the brand name is read. For established brands the test offers a measure of recognition as well as readability.

T-scope test scores have limited application but can be helpful in cases where pictures must be used. Some examples are as follows: to develop indications of differentiation within a line of products, to test custom-designed containers where several alternative models are being considered, and to provide indications of recognition elements when a redesign is being considered for an established brand.

In an eye-movement test, the respondent controls the length of time the picture will be viewed. A device records where the eye moves and where it stops over the surface of the picture. The results are evaluated on the basis of this record. In addition to drawbacks related to the test environment and possible photographic distortion, this method provides information about where the eye travels but not about what the brain absorbs.

Regardless of the method used, visual-impact scores are rarely used as a basis for accepting or rejecting a package. Packages that score well in a visibility test but do not meet communications objectives are not usually adopted. However, when communications objectives are met but the visibility score is low, a package is often selected, although graphics may be modified to enhance visual impact.

Communications Measurements. Most packaging tests include communications measurements. Designers can predict the visual effectiveness of a package based on their knowledge of the physiology and psychology of seeing. However, they find it more difficult to determine the package's communications effectiveness (the ideas the package suggests about the brand).

Packages have a substantial impact on people's ideas about products and brands. To measure this impact, research methods and exhibit materials used need to be appropriate for the product and the particular packaging design problem, as well as economically feasible. There are many options for testing package communications, and no standard techniques or series of techniques.

Most package communications studies evaluate the brand in relation to competition, and measure several packaging aspects. Some of the more popular approaches are as follows:

1. Experimental design matched samples of potential users are interviewed about one or two competitive brands, as well as the test brand in *one* of the package designs. Questioning and test procedures are identical so that differences in results can be attributed to the different packages. Within this framework, the most often used approaches are as follows:
    a. Brand expectation study, which measures impressions of the brand on the basis of package appearance
    b. Brand trial study, which measures brand and package performance on the basis of a single trial
    c. Location use test which measures brand and package performance in-home or in the workplace on a one-time or multiple-use basis.
2. *Product formulation/structure study*, which treats each package as a separate formulation or structural version of the brand and determines perceived differences.

Aesthetic Appeal. If the purpose of the study is to measure aesthetic appeal, consumers are asked to rank proposed packages in regard to how attractive they are.

CONCLUSION

In addition to standard specifications for conducting useful surveys, the following are the primary requirements for conducting research to evaluate the marketing effectiveness of packaging:

1. The packaging dimensions of interest need to be measurable. Subtle differences in graphic design and some packaging objectives (such as "generate trade excitement") cannot be measured.
2. Study objectives should be stated clearly in writing, related to the packaging objectives, and indicate the kind of information to be obtained and how it will be used.
3. The study plan must be capable of yielding the information specified in the objectives.
4. Action standards should be established in advance. These standards provide a common framework for judging study results by indicating the order of importance of each measurement used and the research criteria to be met.
5. The people interviewed need to be capable of providing meaningful information.
6. Alternative test packages must be equally acceptable to management. If, for any reason, a package cannot be adopted, then it should not be included in the test.
7. Exhibit materials need to be appropriate and equivalent to avoid biasing results.
8. When developing packaging communications information, the tester is measuring how the package influences ideas about the brand. This means people must be asked about the product and brand before any direct questions about the package.
9. Package designers and developers should be involved in the research to be sure that the study plan is compatible with the packaging objectives, to control the appearance of exhibit materials and to add valuable insights in explaining or interpreting test results.

In conclusion, the package is an integral part of most brands and can provide a competitive marketing edge. Successful package development is the result of careful consideration of alternatives. As each packaging decision is made, it narrows the options to be considered at the next step. Survey research assures that choices will result in a package with maximum marketing effectiveness.

TESTING, PACKAGING MATERIALS

Patricia D. Guerra
Marcondes
Duncan O. Darby
Clemson University, Clemson,
South Carolina

INTRODUCTION

The need to test packaging materials and components may arise for a variety of reasons. Maintaining production standards is the most common one. Verifying that the material will perform in a new application might be another. When a problem is identified and the source is unknown, investigative tests, both qualitative and quantitative, are often needed.

It is helpful to think of packaging materials testing as a function of factors such as packaged product class, package component, and package function, as these factors may determine the types of tests necessary. Product protection is a package function that leads to tests such as drop and vibration. Certain package components need to comply with industry-defined dimensional standards. Products such as food, drugs, medical devices, and hazardous materials are highly regulated, so the packages that contain these products are also regulated.

This article is organized by material: plastic, paper (including paperboard and corrugated), metals, glass, and wood. Many other materials are used in packaging, and many containers, which are available, include components made of different materials. An effort was made to include these components and their related testing under the materials discussion.

REGULATORY AGENCIES AND STANDARDS ORGANIZATIONS

In the United States, the Food and Drug Administration (FDA) is charged with safeguarding the quality of products destined for human consumption. There are many ways in which the quality of foods, pharmaceuticals and medical devices can be adversely affected by packaging issues. Packages may not be correctly closed. Tears, holes, and cracks can occur that allow the product and the environment to interact. Packaging materials and components might be a source of indirect additives through the migration of chemicals through the package into the product. The directives guiding packaging of these classes of products are found in the Code of Federal Regulation, Title 21 (CFR 21). It is common for the FDA to recognize standards from consensus-based standards organizations, such as the International Standards Organization (ISO) and/or ASTM International, for the measurement of compliance with these objectives.

When the package function is protection from transportation hazards, the National Motor Freight Classification Committee (NMFC), the Department of Transportation (DOT), and the International Civil Aviation Organization (ICAO) regulate the types of materials that may be used for different product classes and the standards that these materials must meet. The International Safe Transit Association (ISTA) in the United States has a set of standard procedures for testing the performance of shipping containers for a variety of shipping environments and products. ASTM International has developed test procedures that prescribe how testing should be conducted for a variety of properties of a variety of materials used for packaging, including performance during transport. The ASTM technical committee D10 deals specifically with developing standard procedures for testing packaging materials and components. Other ASTM International technical committees also have jurisdiction over areas of interest to packaging professionals in terms of testing, such as committee F02 on flexible barrier packaging and committee D06 on paper and paper products. The Technical Association of the Pulp and Paper Industry (TAPPI) also offers standard procedures for testing pulp and paper materials, including paperboard and corrugated. In some cases, there is some overlapping in standards from ASTM, TAPPI, and ISO. It is up to the packaging professional to identify the one that is mostly accepted by his or her sector of the industry.

In addition to the already mentioned federal regulatory agencies, packaging professionals must also be aware of state and even local regulations. Because regulations change over time and from state to state and country to country, it would be impractical to cover every one in an encyclopedia. This article attempts to make the reader aware that these exist and that every packaging professional should be familiar with the ones that pertain to his or her sector of the industry and distribution cycle.

PLASTICS

Plastics are widely used in flexible, semirigid, and rigid packages. Polymer films are used alone or in multilayer structures in the form of bags, pouches, and overwrap films to name a few. Rigid plastic containers are also common in the form of jars, drums, pails, jugs, bottles, trays, and others. Foamed polymers may be used for protection against drops and vibration and for temperature control. Woven plastic fibers are used in large packages of relatively heavy products, such as dry pet foods and industrial goods. Nonwoven fibers are a common component of medical device packaging.

Several fundamental plastics properties are used to characterize and compare plastic materials used in packaging applications. This includes thermal transition properties, such as the glass transition temperature (for amorphous and semicrystalline plastics), and the melt point (for semicrystalline plastics). For semicrystalline plastics, the percent crystallinity may also be estimated.

Measurement of these properties is best conducted with thermal analysis equipment such as differential scanning calorimetry (DSC). Other thermal analyses, including thermo-gravimetric analysis (TGA), thermo-mechanical analysis (TMA), and dynamic mechanical analysis (DMA), may also be used to characterize how plastic behavior changes with temperature. Melt flow properties, such as melt flow indices, melt flow rates, melt viscosities, melt strength, and so on, are predictors of performance on package-manufacturing equipment, as well as of performance in the field.

Datasheets that include the basic characteristics of films and other flexible plastics are available from suppliers and include basic information such as yield, gas-barrier properties, gauge, tensile strength, optical properties, and dimensional stability. Table 1 lists some of the more common properties of flexible plastic materials. Most of these properties are discussed in detail in other sections of this encyclopedia. Properties of multilayer materials are also included in Table 1.

It is important to test the properties in Table 1, because they have a direct influence on how the individual materials will perform as part of a package system. This includes how a material will work on the machinery that converts it into a package, and how it will interact with the product it contains.

The weights of substrates, coatings, inks, adhesives, and sealants are usually measured on a certain size specimen, and the overall weight is extrapolated from that. Weight is often measured per area of flexible substrates, and the term used for this is basis weight. The basis weight is usually specified for the product to perform the desired function.

Table 1. Flexible Plastic Material Properties

Weight (coatings, adhesives, and sealants)

Thickness (gauge)

Adhesion (adhesive to substrate, inks to substrate, extrudate to substrate, coextruded layers)

Strength

- Tensile
- Puncture
- Tear resistance
- Burst resistance
- Impact resistance
- Flex resistance

Surface

- Surface energy (contact angle)
- Friction [coefficient of friction (COF), film to film, and film to steel]
- Abrasion

Visual/optical

Gas barrier (transmission rates)

- Oxygen
- Water vapor
- Carbon dioxide
- Nitrogen
- Flavors/aromas

Organoleptic (retained solvents and other volatiles)

Shock and vibration Transmission (foams)

The uniformity of a substrate's thickness is important. A lack of uniformity may lead to variations in other test results, such as permeation rates and tensile strength, and it may interfere with performance on the packaging line or in the field. A certain amount of variation may be accepted. Several measurements are taken and values are averaged.

For multilayer applications, the strength of the adhesion between layers is evaluated to make sure that the layers will hold together for the intended applications. The force necessary to separate the layers is measured and compared with the minimum specification for the application.

Knowledge about the strength properties such as tensile, puncture, tear, and so on are helpful in selecting materials for flexible packaging. This selection is based on application and hazards that the product is likely to encounter in its lifecycle. Actual data from these tests doesn't always apply directly to an application, but it may still prove helpful in comparison of materials.

Surface properties impact the ability of materials to stick together and flow over machinery. For finished packages, these properties impact the stacking stability. Minimum treatment levels are specified for materials used in printing and laminating applications. Films may not track well on packaging machines when the coefficient is too low or too high. Large bags of products such as pet food or industrial products must meet a coefficient of friction range to prevent sliding when stacked.

The outside of packages is often part of the marketing effort for a product. Therefore, the aesthetic appearance of materials is important. Visual properties such as gloss can add value from a marketing perspective. Print quality is another important factor that is measured and tracked in various ways all the way from the printing plant to the store shelf. There are regulations on type size and legibility for certain information communicated to the consumer in industry sectors such as food and drugs. Colors can also be measured. Many of these properties are measured using the naked eye, or instrumentation, or both.

Opacity is also a visual property of materials. The amount of light transmitted through a packaging material may accelerate deteriorative reactions in food products, for example. There is more than one way to express opacity. It may be done in terms of optical density or light transmittance. Metalized materials are often compared based on these parameters.

It is often necessary to control the atmosphere within a package. For example, too much or too little oxygen impacts the shelf life of many perishable products. Thus, the tendency of gases to move through the package materials must be understood and measured. The most common permeants are listed in Table 1. Please see the permeability section of this encyclopedia.

Organoleptic tests involve qualitative and quantitative tests to verify that packaging materials or their additives do not adversely affect the flavor of products. Panels of humans trained to detect solvent odors are routinely used to evaluate packaging materials as they are made. Food companies often use sensory panels to study product/

package flavor interactions. These activities are typically combined with analytical instrumentation such as gas chromatography, microbial analysis, color measurement, and so on.

Foams placed inside or outside of primary packages protect by absorbing part of the energy of an impact. Different densities of foam and different materials (polystyrene vs polyethylene, for example) offer different levels of protection (see Cushioning, design section for more information).

Table 2 includes a selection of tests that are commonly performed on packages to evaluate their performance. In addition to these, some properties of the resins such as melt index and flow rates are also measured.

In most plastic packages, the closure system is essential to the package's performance. Closing the package assures that the package is allowed to perform its functions, by keeping the product within the package and also preventing exchange of the package's atmosphere with that of the outside environment. In many plastic packaging applications, closure is achieved by creating a thermoplastic seal. The seal strength can be measured to help predict the ability of the package to survive its lifecycle and to assess the force or energy required to open the package. In the hot tack test, the seal strength is measured immediately after the seal is made to predict the ability of the packaging material to contain the product when it is hot. This property is useful in predicting performance on the packaging machine or in cases where the product is filled at an elevated temperature. See section Seal, heat for more detailed information.

Other tests may be needed to verify that the package was successfully sealed throughout the seal perimeter and that it will not leak or open prematurely in the distribution cycle. Tests used for seal integrity include burst tests, dye leak tests, pressure or vacuum decay tests, and many others. Simulated or actual shipping tests may also be run, either as a standalone method to check the package integrity or to verify that the seal integrity tests chosen correlate to reality.

Burst tests on packages may be run not only for seal integrity testing but also to verify that the package has the strength to be stacked and dropped in the distribution system.

Table 2. Container Properties (Rigid and Flexible)

- Nitrogen

Dimensional consistency and stability

Chemical resistance

Stacking strength

Dimensions, dimensional consistency, and dimensional stability of packages are important for space usage, processibility on packaging machines, and for aesthetic considerations. Packages must consume the correct amount of space when stored, shipped, and on the shelf in the marketplace. Internal dimensions must be consistent to assure that the net weights or volumes on packages are correct. Automated packaging machines often require specific tolerances on the package dimensions to facilitate the desired productivity. Dimensional stability must be maintained during thermal processes, such as retorting and autoclaving. Packages must resist deforming dimensionally to assure that the packages remain closed and present an attractive marketing message to the consumer.

Chemical resistance is an important consideration and is one of the reasons that we find chemicals packaged in several different packaging materials. The packaging materials must offer chemical resistance to the components of the product as well as from any outside elements that might come in contact with the package.

When a package is designed with the expectation that it will bear some or the entire load in a stacking situation, that package must be evaluated for its stacking strength. In many cases, the products can bear the load.

PAPER, PAPERBOARD, AND FIBERBOARD

Paper is used as a layer in multilayer structures (some of these are various layers of paper, others include coatings, films, and foils) and it is also used on its own. Paperboard is converted into cartons and boxes that can function as primary, secondary, or tertiary packages.

Corrugated fiberboard is made of linerboards and a corrugated medium. Once it is converted into boxes, it is required to carry a box manufacturer certificate listing the burst strength or the edge crush test (ECT). Both certificates also list the size limit and gross weight limit. Another common use for corrugated in packaging is trays (Table 3).

Table 3. Materials and Container Properties

Basis weight

Strength
- Tensile
- Tear resistance
- Puncture resistance
- Burst (mullen)
- Edge crush (corrugated fiberboard)
- Flat crush (corrugated fiberboard)
- Folding endurance
- Structural design performance (finished containers)

Moisture resistance

Permeability (body of composite cans)
- Oxygen
- Water vapor

Like plastic materials, paper and paperboard are often specified and ordered in terms of basis weight, so this test can confirm that the material at hand conforms with the order, for example.

As with other packaging materials, the strength properties of paper, paperboard, and corrugated are important for matching the materials to the packaging application being considered. For example, the results of a tear resistance test are an indication of how a material might perform in an application that requires windows or other cutouts.

The burst resistance test is done to find a board's ability to withstand external and internal pressures. It is not considered the best way to evaluate double- or triple- wall corrugated boards. Flat crush is used to evaluate those boards.

Structural design performance tests evaluate the ability of the erected container to perform from the time it is put together to when it reaches the ultimate user. These tests are designed to simulate various shipping and distribution cycles in terms of shock, vibration, and compression A container might be exposed to moisture in several ways. It may come from the outside as rain, or it may come from the packing environment in the case of washed vegetables for example. Depending on the application, it is important to measure the impact of moisture on paperboard and corrugated fiberboard properties to assure that they will perform correctly for the packaged product and distribution environment.

METALS

Steel and aluminum are used to make containers and components, such as cans, drums, trays, and caps. Steel cans are widely used in applications such as processed foods, chemicals, and paint. Steel containers and container components such as caps are also found in packaging systems for foods, cosmetics, consumer goods, and industrial goods. Aluminum is used in the form of foil (less than 0.006 in. thick), as a layer in multi-layer structures, and as trays in frozen foods and preserves. It is also converted into cans and bottles used for beverages, food, and cosmetics. Metalized materials are produced by vacuum deposition to create a thin light and gas barrier onto substrates or formed packages.

Metal for packaging uses often begins in the molten form. Then, it is cast into either ingots or thick sheets. Ingots will subsequently be rolled into thinner strip metals in the hot rolling process and wound into coils. Cast metal sheets are rolled into coils as a part of processing. More reductions in thickness are achieved by cold rolling. In the case of foils, the rolling will continue down to thicknesses around 6 microns. Rigid metal packaging such as cans are made from either coils or cut sheets.

Although steel packaging is mostly iron and aluminum packaging is mostly aluminum, other alloying metals at varying concentration actually provide many properties we depend on for packaging applications (Table 4). Additionally, processing has a significant effect on the grain structure of metals, which also have a significant effect on the final package properties. Thus, effective measurement of metal properties may include the measurement of concentration and of grain size measurement.

Dimensions

As in all packaging materials, cost is a key factor. Thus, basis weight and thickness are monitored in the production of sheets, coils, and finished metal packages.

The substrate materials may endure processing, such as washing coating and printing, in the sheet form before being formed into packages. In other cases, some of these processes may occur on the shaped package rather than on sheet form. Plating with another metal may also be used for corrosion resistance or for other properties. In each case, it is important to measure the adhesion and basis weights of coatings or platings.

The mechanical properties of these metallic materials, such as tensile/compression strength, are routinely measured in the production and use of metals. As in plastics, these properties can serve as either direct measures of predicted performance, or as relative measures for comparison. Most metal packaging is formed at temperatures that are relatively low compared with the metal's melting point. Thus, it is important to understand the ductile properties of the metals used. Measurement of formability and ductility properties, beyond those found in the tensile test, may be required. For example, Rockwell hardness testing can be used with evaluate the temper of steel cans. Denting of cans is considered to be a defect in some cultures, and it can reduce the can's axial strength, so denting resistance may also be measured. Many cans are subjected to significant pressure "events," such as sterilization for canned foods or the pressure effects of containing carbonated beverages. Pressure testing is required to assure that the package can withstand these events.

Some cans are rolled pieces of sheet that are welded together at the overlap of the metal, which is called the seam. Cans are inspected to make sure that the seams are hermetic to ensure the sterility of the product. For a variety of reasons, the casting and rolling processes can result in tiny holes in the aluminum sheets or foil. These holes, which are referred to as pinholes, can be viewed by the naked eye or by using automated optical comparator systems. Leak testing systems are also used to verify the integrity of cans. Most metals are largely impenetrable by most common permeants. Thus, metals are used in cases where absolute barrier is needed. However, thin-gauge aluminum foils (below 20–25 micron) may have pinholes present, and metalized films seldom have sufficient metal for an absolute barrier to exist. In these cases, gas barrier permeability evaluations can be conducted.

As with other packaging materials, the visual appearance of metallic packaging is sometimes an important factor. Because metals can be highly reflective, reflectance values are sometimes specified. Metallic packaging is often printed, so print quality is also an important property. Metalized films are tested for optical density and/or light transmission to ensure the needed opacity has been achieved during the metallization process.

Dimensions for metal cans and bottles are important to assure proper space consumption, proper filling capacity, and processibility on high-speed filling lines. Metal caps for bottles, jars and cans also have to conform to dimensional requirements for the filling and capping process to occur at the speeds required by the production equipment, as well as to assure that the package is hermetic.

GLASS

Bottles, jars, and jugs and ampoules made of glass are used in the industry for food and pharmaceutical packaging. Glass packaging is usually formed directly from the molten raw materials into the package. This means that material testing generally must be conducted on the package itself rather than on a sheet or resin pellet as is an option in papers, metals, and plastics. Most standards have to do with maintaining production quality and dimensional consistency (Table 5).

Glass properties are dependent on the composition. Appropriately equipped analytical laboratories can determine this, but in glass manufacturing plants, density and softening point can be substituted for a full analysis.

Strength in glass is not typically measured using a tensile strength as in most other materials, because it is extremely strong but extremely brittle. Compressive strength measurements of glass result in much higher strength values than tensile strength measurements. Glass packages generally break at lower values than the theoretical expectations because of small cracks on the surface that serve as stress concentration points. Online application of pressure, at squeezing stations on glass package-making lines, is used to prevent cracked, broken, or weak packages from advancing into the process. Internal pressure resistance is an important property of glass containers, which will endure pressures such as sterilizing in the package and carbonation. The compressive strength of glass packages reflects their ability to support the load in stacking systems and when closures are applied. It is generally addressed during the design stage by selecting appropriate neck and body diameters and shoulder radius. The heel design of containers can also improve strength.

Permeability

Thermal shock is a measure of glass' tendency to crack under heat. This is important for hot fill, retorting, and applications in which the product is heated in glass by the consumer to be served. Finite-element analysis is used to model this.

Glass is often used for its superior optical properties. Thus, measurement of these properties is important. On glass production lines, automated inspection stations are used to verify that the containers are free of sand, dirt, stones, and other visual defects. Clarity and color, and the consistency of both, are important in glass manufacture and use. When printed or when graphics are formed into the glass surface, the appearance of these aesthetics also needs to be measured.

The containment capability of a glass container is dependent not only on the properties of the particular glass formula but also on the thickness of the container walls. Additionally, the total weight of each container must be measured and controlled to assure consistency of cost, performance, and fill weights. The finish dimensions must be consistent to assure that the cap/closure system fits properly, offers correct opening strength, and provides an appropriate seal of the package.

Glass offers excellent water vapor and gas-barrier properties. When pigmented, it provides light control as well.

WOOD

Wood is an important packaging material that is specifically used for pallets, crates, and boxes used in transport packaging. A limited amount of testing is conducted on the wood materials themselves, but in the construction of wood packaging, moisture content and shrinkage properties are specified. In the case of pallets, tensile properties are seldom measured, but compression and flexural properties (strength and moduli) are both important for the application. These are generally controlled through selection of woods that deliver the desired performance at the best cost.

CONCLUSION

Entire books could be written about testing systems for each of the packaging materials/package types outlined above. This article has been written to attempt to briefly describe that what and the why involved in packaging material testing. The reader is encouraged to review the references as well as the individual sections elsewhere in this encyclopedia.

Ideally, the package is developed along with the product and adjustments are made along the design and development stages to provide the best fit between package and product. Packaging is usually a system, so even though testing the individual components is a good starting point, it does not exclude the need to test the package system as whole at every stage of the product cycle from the time it is packaged to its ultimate use.

TESTING, PERMEATION AND LEAKAGE

Bert Johnson
Robert Demorest
MOCON,
Minneapolis, Minnesota

These two factors, permeation and leakage, can have similar effects on packaged goods, but they are totally different processes. When oxygen (O_2), water vapor (H_2O), carbon dioxide (CO_2), odors, and flavors move out of packages or into other packages, quality is lost, and shelf life is shortened.

Great strides have been made in permeation, which is a science relatively unknown to the average citizen, but leakage, a subject familiar to many, seems to be slower in developing a universally accepted testing technology. Testing methods for both permeation and leakage are discussed here.

PERMEATION

In general, three separate phenomena occur simultaneously.

Solubility—penetration into polymer
Diffusion—penetration through polymer
Desorption—evaporation from polymer

The total permeation through the barrier is made up of the sum total of all three parameters, and it is referred to metrically as

Permeation rate—$(\text{mL}\cdot\text{mm})/(\text{m}^2\cdot 24\,\text{h}\cdot\text{atm})$, dry, at (temperature, 0°)
Transmission rate—$(\text{mL}/(\text{m}^2\cdot 24\,\text{h})$, dry, at (temperature, 0°)

Note that the transmission rate (TR) has not been normalized for atmospheric pressure or thickness. The laboratory must decide the best units. However, if the instrument is equipped with a pressure transducer, so that results are adjusted to sea level, then it is common to state the TR

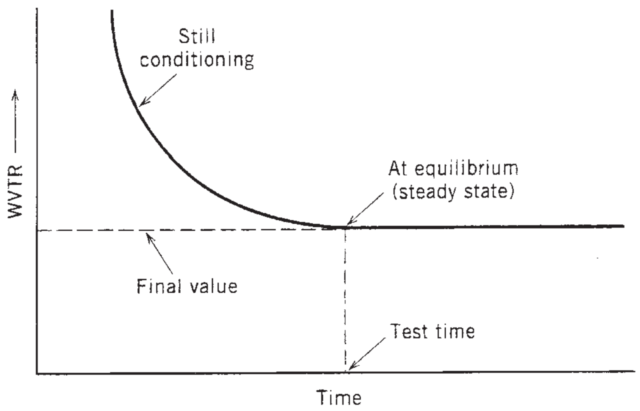

Figure 1. Typical example of time to condition specimen.

value at sea level and is, therefore, easily compared from one laboratory to another.

Equilibration. A sample of barrier film is mounted in a permeation instrument test cell and the test is started. Note the time data in Figure 1. The results of a test are valid only once the barrier material has reached equilibrium.

- Material thickness
- Relative humidity
- Temperature
- Time
- Barometric pressure

The time for the sample to reach equilibrium cannot be appreciably accelerated or shortened. Time is a physical function of the material. The better the barrier, the longer it takes to get results. For example, 1 mil (25 μm) PET takes 1 h, whereas 5 mils (125 μm) PET takes 8 h to stabilize. If the result is taken prematurely, it will be wrong, as steady state has not yet been reached.

Five major factors that affect permeation rate through a barrier polymer are listed in Figure 2.

- Material thickness
- Relative humidity
- Temperature
- Time
- Barometric pressure

Figure 2. Five major factors affecting permeation rate.

PIONEERING METHODS

We must acknowledge some of the pioneer work in the field of permeation, in particular the water-vapor permeation cup test (1, 2) (see also Figure 3) developed in the early 1940s. These test methods determine the loss of water from a cup through a barrier sealed on top of the cup and are still used in a few locations. Permeation does have disadvantages, such as a long time to obtain results (days vs. hours), limited testing range, being labor intensive, requiring expensive climate-control chambers, and being operator dependent. However, steady progress has been made in instrumented testing systems that allow shorter test times, greater limits, better repeatability, increased sensitivity, computerized control, and documentation.

Also, recognition is due to other early developments as listed in ASTM D1434 (M) on the manometric cell (also known as the *Dow cell*) and ASTM D1434 (V) on the volumetric cell. These were gallant attempts, but are no longer in widespread use.

CURRENT METHODS

Oxygen Transmission Rate (O_2TR). Oxygen is often referred to as the “thief” of flavor, texture, color, nutrition, and shelf life. The importance of testing O_2TR was recognized early in the development of barrier materials such as coated papers and plastics. The coulometric sensor (also known as the coulox sensor) soon dominated because it could detect O_2 down to the parts per billion (ppb) level, was stable, and was easy to maintain and reliable.

Initially only “dry” tests were performed, 0% rh, which was adequate for many of the barriers of that day. However, subsequent barrier materials were developed that had superior O_2 permeation characteristics, but the O_2TR of these new materials was a function of humidity.

Oxygen permeation testing has advanced in capability to allow testing of the most recent developments in barrier materials. The ability to control the percent relative humidity (% rh) independently on each side of the barrier has been one of the most significant advancements. This allows a better simulation of true-to-life shelf conditions and, therefore, more credible results.

The effect of % rh and temperature on O_2TR can be observed in Figures 4 and 5.

Performance expectations are important. The measurable range of O_2 transmission rates is 0.001 mL/($m^2 \cdot$ day) to over 1,000,000 mL/($m^2 \cdot$ day). The following list is specifications on Ox-Tran systems,[3] as used in ASTM D3985 and F1307:

Sensitivity—films, 0.01 mL/($m^2 \cdot$ day) [0.0006 mL/(100 in.$^2 \cdot$ day)]; packages, 0.00005 mL/package $\cdot$ day)

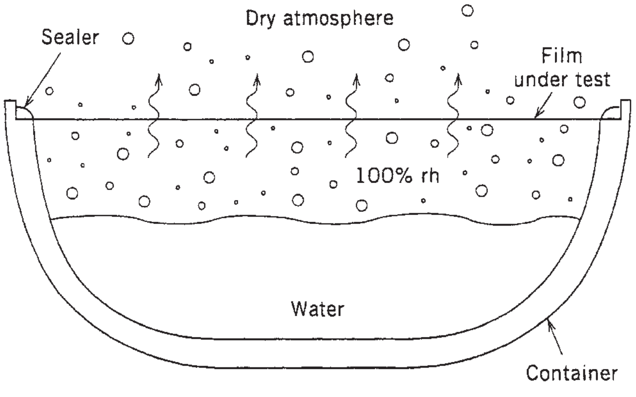

Figure 3. Wet cup test.

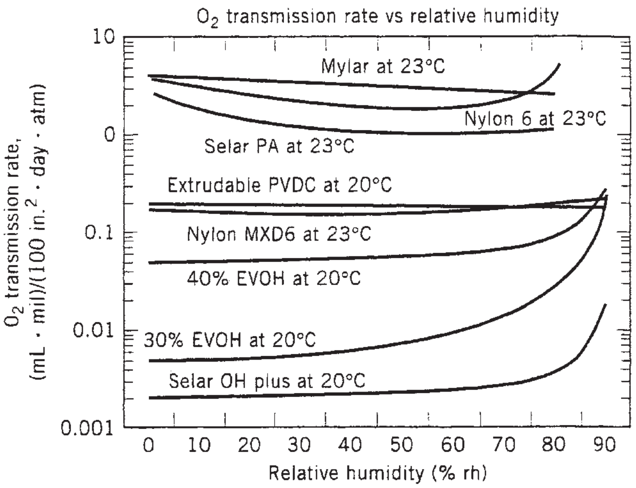

Figure 4. Effect of relative humidity on O_2 transmission rates of several plastic films.

Repeatability—films, ±0.05 mL/(m^2 · day) [0.003 mL/(100 in.^{2} · day)] or 1% of reading; packages, ±0.00025 mL/(package · day) or 1% of reading

A new high-sensitivity method and apparatus now makes it possible to attain the following specification:

Sensitivity—films, 0.001 mL/(m^2 · day) [0.00006 mL/100 in.^{2} · day)]; packages, 0.000005 mL/(package · day)

Repeatability—films ±0.005 mL/(m^2 · day) [0.0003 mL/(100 in.^{2} · day)] or 1% of reading; packages, ±0.000025 mL/(package · day) or 1% of reading

The importance of temperature control cannot be over emphasized. Relative humidity is a function of temperature, and to control % rh is not an easy task because it can vary by 5% rh/ °C in a region of the test.

Measuring High O_2TR Values. At first, all efforts were directed toward low permeation readings (high barriers). An emerging need also exists to measure *high* O_2TR values. Initially, the use of a mask (to decrease the permeation test-cell area) was used for years. As higher O_2TR were required, new test techniques were developed to yield more repeatable results and to keep the O_2 sensor from swamping. With care, values of ≤155,000 mL/(m^2 · day) can be measured. So the measurable range of O_2TR is 0.001 mL/(m^2 · day) to over 155,000 mL/(m^2 · day).

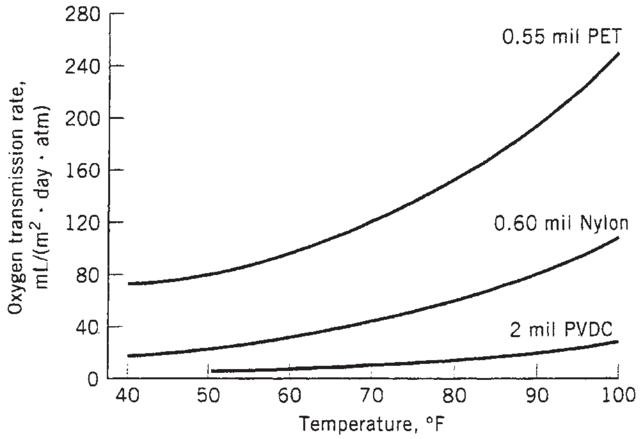

Figure 5. Effect of temperature on O_2 transmission rate of 0% rh for several plastic films.

The following international test methods, as shown in Figure 6, were written around the use of the coulox sensor for oxygen and the infrared method for water vapor, which makes it possible for laboratories in different parts of the world to compare O_2TR and water vapor transmission rate (WVTR) test results.

Water-Vapor Transmission Rate. After the cup test, instrumented systems (ASTM F372, F378, TAPPI 378), and infrared (IR) systems were developed that achieved results in a shorter time (hours vs. days). Comparison of WVTR using the IR method and the cup test revealed remarkably similar results. Today, it is estimated that 95% of WVTR testing in the United States is done using ASTM method F1249 and TAPPI method T557 pm-95.

It was standard practice, at one time, to run all WVTR tests at a given rh, (e.g., 100% rh). Then, if the WVTR at another % rh was desired, then one would simply multiply the 100% rh results by the % rh of interest. For example, the 100% rh result was multiplied by 0.8 if a result at 80% rh was of interest. This was done because there was no convenient, clean method to generate precise % rh values.

The results using this technique, called *factoring*, can be observed in Figure 7.

Notice the excellent correlation between these two methods of creating the driving-force RH. The test results from four common packaging films were almost identical, no matter whether the actual rh was created with salts or distilled water, and the result then factored.

Considerable advantages have been obtained with factoring, including

1. Elimination of messy, uncontrollable salt solutions
2. Greatly reduced possibility of instrument corrosion
3. Increased ease of equipment operation

This method of testing without salts is widespread today. By about 1990, however, it became apparent that this technique may not work for all barrier materials, most notably hydrophilic polymers. In these cases, water vapor is so soluble that the "factoring" relationship does not

1.0 mils (25.4 μm)	#2	6.80	6.99	2.8

Figure 7. Comparison of four films "factored" with 100% rh vs tests with a saturated salt solution of zinc sulfate. (Saran Wrap is a registered trademark of Dow Chemical USA.)

seem to hold true. Nylon 6 is a good example of this (see Figure 8).

As can be observed, factoring does not work for all barriers. Therefore, a system was developed that is more universally applicable by creating humidity and temperature test conditions close to actual shelf conditions of the package. The advantages are as follows:

1. Tests can be conducted close to actual shelf conditions.
2. A range of RH values is available.
3. Relative-humidity values easily changed.
4. No mess.

The water-vapor transmission rate is expressed in g/($m^2 \cdot$ day), or g/(100 in.$^2 \cdot$ day). The measurable range of WVTR is 0.0001 g/($m^2 \cdot$ day) to 1000 g/($m^2 \cdot$ day). The specifications of some WVTR systems are as follows:

Sensitivity—films, 0.0001 g/($m^2 \cdot$ day) [0.000006 g/(100 in.$^2 \cdot$ day)]; packages, 0.000001 g/(package · day)

Repeatability—films, ±0.002 g/($m^2 \cdot$ day) [±0.00015 g/(100 in.$^2 \cdot$ day) or 1% of reading; packages, ±0.00 001 g/ (package · day) or 1% of reading

Carbon Dioxide Transmission Rate (CO_2TR). An IR sensor is used to detect CO_2, and when incorporated in an instrument system to detect permeation, it yields CO_2 TR. The major applications are for cola drinks (CO_2 escaping from PET containers), cheese packaging, and other CO_2-sensitive products. There is no way to extrapolate the action of one gas to determine the action of another gas. Each gas is independent of the other gases and must be tested as an individual gas to determine its TR.

The measurable range of CO_2 transmission rate is 1.0 mL/($m^2 \cdot$ day) up to 100,000 mL/($m^2 \cdot$ day). Specifications for CO_2 systems are

Sensitivity—films, 1 mL/($m^2 \cdot$ day) [0.07 mL/(100 in.$^2 \cdot$ day)]; packages, 0.005 mL/(package · day)

Repeatability—films ±5 mL/($m^2 \cdot$ day) [±0.35 mL/(100 in.$^2 \cdot$ day)] or 1% of reading; packages, ±0.025 mL/(package · day) or 1% of reading

CO_2TR permeation systems can detect 100 ppm CO_2. This is an important factor when considering permeation or leakage. Efforts have to be made to keep the CO_2 from being diluted during the testing process. Diluting the CO_2 level can make a bad situation look good. This is just the opposite for O_2. Diluting a low-O_2 signal with air (20.8% O_2) will make it worse, not better.

An outstanding example of *partial pressure* can be observed using CO_2. Fill a PET container with 100% CO_2 and seal securely. The partial-pressure phenomenon happens over a period of time. CO_2 leaves the PET container much faster than O_2 or N_2 air enters the container. As CO_2 leaves, a vacuum is formed, which eventually causes the container to collapse. Even though CO_2 was removed, it left a vacuum, and O_2 and N_2 followed the partial-pressure law. The vacuum seems to play no part in the permeation process in this case.

Aromas and Flavors. As stated above, these need to be tested as individual gases, and there are a host of these in

All values are g/($m^2 \cdot$ 24 h) at 37.8°C (100°F)		WVTR value using zinc sulfate salt to create 84.5% rh	WVTR value using distilled water to create 100% rh, then factored by 0.846	% DEV

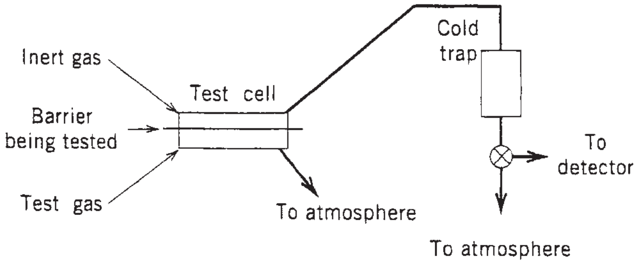

Figure 9. Aromatran schematic.

organics. This is a developing field with many opportunities, such as citrus flavor, D-limonene from an orange-juice container, citrus flavor into other food products (e.g., breakfast cereals), petroleum gases out of packages and into other packaged goods, and so on. Fortunately, a technique has been developed to handle all these organic molecules, however, only one at a time.

In brief (referring to the Aromatran schematic in Figure 9) a carrier gas (helium, N_2, or any number of inert gases) carries the test gas (D-limonene, butane, methane, apple flavor, etc.), which has permeated through a barrier to a *cold trap*, where it is captured and accumulated over a period of time. At the end of the "accumulate" time, the cold trap is heated quickly, which thereby releases the test gas molecules that had been captured.

The carrier gas, which is not affected by the cold trap, continues to flow and carries the test-gas molecules to a sensor. The sensor is an FID that is set up to detect the amount of test gas captured.

The results are given in common permeation terms:

$$X\,\mathrm{TR} = \mathrm{mL}/(\mathrm{m}^2 \cdot \mathrm{day}) \text{ at } 30^\circ\mathrm{C}$$

Permeation becomes more critical as the shelf life is extended. Not only is there concern about gases, such as O_2, water vapor, and CO_2 entering and leaving packages, but also the effects of aromas and flavors are playing an important role in the industry.

LEAKAGE

Everyone knows what a leak is—leaks in the roof, a leak in a tire, even a secret can be leaked out. It is something everyone can define, and everyone has an opinion on the subject.

In the previous section, we discussed permeation. Both permeation and leakage do the same thing: shorten shelf life.

Permeation can be determined, as described above; however, leaks are more erratic, evasive, and unpredictable. Where a permeation value might hold true for a production run of plastic film, leaks can vary from one package to the next. The ideal is to have 100% leak testing on a production run. This is ideal but not practical in most applications.

The perpetual issue of "hole size" is debated among manufacturers of food, pharmaceutical, and sterile medical products. Each has different criteria. The hole that will allow bacteria to enter a sterile package is much smaller than a hole that will allow gravy to drip out of a microwave entrée. First, we must agree on a term called "effective hole size." This is the summation of all the holes in the package. It could be the summation of round holes, square holes, holes with long tunnels, slight tears, big tears, hairline cracks, and so on. Let one hole represent the combination of all the leaks. By so doing, we provide a way of comparing one package to the next. Figure 10 illustrates the flow rate that one would expect through a round-style hole under various differential pressures across the hole. These curves apply to air at ambient temperature through a hole in a thin material.

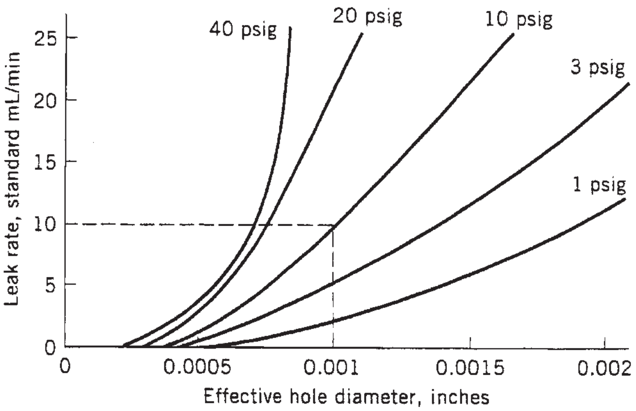

Figure 10. Flow rate of air through a round hole.

DESTRUCTIVE TESTING FOR LEAKS

Waterbath or dye–leak test. (See Figure 11). Throughout most of the twentieth century, package integrity has been verified by placing the package under water and looking for bubbles. Variations of the "waterbath" test have generally involved attempts to improve on the problems inherent in looking for bubbles. The "dye test" was an

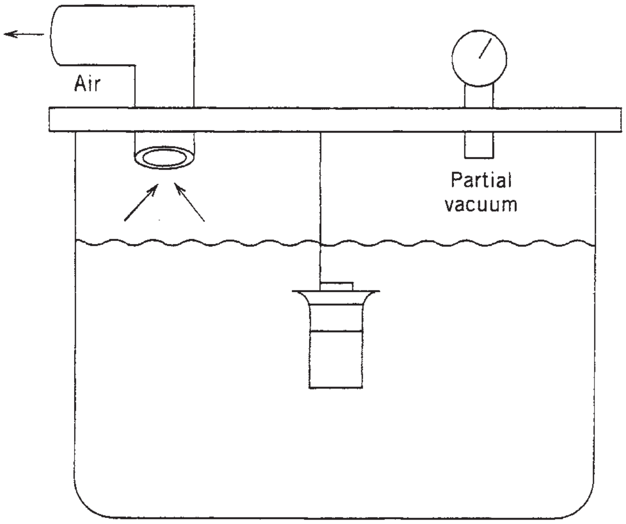

Figure 11. Waterbath or dye leak test.

improvement, but the two remaining problems are lack of repeatability and destruction of the package. Advantages and disadvantages of these tests are as follows:

1. The waterbath test
   a. Advantages
      (1) Can provide sensitivity
      (2) Inexpensive equipment requirements
      (3) Low-level technology, easy to train operator
   b. Disadvantages
      (1) Destructive
      (2) Results are very operator-dependent
      (3) Expensive labor requirements
      (4) Messy
      (5) Capillary attraction can give false results
2. The dye test
   a. Advantages
      (1) Ability to test many samples at once
      (2) Inexpensive equipment requirements
      (3) Low-level technology, easy to train operator
   b. Disadvantages
      (1) Destructive
      (2) Unreliable and operator dependent
      (3) Slow and labor intensive
      (4) Messy
      (5) One-way valve effect

Pressure/Pressure-Decay Method. This technique allows two tests to be run sequentially: (a) burst/seal strength and (b) leak.

Burst/Seal Strength. This is a practical starting point. It is important to ensure that handling and shipping does not destroy the package, which left the plant without leaks. It must remain sealed to maintain adequate shelf life and/or the desired quality when it reaches the consumer. Air pressure is introduced into the package until it *bursts!* The burst-point pressure is held so that it can be recorded. This burst test should be repeated several times to obtain an average. Analysis of this data would be required if damaged packages were discovered by a consumer. This also allows research and development (R&D) to investigate new packaging materials and sealing techniques. The average test time is 15 s.

Leakage. Once the burst/seal strength has been determined, look for leaks. Introduce a pressure into a new package at less than 50% burst pressure and monitor pressure decay. Pressure decay is a function of effective hole size and pressure differential and is inversely proportional to the volume of the package under test. It has been shown that holes as small as 1-mil diameter are detectable in small packages such as pharmaceutical bubbles, but it would be almost impossible or impractical to sense a 1-mil hole in a blimp. This method does not indicate the location of leak(s). The average test time is 10 s.

Other techniques that are destructive include halogen detection where a halogen agent, such as iodine, bromine, or fluorine, is used as a tracer gas. The system is pressurized with the tracer gas, and a probe is used to detect a leakage point. Although this test does detect leakage points, it is highly operator dependent; thus, a poor operator will get the best results, only on the basis of fewer rejects. The instrument response is slow and lacks quantitative accuracy. Food or drug products are not normally tested by this technique.

Halide Torch. Similar to the halogen system described above, in the halide-torch test, the tracer gas is sucked into a burner through a hose attached to the bottom of a burner. A change in the color of the flame indicates a leak.

Thermal-conductivity detector. A tracer gas, such as helium, carbon dioxide, or butane, is pressurized in the package, and a probe senses a change in gas thermoconductivity as the tracer gas enters the probe. This method does detect the leakage point; however, it also is highly operator dependent because if the probe is moved too fast or too far away from a hole, nothing will be indicated.

Helium Leak Detector. This has the greatest sensitivity. Inflate the package with helium. Then, using a probe, *sniff* around the package to find a leak. The major disadvantages are, besides high operator dependence, initial costs (for supplies, etc.) and unit maintenance, that if the instrument is swamped, it takes hours or days for a skilled technician to get it back on line.

Headspace analysis. A practical way to check for leaks is to measure the headspace of a package, and this can be done at any time, such as immediately following sealing or later, or even years later. Using a syringe, a sample of the headspace is taken from the package and injected into an instrument. If the O_2 content is to be determined, a zirconium oxide sensor is used; if CO_2 content is to be determined, an IR sensor is used. The results are given in percentage of contents, such as 0.5% O_2 or 30% CO_2, and within a few seconds after injection of the sample into the instrument. Applications include checking for cap/map effectiveness, shortly after testing to determine whether sealing was effective and met specifications and much later, to determine whether permeation had any effect. Note, in this latter case, that the long-term effect could be either a slow leak or permeation; this instrument cannot separate the two.

Nondestructive Testing for Leaks. The CO_2 leak detector is most commonly used in nondestructive testing of food and pharmaceutical packages. It is ideal if the package has been flushed with CO_2 before sealing or if CO_2 is generated inside, as in the case of coffee.

Leak Detection Using CO_2 Tracer Gas. Figure 12 shows the flow diagram of a CO_2 leak detector. The pump pictured is always running, sweeping room air in from the left and purging the test fixture and CO_2 sensor. When the test sequence is initiated, the dwell solenoid closes, thus causing the pump to draw a vacuum on the package inside the test fixture, which draws CO_2 out of the leaks. At the end of the test cycle, room air is again allowed to

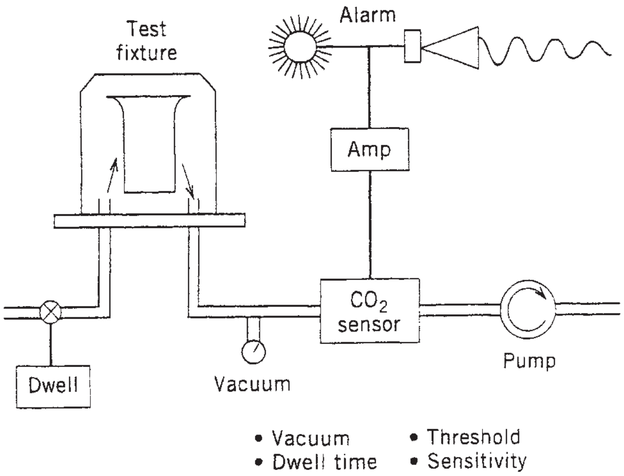

Figure 12. Co_2 trace-gas leak detection; nondestructive.

sweep into the test fixture. This flushes any CO_2 gas into the CO_2 sensor. If this CO_2 concentration exceeds the alarm threshold, the instrument signals that a leak is present. Throughout this cycle, room CO_2 concentration is viewed as the unit's zero, i.e., reference, point.

An important factor is the size of the test fixture compared with the package under test. The sensitivity is inversely proportional to the space outside the sample being tested. As mentioned, care must be taken to avoid diluting the CO_2 signal. Therefore, a specially designed fixture is needed for best results, i.e., to sense small leaks, and in most foods and/or pharmaceutical applications, small leaks are important.

In those cases where no CO_2 is in the package, CO_2 can be forced into the packages through the leaks by use of a pressure chamber filled with CO_2. The vacuum, shown in Figure 14 then draws CO_2 out of the package, which is sent to the CO_2 sensor. The tests that use this technique take 15 s on average.

Carbon dioxide trace-gas leak detection has been shown to be a sensitive, repeatable, and nondestructive alternative to traditional waterbath and dye-leak techniques. Justification is easiest when the product is expensive, as this nondestructive test procedure enables product to be exposed to additional laboratory tests, or to be returned to the production line.

CONCLUSION

The search for better leak-testing methods continues. The challenge is to devise a system that is nondestructive, can conduct 100% inspection at high speed, and, of course, is low cost. To date, the diversity of applications has precluded this. Each application must be evaluated to determine the best solution. Testing-systems manufacturers are challenged to write their specification legibly, clearly, and precisely to ensure that they are understood and can be applied.

Permeation is well defined and accepted in American Society for Testing and Materials (ASTM) specifications. Leakage requires the same attention.

TESTING, PRODUCT FRAGILITY

H. H. Schueneman
San Jose State University,
San Jose, California

The vast majority of products undergo a certain amount of handling and transportation from the time they are manufactured until they are ultimately used. This is especially true in a global economy. Normally, products are enclosed in a protective-package system during the time they are exposed to the hazards of the distribution environment. This article outlines engineering principles and procedures that optimize the protective function of a package system and help guarantee the product's safe arrival at favorable cost.

The waste of resources caused by improper packaging is enormous. Whether this waste shows up as damaged product or an overly expensive package system, it is still waste that can be avoided. The application of sound engineering principles to optimize the product protection system must receive significant endorsement by product managers, quality assurance (see Specifications and quality assurance), and all those concerned with delivering a quality product to the customer.

To develop a protective-package system, three important pieces of data are necessary: (i) information on the likely hazards (shock and vibration) from the distribution environment; (ii) product fragility characteristics and sensitivities in terms of the environmental inputs; and (iii) the performance characteristics of commonly available packaging materials.

The engineering process for developing a protective-package system involves a step-by-step problem-solving approach similar to other engineering disciplines. The principal focus is on product characteristics because it is impossible to optimize a package system without first knowing basic engineering data of the product itself.

Once the environmental hazzards have been defined, and product fragility has been determined, the engineer can evaluate the economic feasibility of possible product modifications. For example, if a certain component within the product keeps failing at a relatively low input level, it may be economically more desirable to modify that component and increase its ruggedness rather than design an expensive and inefficient package system for the entire product based on the sensitivity of that one component. If it is economically feasible to modify the product in order to effect a package-cost savings, this option should be studied carefully. Many examples exist where slight product modifications have resulted in substantial cost savings in packaging materials, reduced damage in shipment, and potentially large savings from improved logistics and shipping costs.

There are many potential hazards in the distribution environment, including shock, vibration, temperature or humidity extremes, electrostatic discharge, magnetic fields, and compression. This article deals primarily with shock and vibration inputs; however, it is important to explore carefully those areas where the product is sensitive or a large environmental input is likely.

The steps involved in designing an optimized package system are as follows:

1. ***Define the environment*** in terms of shock and vibration inputs likely during the product's manufacturing and distribution cycle.
2. ***Define product fragility*** in terms of shock and vibration.
3. ***Obtain product improvement feedback***; that is, examine product improvements in light of the economic tradeoffs between packaging/distribution costs and product modification costs.
4. ***Evaluate cushion material performance***; that is, evaluate the shock and vibration characteristics of available cusion materials and systems.
5. ***Design the package system***; that is, select cushion materials and design for optimum shock and vibration performance and minimum cube.
6. ***Test the final package***; that is, verify that the package system performs as designed and properly protects the product.

The primary purpose of this article is to examine product fragility testing in detail, and therefore the other steps are not covered in a comprehensive fashion. Refer to the bibliography for excellent background material on the other steps in this process (1–6) (see also Cushioning, design; Distribution hazards).

DEFINING THE ENVIRONMENT

The end result of defining the environment should be the establishment of a *design drop height* and a *resonant-frequency spectrum* for a particular product in a given distribution environment. That is, based on the size and weight of a packaged product, the engineer selects a drop height that represents a given probability of input. Also, vibration profiles for likely modes of transportation are selected. Both of these pieces of information are used in the last step, testing of the package system (7–10).

DEFINING PRODUCT FRAGILITY

The term *product fragility* is misunderstood by many people and often conjures up images of totally destroyed products, broken bottles, and the like. In reality, product fragility is simply another product characteristic such as size, weight, and color. Just as other product characteristics are determined by measurement, product fragility (or product ruggedness) can be measured with shock inputs. This measurement takes the form of a damage-boundary curve for shock and resonant frequency plots for vibration. In both cases, the importance of determining these characteristics cannot be overemphasized. Most people would not think of buying a pair of shoes based on guessing their foot size. It is just as short-sighted to design a package system by guessing at product fragility.

Shock Fragility Assessment

The damage boundary is the principal tool used to determine the ruggedness of a product; it takes the general shape shown in Figure 1. This plot defines an area on a graph bounded by peak acceleration on the vertical axis and velocity change on the horizontal axis. Any shock pulse that can be plotted inside this boundary will likely cause damage to the product regardless of whether it is packaged or not. (This is a *product* test.)

Acceleration is a vector quantity describing the time rate of change of velocity of a body in relation to a fixed reference point; that is, it describes the rate at which velocity is increasing (acceleration) or decreasing (deceleration). The terms *acceleration* and *deceleration* are often used interchangeably because most products respond similarly to a rapid start or a rapid stop. Both terms are expressed in G values, multiples of earth's gravitational constant, g. The SI units are m/s^2.

Velocity change is the difference in a system's velocity magnitude and direction from the start to the end of shock pulse. Velocity change is the integral of the acceleration versus time pulse and is directly related to drop height.

To run a damage boundary, mount the product to be tested on the table of a suitable shock-test machine (see Figure 2). Secure the product with a rigid fixture that lends even support to the product over its entire surface.

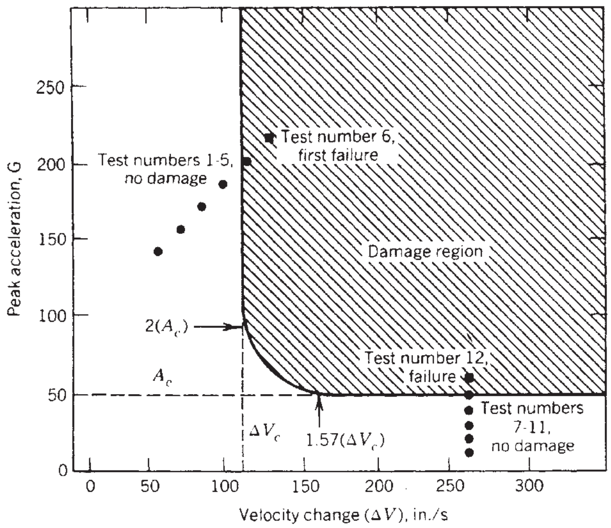

Figure 1. Damage boundary (single orientation). A_c, critical acceleration; V_c, critical velocity. To convert in. to cm, multiply by 2.54.

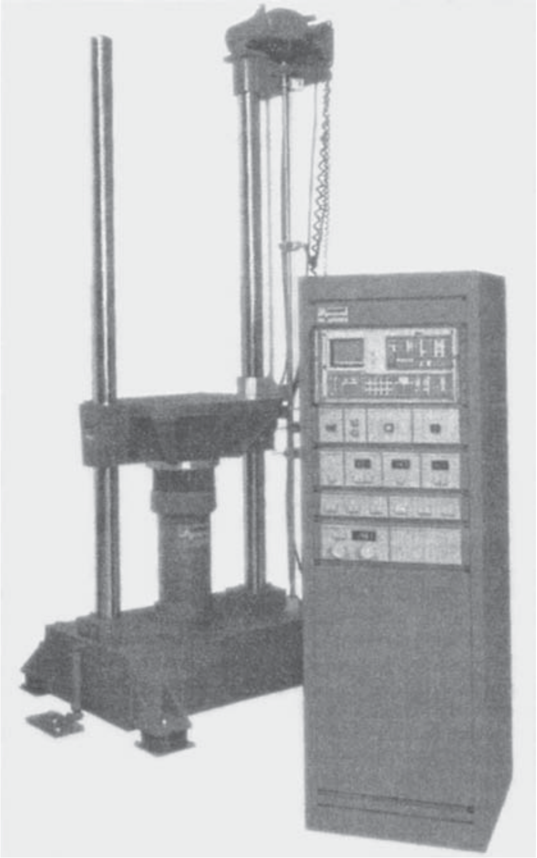

Figure 2. Shock-test machine.

The fixture must be as rigid as possible so that it does not distort the shock pulse transmitted to the product.

Set the shock machine to produce a low velocity-change shock pulse with a duration of approximately 2 ms (a half-sine waveform is generally used for this test). After the shock pulse is delivered to the product, examine it to determine if damage has occurred. If not, set the shock machine to produce a slightly higher velocity change and repeat the test. Continue this process with small incremental increases in velocity change until damage occurs. The last nonfailure shock input defines critical velocity change ΔV_c for the product in that orientation.

Next, fasten a new test specimen to the shock table and set the machine to produce a trapezoidal pulse with a low acceleration level and a velocity change at least two times that of the critical velocity determined in the previous test. Program the shock pulse into the product and, as before, examine the product to determine if failure occurs. If no failure has occurred, set the shock machine to produce a higher acceleration level at approximately the same velocity change. Repeat this procedure with small increments in acceleration until the failure level is reached. The last nonfailure shock input defines the critical acceleration, A_c, for the product in that orientation (11).

The damage boundary curve may now be plotted by drawing a vertical line through the critical velocity change point and a horizontal line through the critical acceleration point. The intersection of these two lines (the knee) is a smooth curve as shown in Figure 1. A rectangular corner may be used as a conservative approximation of the damage region (12).

Note that the critical acceleration as determined by a trapezoidal pulse is conservative when compared to that generated through the use of other waveforms; that is, a trapezoidal pulse is more damaging than other waveforms of the same peak acceleration and duration. This is shown graphically in Figure 3.

Since the shape of the waveform transmitted through various packaging materials during impact is generally not known, the use of a trapezoidal wave during damage boundary testing results in a higher confidence level in a packaging system and is recommended for this purpose. It should also be pointed out that the use of the trapezoidal waveform results in a nearly linear abscissa on the damage boundary. This means that it is necessary to determine only one point on that axis in order to determine the critical acceleration for the product in that orientation. Other waveforms result in critical accelerations that are a complex function of the natural frequency of components within the product. The procedure described is based on ASTM D3332 (13).

The damage boundary is a valuable and powerful tool. Critical velocity change is equated to equivalent free drop height from the formula $\Delta V = (1 + e)\sqrt{2gh}$, where e is the coefficient of restitution of the impact surfaces (V_i/V_r), g is acceleration of gravity [386 in./s^2 at sea level (9.8 m/s^2)], and h is equivalent free-fall drop height in in. (or m). The critical velocity change tells the designer how high the unpackaged product can fall onto a rigid surface before damage occurs in that axis. If this equivalent drop

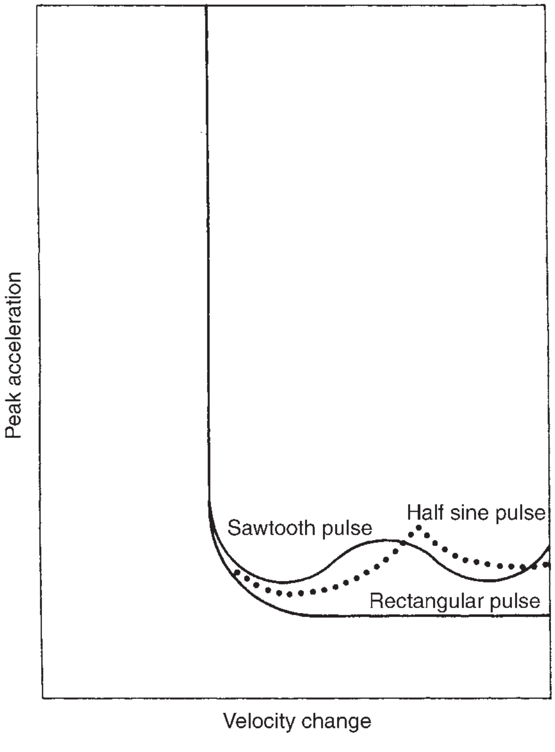

Figure 3. Damage boundary for various pulses.

height is likely to be exceeded in the distribution environment, then the product must be cushioned. The performance requirements of the cushion are that no more than the critical acceleration be transmitted to the product.

In theory, the value of *e* (coefficient of restitution) can vary from zero to one. A value of zero would imply a totally plastic impact with no rebound whatsoever. A value of one implies a perfectly elastic impact where the rebounded velocity is exactly equal to the impact velocity. As a practical matter, a range of $e = 0.25–0.75$ produces good accuracy in calculating the range of equivalent freefall drop height. The chart in Figure 4 shows the effect of *e*.

The damage boundary also tells the engineer that at low velocity changes, infinite accelerations are possible and that at low acceleration levels, infinite velocity changes are possible without product damage. That means that it is necessary to define both critical acceleration and critical velocity change to properly characterize the fragility (or ruggedness) of a product.

Before running the damage-boundary test, the engineer must define what constitutes *damage* to the product. On one extreme, damage may be catastrophic failure. However, there are many less severe damage modes that can make a product unacceptable to the customer. In some cases, damage can be determined by observation of the product; at other times it involves running sophisticated functional checks. Once the determination of damage is made, the definition must remain constant throughout the testing and must be consistent with what is deemed unacceptable to the customer.

In general, damage-boundary tests must be run for each axis in each orientation of the product. In the case of a rectangular product such as a television set, this means that a total of 12 specimens are necessary for a rigorous test. However, since this testing should be done in the product prototype stage, this quantity is rarely available for a potentially destructive test. As a practical matter, much information can be gained from a limited number of samples, and multiple damage boundaries are often run on the same unit in different orientations.

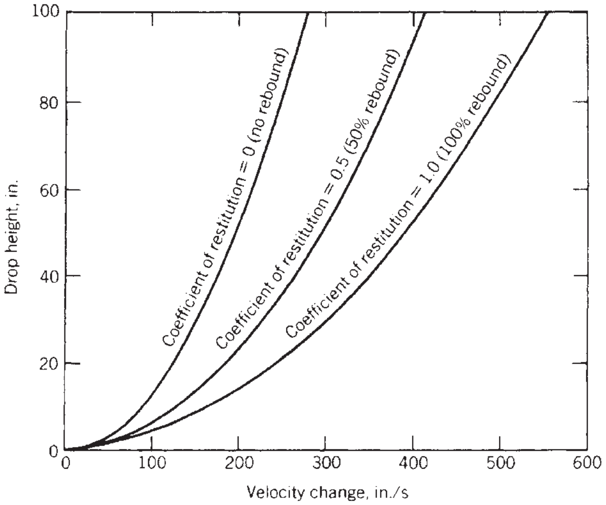

Figure 4. Coefficients of restitution. To convert inches to centimeters, multiply by 2.54.

Vibration-Fragility Assessment

Determining product-vibration sensitivities involves identifying resonant frequencies of components within the product in each of the principal axes. Resonance is that characteristic displayed by all spring/mass systems wherein at a given frequency, the response acceleration of a component is greater than the input acceleration. This characteristic is shown graphically in Figure 5.

As a general rule, the product will not be damaged due to nonresonant inertial loading caused by vibration in the *distribution environment*. This is because the acceleration levels of most vehicles are relatively low when compared to the critical acceleration of most products. It is only when a component within a product is excited or forced by vibration at its natural frequency that damage is likely to occur.

At frequencies below the resonant frequency, the response of a critical component is roughly equal to the input (the response/input ratio is 1). At frequencies higher than the resonant frequency, the response acceleration is lower than the input. In this region a component acts as its own isolator and results in a condition known as *attenuation*.

At (and near) the product resonant frequency, however, the response acceleration can be very much greater than the input, causing product fatigue and ultimate failure in a relatively short time. The purpose of vibration sensitivity assessment is to identify those critical frequencies likely to cause damage to the product.

A *resonant frequency search test* is run by attaching a product to the table of a suitable vibration test machine (Figure 6) and subjecting it to an acceleration input at a low level (typically 0.25–0.5 *G*) over a suitable frequency

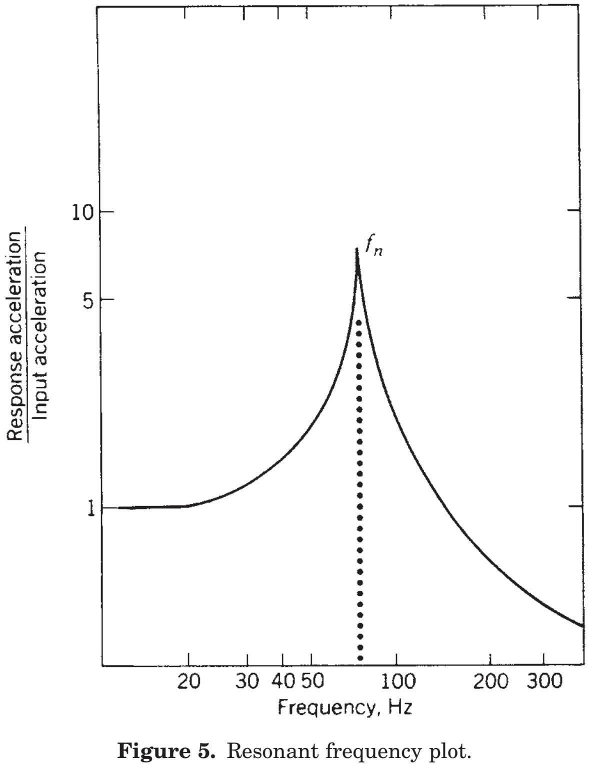

Figure 5. Resonant frequency plot.

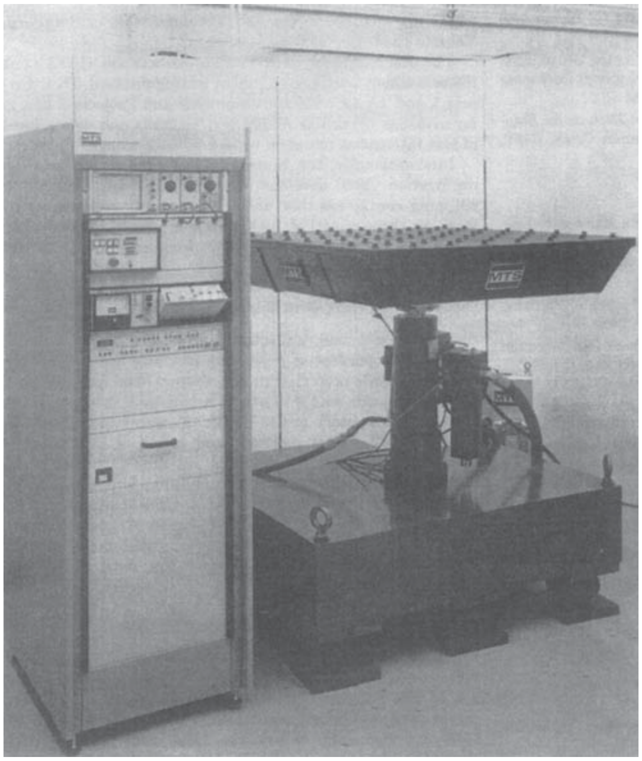

Figure 6. Vibration-test machine.

range, typically 1–300 Hz (cycles per second). Accelerometers are fastened to critical components within the product in order to determine the components' responses to the input acceleration. The response/input ratio is plotted as a function of frequency for each "critical" componant. This ratio reaches a maximum at the component resonant frequency. The test usually involves monitoring many components in each axis of the product in order to characterize its overall vibration sensitivities (14). Sinusoidal or random excitation can be utilized for this test, but random vibration excitation has gained wide popularity due to the ease of use, test efficiency, and potentially more accurate data.

The importance of vibration teting cannot be overemphasized. Any product shipped from point *A* to point *B* is subject to vibration because of the transit vehicle it is riding. The probability of this input is 100%. In contrast, the probability of a shock input because of a drop is exactly that, a probability function. In some cases, the drop height experienced by a product may be severe, in most cases, it is hardly measurable. However, any product that is shipped in a vehicle is subject to vibrational input and it should be tested for sensitivity to that input.

CONCLUSION

At this point, the engineer has sufficient data to make intelligent decisions about tradeoffs between the product modifications and package costs. If a fragile component can be ruggedized at minimal cost, resulting in substantial package savings, then it makes sense to pursue the product modification.

The package-design process uses environmental data, product-fragility information, cushion-performance data (see Foam cushioning; Testing, cushion system), and a healthy dose of designer creativity. Knowledge of package-fabrication techniques, as well as other vital information on flammability restrictions, maximum weight and cube for storage and transportation, recyclability of the package components, future cost trends of various key materials, and so on. (1, 3, 5, 6, 15), is essential.

Once the design has been finalized and a prototype fabricated, it must be tested to verify compliance with product requirements. It is important to specify the correct inputs, both their magnitude (or duration) and sequence, in order to closely duplicate the potentially damaging effects of the distribution environment. Test procedures such as ASTM D4169 (7) and a variety of new ISTA test procedures (17) have done much for improving the correlation between laboratory tests and field experience (2, 4, 16).

A properly engineered packaged system is now within reach of all manufacturers, distributors, and other package-system users. The wasteful practice of overpackaging can virtually disappear along with damage-in-shipment reports. The tools are available and the technology is straightforward. Optimized packaging is indeed an attainable goal.

TESTING, SHIPPING CONTAINERS

Alfred H. McKinlay
Consultant, Pattersonville,
New York

Shipping containers are tested in the laboratory to verify their ability to survive hazards in the distribution environment. Tests may be conducted as a packaging development tool for quantitative purposes, or as a qualitative measure of performance. Objectives may be reduction of damage, cost improvement, assurance of safe product shipment, or other package-design reasons. Laboratory preshipment tests, utilizing proven industry standards, will provide a high level of assurance that a package design will function properly and safely deliver its contents, without cumbersome trial shipments. Such trials require a large number of test packages and significant time delay before an indication of success or failure. They provide no fundamental data, are expensive to conduct, and may severely delay introduction of new products to the marketplace. While some trial shipments are a good idea as a final check, prior laboratory testing is a much quicker indicator of success or failure and can precisely identify causes of inadequacy.

SOURCES OF TEST METHODS

The oldest and largest developer of packaging test methods, including those for shipping containers, is ASTM International (American Society of Testing and Materials). ASTM test methods, which are based on a balanced consensus approval process, have worldwide acceptance. Updated at least every 5 years, their standards for packaging began development in 1914 and now include over 130 test methods, specifications, or practices, which are included in the ASTM *Annual Book of Standards*, Volume 15.10 (1).

The International Safe Transit Association (ISTA) publishes several types of preshipment testing procedures. These include: Series 1 Non-simulation Integrity Tests, Series 2 Partial Simulation Tests, Series 3 General Simulation Tests, Series 5 Focused Simulation Tests, and Series 7 Development Tests (2).

Internationally, the International Organization for Standardization (ISO) develops and maintains test methods for shipping containers that are similar to, but not exactly the same as, those of ASTM. ISO standards may be obtained from the American National Standards Institute (ANSI) in New York City.

ENVIRONMENTAL HAZARDS TO SHIPPING CONTAINERS

Shipping containers and interior protective packaging serve the primary purpose of protecting products against environmental hazards occurring in distribution. An early definition of these hazards was set forth in a 1979 report by the Forest Products Laboratory of the USDA (3), FPL 22, and still remains a source of many test methods and levels of intensities. It identifies the following hazards as the major causes of damage in distribution: rough handling, shock and vibration in transit, compressive forces, and temperature and humidity extremes. Experience of many shippers supports the contention that these hazards are still the major culprits, with rough handling clearly the most severe and frequent cause of damage. Since the late 1980s, instrumentaion progress has made it possible to measure shock, vibration, temperature, and humidity much more accurately and easily. Packaging researchers have used these instruments to update and enlarge the database from FPL22 (3) since that time.

TEST METHODS FOR REPRODUCING SHIPPING HAZARDS

Each of the major distribution hazards of handling, shock and vibration in transit, and compression can be reproduced by one of several test methods, depending on the type of container, test equipment availability, or purpose of test. The following discussion covers the most widely used ASTM methods.

Drop test

Accidental or purposeful dropping or striking of containers during handling, loading, and unloading is the prime source of damage to most packages under 200 lb. ASTM test method D5276, *Drop Test of Loaded Containers by Free Fall*, describes the equipment and methodology for conducting a laboratory simulation of this hazard. All types of shipping containers may be tested, including boxes, cylindrical containers, bags, and sacks. Accuracy of the drop-test equipment is specified, including a requirement for impact surface mass of at least 50 times that of the heaviest container to be tested. The method may be used to check the ability of the container to survive free fall, evaluate the protective capability of container and inner packing, compare performance of different package designs, or permit observation of progressive failure of a container and damage to its contents.

An alternative to free-fall drop is ASTM test method D5487, *Simulated Drop of Loaded Containers by Shock Machine*. This method provides more accurate package positioning for impacts, particularly on flat impacts where the shock transmitted to package contents is usually greatest. While the shock machine method has been shown to be quite accurate for most applications, rigid package systems are not recommended for testing by this method (where “rigid” means a natural frequency above 83 Hz for the system).

Incline Impact Test

For large shipping containers, an alternate method for obtaining an impact is ASTM test method D880, *Impact Testing for Shipping Containers & Systems*. A guided test carriage, tilted at 10°, is loaded with the test specimen on the leading edge and pulled up the incline to a distance sufficient to produce the desired impact velocity. The carriage is then released and travels down the incline until the container strikes the impact surface, also tilted at 10°. When the incline test equipment, dubbed the “Conbur test,” is constructed with impact surface at least 50 times the mass of the heaviest test specimen, it is considered equivalent to a free-fall drop test for intensity of shock. ASTM D880 also includes the use of pendulum equipment as an alternative to the incline.

A popular test sequence and level of intensity for the incline impact test is the ISTA 1B procedure for containers and skidded or palletized items weighing over 150 lb. It specifies an impact velocity of 5.75 ft/s with impacts on all four sides, followed by a rotational bottom drop from 8 in. high. The incline impact equipment may also be modified such that it can reproduce shocks similar to railcar switching impacts. ASTM test method D5277, *Performing Programmed Horizontal Impacts Using an Inclined Impact Tester*, describes the required carriage bulkhead, programming material or device, and other modifications that are necessary for simulating standard railcar draft-gear impacts. The method is not appropriate for long-travel draft gears or cushioned railcar underframes.

Horizontal Impact Test

A more accurate method of reproducing all types of railcar impacts is described in ASTM test method D4003, *Programmable Horizontal Impact Test for Shipping Containers and Systems*. The test equipment specified is a horizontal shock machine with precise control over impact and rebound velocities. Dynamic compression of containers during railcar switching is great, due to backload of other freight pressing against it; therefore, the test method describes how such backload should be simulated during testing. Proper instrumentation and calibration, critical to the method’s accuracy, are specified in some detail. ASTM D4003 may also be used for other types of horizontal impact simulation, such as pallet marshaling.

Bridge Impact Test

Some handling systems place heavy stress on long packages, particularly in small-parcel shipping. ASTM test method D5265, *Bridge Impact Testing*, specifies equipment and methodology for applying impacts to the center of long packages. Two options are included; A, for using a free-fall drop tester; or B, for using a SMITE tester. In both methods, the package is supported on its ends and an impacting device drops onto its center at a specified impact velocity.

Concentrated Impact Test

Thin-walled shipping containers and plastic wrapped items often incur damage to contents due to impacts from other packages or handling devices. The impacts typically do not cause a puncture but do impose severe deflection of the container wall, resulting in damage to the contents. ASTM test method D6804, *Test Method for Concentrated Impacts to Transport Packages*, specifies equipment and methods for applying concentrated impacts to specific surfaces of the package.

Other Handling Tests

ASTM Standard D6179, *Rough Handling of Unitized Loads and Large Shipping Cases & Crates*, contains a number of test methods particularly suited to reproducing handling hazards for either unitized loads or large containers or both. Included are the following:

Free-Fall Drop Test. This utilizes a quick-release hook and sling for equipment to drop test on any container surface.

Rotational Edge-Drop Test. One end of the specimen is supported on a block while the opposite end is raised to specified height and then dropped to the floor.

Corner Drop Test. One bottom corner is supported on a block while the diagonally opposite bottom corner is raised to specified height and then dropped to the floor.

Raised-Edge Drop Test. One end of the specimen is raised to a specified height while the opposite end rests on floor, and then the raised end is dropped to floor.

Rolling Test. This determines the ability of a container to withstand the effects of rolling.

Tip Test. This determines the ability of tall or top-heavy containers to resist tipping over.

Tipover Test. This determines the protective ability of loaded shipping containers when subjected to tip-over impacts.

ASTM Standard D6055, Mechanical Handling of Unitized Loads and Large Containers or Crates, provides methods of testing handling capabilities using lift trucks, grabhooks, or slings. A test course and methodology is described for handling tests by four types of lift truck: fork, spade, clamp, and push–pull.

VIBRATION TESTS

Although vibration-induced damage is not a frequent problem for most packaged products, vibration does occur with certainty on every shipment by any mode of transport. It is therefore important to test all types of shipping containers for vibration. Four methods of vibration testing are available, depending on equipment and test objective.

ASTM test method D4728, *Random Vibration Testing of Shipping Containers*, provides the closest simulation to actual vibration received by containers in transit. Input for the test may be generated from field measurements made with accurate recording instruments or from use of the sample vibration spectra for commercial transport that is included in the standard. Test durations frequently run as long as 3 h or more, depending on the packaged product, distance shipped, and objective of the test. Resonance buildups during random vibration are less intense than by sinusoidal vibration methods, and unrealistic fatigue damage is therefore minimized.

ASTM Standard D999, *Vibration Testing of Shipping Containers*, actually contains four distinct test methods and utilizes two entirely different types of vibration equipment. Method A is a repetitive shock test, not really vibration in the pure sense, and is divided into A1 for rotary motion and A2 for vertical motion. Both tests are conducted with the package free to bounce on the table, which is running at a frequency causing the package to just lift off during the upstroke of each vibration cycle (known as 1*G*+). The operating frequency and table displacement are constant throughout the test, which is usually performed on a mechanical-type vibrator. Typical test duration is about 1 h with smaller, nonskidded containers tested one-third of the duration on each axis. The two methods do not create the same type of motion; therefore, they also do not cause the same types of damage.

Methods B and C of D 999 are resonance search and dwell tests, typically performed on electrohydraulic equipment that easily performs at 3–200 Hz as required for most packaging tests. The table displacement varies inversely with the frequency so as to maintain a constant level of force, usually 0.25 *G* to 1 *G*. The purpose of the test is to locate natural frequencies of the packaged product and then dwell for a specified time at each natural frequency while the package resonates. Procedures are described for sweeping the vibration frequency up and down to locate the natural frequency points. Method B is conducted on single containers while Method C is conducted on stacks of containers or unitized loads. Typical dwell times at resonance for both methods is 5–15 min for each point, although some users dwell for up to 1 h.

Compression Tests

The effects of stacking one container on another in storage or transportation can be studied by means of the compression test. Two ASTM test methods are available: D642, *Determining Compressive Resistance of Shipping Containers*, and D4577, *Compression Resistance of a Container Under Constant Load*. The former requires a testing machine that applies a steadily increasing force to the container until it fails. A recording device notes applied load and container deflection during testing that generally requires ≤ 2 min for completion. ASTM test method D4577 may use a similar machine, but more typically utilizes a simple stationary apparatus that positions the test specimen under a fixed constant load for the desired time, anywhere from 1 h to 1 year. Both methods may be used on filled shipping containers or on empty ones, depending on test objective.

Water-Vapor Transmission Test

To measure the resistance of shipping containers to water vapor, ASTM D4279, *Water Vapor Transmission of Shipping containers*, provides two test methods. The constant-atmosphere method is conducted at 90% rh and 100°F. The cycle method goes up and down, from 0°F to 100°F., 90% rh and back, for a number of specified cycles. Different procedures are defined for reclosable and nonreclosable containers.

Water-Resistance Test

ASTM test method D951, *Water Resistance of Shipping Containers by Spray Method*, determines how well a filled container will resist water spray such as produced by heavy rains or waves over the deck of a ship. The test is frequently conducted in a series with other tests such as drop or incline impact.

CONDITIONING FOR TESTING

A requirement in all ASTM shipping container test methods is for testing at a specified condition of temperature

Table 1. Special Atmospheres

Environment	Temperature, °F (°C)	Relative Humidity (rh), %
Cryogenic	−67±6 (−55±3)	
Frozen-food storage	0±4 (–18±2)	
Refrigerated storage	41±4 (5±2)	85±5
Temperate, high-humidity	68±4 (20±2)	90±5
Tropical	104±4 (40±2)	90±5
Desert	140±4 (60±2)	15±2

and humidity. A variety of atmospheric conditions are described in D4332, *Conditioning Containers, Packages, or Packaging Components for Testing*. This standard practice provides special conditions that may be used to simulate particular field conditions that a container may encounter during distribution. The standard also describes procedures for preconditioning the containers to ensure that they reach equilibrium in the atmosphere before they are exposed to the final test conditions. Following preconditioning, containers are placed in the conditioning chamber for a specified time, ordinarily at least 72 h, to reach equilibrium at test conditions. Most testing is conducted at the U.S. standard conditioning atmosphere of 73°F and 50% rh, but other test atmospheres may also be used, as listed in Table 1.

PERFORMANCE TESTING

The test methods described to this point may be used in several ways by package designers. The most frequent use is as an engineering development tool to ascertain how well design and materials are doing their job of protecting the product. But the same methods may also be utilized to indicate whether the package will *perform* as expected for the total distribution cycle. Whereas engineering development testing often overstresses the package to determine its limits when subjected to a particular hazard, the performance use of the same methods is a pass/fail, go/no-go situation with the same container going unopened through the full set of tests. Development testing is a quantitative measure, while performance testing is qualitative.

ASTM D4169, *Standard Practice for Performance Testing of Shipping Containers and Systems*, has received wide acceptance as a national standard for measuring expected shipping-container performance. It is essentially a matrix of test methods, distribution modes, and levels of test intensities. Putting them together in a sequence that simulates a particular distribution environment produces a “distribution cycle” (DC) containing certain hazards (tests). If the shipping container and contents survive the DC, then it can be assumed that they will also survive in actual handling and shipping by the same method of distribution (DC). ASTM D4169 also requires that the criteria of acceptance (definition of success or failure) be predetermined and documented prior to testing.

Each hazard in distribution is identified in D4169 with a test method to reproduce it. Table 2 lists the nine hazard elements recognized in the performance standard, along with the corresponding test methods.

Presently, there are 18 distribution cycles in D4169, each containing a sequence of hazards expected by that particular distribution method. Table 3 is a listing of the cycles with hazards noted by their code letters from Table 2.

For those packaging engineers with a good knowledge of their distribution environment(s), DC 2 has become the performance test plan of choice. It permits them to develop a test plan that fits the often unique sequence of hazards that their packages encounter in distribution.

Since 1997 ISTA has also developed several performance or general simulation test procedures which are somewhat different than ASTM’s. They are Procedure 3A for Parcel Delivery System Shipments, 3E for Unitized Loads of Same Product, 3F for Distribution Center to Retail Outlet Shipments, and 3 H for Mechanically Handled Bulk Transport Containers. There is also a focused simulation Procedure 5B for Temperature Controlled Transport Packages.

REGULATORY AGENCY USE OF CONTAINER TESTING

Shipping-container performance requirements, as a substitute for material or design specifications in regulatory documents, has been slowly making progress. The U.S. Department of Transportation (DOT) now requires that many hazardous materials be packaged in conformance to a brief set of performance-test specifications rather than to cumbersome and complex material and design specifications previously required (4). The National Motor Freight Classification in 1995 authorized an alternate rule, Item 180, performance requirements for LTL shipments, which can be utilized at the shipper’s discretion

Table 2. Hazard Elements and Corresponding Tests

Code	Hazard Element	Test Simulation of Hazard	ASTM Designation
A	Handling— manual and mechanical	Drop, impact, stability	D5276, D880, D4003, D6055, D6179
B	Warehouse stacking	Compression	D642
C	Vehicle stacking	Compression	D642
D	Stacked or unitized vibration	Random vibration	D4728
E	Vehicle vibration	Random or sinusoidal vibration	D4728, D999 Method B or C
F	Loose-load vibration	Vibration (aka repetitive shock)	D999 Method A1 or A2
G	Rail switching	Longitudinal shock	D4003, D5277
H	Climate, atmospheric conditions	Temperature, moisture humidity	D4332
I	Low Pressure	Vacuum	D6653

Table 3. Performance Test Sequence by Distribution Cycle

	DC Hazard Element	
Distribution Cycle (DC)	Number	Sequence
General schedule—undefined distribution system	1	A, D, F, G, A
Specially defined distribution system, user-specified	2	User-specified from Table 3 Hazard Elements
Single-package environment, ≤100 lb	3	A, C, F, E, A
Motor freight		
Single package >100 lb	4	A, C, F, E, A
Truckload, not unitized	5	A, D, E, A
Truckload or LTL, unitized	6	A, D, A, B

THERMOFORM/FILL/SEAL

Edwin Ho
OSI Industries,
Lisle, Illinois

Thermoform/fill/seal equipment is used for a variety of food and nonfood packaging applications. Thermoform/fill/seal (TFFS) machines use two continuous webs or rolls of film (see Figure 1). Typically, the lower web is formed into a cup, pouch, tray, and so on, which is then filled with product. The upper web becomes the lid or cover. Although over 90% of all TFFS machines are run with formed bottom webs and unformed lidstock, it should be mentioned that this is not always the case. Sometimes both webs are formed; sometimes the top web is formed, and the bottom one is not, depending on product presenatation, marketing need, competitive packaging advantages, and so on.

PACKAGING APPLICATIONS

TFFS machines were originally designed as vacuum-packaging machines to package ham, bacon, or sausage. From cured meats, their use spread to other sectors of the meat industry (frozen steaks, certain fresh meats, cook-in-package delicatessen meats), and then to cheese products, baked goods, fresh pasta, and a variety of perishable food products requiring extended shelf life.

Nonfood applications of TFFS evolved from the original vacuum-packaging machines for sausage and meat products. These are primarily sterile-medical applications. Typical medical items packed on TFFS equipment are syringes, needles, catheters, kidney-dialysis filters, scrub sponges, surgical drapes and clothing, operating-room kits, and many other items. Although medical TFFS machines are structurally and conceptually the same as TFFS machines used in the food industry, the materials

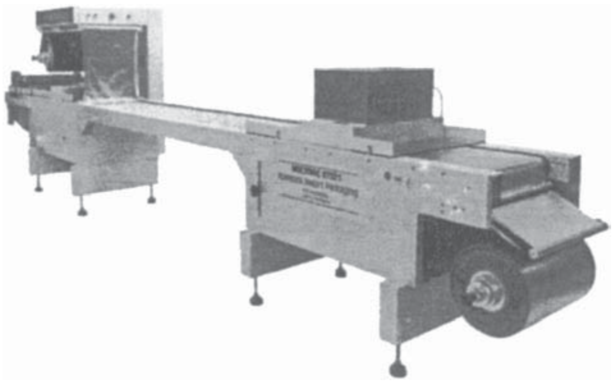

Figure 1. Thermoform/fill/seal machine. Shown with lower web-forming station in foreground. Note extensive product-loading area.

tend to be more difficult to run and the quality standards for cutting and thermoforming are more difficult to meet. Among the TFFS applications that are not food or medical are the following: hardware items, cigarette lighters, cosmetics, and similar applications where packages made on continuous-web machinery are replacing preformed plastic “blisters” (see Carded packaging).

Food Packaging

In food applications, the packages are almost always hermetically sealed, and the films have various degrees of barrier properties. The primary application for vacuum packaging is to improve shelf life of foods that are sensitive to oxygen or susceptible to dehydration. Almost all cured-meat products (ham, bacon, sausage, corn beef, beef jerky, etc.) are vacuum-packaged, as are many cheeses. An off-shoot of vacuum packaging is controlled atmosphere packaging (see Modified atmosphere packaging). A modified atmosphere package produced on TFFS equipment is a step beyond vacuum packaging. First, the unsealed package is indexed automatically into a vacuum chamber. Then all the air is removed from the package. Once the air is removed, the desired gas mixture is injected into the package, usually until the pressure of gas inside the package reaches about one atmosphere. Table 1 lists some commonly used gas mixtures and their application.

Vacuum and modified atmosphere packages are generally used to protect refrigerated perishable foods that would otherwise spoil in less than a week. In a modified atmosphere, they may stay fresh for 4–6 weeks or longer. Many frozen foods are also packed on TFFS machinery, and a modified atmosphere can sometimes replace freezing (see Figure 2). Some nonperishable foods with shelf life of over one year can be packaged on TFFS equipment. In Europe, for example, shelf-stable heat-processed vegetables are marketed in retorted thermoformed packages. Thermoforming machines can be modified to mechanically cold-form aluminum foil for retort processing of various meat and nonmeat dishes. The taste, texture, and nutritional quality of food in retort-sterilized aluminum foil pouches is generally higher than that of conventionally canned foods (see Retortable flexible and semirigid packages).

TFFS MACHINES

The essence of TFFS machines is their modularity. Within any given machine designation, an almost infinite number of configurations is possible. There are six basic operations that make up the production of a package on TFFS equipment: film advance, thermoforming, loading, sealing, cutting, and labeling/printing (see Figure 3).

Film Advance

TFFS machines are built like miniature assembly lines with separate stations for different operations. There are several film-advance mechanisms for moving the webs through these stations. The drive mechanism such as 2

Table 1. Gases Used in Packages Produced on TFFS Equipment

Gas	Application
N_2	As a pressure-relief agent to prevent external atmosphere from crushing the product. N_2 is an inert gas. It does not react with either the food substances or bacteria. Common applications include bulk-pack bacon and sausage, shredded and sliced cheese, and beef jerky.
CO_2	Depending on the application, 25–100% CO_2 may be used. CO_2 lowers the pH of the food product and can exert a powerful slowing effect on the growth of bacteria and molds. Primary application is for baked goods, cookies, cakes, and breads, as well as dough and pasta products. CO_2 tends to be absorbed into the actual body of the food product itself. On one hand, CO_2 is frequently mixed with N_2 to prevent the package from clinging too tightly to the product. On the other hand, some products that are not sensitive to strong pressure or tight cling, but that are susceptible to spoilage by mold growth, are packed in an atmosphere of 100% CO_2. An example of this is chunk cheese. Many CO_2 gas packages have the appearance of a vacuum package, with much of the CO_2 absorbed into the product itself. In an extreme instance, container collapse in shredded cheese can occur due to extended CO_2 absorption by cheese causing negative internal pressure if 100% CO_2 is used. A mixture of 80%/20% of CO_2/N_2 is recommended to prevent package collapse and is still able to prevent mold growth in cheese.
O_2	The application using O_2 are primarily for red meat. The concept has been progressively used in the United States and Europe for centrally packed retail cuts in the past decade. The O_2 is used as an oxygenating agent, at levels in the range of 40–80%, to form the bright-red, fresh-meat color called oxymyoglobin. When O_2 is used, it is usually mixed with CO_2 and N_2: CO_2 for its preservation effect, N_2 to provide a bulking agent. The O_2 tends to disappear inside the package. It can be metabolized by the meat to CO_2 that is absorbed in the water phase of the meat as carbonic acid.

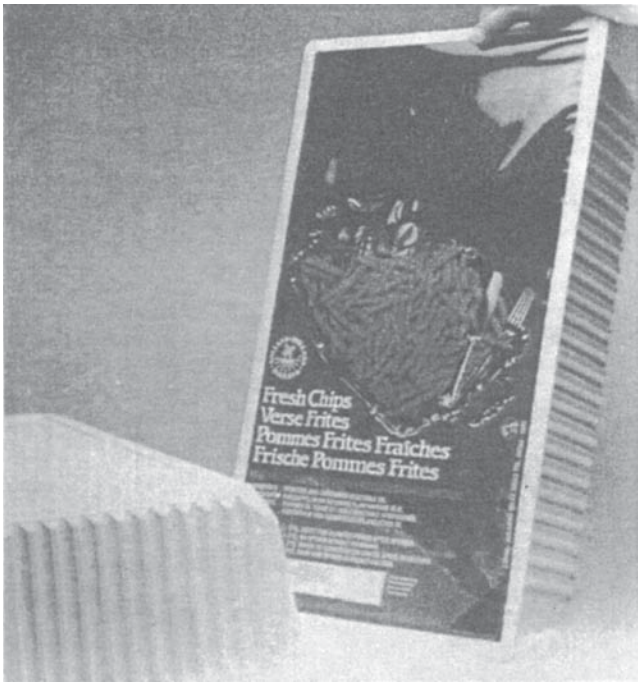

Figure 2. Modified atmosphere package for perishable foods. Fresh (unfrozen), precooked French fries (10 kg) packed in N_2 atmosphere. Positive (male) formed PVC/PE bottom, polyester/PE cover. Print registration of flexible upper web by means of stretching with a brake.

speed motor, frequency, servo driven, and so on (i.e., AC Digital, DC Digital, Geneva, Elliptical Gear, Planetary Gear, Emerson), differ as to accuracy of advance, acceleration curve, or suitability for print registration of stretchable or nonstretchable materials.

Thermoforming

This is the first step in the formation of a package. Thermoforming (see Thermoforming) may involve heating in the forming die or preheating in a separate station. There are two main ways to thermoform: positive (male) and negative (female). Female forming involves using compressed air or vacuum to pull the heated, softened film into a mold. It is this mold or concave surface that is the die that produces package shape and surface detail. A mechanical plug (plug assist forming) may help to push the film down into the cavity and provide more uniform material distribution.

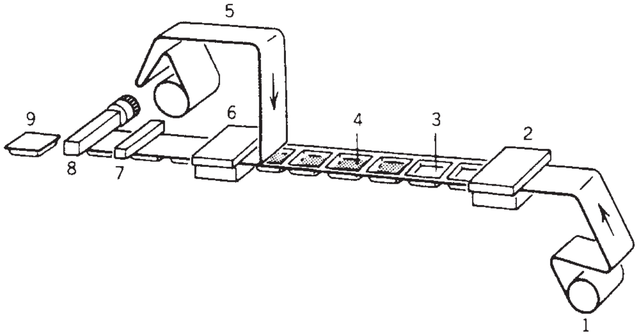

Figure 3. A schematic of the simplest and most basic configuration of a TFFS machine as would be used for flexible, not semirigid, upper and lower webs: 1, Lower or forming web; 2, thermoforming die; 3, formed, unfilled pocket; 4, filled pocket; 5, upper or lidding web; 6, vacuum/sealing die; 7, flying knife for across-the-machine direction package cutoff; 8, high-speed rotary knives for package cutoff in the machine direction; and 9, finished package (rectangular).

Positive (male) forming is the reverse. Positive forming usually permits the production of a package with greater surface detail and more-uniform wall thickness. A male die part operated by a piston provides package shape and surface detail. Air outside the film or vacuum on the inside, or both air and vacuum, force the preheated film to drape itself onto the exterior of the plug. Positive forming requires a separate station or two separate stations to preheat the film. A typical package requires thermoforming of only the lower web, but the machines can also form both lower and upper webs. Usually each product to be packaged requires its own separate forming die. Major machine manufacturers have designed and built thousands of different forming dies.

Loading

The lower web emerges from the forming station with the pocket formed and ready to accept product. The loading area must be long enough to accommodate the people required for loading and inspecting, or automatic loading equipment.

Sealing

Once the pockets on the web are loaded, the upper web is indexed over them and the two webs are sealed (see Sealing, heat). In food packaging, evacuation and, if needed, gas injection (through nozzle or pin gas mechanism) are performed at the sealing station. In order to provide a more attractive package, sometimes all surfaces of the top and bottom webs not in contact with the product are sealed to each other. Sometimes, using a patented process, steam is injected into the sealing die to shrink the lower web (forming web) around the product to form an attractive skin-tight package.

Cutting

Cutting systems range from the simple and inexpensive to the complex and costly: paper-cutting-type knives (i.e., flying knives and high-speed rotary knives); shear cutting (machine direction) with cross-direction strip removal by means of matched male and female dies; shear cutting (machine direction) and cross-direction cutting by means of steel rule dies; and complete package cutting with matched male and female dies (Table 2). Among them, matched male and female dies are the most suitable for cutting application on semirigid and rigid material, but they are also the most expensive compared to other cutting methods.

Table 2. Cutting Methods for Rigid Materials

In-the-Machine Direction	Across-the-Machine Direction
Squeezing knives	Steel rule dies with rounded corners
Shear cut knives with or without strip removal	Strip removal for rounded corners by means of matched male and female dies
Complete 360° cut by means of matched male/female dies	

Labeling and Printing

Online printing may consist of simply printing, or embossing, a code date or lot number (see Code marking and imprinting) or may consist of printing an entire index, actually "bleeding" finished package edges. Labels may be applied to either surface of either web by appropriate top or bottom web labeler.

VACUUM AND SEALING-DIE OPERATION

At this station the package is evacuated and the two webs are sealed together. In order to understand how this die operates, it helps to think of the die as consisting of two nesting, concentric boxes that close in sequence. The outer box closes first (see Figure 4). It mechanically seals off that portion of the package represented by the lower web. The upper web is narrower than the lower web and is not sealed at this stage. Therefore, until the inner box closes, atmosphere is free to enter or leave the package under the lip of the upper web. The inner box is made up of the seal mechanism. After the entire die chamber, including the interior of the package, is evacuated, the inner box (the seal mechanism) closes on both webs, first sealing them mechanically, so no air can enter or leave the package, and then applying a permanent heat-seal (see Figure 5). The key operation, package evacuation, takes place when air flows out of the package through the gap between the narrow upper web and the outer wall of the die chamber. This occurs during the interval after the outer box has sealed off the lower web, but before the inner box has closed off the package itself.

This is one of the most common methods of package evacuation, also called the narrow web vacuum method. If gas injection is required for modified atmosphere packaging, the operation takes place in the sealing die using nozzle or pin gas mechanism.

MATERIALS

The detailed design of a TFFS machine depends on the packaging materials to be run. Therefore, any discussion of how TFFS machines operate must refer to materials as well. The two webs consist of a bottom web and a top web on the type of equipment generally known as horizontal thermoform/fill/seal machines. In the usual case, the bottom web is thermoformable and is formed by heat into a cup or cavity, which forms a receptacle for the articles to be packaged. However, all variations are possible:

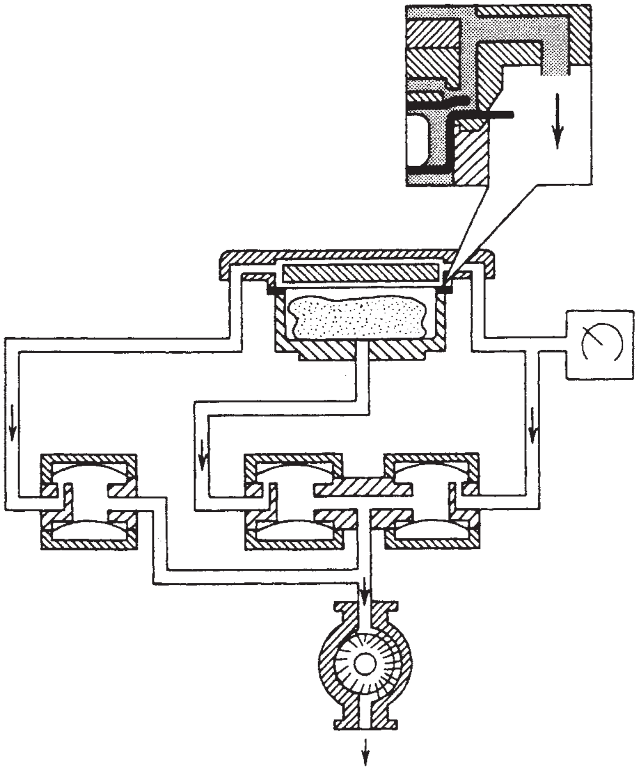

Figure 4. Evacuation. This shows the die after the first or outer box has closed. Vacuum is drawn inside the die chamber. Because vacuum is drawn on the outside of the package from both above and below, air pressure inside the package forces the two webs to separate, providing a large opening for air to flow out of the package. During evacuation, the travel of air from the inside of the package is through the gap between the narrow upper web and the wide lower web. Package air exits along with air from above the upper web. In this figure, the seal bar is in its upper, or retracted, position so that air can leave the package.

Top Web	Bottom Web
Nonformable	Formable
Nonformable	Nonformable
Formable	Formable
Formable	Nonformable

When food products are packaged, the webs are usually made of multilayer materials selected for their barrier and strength properties. Typically, a barrier material protects against transmission of water and oxygen into or out of the package. In the medical industry, however, products are typically sterilized by ETO (ethylene oxide) gas. In this case, high gas transmission is desired. As a result, the TFFS machines use an upper web (also called lidding material) (see Lidding) selected for high-gas transmission

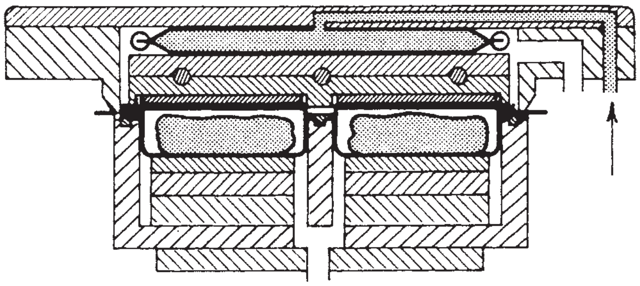

Figure 5. Heat sealing. After the package is evacuated, an air bladder lowers the sealing bar and the package perimeter is clamped shut and heat-sealed. In the next step, air is readmitted into the die, the die opens, and the package is indexed out.

properties as well as strength. Typical high-gas porosity (lower gas barrier) materials include paper and Tyvek (DuPont Company), a tough, spunbonded polyolefin. Tables 3 and 4 list some commonly used materials in TFFS applications.

Flexible materials such as nylon (see Figure 6) can usually be formed by heating and pressure-forming into a female die part. Cutting is usually by means of a flying knife in the cross-direction and high-speed rotary knives in the machine direction. More severe draw ratios call for a preheat station and plug assist. Nonrectangular shapes, such as circles and ovals, can be cut with a flying knife traveling on a cam or with punch cutter.

Rigid and semirigid materials (Figure 7) usually require higher cost and more-elaborate forming and cutting methods. Rigid films usually call for one or more preheat stations (single sandwich or double sandwich preheat) and plug-assist forming in order to meet the package performance and higher production speed requirement. If good surface definition and uniform wall thickness is required, positive (male-plug) forming is usually required.

In order to avoid sharp corners, rigid materials must be cut by one of the methods shown in Table 2.

LATEST TTFS MACHINE DEVELOPMENT

Sanitary, easy-cleaning, easy-to-use design in TTFS machine development has been emphasized by the leading suppliers in the past decades, especially for meat/food packaging industry in which complete wash down at the end of production prior to next production is required by the USDA. Sanitary equipment design is needed to ensure effective and easy cleaning to meet strict cleaning requirements. Aluminum frame machine has been completely replaced by all stainless steel frame machine against corrosion from caustic cleaning chemicals. In addition, the latest TTFS machine has curved panel and tilted cover to eliminate any possible harbors for bacteria growth that may pose a food safety risk to consumers. An automatic clean-in-place (CIP) feature is an option for the latest machine manufactured by Multivac, a leading machine supplier, if required. The interior of the machine can be thoroughly cleaned under a predesigned programmable automated cleaning protocol that includes four-stage cleaning and sanitation sequence to rinse, clean with

Table 3. Common Food-Packaging Webs[a]

Structure	Comments
Nonforming Web	
Polyester/polyethylene or polyester/ionomer	Polyester is used for printability, strength, and general resistance to moisture and abrasion. Normally it is reverse (capture) printed (i.e., the polyester is printed on its inside surface for protection of the printing). Printed polyester is normally stretch-registered.
These structures may contain an intermediate layer of PVDC or EVOH as oxygen barrier.	
Forming Web	
Flexible	
Usually a nylon-base web is used for strength and formability, combined with PE or ionomer as heat sealant and moisture barrier, and, if needed, PVDC or EVOH as oxygen barrier.	Forming of flexible web by compressed air, vacuum, or compressed air and vacuum possibly has a heated plug for severe draw ratios. Cutting by means of flying knife in the cross-direction (XD), and high-speed rotary knives in the machine direction (MD) for rectangular packages. Circular, oval, or shape cutting by means of flying knife following a pattern or cam or by punch cutter.
Rigid	
Semirigid PVC, acrylonitrile, amorphous PET, PETG, or HIPS, combined with PE or ionomer for moisture barrier and, if needed, PVDC or EVOH as oxygen barrier.	Forming of rigid web by either negative (female) forming with plug assist or positive (male) forming for more uniform forming and surface definition. Cutting by steel-rule die, or matched male and female die and strip removal in XD with shear, cut strip removal in MD. Complete cut by means of matched male and female dies shaped to the final package size.

Table 4. Common Medical-Packaging Webs

Structure	Comments
Nonforming Web	
Tyvek (spun-bonded polyolefin) or paper used for wet strength and resistance to puncture, also exhibits minimal fiber generation when cut. Paper is used for superior printability and lower cost.	Tyvek can be stretched registered (by means of photocell and brake). Paper cannot be stretch-registered, so it needs to be registered by controlling the advance with either an AC or DC servo drive. Stretch or advance registration.
Both Tyvek and paper are usually heat-seal coated. Used for ETO gas sterilization because of their porosity. Polyester or polyester/aluminum foil for gamma sterilization or gas or moisture barrier. These materials are used in conjunction with appropriate heat-seal coatings and laminating adhesives.	
Forming Web	
Flexible forming webs: polyolefin laminates or blends.	Forming methods are similar to those used in flexible food packaging. Shear cutting is normally used in both directions for superior cleanliness of cut with paper or Tyvek upper webs.
Rigid forming webs: PVC or acrylic multipolymer or high-impact polystyrene (HIPS) or copolyester.	Forming is typically with temperature controlled plug or positive forming depending on draw ratio and degree of surface definition required. Cutting, typically, matched male–female in across-the-machine direction. Shear cut in-the-machine direction. Or 100% matched male–female cutting. These cutting systems provide relatively particulate-free packages with radial corners.

foaming detergent, rinse, and sanitize with alcohol-based agent. Particularly the latest machine chain transport redesign by Multivac, the first one offered the CIP feature in the field, allows CIP features feasbile in their TTFS machines. Side extraction tooling change feature in forming and sealing stations is offered by leading TTFS suppliers that minimizes downtime and negative ergonomic impact from the tooling changeover process.

Figure 6. Sliced luncheon-meat package. Nylon-ionomer flexible forming web, OPET/ionomer top web. Circle cutting by means of flying knife. Print registration by means of stretching film with a brake.

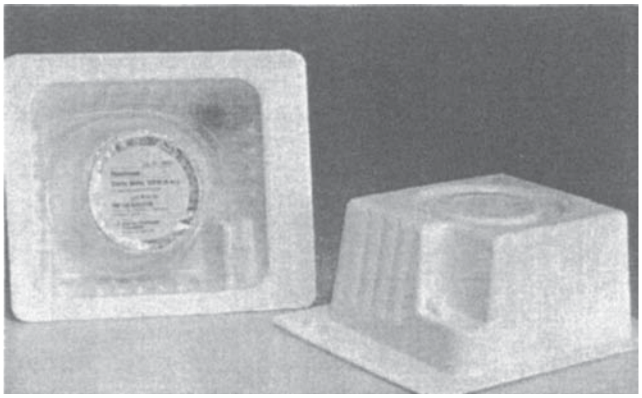

Figure 7. Thermoformed medical-kit package. Typically, this type of package would have a semirigid HIPS (high-impact polystyrene) thermoformed bottom and a Tyvek or paper lid. Forming would be positive (male-plug). Note both severe draw ratio and enhanced surface detail. Print registration would be by means of a dc drive since paper cannot be registered by stretching. Cutting could be a complete 360° cut with matched male/female dies, or shear cut (machine direction) with strip removal by means of matched male/female dies (cross-direction). Package is shown with lid removed.

Some major TTFS equipment suppliers to the United States market include Convenience Food Systems, Harpak, Multivac, Rapid-Pak and Ulma Packaging.

THERMOFORMING

Vivek Chougule
Matt Piercy
Printpack, Inc., Williamsburg, Virginia

Thermoforming is a process of shaping thermoplastic sheet into a product through the application of heat and force. In most cases, the heat-softened plastic assumes the shape by being forced against the mold until it cools and sets up. Forming force may be developed by vacuum (atmospheric pressure), positive air pressure, or mating matched molds.

Thermoforming is an important thermoplastic fabrication process. Early developments involved thermoforming of cellulose sheets. Industrial scale thermoforming began in the early 1960s when containers and lids formed from high-impact polystyrene (HIPS) were first used by the dairy industry to package cottage cheese, sour cream, yogurt, and other dairy foods. The word *sheet* as it relates to thermoforming is used to describe flat extruded plastic material that is generally relatively thick, in contrast to comparatively thin plastic films. It is ambiguous, however, in two ways: Thermoforming is also used to shape relatively thin films, and the word *sheet* is also used to distinguish between thermoforming machines that form cut pieces (sheet-fed) rather than as extruded webs (web-fed or roll-fed). The distinction between sheet-fed and web-fed machines is similar to that between sheet-fed and coil-fed equipment in the metal-can industry. The exception is that in plastics forming, the wide sheet web can come either from coiled stock or directly from the extruder. When the thermoformer is fed directly by a sheet coming from the extruder, it is called in-line thermoforming. Sheet for thermoforming is commonly produced by extrusion. Use of multilayered sheet structures is increasing for a variety of applications. Multilayered sheet structures can be produced by coextrusion, coating, lamination, or a combination of these processes. Roll-fed thermoforming machinery is available that can produce beverage cups at rates of 75,000–100,000 pieces/h while consuming plastic sheet in excess of 1 ton/h (910 kg/h). Sheet consumption for larger and heavier containers can exceed 2 tons/h (1.8 metric ton/h), but unit production rates may be lower because fewer mold cavities can be mounted in the machines and more time is required to cool the thicker walls.

The ability to produce extruded HIPS foam sheet (see Foam, extruded polystyrene) has provided additional packaging markets for thermoforming. The first of these was meat and produce trays, followed by egg cartons. Other applications include fast-food carryout cartons, institutional dinnerware medical trays and blisters, and inserts for rigid boxes. Use of oxygen and moisture barrier thermoformed containers is on the rise for variety of shelf stable and refrigerated food packaging. Thermoformed plastic containers have rapidly replaced other packaging materials (metal, glass) in the last 20 years. Common applications include containers for fruit, apple sauce, puddings and baby food. One of the growing new applications is the use of high-barrier thermormed containers for retorted shelf-stable foods. Retort applications require special considerations for material selection, structure, and shape of the container.

PROCESS STEPS

The thermoforming process is used to make products from thermoplastic sheet by a sequence of heating, shaping, cooling, and trimming. Trimming is not necessarily an integral part of the forming cycle. Only a few applications (e.g., pharmaceticul blisters) can use the formed web without some kind of trimming.

Heating

Thermoplastic sheet is heated to a temperature range adequate for forming, depending on the thermoplastic material used. Temperature control is critical because of plastic's poor thermoconductivity and because temperature affects the forming characteristics (i.e., ductility) of the materials: Too much heat causes the sheet to flow without drawing; too little heat causes it to rupture early in the forming process.

Heating time is governed by the heating process used, materials used, sheet thickness, surface conditions of the material, and the combination thereof. Any of the common heat transfer processes such as convection, conduction, or radiation can be used, but low thermoconductivity and relatively high specific-heat capacity of thermoplastics should be taken into consideration. Radiation heat could be absorbed, transmitted, or reflected by thermoplastics, depending on radiation wavelength and material properties. Most thermoplastics absorb infrared energy emitted in the 3.0 to 3.5-μm wavelength range, which makes them ideally suited to heating by radiation. Convection heating would be ideal because the sheet could be soaked in hot air at just the right temperature with the assurance that the entire sheet would be uniformly heated. However, straight convection systems are not practical because they are relatively slow and they present materials-handling problems relative to transferring the sheet from the oven to the forming station. Conduction heating requires contact of a heated surface to the thermoplastic sheet. Although conduction heating by contact is more efficient than convection heating, it has unique challenges of material handling such as thermoplastic sticking to heated surface. Conduction heating is used in applications where thermoplastic requires relatively less heat to form or as preheaters where contact surface temperatures are relatively lower. Therefore, many thermoforming machines are equipped with systems that take advantage of radiation, convection, and conduction. Most of these ovens are electrically heated, but there are also a large number of cut-sheet machines using gas-fired ovens. Most are capable of heating the sheet from two sides, which is especially advantageous if the sheet is $\geqslant 40$ mil ($\geqslant 1$ mm). The ovens should also be appropriately zoned and temperature-regulated by instrumentation enabling the operator to maintain good control over the heating process.

Today, any number of electrically powered heating systems can be specified, including the conventional tubular steel rods, glass or ceramic panels, quartz lamps, emitter-strip panels, and small ceramic modules. The most common continues to be the calrod type, but use of rectangular ceramic elements has been steadily increasing. Their relatively small size permits them to be incorporated into elaborate microprocessor-control systems to provide preferential heating in localized areas. Emitter strip panels have been introduced as an alternative to provide temperature uniformity with a less-complex installation. They are gaining popularity because they provide a full-area heat source and can be mounted closer to the sheet and are operated at lower temperatures, thereby conserving energy.

Conduction or contact heating, sometimes called trapped-sheet heating, has been used successfully with easy-to-form materials such as polystyrene (PS) and PVC. Here, the plastic sheet is trapped between the mold and the temperature-controlled hot plate, which is perforated with extremely small holes [i.e., $\sim$0.020-in. (0.5-mm) diameter]. The holes are drilled in a grid pattern on $\leqslant$1-in. (2.5-cm) centers. After the sheet has been in contact with the heated plate for a predetermined time, compressed air is injected through the plate, forcing plastic off the heated platen and into the mold. This system is generally reserved for materials $\leqslant$0.015 in. (0.38 mm) thick.

Solid-Phase and Conventional Thermoforming

Solid-phase pressure forming (SPPF) means forming below the crystalline melting point—that is, generally 5–8% lower than melt-phase forming, depending on the material. For example, homopolypropylene (hPP) is formed in the melt phase at 310–315°F (154–157°C) but at 285–295°F (141–146°C) in SPPF. SPPF does not require special thermoforming equipment but demands much tighter process control. A thermoforming machine forms products within the thermoforming window, and product-configuration requirements (i.e., stress, strength, rigidity, flexibility) determine the proper temperature range.

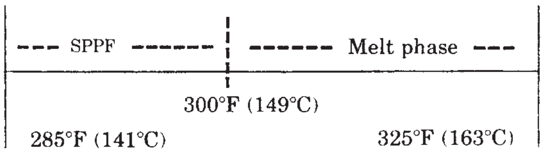

Figure 1. Thermoforming window.

Figure 1 indicates that SPPF is done in a temperature range within the window, as in melt-phase forming. Compared with products formed in the meltphase, SPPF can produce stiffer parts with lower part weight. Solid-phase forming improves the sidewall strength of a container and increases the stress factor. When forming cups, trimming in the mold is recommended. Plug assist and high form air pressures [i.e., 100 psi (689 kPa)] are required, and the plug design is more critical than in conventional melt-phase forming.

Forming

There are two basic forming methods from which all others are derived: (1) drape forming over a positive (male) mold and (2) forming into a cavity (female) mold. Product configuration, stress and strength requirements, and material specifications all play a part in determining the process technique. Generally, forming into a female mold is used if the draw is relatively deep (e.g., cups). Female molds generally provide better material distribution and faster cooling than do male molds. Malemold forming is preferred for certain product configurations, particularly if product tolerances on the inside of a part are critical. Male-mold forming produces heavier bottom strength; female-mold forming produces heavier lip or perimeter strength. An advantage of straight forming into a female mold is that parts with small sidewall angle (near vertical) can be formed and extracted, stress-free, from the molds because of the shrinkage that occurs as the part cools.

In drape forming, when the hot plastic sheet touches the mold as it is being drawn, it chills and start to set up. To successfully drape-form, several variables must be considered. One of the most significant is shrinkage. Since all plastic materials have a high coefficient of thermal expansion and contraction (i.e., about 7–10 times that of steel), care must be taken when designing the mold to provide sufficient draft on the sidewalls so the part can be extracted from the mold. It is not unusual for parts to rupture on cooling on an improperly designed drape mold. Another potential problem is that the part may become so highly stressed during forming and cooling that it loses most of the physical properties that the sheet would otherwise provide. High stress in the part may also cause shape distortion also known as warpage.

Natural-process evolution has combined the two systems to take advantage of the better parts of each method. The plug-assist process, similar to matched-die forming, involves a male mold (of plug) that ranges in size from $\sim$60% to 90% of the volume of the cavity. By controlling

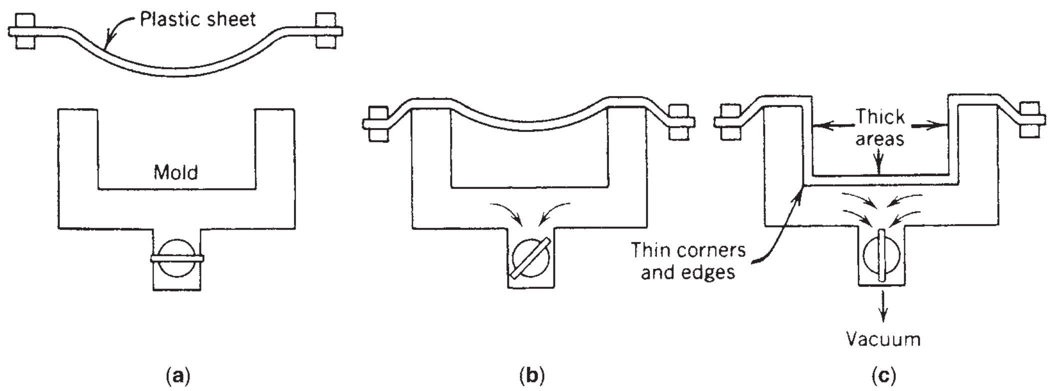

Figure 2. Shallow-draw forming, female-mold bottom. (**a**) The plastic sheet is clamped and heated to the required forming temperature; (**b**) a vacuum is applied through the mold, causing the plastic sheet to be pushed down by atmospheric pressure—contact with the mold cools the newly formed plastic part; (**c**) areas of the sheet reaching the mold first are the thickest. Applications: ice-chest lids, tub enclosures, and so on.

the geometry and size of the plug and its rate and depth of penetration, material distribution can be improved for a broad range of products. The plug-assist technique is used to manufacture cups, containers, and other deep-draw products.

Many thermoforming techniques have been developed to obtain better material distribution and broaden the applicability of the process. Some of the more popular methods are illustrated and described in Figures 2–10. Most of these techniques can employ vacuum, pressure, or a combination to apply the force necessary to shape the heat-softened plastic sheet.

Cooling

The time required to cool the heat-softened plastic below its heat-deflection temperature while it is in contact with the mold is often the key to determine the overall forming cycle time. Cooling is accomplished by conductive heat loss to the mold and convective heat loss to the surrounding air. Cooling rate depends on the tooling, because in all methods except matched mold, the plastic is in contact with the mold on one side only. Time duration for which the mold is closed after forming significantly affects cooling. The opposite side of the thermoformed part is cooled convectively by forced air or ambient air. Water sprays are sometimes used but often pose as many problems (e.g., water spotting) as they solve. Pressure forming helps minimize cooling time because the higher air pressure keeps the sheet in more intimate contact with the mold surface.

Trimming

A number of trimming methods are available, including hand cutting, rough shearing of the web, punching parts out from the web, or trimming around a periphery with a steel rule or sharp-edged die used to penetrate the web. The punch-and-die trim provides the greatest accuracy and longest life, but at the highest cost. These dies are usually designed with a hardened-steel punch and will pass through a slightly softer steel die that can be peened when it dulls. These trim dies are designed so the parts are punched through the die successively and exit from the trim station in a nested fashion. This simplifies the material handling required to pack or prepare the parts

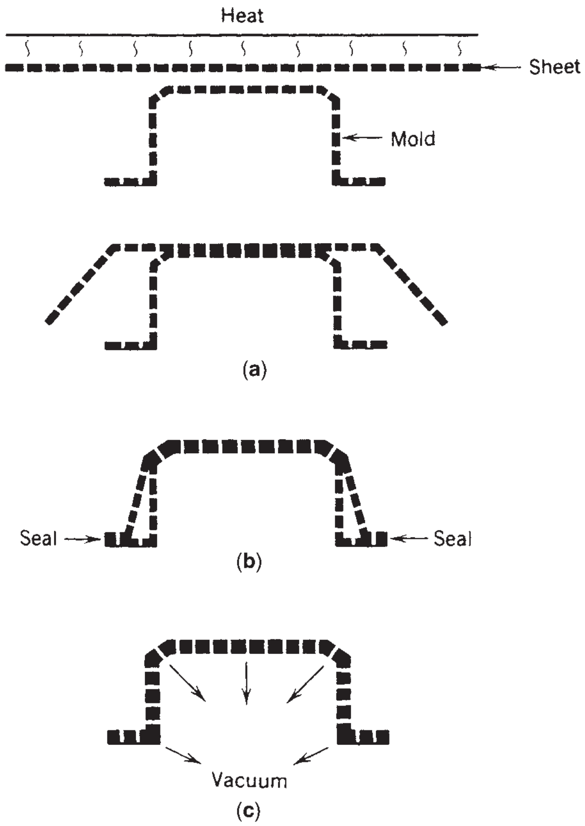

Figure 3. Vacuum (drape) forming. (**a**) The plastic sheet is clamped and heated to the required forming temperature; (**b**) the sheet is sealed over the male mold; (**c**) vacuum from beneath the mold is applied, forcing the sheet over the male mold and forming the sheet. Material distribution is not uniform throughout the part, because the portion of the sheet touching the mold remains nearly the original thickness. The walls are formed from the plastic sheet between the top edges of the mold and the bottom-seal area at the base. Applications: trays, tubs, and so on.

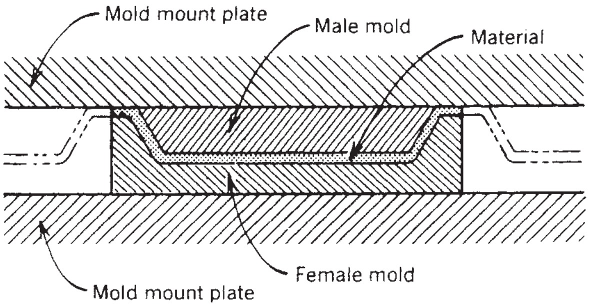

Figure 4. Matched-mold forming. The plastic sheet is clamped and heated to the required forming temperature. The heated sheet can be positioned over the female die, or draped over the male mold. The male and female halves of the mold are closed, forming the sheet, and trapped air is evacuated by vents located inside the mold. Material distribution varies with mold shape. Detailed reproduction and dimensional accuracy are excellent. Applications: foam products, egg cartons, meat trays, and so on.

for the next postforming operation (e.g., rim rolling or printing).

Steel-rule dies are better suited for the lower-volume, thin-sheet operations. Steel-rule trim dies are used predominantly in custom thermoforming operations, where the run size does not justify the cost of matched shearing dies. They are used almost exclusively in the manufacture of blister packages and decorative packaging for the cosmetics industry.

The trimming operation can be done inside or outside the mold. The remote-trim configuration utilizes a separate trim press, which punches out one or more rows of parts at a time. The parts are discharged in nested stacks ready for subsequent operations or for packing. Trimming within the mold provides the most accurate alignment of the trim cut to the formed part, but the close proximity of the trimming to the mold body is a complex arrangement that may limit cooling capacity near the cutting surface; and after trimming, precise control of the part ceases. Complex mechanisms are required to sort and nest these parts downstream. Trimming is done by sawing or routing in the production of low-volume odd-geometry industrial parts (e.g., boat hulls, recreational vehicle bodies, bathtubs) but not in packaging.

Forming Machines

There are basically two types of thermoforming machines: sheet-fed and web-fed (roll-fed). Sheet-fed machines operate from sheet cut into definite lengths and widths for specific applications. The sheet is generally heavy [i.e., 0.060–0.5 in. (1.5–13 mm)] and the products are industrial. Packaging-related applications include dunnage trays and pallets, large produce bins, shipping-case dividers, box liners, crates, and carrying cases formed to the shape of the product.

Packaging applications generally employ web-fed machines, which use either coil stock or a web that comes directly (i.e., in-line) from a sheet extruder. The need to form a coil limits the thickness of the web to ~0.125 in. (3.2 mm) due to sheet winding and reheating issues. Web thickness can be increased by operating directly in line with an extruder.

TOOLING

Among the plastic-fabricating processes, thermoforming permits the use of the broadest range of mold-tooling materials. Mold materials such as wood, epoxy, polyesters, or combinations thereof can be used if the volume is not sufficient to warrant the cost of advanced, temperature-controlled metal molds or for prototyping. For high-volume applications (e.g., food packaging) molds are normally manufactured from cast or machined aluminum, sometimes with hard coats applied to the wearing surfaces for longer service life. Molds are occasionally made from beryllium copper or brass that is chrome-plated for extended service life.

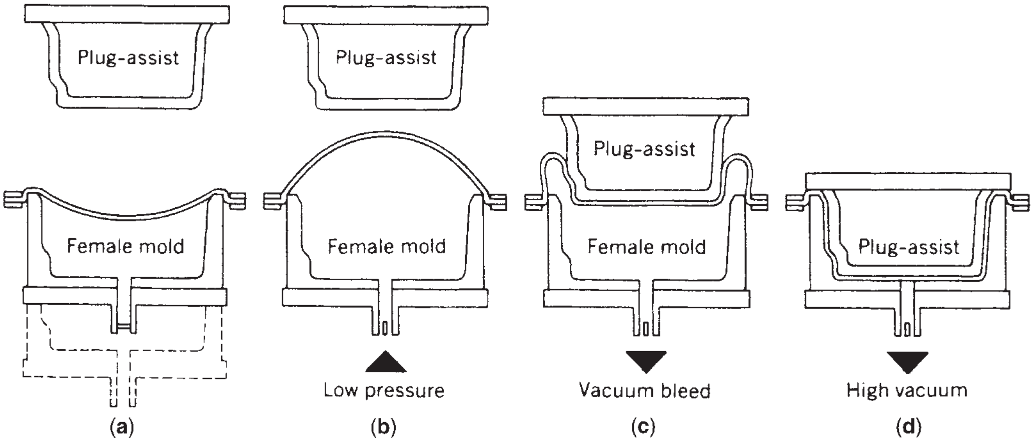

Figure 5. Pressure-bubble/plug-assist vacuum forming. The plastic sheet is clamped and heated to the required forming temperature. (**a**) The heated sheet is positioned over the female mold and sealed. (**b**) Prestretching is accomplished by applying controlled pressure through the female mold, creating a bubble. (**c**) When the sheet is prestretched to the desired degree, the male plug is forced into the sheet. (**d**) When the male plug is fully engaged, a vacuum is applied through the female mold to form the sheet. Pressure may be applied through the plug to assist forming, depending on the material and forming requirements. Applications: refrigerator liners, bathtubs, and so on.

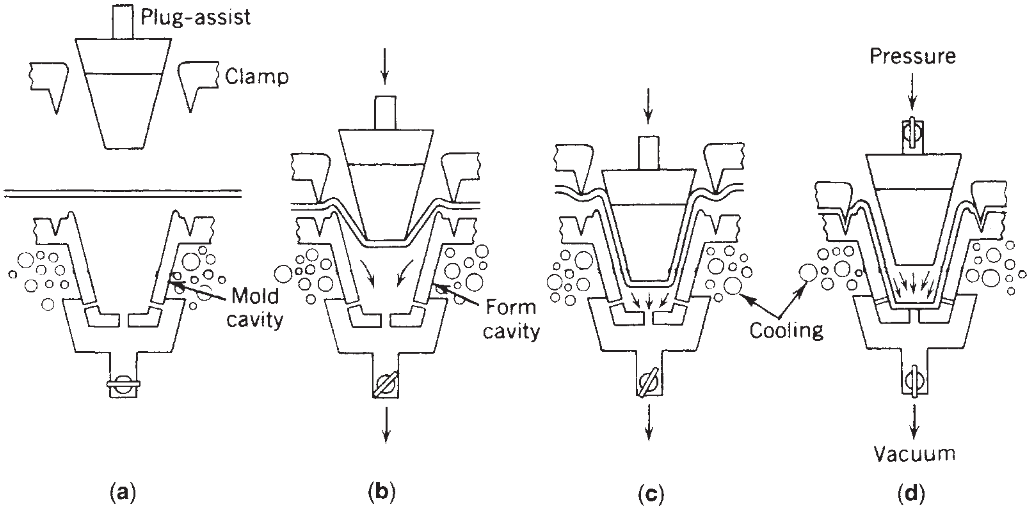

Figure 6. Plug-assist forming sequence: (**a**) The plastic sheet is clamped and heated to the required forming temperature—the sheet is then sealed across the female-mold cavity; (**b, c**) the male plug is forced into the sheet—the depth and speed of penetration, as well as plug size, are are the primary factors in material distribution; (**d**) when the plug is fully engaged, vacuum, pressure, or a combination are applied to form the sheet. Applications: cups, food containers, and so on.

Vacuum and compressed air are the primary means used to form the heated, thermoplastic sheet to the mold configuration with rigid-type materials. For foam materials, matched metal molds are frequently used to compress the material to the desired thickness without compressed air. Vacuum is transmitted through small holes that are located to allow the sheet to come in intimate contact with the mold surface. The diameter of these holes usually ranges from ~0.013 to 0.030 in. (~0.33 to 0.76 mm), depending on the type of thermoplastic to be formed. Other means of applying vacuum in the mold include the incorporation of narrow grooves or slots, which often are easier to incorporate than vacuum holes and allow greater evacuation of the air in the tool. Polyolefin materials require small vacuum holes and slots; PS materials, which cool faster, can use larger holes. Final product design and material selection determine the exact size of the holes required.

In addition to vacuum holes and slots, molds can be sandblasted to minimize the possibility of trapped air between the sheet and the mold. Sandblasting molds also results in mat surface finish and better cooling due

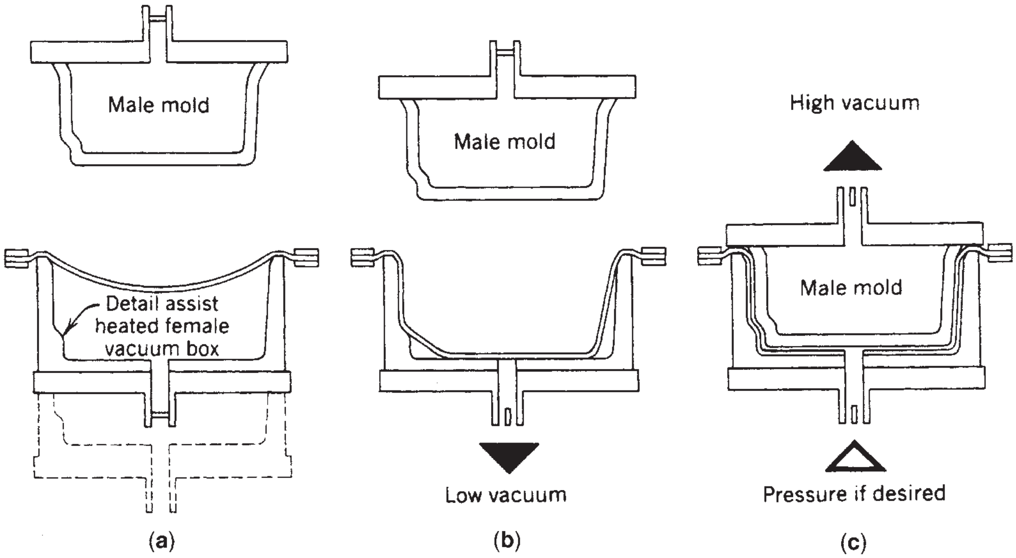

Figure 7. Vacuum snapback. (**a**) The plastic sheet is heated and sealed over the female vacuum box; (**b**) when vacuum is applied to the bottom of the vacuum box, the plastic sheet is prestretched into a concave shape; (**c**) after the plastic sheet is prestretched to the desired degree, the male plug enters the sheet. A vacuum is applied through the male plug while the vacuum box is vented, creating the snapback. Light air pressure may be optionally applied to the vacuum box, depending on the materials used and forming requirements. Applications: deep-draw parts (e.g., luggage, auto parts), gun cases, cooler liners, and so on.

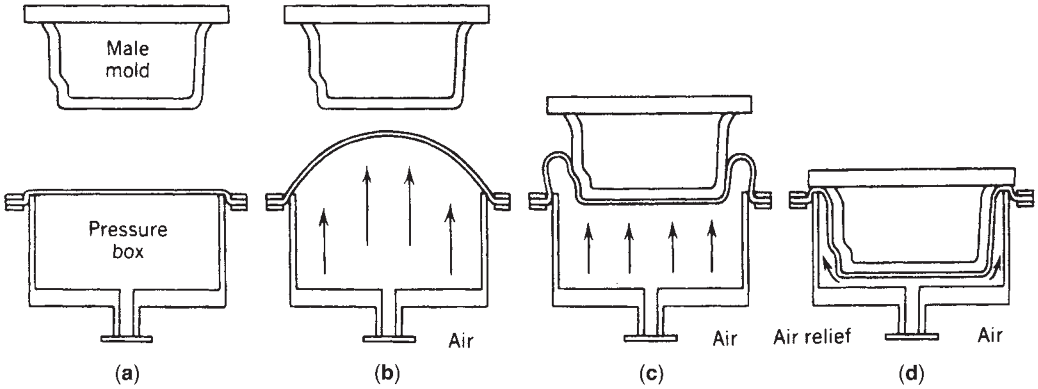

Figure 8. Pressure-bubble vacuum snapback. (**a**) The plastic sheet is clamped and sealed across the pressure box; (**b**) prestretching is accomplished by applying controlled air pressure under the sheet, through the pressure box, creating a bubble; (**c**) when the sheet is prestretched to the desired degree (i.e., 35–40%), the male plug is forced into the sheet while the air pressure beneath the sheet remains constant; (**d**) after the male plug is fully engaged, the lower air pressure is increased. A vacuum is simultaneously applied through the male plug, creating the snapback. Applications: intricate parts where material distribution is critical.

to higher surface area. Eliminating trapped air is important because it prevents imperfections on the part surface and aids in rapid transfer of heat out of the material by providing close contact between the plastic and the cavity. Molds for PS are normally not sandblasted because this material is relatively rigid and sandblasting would make part removal difficult. Vacuum is usually pulled through the forming mold, male or female, and the compressed air is introduced from the opposite side of the sheet material. In foam-forming with matched metal molds, vacuum is normally applied only through the female cavity.

Tooling for high-production applications is most often aluminum because of its thermal conductivity, light weight, and cost. Most crucial is thermal conductivity, because in any thermoforming process the residual heat of the plastic must be removed as rapidly as possible for rapid cycling. The temperature control of the mold is accomplished by water channels in the mold and designing them to provide maximum heat removal from the sheet. Ideally, all molds should provide a temperature differential between inlet and exit water temperature of no more than 5°F (3°C).

Many techniques are used to incorporate cooling in the molds for improved cycle times. The most common methods are contact cooling and direct water cooling. Contact cooling consists of coring a mold base and carefully machining cavity inserts so that contact occurs when the cavity insert expands from the heat of the plastic sheet while the mold base contracts from the coolant circulating through it. The most common method today for rigid HIPS is to circulate water through hollow-shelled cavities. This is more expensive but is the most effective way to cool the plastic sheet rapidly.

Tooling for low-volume work (e.g., box inserts, blisters, and other nonfood packaging) and prototyping can often be simple and effective without any of the special cooling features described above. This is because it normally takes longer to heat the sheet than to cool it, and the work is generally done on slow, low-production equipment that does not require the rapid cycle rates. With these molds, cooling is very often augmented by the use of fans to increase the air circulation over the material after it is formed. In such applications, low-cost, simple molds of plastic, plaster, wood, or other materials are used

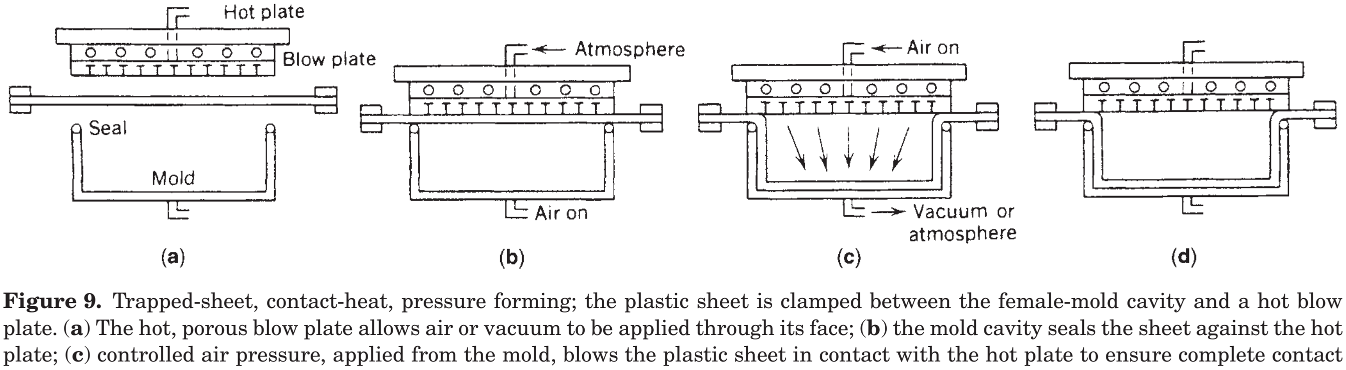

Figure 9. Trapped-sheet, contact-heat, pressure forming; the plastic sheet is clamped between the female-mold cavity and a hot blow plate. (**a**) The hot, porous blow plate allows air or vacuum to be applied through its face; (**b**) the mold cavity seals the sheet against the hot plate; (**c**) controlled air pressure, applied from the mold, blows the plastic sheet in contact with the hot plate to ensure complete contact with the heating surface; (**d**) when the desired heating has been accomplished, air pressure is applied through the hot plate, forcing the plastic sheet into the mold. Venting of the mold can be simultaneous, depending on materials and forming requirements. Steel knives may be inserted in the mold for sealing and in-place trimming if additional closing pressure is available. Applications: OPS containers, covers, and so on.

Figure 10. Twin-sheet forming. This technique utilizes a rotary-type machine with two heating stations and bottom-load clamp frames. The first sheet (**a**) is heated and formed into the lower half of the mold (**b, c**) while the second sheet is being heated. After forming the first sheet, the second sheet is indexed into the forming station (**d**) and vacuum is applied to the upper mold half to form the sheet (**e**). A bond is simultaneously made between the parts by pressure applied to the mating surfaces (**f**). After cooling, the molds are removed to give the product (**g**).

effectively. Mold dimensions must allow for the different shrinkage rates of different types of thermoplastics. In the manufacture of a family of products, it is sometimes possible to utilize the same cooling base and interchange only the molding inserts. Depending on the trim dimensions of the products, the same cutting tool might be suitable for more than one product; if not, they can be designed to be easily interchanged from the trim die shoe.

CUT-SHEET THERMOFORMING

Cut sheet is processed on two types of thermoforming machines: the shuttle style and the rotary, or carousel, style. In single-station shuttle machines, the plastic sheet is placed in a clamping frame that shuttles into the oven for heating and back again for forming. Another very popular shuttle machine is the double-ender, which has a common oven with a form station at each end. This arrangement provides 100% utilization of the oven because heating and forming can be done simultaneously.

Rotary or carousel thermoformers are most frequently used for heavier-gauge materials—that is, starting at ~0.050 in. (1.3 mm). Most rotary machines have three working stations: load/unload, heat, and form. In a typical machine, the carousel frame rotates 120° on a time-controlled basis. Generally, the time cycle is dictated by the period required for the plastic sheet to cool below its heat-deflection temperature. When cooling time is faster than the heating time, four-station rotary machines are often used; these have two heating stations. Another type of four-station machine has a separate load and unload for automation and parts handling.

Most cut-sheet thermoformers are designed to operate as vacuum formers, but rotary and single-station (shuttle-type) machines are available with pressure-forming capabilities and sustain forming pressures up to 50 psi (345 kPa), depending on mold area. Most sheet-fed machines can be adapted for any of the standard thermoforming techniques. Cut-sheet machines have been built to accept sheet 10 ft (3.05 m) wide and 20 ft (6.1 m) long with the capability of making parts up to 4 ft (1.22 m) deep.

TWIN-SHEET THERMOFORMING

Twin-sheet thermoforming can produce hollow parts (e.g., pallets) from cut sheet. These parts can be produced from both cut-sheet and roll-fed machinery. In sheet-fed machinery, the material to be formed can be 0.050–0.500 in. (1.3–13 mm) thick. Roll-fed machines are limited to materials 0.005–0.125 in. (1.3–3.2 mm) thick. With a typical web-fed, twin-sheet system, two rolls of plastic materials are simultaneously fed, one above the other. The webs are transported through the oven on separate sheet-conveyor chains and heated to a formable temperature. At the forming station, a specially designed blow pin enters the space between the two sheets before the mold closes. Air pressure is introduced between the sheets through the blow pin, and, at the same time, vaccum is applied to each mold half.

Twin-sheet forming is done by a slightly different method on specially designed rotary thermoformers.

EQUIPMENT IMPROVEMENTS

Rapidly expanding markets for thermoformed products are attributable to technological advancements in equipment design. Most of the development is focused on continuous roll-fed machines for packaging. New productivity enhancements such as bigger machines, faster cycles, quicker changeover, and greater automation are gaining in importance. Better process control has enabled converters to increase productivity and improve product quality. Use of microprocessor-control systems allows the operator to enter data, examine existing values in the program, or troubleshoot problems by viewing a monitor. The conventional control panel includes a cathode-ray tube (CRT) and keyboard, form-on and emergency stop push buttons, and indicator lights to signal form or automatic modes. Machine functions may be displayed on the CRT upon request, and function control is obtained by means of the simplified keyboard. The newer systems use touch screen LCD panels.

The microprocessor-control systems feature control of oven-temperature orientation in multiple zoned ovens, interface speed between former and trim press, sheet-index length, machinery functions and timing, and control and graphic display of start end points of forming functions, storage of production information, and diagnostic capabilities. Use of the microprocessor results in tremendous savings in labor, energy, and downtime. Many of these systems are available as a retrofit to existing equipment. Equipment has also been designed to monitor several lines of similarly equipped machines from one central location. Such data-management systems provide comparative data, setup parameters, production rates, maintenance schedules, alarms and safety signals, and storage of reference information, resulting in a true on-line management-information reporting system.

Design improvements that have contributed to improved productivity include redesigned forming presses that provide front and rear access to the forming station to facilitate tooling installation and periodic maintenance; access doors to oven heaters for quick cleaning; ovens that eject automatically if the sheet overheats; and automatic lubrication systems that increase component life substantially and allow faster mechanical operation due to reduced friction.

Microprocessor heating control allows the operator to control the temperature profile of the sheet from edge to edge or to provide localized heating. Solid-state instruments used in conjunction with mercury or semiconductor-controlled rectifier (SCR) relays have made it possible to maintain extremely close heater temperature control.

Forming presses are now available with precision guidance systems on the platens to permit critical operations to take place in the forming molds that formerly had to be done on auxiliary equipment. An example is the method of incorporating the latching slots that are cut in the sidewalls of egg cartons, fast-food cartons, and trays. Previously, these slots were punched in on a special press located downstream from the forming station. Registration problems relative to the slot location were often encountered because of variations in the index length by the thermoformer web-conveyor system. These problems were overcome by expensive drive systems. On machines with precision-guidance systems, mating punches can be incorporated in the forming molds that engage during the last 5–10% of press closure and form a slot in the heat-softened plastic that has reinforced edges similar to button holes.

High-speed trim presses are available with supported moving platens that carry up to 85% of the gross-platen and trim-tool weight. The advantage of this system is that it permits the press tie rods to function primarily as guidance members rather than as both platen transporters and guides, in addition to serving as tie rods. The system reduces trim-tool maintenance by up to 50%.

Significant improvements have been made in product-handling systems, which can now automatically count, stack, and package products at the trim-press discharge. The design of these automated systems varies from relatively simple systems using guide chutes or magazines and transport conveyors to those employing robotics and advanced packaging machinery.

Automation has been extended to the materials handling of large plastic sheets into sheet-fed machines. The development of automatic sheet loaders provides automatic loading systems that enable use of the entire machine area. This results in a 20–30% increase in productivity, achieved largely from savings in loading time, since a manually loaded machine normally used only one-quarter of the machine effectively.

IN-MOLD LABELING

Unlike injection molding for which in-mold labeling (IML) is a very well established process, thermoforming process has challenged IML to address several important limitations in machinery and labeling technology that. Use of IML for thermoformed products is on the rise in recent years with development of automation and labeling technology. Even with the current improvements in output, there still remains a gap between IML thermoforming versus the productivity of conventional thermoforming. For example, IML slows down the process reducing output to 20 cycles/min versus 40 cycles/min for standard thermoforming of PP cups. Most of the current machines for IML incorporate tilting-mold technology, which provides greater accessibility and easier label placement. Another new technology for IML uses a dual-mold configuration instead of a tilting mold. The dual-mold system allows removal of the finished part and placement of the label in one mold while a part is being formed in the other mold.

In-mold labeling (IML) is a technique that typically uses a heat-activated adhesive applied to the paper or film label backing. The in-mold label is placed in a mold and held in place by vacuum, electrostatic attraction, or other means. The mold is then closed and the part is produced as normal. The adhesive's activation takes place during the manufacture of the packaging itself via thermoforming. The label becomes molded to the container wall. The material used for in-mold labels is generally paper or film. It must have sufficient temperature resistance and stiffness to resist the rigors of the molding operation. The adhesive that is utilized is generally heat-seal coating adhesives. Depending on the packaging and labeling materials, the in-mold label may not even require an adhesive. The container resin itself will, in certain cases, provide the adhesive material necessary to firmly and permanently attach the label.

One of the advantages of IML is that the label appears as part of the container compared to a label that is applied by conventional (e.g., pressure sensitive adhesives) techniques and appears above the surface of the container. Thus, the in-mold label has greater consumer shelf appeal. IML also eliminates the need, equipment, and labor required of a separate labeling process. Other advantages of IML include reduction in container weight (the IML provides structural as well as decorative value, allowing as much as 10–15% reduction in package weight) to provide improved container sidewall strength and better squeeze resistance.

High-density polyethylene (HDPE), polypropylene (PP), polyester, and polyvinyl chloride are the most common container resins that are used with in-mold labeling. Among the wide variety of consumer products packaged with in-mold labels are laundry products, household cleaners, personal care products, automotive products, agricultural and garden products, food, and beverages.

TIME TEMPERATURE INDICATORS

R. Paul Singh
Department of Biological and
Agricultural Engineering,
University of California, Davis,
California

Temperature is one of the key environmental factors influencing the storage stability of a food product. For most foods, an increase in storage temperature causes a reduction in their storage life. To determine the deleterious effects of temperature, it is often necessary to know for how long a food is exposed to that temperature. The cumulative effects of temperature and time cause irreversible changes in foods. In the commercial food-distribution chain, specific guidelines for temperature management have been developed. However, when these recommended temperature guidelines are not met, food quality is seriously impaired. Time-temperature indicators (TTIs) are devices that provide useful information regarding the temperature history experienced by a food during storage and distribution.

A food material may undergo physical, chemical, or microbiological change during storage. When these changes accumulate to such an extent that they exceed some predetermined criterion of acceptable quality, the food is considered to have reached the end of its shelf life. A variety of changes such as color, flavor, and texture may lead to the end of a food's shelf life. Similarly, the microbiological changes may render a product unsafe for human consumption. In such cases, a monitoring system that allows an early warning of the approaching undersirable increase in the microbial level would be necessary. The common practice in the modern food-distribution system is to use some type of open dating that indicates the expiration of the shelf life of a product. The open-dating policy assumes that a product has been kept at the recommended temperature. However, if the temperature during storage and distribution exceeds the recommended conditions, the open-dating policy fails. In these situations, TTIs are more suitable predictors of product's shelf life (see also Shelf life).

A TTI affixed to a food package undergoes a temperature history similar to that of food. The indicator response is measured through some physical means, or a certain property of an indicator may change, causing a visually discernible response. The indicator response may be a change in its color such as green to yellow or a change in light reflectance measured with special instruments, or there may be an advance of a boundary between two different colors that is observed visually. When the change in the property of an indicator is irreversible and cumulative with time and temperature exposure, the indicators are referred to as time-temperature integrators, full-history TTIs, or all-temperature TTIs. For certain applications, the indicators may be designed to respond only when the food is exposed to temperatures above some preselected threshold level, thus giving a partial history of the storage period. These types of indicators are called partial history TTIs or threshold-temperature TTIs. The TTIs respond at a rapid rate when the temperature goes up, and their response slows down as the temperature decreases.

For a TTI to correctly predict the end of the shelf life of a food, it must be able to accurately mimic the kinetics of the product quality. Therefore, the first step in the selection of a TTI is to identify one or more quality attributes of a food that are the key determinants of the shelf life of a food. The next step is to quantitatively determine their kinetics. For example, if a food material undergoes an undersirable change in color due to storage at temperatures higher than ideal, and the off-color makes the food unacceptable, then the kinetics of color change in the food, as influenced by temperature, must be known (1).

The kinetics of quality change in a food material is usually expressed by the rate constants. For example, if the change in the attribute is described by a first-order reaction, then the magnitude of the first-order rate constant will indicate how rapidly the attribute may be undergoing change at that temperature. The rate constants are usually determined for at least three different temperatures and then combined into the Arrhenius equation to relate rate constants to temperature. Another common way to express shelf-life kinetics is to use the Arrhenius expression as follows:

$$t_{\mathrm{s}} = Ae^{-\frac{E_a}{RT}}$$

where t_{s} is the shelf life (days or months), A is a constant with same units as t_{s}, T is temperature (K or $^{\circ}\mathrm{C} + 273$), R is a constant (0.001987 kcal/(mole · degrees), and E_a is the activation energy (kcal/mol). If the shelf life of one temperature (T_1) is known, the above equation may be used to estimate the shelf life of the same product at a different temperature (T_2) as follows:

$$t_{\mathrm{s2}} = t_{\mathrm{s1}}\, e^{-\frac{E_a}{RT}\left(\frac{1}{T_2}-\frac{1}{T_1}\right)}$$

From the Arrhenius equation, one obtains the activation energy of a reaction or shelf life. The Arrhenius equation is also used to predict the shelf life at any unknown temperature. The shelf-life data and the activation energy are the key design parameters for a TTI. It is absolutely essential that the activation energy of a TTI match the activation energy of the quality attribute of concern. This equality in kinetic parameters allows the TTI to reach the same level of change as experienced by a food material when exposed to identical storage time and temperature.

The commercially available TTIs use either a biochemical reaction between an enzyme and a substrate (Figure 1), a polymerization reaction in some material resulting in a highly colored polymer (Figure 2), or diffusion of a dye along a wick (Figure 3). In each case the reactions are temperature-dependent and the rates of reactions are carefully controlled by controlling the concentration of the indicator's constituents. Some of the indicators are activated at the time of manufacture, requiring their storage at ultralow temperature until they are affixed to a product package. Other indicators are activable at any desired time, such as when the TTI is fixed on a package at the start of the distribution chain.

TTIs differ in how they display their response to time and temperature. A TTI based on biochemical reactions involves a pouch containing an enzyme and a substrate that are initially kept separate by a thin seal. At the time of activation, the seal separating the pouch contents is broken and the contents are mixed. The pouch is made of a transparent film and is placed inside a plastic sleeve with a window. As the enzymatic reaction in the pouch proceeds as a result of the combined effect of temperature and time, the pH of the mix changes, resulting in a change in color. The user observes the color of the pouch's contents to determine the time–temperature exposure. In another type of TTI, the movement of a dye along a wick is indicative of time and temperature exposure because the diffusion process is temperature-dependent. A rectangular wick is typically sandwiched inside an outer sleeve that contains viewing holes and an appropriate scale. The advance of the dye along the wick is visually observed and related to the extent of the reaction. Another method used to display the indicator response is the use of a bull's-eye concept. In this case an indicator is located at the inner circle, while a surrounding ring is painted with a color that is eventually reached by the indicator when the shelf life of the product is deemed to have expired. In this type of a TTI, a user compares the color of the indicator seen in the center with the color of outside ring(s) as shown in Figures 1 and 2.

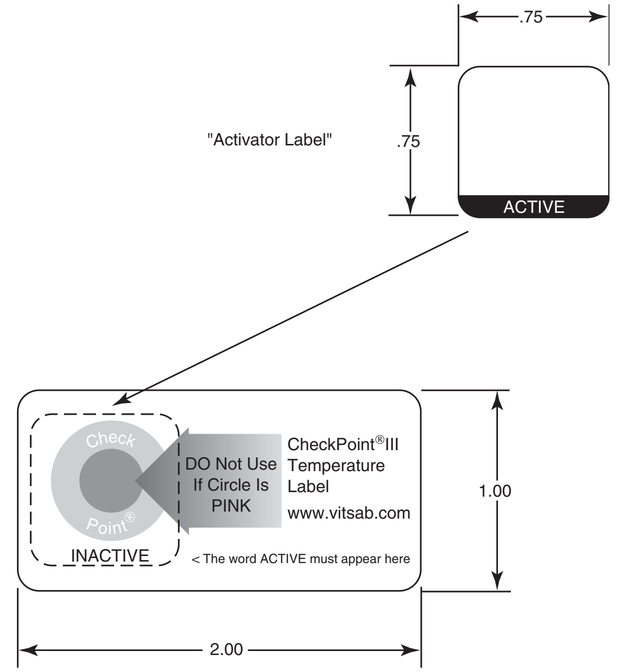

Figure 1. Check point III® temperature label (dimensions in inches) (http://www.vitsab.com/Products2.htm).

TTIs are useful in implementation of inventory management policies other than the commonly used first-in-

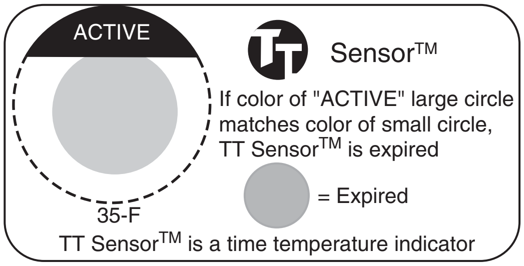

Figure 2. Time–temperature indicator label (http://www.globalspec.com/FeaturedProducts/Detail/TIPTemperatureProducts/TimeTemperature_Indicator_Labels/32742/0).

Figure 3. 3M™ Monitor Mark™ time–temperature indicator (http://www.3m.com/product/information/MonitorMark-Time-Temperature-Indicator.html).

first-out (FIFO) policy. The time-based FIFO policy fails when the food-chain temperature exceeds certain critical limits. In such cases, time–temperature-based policies such as shortest remaining shelf life (SRSL), using the TTIs, offers several advantages (2). For example, SRSL policy ensures more consistent quality at the final consumption of food items that may have been exposed to different abusive temperature conditions during storage and distribution. In the SRSL policy, using TTIs, those foods that receive an elevated temperature exposure are moved more rapidly through the system.

The TTIs are smart labels that offer a new and improved method to manage the food storage and distribution system, with the ultimate goal of providing a higher-quality food for the consumer.

TOTAL QUALITY MANAGEMENT

Mark B. Eubanks
MBE Associates, Alpharetta,
Georgia

OVERVIEW

Since the early 1980s the packaging industry, as well as other industries, have been working with an organizational concept called by various names but generally referred to as *continuous quality improvement* or *total quality management*. And, as with other industries, the degree of success among packaging companies that use the process ranged from successful to not so successful.

A significant problem for the packaging community has been its traditional view of quality as an internal process focused on compliance to regulations and/or specifications. This issue is particularly true of segments that deal with the food, beverage, and pharmaceutical markets. As a result, the industry has maintained much of its historic dependence on quality control, quality assurance, and technical audit concepts. Statistical process control now is used broadly; however, this control has been seen as a technical tool rather than as a management process.

Also, generations of managers had been taught to believe that quality was for specialists and certainly not for executives and that the results of quality techniques were not the appropriate concern of the total organization.

In the last three years, certain elements of the general news media, industry press, and the consulting profession have proclaimed that "TQM is dead." These same pundits also would say that if a ship misses a harbor and runs aground, then it is the harbor's fault. What we have seen as an industry is the need to refine the concept of quality and apply it as a management system aimed at managing change and optimizing business performance.

It is the purpose of this article to present a summary of lessons learned from past experiences of companies that use quality management and the key success factors that will enable organizations to satisfy customers, involve employees, improve work processes, and increase profits.

MANAGING CHANGE

A strong negative perception of quality management is that it takes too much time to effect a change in the way companies do business and obtain positive results. Certainly one of the primary lessons learned from the experiences of businesses large and small is that the quality process must be managed with short- and long-range objectives in mind.

This observation is especially true of the packaging industry. With the tremendous changes occurring in industry consolidation, materials substitution, processing and distribution technology, global competition, intensified government regulation, and environmental concerns, no organization can afford to spend years waiting for major improvements to take place in operating results. One industry response to this situation has been reengineering, which has had mixed results to say the least.

The fact is that, although it does take time to complete a culture change in all except the smallest companies, it is not true that *results* need to be a long time in coming.

Identification and quantification of improvement opportunities within critical processes can be accomplished within weeks of the start of a quality initiative. Common analysis techniques employed include process mapping, value-chain analysis, activity-based cost of quality benchmarking, customer service measures, and variability studies. Cross-functional teams of internal subject matter experts can be educated quickly in advanced problem-solving methodologies and can be supported by specialized software to facilitate planning, decision making, and project tracking, reducing or completely eliminating the need for time-consuming status review meetings. Many companies have shown dramatic results in six months' time.

A ROSE BY ANY OTHER NAME

One important principle is so straightforward as to be considered trivial by some. *Focus on organizational and business results and do not worry about what the process is called*. Many organizations fall victim to the name game and fail to endorse quality management because of the negative stigma associated with "TQM."

The U.S. General Accounting Office report, released in May 1991, was one of the first studies that linked certain organizational competences to improved business results (1). These positive characteristics are further defined in the criteria established by the Malcom Baldrige National Quality Award. If customer focus, cost reduction, employee participation, and competitive advantage are among an organization's desired results, then the name of the process used to achieve these results should not be a major concern.

A STRATEGIC IMPERATIVE

Quality is not a function but a strategic plan for change. Corporate leadership must ensure that quality is defined and integrated into the strategic plan at all levels of the organization. Several areas are critical and are as follows:

Leadership—executives must provide vision, direction, resources, ongoing personal support, and must remove cultural obstacles.

Commitment—executives first must understand the positive business results to be expected from quality management, and they must establish and deploy policies that guide the organization toward the realization of these results.

Evaluation—all levels of management must evaluate the quality process systematically using measurements appropriate to each level.

ALIGNMENT

For quality-management processes to produce superior business results, all functions, areas, systems, processes, groups, and individuals must operate congruently. Internal capabilities must match customer needs. Marketing and sales plans must be based on customers' expectations for product and service excellence rather than on quotas or commission schedules. Financial plans must reflect an investment in customer satisfaction and employee involvement, not just an abstract reference to bottom-line results. Employees must be educated and dedicated to performing their roles in the business, and they must understand the rewards that they, and their workgroups, will receive for minimizing waste and improving their work processes.

CUSTOMER FOCUS

Virtually all companies have learned to say that they are customer-driven. And it is generally agreed upon that the packaging industry has gotten closer to its customers. However, abundant evidence exists that the voice of the customer may not be heard as clearly as it should be throughout many companies.

Communication with customers is one of the major areas where important lessons have been learned over the past decade. Customers were at one time considered to be the responsibility of a few groups or individuals within a company. Typically, this position was a sales/marketing function with some top managements that join in for key accounts. Today, everyone in an organization must be able to listen for and respond to customer messages.

Successful organizations use a variety of tools to monitor present and future customer needs and expectations—surveys, focus groups, formal and informal audits, quality-function-deployment models, and decision matrices, to name a few The old comment, "We know what the customer wants," without actual use of actionable customer data, is being heard less and less.

The key principles are to identify and translate customer requirements from broad categories, e.g., "customer satisfaction," "superior quality," and "competitive price," into specific work-process improvements all levels of the organization can implement.

FINANCIAL IMPACT

One of the major reasons given by senior managers for their disaffection with quality-management process is that a financial payoff does not exist. This attitude is disturbing to quality professionals, because quality management can have a major impact on bottom-line results and stakeholder value.

In their widely quoted book, *The PIMS Principles*, Gale and Buzzell present a compelling case that quality has a major positive effect on market share and profitability (2). Financial impact tools—cost of quality, customer value analysis, and others—have been available for many years but are under used for several reasons, which are as follows:

- General fear or distrust of measurement in general.
- Traditional accounting systems do not lend themselves to process costing.
- Data-collection systems are considered too complex to maintain.
- Cost-of-quality systems are considered to be an extension of the finance function.
- Employees are not properly educated on the use of the financial impact system.

- No constructive action is taken once the data are gathered.
- Interdepartmental turf issues prevent cooperation.
- Financial impact systems are used for punishment or are not linked to compensation.

Financial impact systems are vital to the continued success of quality management processes. They provide a primary means of measuring business success, secure management's involvement and support, and help to identify and prioritize opportunities for improvement.

EMPLOYEE INVOLVEMENT

The word "employees" in the subheading above refers to all individuals in the organization, from senior management through all levels of the workforce. All individuals require an understanding of the quality process and their role in the new culture. They should be aware of several factors that includes the following: the common language of quality, how to apply the concepts to their jobs on a day-to-day basis, and the use of selected skills such as problem solving or statistical process control to cause improvements to happen in their workgroups.

Quality tools and skills are organizational, managerial, individual, and technical. Most organizations concentrate on implementing individual and technical tools before they do anything about the organization and its management. This issue occurs when the senior management does not understand the philosophy behind the quality process. Executives and managers want to satisfy customers in an effective manner, but they must also learn to see quality as a system, and they must learn their role in the system.

When employees have learned their roles, tools, and techniques, they must then be formally (and sometimes forcefully) able to use this knowledge to carry out the business objectives of the company. Many companies are frustrated when recently educated employees fail to participate actively in the quality process. The reasons are clear and include the following: employee involvement was not a part of the traditional corporate culture; they did not understand that they had permission to get involved; they did not see this new behavior as consistent with what their supervisors were doing; they did not know how they fit into the new quality plan; and they had not been convinced of what their benefits would be if they participated.

Next to the lack of sustained management commitment for the reasons cited in the "Financial Impact" section, the biggest obstacle to most companies in achieving success in their quality processes has been the lack of employee involvement. The keys are education, recognition, and compensation.

CUSTOMER–SUPPLIER RELATIONSHIPS

Many packaging companies have established successful partnerships with their key customers and suppliers. Several elements are vital to establishing such productive relationships.

As a part of their strategic planning process, successful companies involve customers and suppliers extensively in planning for new and improved products as well as higher levels of product and service performance. Systems, such as quality-function deployment, aid customers and suppliers in matching customer needs with supplier capabilities and communicating these factors throughout both organizations.

Measurement systems are developed jointly between partners and used as a means of improvement. Measurement extends to the development and sharing of testing methods, equipment, and research techniques.

Vendor certification and rating systems are being used more as companies seek to develop a common language of quality improvement. The exact form of these systems is specific to each customer. Many formats, however, follow the general structure of the Malcom Baldrige or ISO 9000 criteria.

SUMMARY AND CONCLUSIONS

In the remainder of the 1990s and beyond, the packaging industry will be faced with an increasing challenge to manage within narrower time limits and to be even more focused on customers and customers' customers. At the same time, companies will be required to spend more time and effort developing the "people side" of the business at all levels.

Quality-management processes are an effective system for managing 21st Century organizations and maximizing total business performance in the age of intense competition and dramatic change.

The successful organizations will employ the following key success factors:

- Strong management commitment to leading and supporting a quality-improvement process.
- Aggressive customer focus that uses quantitative techniques for requirement identification.
- A planning system that involves broad participation and integrates quality objectives into strategic and operational planning.
- Immediate identification of critical work processes and major business success drivers.
- Effective, open communication system.
- Quality-process education for all employees, suppliers, and customers.
- Measurement systems that support continuous improvement.
- Collaborative relationships with customers and suppliers.
- Compensation system for all employees tied to quality improvement.
- Recognition of all who participate in the quality process.

TRANSPORT PACKAGING

Alfred H. McKinlay
Consultant, Pattersonville,
New York

The objective of transport packaging is preservation of the product in its delivery from point of manufacture to the customer. Without packaging, most products would have a difficult and expensive trip through handling and transportation, many of them delivered to customers in a damaged condition. Transport packaging actually adds to the value of the product, by lowering the cost for customers to obtain possession of the product from its origination.

Transport packaging is a term used throughout the world—except in North American, where it is often known as *distribution or protective packaging*. It includes the shipping container, interior protective packaging, and any unitizing materials for shipping. It does not include packaging for consumer products such as the primary packaging of food, beverages, pharmaceuticals, and cosmetics. In the United States, transport packaging represents about one-third of the total purchases of packaging; the balance is attributable to primary packaging for consumer products.

The goal in transport packaging is to provide the correct design for packaging such that its contents will arrive safely at the destination, without using too much or too little packaging material. In other words, the package designer must ensure that this equation is maintained:

$$\text{Product} + \text{package} = \text{distribution environment}$$

The following text will show how to determine the right amount of each of the three variables so that the equation will always balance, with no excessive overpackaging cost or loss from damage.

FUNCTIONS AND GOALS OF TRANSPORT PACKAGING

The functions of transport packaging can be summarized as follows:

Containment. The basic purpose of packaging is to contain the product. Packaging permits products to move from their source to the customer, supplying use value to products that are otherwise useless to the customer, who is usually remote from the source.

Protection. Most products require some degree of protection from the hazards in distribution. Packaging furnishes the degree of protection needed to safely transport products from source to customer.

Performance. Packaging aids in transportation, handling, storing, selling, and use of the product. This function includes such things as orientation of the product, ease of identification, appropriate quantity, ease of disposal, and handling features.

Communication. The package must identify its contents and inform about package features and handling requirements. It generally provides space for shipping information as well.

To design a transport package, one must have goals in mind. These will vary with products, customers, distribution systems, manufacturing facilities, and so on, but most transport packaging should address the following objectives:

Product Protection. The primary purpose of any transport package is to ensure the integrity and safety of its contents through the entire distribution system.

Ease of Handling and Storage. All parts of the distribution system should be able to economically move and store the packaged product.

Shipping Effectiveness. Packaging and unitizing should enable the full utilization of carrier vehicles and must meet carrier rules and regulations.

Manufacturing Efficiency. The packing and unitizing of goods should utilize labor and facilities effectively.

Ease of Identification. Package contents and routing should be easy to see, along with any special handling requirements.

Customer Needs. The package must provide ease of opening, dispensing, and disposal, as well as meet any special handling or storage requirements the customer may have.

Environmental Responsibility. In addition to meeting regulatory requirements, the design of packaging and unitizing should minimize solid waste by any of the following: reduction–return–reuse–recycle.

Since transport packaging must always be economical, all the above goals should be balanced to achieve the lowest overall cost.

TAKING A TOTAL SYSTEM APPROACH TO PACKAGE DESIGN

The scope of design in transport packaging must consider all aspects of the distribution system, including customers, carriers, and distributors as well as the manufacturing plant, packaging line, warehousing, and shipping. Successful package design is a total-system approach.

Once created, a package does not magically form around the product, float through shipping, travel hundreds of miles in isolation, arrive at the customer's site, and then disappear. It has an influence on and is influenced by everyone and everything it encounters. Many of these encounters will affect either (a) manufacturing and distribution costs or (b) product integrity with indirect impact on sales. Therefore, such events should be considered in the design process.

Unfortunately, there is often too much focus on the cost of packaging materials to the exclusion of other factors, including cost-related ones in handling, storage, and transportation. If the package is slightly larger and/or heavier than it really has to be, costs in all three areas will be higher than necessary, perhaps producing an even greater effect on profits than would higher packaging costs for a smaller and/or lighter package. For instance, although each industry and company is different, a general rule of thumb states that transportation will cost between 3 and 10 times as much as packaging on average for all shipments. A small reduction in package size or weight could mean much more savings in transportation plus handling and storage. For example, a small kitchen appliance in bulky wraparound die-cut may involve less material cost, but molded packaging may pack faster and require less cube, permitting more pieces per unit load, fewer handling trips, more units per storage cube, and more units per truckload, for an overall savings.

An inverse relationship exists between packaging cost and maintaining product integrity with low damage rates, as shown in Figure 1. Other factors being equal, an increase in packaging will provide more protection to the contents and therefore lower the potential for damage. Or, conversely, cutting packaging costs without other improvements generally means less protection and higher damage rates.

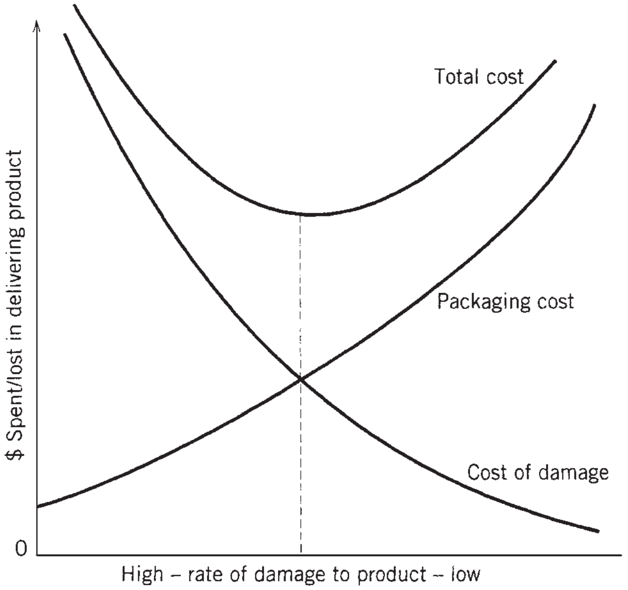

Figure 1. Cost of product protection is a tradeoff between packaging and damage.

The real cost of getting the product safely to market is the *sum* of packaging and damage. Optimizing the total is the true goal of packaging design. As damages rise too high on the left of the graph, both replacement–repair costs and potential for loss of customer goodwill and cancellation of orders increase. For companies where loss of sales and customer satisfaction are more important than costs, there is not much room for movement to the left of the package–damage intersection.

No matter where packaging design takes place—in engineering, in manufacturing, in shipping, or at the supplier—all factors mentioned above must be considered, costed, and involved in a *total-system approach*.

THE PROTECTIVE-PACKAGE CONCEPT

The equation presented earlier is used here to explain the concept of protective packaging for distribution:

$$\text{Product} + \text{package} = \text{distribution environment}$$

Figure 2 depicts this equation and the consequences of an imbalance in the equation, which is what happens when a product plus its package are not exactly what is needed to survive in the distribution process.

Reading from left to right, here is an explanation of the bar chart. *Severity* is the quantitative measure of the *environment*, which can be any one or combination of hazards in distribution. Here are examples of hazards and their severity: The rough-handling hazard to a 20-lb (9.1-kg) package is determined to be 30 in. (76-cm) of drop on any of six package surfaces; or the compression (storage) hazard is determined to be 10 packages high in warehousing; or the high-temperature hazard is 140°F.

Product represents the measured level of resistance to damage of the product. In the rough-handling example, the product has been tested and has shown the ability to survive six drops from 15 in. (38 cm) with no damage, while higher drops will cause product impairment.

The third bar depicts the equation whereby the *product's* measured level of damage resistance plus the *package's* measured abilities to protect the product are exactly equal to the expected environmental hazard(s), an optimum solution. For the example, a product with 15-in. (38-cm) drop resistance is packaged in 15-in. (38-cm) drop protection, which adds up to the 30 in. (76 cm) of drop height the packaged product is expected to encounter in the distribution environment.

When the package provides less protective capacity than needed for the environment, as shown in the shaded area of the fourth bar (Figure 2), this underpackaging will result in *damage in shipment*. For example, the package supplies only 9 in. (23 cm) of drop-height protection instead of the required 15 in. (38 cm).

The next bar defines *overpackaging*. The package protection level is higher than the environment requires, and the shaded area shows amount wasted. Instead of designing for 15 in. of drop protection in our example, packaging supplies 6 in. more than needed.

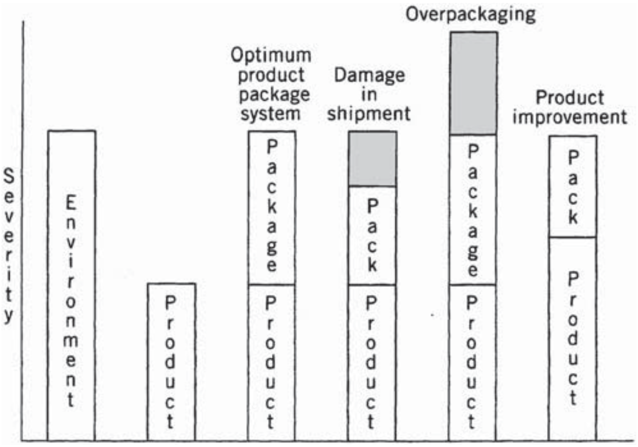

Figure 2. Concept of a protective package.

At times, *product improvement* is an alternative to more packaging. Instead of accepting a certain level of product ruggedness of a product, product engineers may be able to raise the level as shown in the bar chart to the far right. The result is a reduction in packaging needed. Perhaps the product had a component that malfunctioned above 15-in. (38-cm) drop heights, but a redesign improved ruggedness to the 20-in. (51-cm) level. Now packaging need only supply 10 in. (25 cm) of protection, a 33% reduction from the original.

The most elusive part of the equation is the distribution environment. The most difficult part of defining the environment is not in identification of the types of hazards, but what each hazard's expected level is and its probability of occurrence. Dedicated package designers continually search for better methods of defining the environment on the right side of the equation so they can solve for the parameters of product and package on the left side of the equation.

THE 10-STEP PROCESS OF TRANPORT PACKAGING DESIGN

Here is a proven 10-step procedure that will ensure that a transport package design will provide maximum performance at least overall cost.

1. *Identify the Physical Characteristics of the Product.* Product knowledge means more than knowing simply its dimensions and weight. The package designer must be aware of surface characteristics and susceptibility to abrasion or corrosion, the ability to hold a load in compression, internal characteristics affected by vibration, and particularly the product's fragility. Guessing about any of these factors will surely lead to potential problems.
2. *Determine Marketing and Distribution Requirements.* Package design must incorporate marketing and distribution requisites in addition to product characteristics. One must know the number of units that will ship in a container, the composition and attributes of the primary package, the identity of customers and their handling and storage requirements, the package disposal criteria, total volume expected per shift per day per year, expected life cycle, the planned modes of transport, types of distribution channels, and so on.
3. *Learn About the Environmental Hazards Your Products Encounter.* It was emphasized earlier that knowledge of the distribution environment is key to designing an optimum package. Major hazards to be expected in the environment are rough handling, in-transit vibration and shock, compression in storage or in transit, high humidity and water, temperature extremes, and puncturing forces. Learning about them may include observation, reading other's research, or conducting measurements.
4. *Consider Alternatives Available in Packaging and Unitizing.* Many alternatives are available for shipping containers, interior packaging, and unit loads. All should be considered and reviewed before selecting the final types for further development. Tradeoff analysis techniques such as make versus buy often help. Rather than considering only materials that one has experience with, comparing paper versus plastic versus wood vs metal is a good exercise at times to ensure the best for the particular project. Once the basic materials have been selected, detailed work on design can begin.
5. *Design the Shipping Unit (Container, Interior Packaging, and Unit Load).* With basic materials and information established in steps 1–4, the designer can now scientifically engineer a transport package, as well as unit load where appropriate. Each component of the shipping unit (container–interior–unit load) is analyzed for strength and other required properties and compared to technical data available from suppliers. Some packaging materials have good design data available, but most do not. The designer frequently must rely on experience to reach a successful solution; the novice may find that lack of information makes it difficult to arrive at an optimum solution. Trial and error can be shortened for the novice, as well as the experienced designer, by conducting engineering tests in package development. Impact, vibration, and compression testing in the lab not only identifies shortcomings but helps to fine-tune to the optimum solution.
6. *Determine Quality of Protection Through Performance Testing.* After the shipping unit is designed, perhaps with the aid of engineering development tests, it should then be performance-tested. This consists of subjecting the unit to a sequence of anticipated hazards and/or tests in the laboratory for the purpose of a pass/fail decision. Will the shipping unit protect its contents all the way through distribution? The performance test methods should be based on industry standards. Such standards have considerable experience and history behind their development and use, and a successful completion of the test sequence almost

guarantees damage-free shipments. The most widely used standard is the International Safe Transit Association's Project 1 and 1A, in use since 1948 (1). The 1982 approved ASTM D4169 (2) provides a more complete array of distribution possibilities and identified hazards with corresponding test sequences, and it permits the user some flexibility in selecting test intensities. For users who can clearly define their distribution cycles, but find them different from the standard cycles in D4169, the ASTM standard also provides a means of developing a unique sequence of tests, resulting in performance tests that can more precisely simulate the actual conditions.

7. *Redesign the Shipping Unit Until It Successfully Passes All Tests.* There is an old saying: One test is worth 1000 expert opinions. Often performance test results fool even the most experienced engineers, and it is necessary to repeat an entire cycle of redesign and retesting as many times as required to reach a "pass" decision.
8. *Redesign the Product Where Indicated and Feasible.* Occasionally, testing reveals a product weakness that can be compensated for by protective packaging, but at excessive cost. If at all feasible, the product should be redesigned to correct the weakness rather than redesigning the package. This is particularly important when the cost of the redesigned product is less than that of the increased packaging. It is usually difficult for package designers to bring about product redesign when they are located organizationally in other than the product engineering group. If this is the case, the packaging designer should attempt to establish a continuing line of communication with the product engineers. Sometimes this means educating product engineers in the hazards of distribution and showing them how to correct product weaknesses.
9. *Develop the Methods of Packing.* An important part of package design is packing of the product in the shipping container and unitizing of containers. Although this may be the responsibility of someone else, (i.e., industrial engineering), the designer must be aware of cost factors and the appropriateness of mechanizing or automating all or part of the operations. Sometimes a tradeoff in package design must be implemented to achieve overall system economics.
10. *Document All Work.* One step repeatedly overlooked in the design process is documentation. This includes documenting test results, specifications, drawings, and methods of packing. Drawings should be in company-standard formats with appropriate designations for reference in the corporate specification system. Relying on supplier sketches or drawings as the reference document is not a wise idea. They should be transferred to company format so that purchasing, manufacturing, and engineering can reference them. On any package design project, follow these 10 steps and check your work against the checklist below. Doing so will significantly reduce potential of an unpleasant surprise when shipments begin.

Checklist for Each Package Design Project

1. Have you considered the solid-waste aspects of the package and unit load, and their alternatives, to minimize impact on the environment?
2. Have you pondered the use of returnable or reusable containers and dunnage?
3. Have you contemplated all cost factors in the distribution cycle: handling, storage, and transportation?
4. Have you checked cost of this package versus company or plant average for similar products?
5. Have you considered all possible alternatives in materials and methods?
6. Have you used industry standards for materials and design criteria where possible?
7. Have you performance-tested the design against accepted industry standards or regulatory requirements?
8. Have you documented the design in company's spec system?
9. Have you checked damage and customer complaints on this product line?
10. Have you satisfied all rules and regulations applying to this product for all distribution modes it is expected to encounter?

THE COMPONENTS OF TRANSPORT PACKAGING

The components of transport packaging may be broadly classified in the following categories:

Shipping containers
Interior protective packaging
Closure and securement materials
Unitized load shipping bases

Together these represent about one-third of the total U.S. packaging costs.

By far the largest component of transport packaging is shipping containers, representing an estimated 75% of the total purchased. Corrugated boxes represent about 80% of the total spent on shipping containers and probably close to 90% of total units of shipping containers used. Other types of containers include: paper and plastic shipping sacks; wooden boxes and crates; metal and plastic returnables, drums and pails; and composites for textiles.

Interior packaging takes many forms, but the most widely used for cushioning, positioning, or simply to fill space are corrugated pads, die-cuts, partitions, foldups, molded and fabricated expanded polystyrene forms, molded and fabricated resilient foams, foam-in-place, loose-fill, air-bubble and foam wraps, variations of paper waddings, inflatable air bags, and a variety of specialty devices and forms. Barriers against water, water vapor, and various gases and to prevent electrostatic damage are another class of interior materials. Corrosion preventatives are also in this category, such as preservatives, volatile corrosion inhibitors, and desiccants.

Closure and securement includes (a) adhesives, tape, and staples for corrugated box closure and (b) strapping, stretch wrapping, and shrink bags for unitizing purposes.

Shipping bases include wood, corrugated, or plastic pallets; corrugated, solid fiber, or plastic slip sheets; and wood skids.

CONCLUSION

When products are shipped anywhere and by any mode of transport, the packaging surrounding the product must contain and protect it. Ensuring that the product arrives at destination in undamaged condition is the primary objective of transport packaging.

TRANSPORTATION CODES

Mary Alice Opfer
Fibre Box Association, Rolling
Meadows, Illinois

Two types of transportation codes are in use in the United States with regard to packaging: federal regulations and carrier rules. Carrier rules, such as Item 222 and Rule 41, are the type that is more familiar to the packaging community. They have been in effect the longest and have changed the least over the past several years.

CARRIER RULES

Carrier packaging rules are found in the carriers' tariffs and must be followed if the shipper wants coverage by the carrier for damage claims. Carriers reserve the right to refuse articles they consider inadequately packaged, and conformance to packaging rules is implicit in collection of shipping rates as listed in the tariffs. The Airline Tariff Publishing Company (air cargo) and Air Transport Association of America (airline) publish North American tariffs, but these documents do not include detailed packaging instructions except for special articles, such as live animals, human remains, and seafood. Individual carriers, United Parcel Service, Federal Express, and the U.S. Postal Service, publish their own tariffs, which also typically lack detailed packaging instructions.

The American Trucking Association and the National Railroad Freight Committee publish the National Motor Freight Classification (NMFC) and the Uniform Freight Classification (UFC), respectively. These documents contain detailed packaging rules as well as rates, which apply to the participating individual carriers named in the tariffs. The packaging rules mandate minimum quality values for material of construction based on the total gross weight and united dimensions (length+width+depth) of the package and its contents.

Item 222. Item 222 is the rule for corrugated and solidfiber packaging of articles transported in the less-than-truckload (LTL) common-carrier mode. Most goods transported in the United States today are transported by this mode at some time in their distribution cycle. If the NMFC specifies "in boxes" in the entry for the article to be transported, then the outside of the box must carry a circular box manufacturers certificate that precisely coincides with the instructions in the rule and certifies compliance with the manufacturing instructions in the rule, or damage claims and rates may not be honored. If the entry for the article specifies "in package number…," then detailed instructions for that (those) numbered package(s) are listed in the section "Specifications for Numbered Packages," which must be followed, and a rectangular certificate is applied indicating the package number and grade of board used. The numbered package certificate is the only rectangular certificate that is recognized by carriers for tariff compliance. All others are simply advertisements.

Rule 41. Rule 41 is the corrugated and solid-fiber packaging rule for articles shipped by rail. However, piggyback shipments in trucks on railroad flatcars are subject to truck rules. Rule 41 and Item 222 are very similar, but not identical. The numbered packages can be different. Rule 41 is the older of the two and is the model on which Item 222 is based, but articles in boxes are shipped most often by truck making Item 222 the rule to be consulted.

Edge-Crush Test (ECT). In 1990, the corrugated industry trade associations sponsored proposals to revise Item 222 and Rule 41. The primary thrust of the proposals was to have the rules recognize edge crush test criteria as an indicator of box-compression strength, and to allow its use as an option to the traditional linerboard basis weight and combined board-burst requirements. ECT is a characteristic of the combined corrugated board that directly predicts compression strength of the corrugated packaging. By providing alternative requirements in the carrier rules, box manufacturers would have more latitude to design and supply boxes that better meet the customer's performance requirements. This concept is supported by organizations representing carriers, users, as well as box and containerboard producers with the growing recognition that box compression strength may be a more important factor as unitized carrier loading and warehousing has proliferated. Enhanced containerboard materials achieving a guaranteed crush or compression performance at lower basis weights had become available, which provide potential environmental advantages and improved quality through source-reduced packaging systems and increased recycled content.

Use as Standards. Over a long period, the terminology and minimum requirements for corrugated packaging used in the carrier rules became an assumed standard for boxes. Using the carrier rules as standards is often inappropriate, as the carrier rules were not developed to address the box users' warehousing and other distribution needs. They were developed to delineate the carrier's liability. As the box-manufacturing industry and its customers emphasize quality and efficiency, corrugated-box standards should evolve to support the new emphasis.

FEDERAL REGULATIONS

Packaging itself is not typically of federal interest; however, certain specific issues are regulated by U.S. government agencies. Consequently, packaging is sometimes regulated by those agencies. Federal regulations that affect packaging are found in the *Code of Federal Regulations* (*CFR*) of the agency under whose jurisdiction the issue resides. For example, the U.S. Department of Transportation (DOT) regulates the transportation of hazardous materials. Regulations for packaging hazardous materials for transport are in the DOT's *CFR*, Title 49. Packaging of these materials is based on the capability of the packaging to pass a battery of tests that are dictated by the degree of hazard of the material, or its "packing group." These regulations were adopted by the DOT from the United Nations (UN) Recommended Rules, which replaced the former DOT specification packages such as the DOT 12B.

The DOT shares the regulation of packaging infectious substances and regulated medical wastes with the Department of Labor (29CFR) due to OSHA concerns over bloodborne pathogens, and of packaging hazardous wastes and pesticides with the Environmental Protection Agency (EPA) (40 *CFR*) because of potential environmental impact. The Food and Drug Administration (FDA, 21 *CFR*) regulates direct contact packaging of fatty and aqueous foods as indirect food additives. The Department of Agriculture (9 *CFR*) regulates the packaging of meats and poultry under meat inspection and poultry inspection.

Labeling. The EPA assisted the Federal Trade Commission (FTC 16 *CFR*) in defining the voluntary ecolabel statements that are allowed, such as recycled, recyclable, and biodegradable. Aside from environmental claims, package labeling issued are generally specific to the article inside the package. With transport packaging often doubling as consumer packaging, this process has become an important concern. The FDA regulates the nutritional labeling of packages with respect to food contents. Both the FDA and FTC require metric as well as standard measurement units displayed on the packages of many consumer products. The DOT gives specific instructions for labeling hazardous-materials packages, even specifying the colors to be used. The EPA requires products (including packages) that are manufactured using or containing ozone-depleting substances to be specifically labeled. Package labeling of regulated articles should be a joint effort between package manufacturer and user.

TRAYS, FOAM

Huston Keith
Keymark Associates,
Marietta, Georgia

These lightweight, inexpensive trays are made of expanded polystyrene. The major packaging applications are for packaging fresh meat, poultry, eggs, produce, and other foods for retail sale or for packaging prepared foods for imminent consumption. Other uses include industrial protective packaging and disposable tableware (plates, bowls, cups, trays, etc.). The primary process used for making trays is extrusion of foamed polystyrene sheet (Figure 1) and thermoforming the trays. A minor quantity of trays are made from steam molding of precharged beads—this process is used mostly for cups, industrial packaging, and insulation. This article focuses on the thermoformed trays as being of primary interest to packaging, but it discusses the other applications briefly in context of packaging use.

HISTORY

The process of making a polystyrene foam sheet for thermoforming was developed in the late 1950s based on technology first commercialized by Dow Chemical Company in 1943 for extruding foam board for insulation. It was called the "direct-injection process," because gas was injected into the extruder and mixed with melted polymer, as compared with the precharged bead process, where resin beads are impregnated by the gas. Dow then started a plant in Carteret, New Jersey to produce sheet and

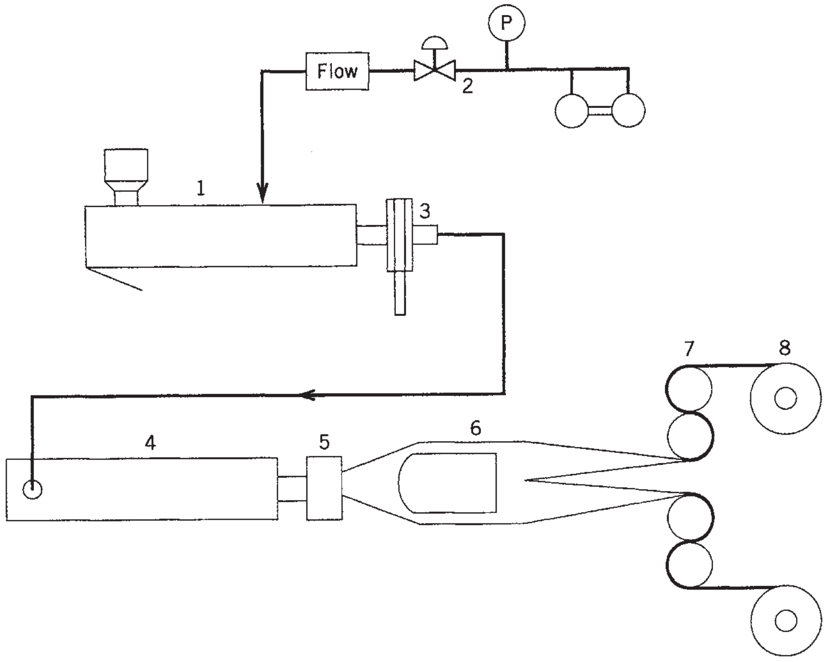

Figure 1. A tandem extrusion process for the manufacture of polystyrene foam sheet: 1: primary extruder, 2: blowing-agent addition system, 3: screen changer, 4: secondary extruder, 5: annular die, 6: cooling mandrel, 7: S-wrap, 8: winders.

trays. Because of Dow's prominence in commercializing these processes and continued dominance of the polystyrene resin market, its trade name Styrofoam for foam insulation board became associated with nearly any form of expanded polystyrene. In fact, many people improperly use the trade name Styrofoam for all polystyrene foam products.

The initial application for this process for packaging was for forming meat trays. By the mid-1960s, equipment and techniques were developed for forming egg cartons. Dow formed a joint venture with a major egg producer, Olson Farms, to produce egg cartons. The venture, Dolco Packaging, later became an independent company. In the late 1960s, food-service containers and packaging were developed. Foam trays began to replace pulp trays for meat and egg packaging at an accelerated rate because of lower cost and better durability. In addition, the growth of the supermarket and especially the food-service industry propelled rapid increases in the use of this package.

The rapid growth of extruded-polystyrene foam packaging continued as more users were found. Foam disposable plates and bowls found acceptance, as did carry-out containers in an affluent society driven more and more by convenience. The fast growth of polystyrene attracted petrochemical giants Amoco and Mobil into the business. In 1973, polystyrene foam containers were adopted by McDonald's as its primary hamburger package. Better heat retention, enhanced produce protection, and concerns for forest depletion and landfill stability were cited as benefits. This led to over two decades of unprecedented industry growth, from 15 million lb (6800 metric tons) in 1966 to 651 million lb in 1988 (295,900 metric tons) in the United States alone. Costs were driven lower by more efficient production, which made the replacement of substitutes (mostly paper) more and more compelling.

Under pressure from environmental groups, led by the Environmental Defense Fund (EDF), McDonald's first placed a moratorium on chlorofluorocarbon (CFC) use in its containers, then announced in November 1989 that it would discontinue the use of polystyrene foam trays for hamburger packaging; they would be replaced with a paper-based wrap. Other fast-food suppliers followed suit. This caused a loss of 90 million lb of demand in the face of industry overcapacity. One supplier entered Chapter 11 bankruptcy (since recovered), and at least two plants were closed.

After a period of retrenchment, the industry began to slowly recover. Although the fast-food packaging market is moribund, the low cost and stiffness of foam relative to alternatives has provided continued growth in disposable tableware. The growth of the poultry market has also pulled along foam tray consumption. Whereas the foam tray may never visualize the usage in fast food as before, it has proved to be an almost irreplaceable packaging container for fresh meat and poultry.

MANUFACTURING PROCESS

As mentioned earlier, most foam trays are made by extruding foam sheet and thermoforming it into trays. Although this process is similar to the process used to make solid plastic trays, it also differs in several significant aspects. Two extruders are used instead of just one, an annular die is used rather than a flat one, rolls must be aged before forming, and matched metal dies are used for forming. As a result, the capital costs are much higher than for solid plastic. However, raw-material costs are much lower as a percentage.

The typical tandem extrusion system includes a primary extruder for melting and mixing the polymer and a secondary extruder connected in series for allowing the extrudate to cool and expand. Whereas a single extruder may be used, large commercial operations use tandem systems for a better quality sheet. The blowing agent is injected into the primary extruder. The melt then passes into the secondary extruder, which is usually one third larger in diameter (78% larger in volume), primarily for cooling. The extrudate then exits through an annular die, expands, and flows over a mandrel. The resulting tube is slit to make a flat sheet. Sometimes it is slit twice to form two sheets. The diameter of the mandrel determines the sheet width and provides biaxial orientation. The sheet is then pulled through a series of two to three rollers (S-wraps) to remove the curl, make the thickness uniform, and cool it for winding.

A typical commercial extrusion setup is 4.5 in. (115 mm in nominal size) in diameter for the primary extruder and 6.0 in. (150 mm) for the secondary extruder for 500–1000 lb (275–450 kg) per hour. A common configuration for output of 800–1500 lb (350–700 kg) involves a 6.0 in. (150-mm) primary and 8.0 in. (200-mm) secondary. The resulting foam has fine, closed cells with a density of 2–10 lb/ft^3 (32–160 g/L). For packaging applications, the resulting sheet typically has a basis weight of 3–25 g/100 in.^{2} (50–400 g/m^2 with a thickness of 30–200 mils (0.75–5.00 mm). The width typically ranges from 20 to 52 in. (500 to 1325 mm).

A variety of blowing agents may be used. Most producers used chlorofluorocarbons until 1988 (see below). Others used butane, pentane, or other hydrocarbon gases. Although hydrocarbons are much less expensive, they are highly flammable. Extreme precautions had to be taken to prevent fires and explosions. As noted below in the “Environmental Issues” section, all these gases are being reduced or eliminated for environmental concerns. A leading replacement candidate is carbon dioxide (CO_2). Dow has developed technology for using 100% CO_2 that it is licensing. Other gases are being investigated.

During the extrusion process, special finishes and laminates may be applied for graphics, gloss, thickness reduction without loss in strength, gas barrier, or other purposes. As the foam exits the extruder, it may be hit with a stream of air from completely around the tube. Called an *air-ring coating*, the foam cells near the surface are collapsed, which a forms thin glossy skin on one side of the sheet. Some producers have also developed a technique of coextruding a thin (<1 mil or 25 μm) layer of polymer (usually polystyrene) through the same annular die that produces the foam. At the S-wraps, a premade and sometimes preprinted film (oriented polystyrene or barrier) may be laminated in the nip. One producer accomplishes the same feat by extruding a thin-impact polystyrene film onto the foam sheet in the nip.

After the foam has been extruded and wound onto rolls 60–84 in. (1.5–2.1 m) in diameter, it is placed in a storage area for 1–3 days to allow the blowing agent to partially escape, for optimal expansion in thermoforming. After aging, the foam is taken and placed on an unwind stand for thermoforming.

Thermoforming a foam sheet into trays is somewhat more complex than forming a plastic sheet. Because foam is an insulator, heating the sheet to forming temperatures requires more time. Distribution of heat is also critical. During the heating process, the foam reexpands to nearly twice its stating thickness. The expansion needs to be as uniform as possible to produce a good part. Thus on production machines, ovens are much longer than typical thermoformers. When the sheet enters the mold platen, the male and female molds close to a thickness slightly less than the starting sheet thickness. This technique provides uniform wall thickness throughout the part. This helps provide the same strength as a much heavier comparable plastic part. Although foam trays can be trimmed in place, most large commercial equipment uses a separate trim station. Punch-and-die trimming is normally used for large commercial operations for higher speed and more durability, although steel-rule dies may be used for lower volume situations.

After molded parts are trimmed, the remaining sheet “skeleton” is ground up immediately to be stored in a silo for reuse. Because the unused scrap sheet is as much as 50% of sheet area, reusing scrap is critical to producing parts economically. While the ground-up foam or “fluff” may be reused directly, it is difficult to blend and feed properly with virgin resin pellets. Thus, most producers have a reclaim operation that remelts the fluff and extrudes it as pellets.

Key builders for foam-extrusion equipment are Battenfeld Gloucester (Gloucester, MA) and Berstorff of Germany. Davis Standard (Pawtucket, RI) and Egan (Somerville, NJ) also produce foam lines. Most foam thermoformers are built by Irwin (Yakima, WA) and Brown (Beaverton, MI). The typical resin used is a high-heat grade of crystal polystyrene. Dow Chemical (Midland, MI) is the largest supplier worldwide. Others include BASF (Frankfurt, Germany), Huntsman (Salt Lake City, UT), and Chevron (Houston, TX).

The cost of an extruded-polystyrene foam tray plant is more than double the cost of a thermoformed solid-plastic tray plant for comparable output in trays. A typical setup of an extrusion line, reclaim line, silos, two thermoformers, and tooling as of 1994 would cost about \$3–\$5 million. In addition, a foam plant requires more land and building for equipment, roll storage, and finished-goods storage. As a tradeoff, however, raw materials are a much lower proportion of manufacturing costs (30–50% vs 50–80%).

KEY PRODUCERS

The major producer of foam trays by far is Tenneco Packaging (Evanston, IL) with five plants around the country, which purchased Mobil Chemical Company’s foam business in October 1995. Amoco Foam Products Company (Atlanta, GA), with nine plants, is the next largest and is expected to be sold before this article is published. Both of these companies offer a broad line of both disposables and packaging products. Four other manufacturers have also recently changed ownership. Tekni-Plex (Somerville, NJ) was bought in 1994 by MST, a financial group, which then also purchased Dolco Packaging (Studio City, CA) in February 1996. Sweetheart Cup

(Owings Mills, MD), primarily a disposable manufacturer, was acquired in 1993 by American Industrial Partners Capital Fund (San Francisco) from Morgan Stanley (New York). Elm Packaging, (Memphis, TN) management-led financial group acquired Fripp Fibre's operations in 1994. Other foam producers Genpak (Glens Falls, NY), Linpac (Wilson, NC), Solo Cup (Highland Park, IL), Dart Container (Mason, MI), and W. R. Grace (Reading, PA) have not changed ownership since 1993. All producers except Amoco and Tenneco specialize in one or two market segments and often compete within a limited geographic area.

Because foam is lightweight and parts are generally three or more times thicker than parts made from competing materials, storage and transportation costs represent a much higher proportion of costs. Shipping products within one day's drive (400–500 m or 600–800 km) from the manufacturing facility can hold transportation costs under 5% of the selling cost. Some makers have been able to offset this somewhat by the use of laminates. In some applications, such as fast-food or carryout packaging, where retail storage is minimal, the value of this thickness reduction more than compensates for its increased cost. For the most part, however, foam producers have found it generally more cost effective to locate near key markets. This easily offsets economies of scale from larger production facilities. Only in the case of specialized products can manufacturers ship products farther than a day's drive.

PRODUCTS, USES, AND APPLICATIONS

The primary packaging applications for foam trays are fresh meat, poultry, and eggs. There is also considerable usage for packaging carryout foods in restaurants, although that market segment has dropped considerably since McDonald's discontinued using clamshells for hamburgers. McDonald's still uses large quantities for packaging breakfasts. There are minor quanitites used for a variety of industrial packaging applications, primarily as cushioning. Because disposable tableware is used for immediate food consumption and is not meant to protect food for transit to another location, it will not be discussed here.

The major application is for packaging fresh meat, with about 8 billion trays. These trays are sold to supermarkets and grocery stores, which cut and package meat in the back room to display in self-service cases. Because a red, watery fluid called "purge" oozes out of the meat, an absorbent pad is placed in the tray just prior to placement of the meat. The entire package is wrapped with a clear film, usually poly(vinyl chloride) (PVC). Wrapping is now done on manual or semiautomatic equipment. The package is placed on display in a self-service case for a maximum of 2–5 days depending on the freshness life of the meat cut.

The industry has developed fairly standard sizes and colors, although there is some variation by producer. Most supermarket foam trays are white, although there is growing interest in other colors. Rose has been used for pork more frequently, blue for fish or seafood, green for produce, and yellow for poultry. Within the past 5 years, the use of black has grown dramatically, especially for upscale or niche products such as natural beef, low-fat meats, or marinates. Even though nearly any shape or size is possible, most of the industry has standardized on a set of shallow, square trays, partly for merchandising and partly for cost savings (see Table 1). Most meat and seafood trays are about $\frac{1}{2}$ in. (13 mm) deep, which allows most cuts to be observed from three sides. Poultry trays are typically ≥ 1 in. deep (25 mm), because of greater purge and typical practice of packing more product in each tray. Product trays are often as much as 3 in. (75 mm) deep because of the greater height of the product.

In the mid-1960s, many supermarkets began to discontinue cutting chicken for sanitation and cost reasons in favor of purchasing it already cut and packed in foam trays. Holly Farms (now Tyson) led the industry with its "deep chill" technique of crust-freezing the chicken with a quick blast at -40°F (-40°C), usually after packing it in the tray. This technique gave chicken up to 18 days' shelf life for travel to the retail store and sale. The poultry industry also began using high-speed wrapping machines to gain efficiency. The deep-chilling, longer life, and high-speed wrappers were too demanding for lightweight supermarket trays, so Amoco, Grace, and Tekniplex developed heavier gauge trays (150–200 mils or 3–5 mm) to address this market. Increasing demands from wrapping machines have led to not only increased tray weights but also design changes such as gussets and bowed sidewalls. The processor segment now accounts for about 3 billion trays and has grown much faster than the total market as a result of increasing poultry consumption.

Because of environmental pressures and easy substitution, pulp has regained considerable market share in the 3-billion-unit egg-carton market, where the wet strength of foam is less of an advantage. The primary size are for one dozen large eggs, although half-dozen and 18-count packages are available. Colors are primarily white or yellow. Most packages are printed off-line with the packer's name. Dolco is the major producer in this market.

Although produce uses almost 2 billion trays, less than a quarter are foam, with the remainder being pulp, oriented polystyrene, and injection molded. Trays are sold to both supermarkets and packers for packing tomatoes, mushrooms, corn, and a variety of other items. A small number goes to various berry packers. Cut fruits and vegetables are sometimes packed in supermarket trays. Because of consumer preferences for bulk produce, industry fragmentation, environmental pressures, and questionable need for rigid packages for many items, foam trays have made little progress gaining usage in produce. Seafood is similarly fragmented. Tray usage is confined largely to frozen items, with fresh products sold over the counter wrapped in paper. Miscellaneous other foods such as pasta, deli meats and cheeses, and prepared foods are also wrapped foam trays using typical processor or supermarket sizes.

A new development in foam trays is the *barrier-foam trays* (see the Trays, barrier-foam article). This product is a composite of a barrier film laminated to foam sheet then formed into trays. This tray can be evacuated and/or gas

flushed and sealed with a barrier-film lid to make an extended-shelf-life modified-atmosphere package. It is used for precooked chicken, fresh turkey, and fresh sausage in the United States. Beef and prok are also packed in them, mostly in the United Kingdom.

Other Packaging. Hinged-lid or clamshells for carryout packaging address a market of 4–5 billion trays. These trays are only designed to hold food for 1–2 h, or long enough to protect it from the kitchen to the point of consumption. They are popular for this application because of low cost, wet strength, and ability to hold food hot or cold for up to 30 min.However, they are not leakproof, and the tab holding the lid closed does not stand up well to transport abuse. The primary users are fast-food chains, restaurants, and institutional feeders. These customers also use large quantities of foam trays, plates, and bowls.

Protective packaging has been a minor market for foam trays. Volumes per part are much lower; thus, mold costs become a significant expense. In addition, thermoforming generally cannot do the vertical sidewalls and intricate details required to hold a product in plate for transit. For these reasons, bead molding of expandable polystyrene beads has been the preferred material for these applications.

ENVIRONMENTAL ISSUES

Polystyrene foam containers came under aggressive attack by environmental groups in the late 1980s and early 1990s. They were fingered for a variety of enviornmental ills, from creating holes in the ozone to filling landfills to over capacity to litter problems to choking water animals. Although the industry began a vigorous lobbying and public relations campaign to show that these notions were greatly exaggerated or erroneous, much damage could not be prevented. Several local governments, notably Suffolk County, New York on Long Island; Berkeley, California; and Portland, Oregon, placed outright bans on the product's use. Even though Suffolk's law was later rescinded, others are still in place. Other locales such as Minneapolis and the State of California have passed sweeping recycling mandates that foam and other plastic containers will have difficulty meeting.

Most producers used a blowing agent called CFC, which is also known by the DuPont trade name Freon 12. In 1987, the Montreal protocol established a timetable for halving CFC use by 1999, because these compounds react with ozone in the upper atmosphere, which reduces the filtering of ultra violet rays provided by the ozone layer. Then, McDonald's placed a moratorium on using packages with CFCs in 1988, forcing users to seek alternatives. Although foam was actually a very small consumer of CFCs relative to air conditioning, refrigeration, and electronics manufacturing, its visibility with McDonald's caused it to receive an inordinate share of the blame for ozone depletion. Many foam producers switched to a hydrochlorofluorocarbon (HCFC), which had less than 5% of the ozone-depletion potential of a CFC but at a much higher cost. But in 1990, the Montreal protocol was updated to eliminate all CFCs. Now, most producers have been forced to switch to hydrocarbon blowing agents, although Dow's CO_2 process is used by a few.

One main issue with foam trays is its supposed contribution to the solid-waste problem. Whereas the industry convincingly proved that polystyrene foam accounted for less than 0.5% of landfill weight, again visibility caused it to be a target. The package was also faulted for lack of biodegradability, although it was clearly shown that nothing degrades in a landfill. The industry, particularly Amoco, Mobil, and Dart, countered this with lobbying, public-relations efforts, and developing three recycling plants, which now operated by the National Polystyrene Recycling Company, a joint venture. McDonald's even participated briefly in a recycling program, prior to its decision to discontinue using foam.

Even though the industry gradually recovered from the CFC and solid-waste issues, it slowly began to face a new one. The hydrocarbon blowing agents are volatile organic compounds (VOCs), which most states are restricting to protect air quality. In many states, it is virtually impossible to expand, others require an environmental impact study before issuing a permit, and California is demanding outright reductions. Thus, most producers are vigorously pursuing new blowing-agent technologies that will allow for expansion.

TUBE FILLING

Thomas Miller
T. J. Boedekker
IWKA,
Fairfield, New Jersey

Industrial production of collapsible tubes in two processes that include the following:

1. The manufacture of an empty tube.
2. Filling and closing of the tube.

Most tube-filling and tube-closing machines can handle different tube shapes, materials, and a large variety of filling products by means of versatile accessories. Different tube shapes such as round, oval, conical, and cylindrical can be handled with the use of size parts. Cylindrical tubes range within 10–52 mm in diameter and 50–250 mm in skirt length. Tubes are made from metal (aluminum, lead, tin) or laminates (foil laminates, plastic laminates). Filling materials range from thin products (shampoo), or cremes (toothpaste, ointment), to extremely viscous materials such as caulking compounds.

Depending on the different materials, production speeds range from within 30–200 tubes per minute. A speed of $\leq 120\,\text{min}^{-1}$ single-lane machines are used, where as two-lane machines are common for higher speeds. All tube fillers are using an intermittent production process in which tubes, positioned in tube holders or pucks, are indexed at consistent speed and spacing through the workstations.

TUBE FUNCTIONS

The working process of a tube-filling/closing machine can be divided into four main functions.

Tube Handling. For lower speed, tubes are fed manually by infeed conveyors or chutes into the machine. Medium-speed machines are typically fed by cassettes or magazines. High-speed machines are normally equipped with their own tube loader that picks up tubes row by row from the case and feeds them on to conveyors to the first workstation (Figure 1). The tube is put into vertical position and pushed into the tube holder. For safe operation, the tube should not be dropped by gravity. The preferred method is tipping of the tube by suction blocks into the tube holders and vacuum cups for tube discharge. A rotary turret, driven by a Ferguson-type indexing gear, which runs in an oil bath ensures precise positioning of the tube through the workstations. This method guarantees safe and maintenance-free operation for many years.

Tube Preparation. Several machine stations perform different functions prior to filling and are as follows:

- Checking for presence of cap and cap tightening by means of sensors and adjustable clutches or torque-controlled motors.

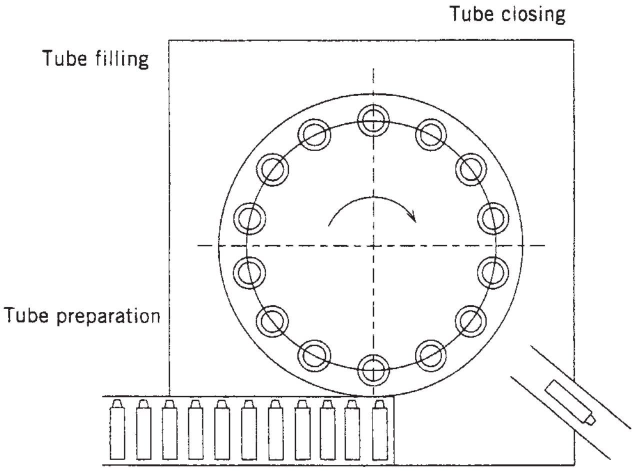

Figure 1. Tube handling.

- Checking for damage to the open end of the tube by mechanical or photoelectric sensors.
- Cleaning of the tube by clean-air blast and vacuum; also purging of the tube with inert gas to reduce the amount of residual oxygen in the filled tube.
- Printing registration and code verification by means of photoeyes and scanners. Tubes are rotated and adjusted by means of clutch brakes or servomotors. Ink-jet coding of the tube can be done while the tube is rotating.

Tube Filling. The tubes are filled by a filling nozzle that dives into the tube before the filling process. As the material is discharged from the nozzle, the nozzle is retracted out of the tube, keeping a constant distance between the nozzle outlet and the rising level. This relative movement between the tube and the filing system ensures continuous filling without air entrapment. After the predetermined amount of filling material has been discharged, the filling material, which in most cases tends to string, has to be cut off and—depending on the behavior of the material—several different nozzle-cutoff systems are available (Figure 2).

Most tubes are filled with a single product. But more applications have developed, mostly in the toothpaste industry, where two or three different components arranged in stripes over the whole tube length have to be filled. This so-called deep-stripe filling system is becoming more popular than the conventional surface stripes (Figure 3).

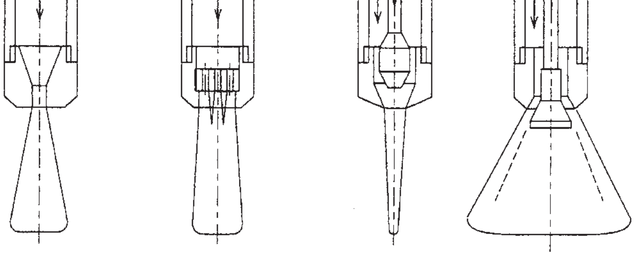

Figure 2. Different types of nozzle systems.

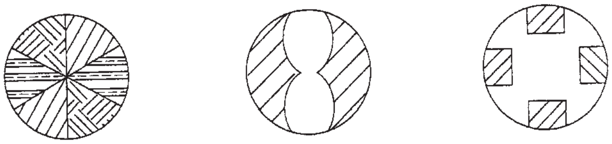

Figure 3. Cross sections of deep-striping.

Although filling nozzle systems depend mostly on the filling product, a basic common design for the dosing system is used, which comprises a volumetric pump dosing system consisting of cylinder and piston with two valves or a three-way rotary valve. One of the most critical parts of this system is the seal between the piston and the cylinder. For abrasive products such as toothpaste, the necessary sealing materials must be carefully selected. The typical cup seals made from polyurethane, Viton, PTFE, or polyethylene are subject to wear and have to be replaced at regular intervals. As an alternative, ceramic components can be used. Unlike ceramic coatings, solid ceramic parts (e.g., aluminum oxide) have absolutely no pores and combine very high hardness and resistance to wear with excellent chemical resistance and food-grade characteristics.

Parts in contact with the filling material in tube fillers easily can be dismantled, cleaned, and sterilized. To avoid any risk of microbiological contamination during assembly of a clean system, the assembled unit can be sterilized in place. These so-called clean-in-place (CIP) systems are used more and more in the pharmaceutical industry.

Tube Closing. Different materials require different types of closure. Normally, most tube fillers are equipped for one type of tube closure.

TUBE TYPES

Metal Tubes. Metal tubes are closed by folding, which means that the tube end is flattened and folded over. Various types of fold are possible: double fold, four fold, and saddle fold (Figure 4).

The actual folding process is carried out by two folding jaws and a hinged folding tool. For the required precision and speed, the system is cam-driven. In many cases, a latex or heat-sealable lacquer is applied inside the fold area for a hermetic seal.

Foil Laminate Tubes. The safest method of sealing plastic tubes with a thin aluminum foil layer is high-frequency sealing. High frequency generates an eddy current in the aluminum layer, which heats up the aluminum and the neighboring plastic layers (Figure 5).

Plastic Tubes. Today the most common tube material is plastic. Originally polyethylene was used in a single layer and the tubes were sealed between heated jaws as shown in Figure 6. The system applies heat on the outside of the

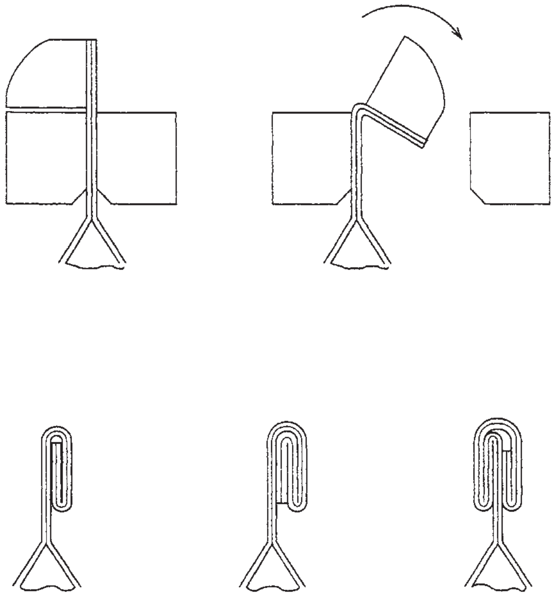

Figure 4. Metal tube folds.

tube to heat to the inside for sealing. This process is less efficient than high-frequency sealing, where the heat is generated directly at the inside layer to be sealed. Consequently, the hot-jaw system requires a longer heating time and, therefore, a reduced cycling speed. This reason is why this system is hardly used today in new machines.

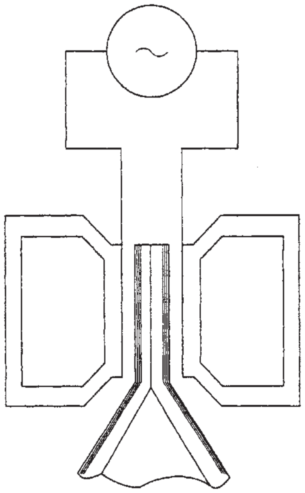

Figure 5. High-frequency sealing system.

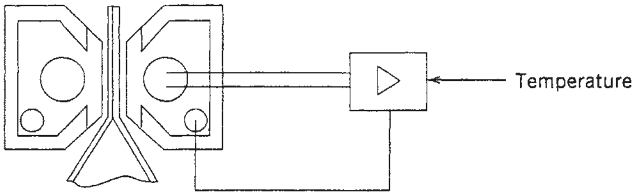

Figure 6. Hot-jaw sealing system.

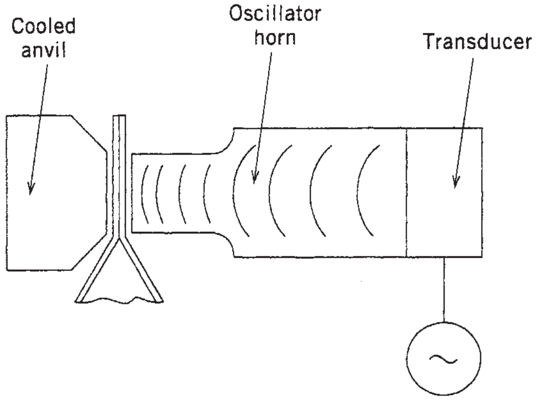

Figure 7. Ultrasonic sealing system.

Another method for closing plastic tubes is ultrasonic sealing (Figure 7). This system applies mechanical vibration to the outside of the tube, which induces friction, which—in turn—generates heat to seal the tube. This sealing method is suitable only for moderate speeds.

Because of the above-mentioned restrictions, the preferred method for sealing laminated and plastic tubes today is hot-air sealing. This system heats the seal area inside the tube by hot air. In a subsequent station, the tube is then pressed and chilled (Figure 8). The system is suitable for speeds well in excess of 100 min^{-1}.

The pressing station for the hot air system is also necessary for the other types of tube closure. It provides a tight seal and improves the aesthetics of the tubes, it

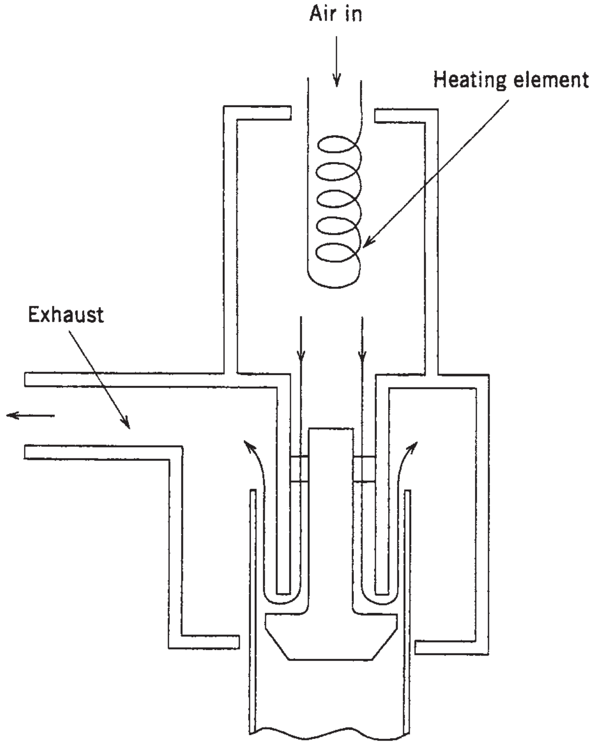

Figure 8. Hot-air sealing system.

also is used to apply a code (i.e., batch number or expiration date).

All modern packaging machines are equipped with programmable logic controllers (PLCs) to control and monitor all machine functions. Clear text displays are used to guide the operator and to provide information about the production process, such as machine speeds and number of packs produced. Interface for data link for central line controls are available.

TUBES, COLLAPSIBLE

Christopher White
The Tube Council of
North America

The collapsible tube, be they aluminum, plastic, or laminate, is a most unique package allowing the user ease of dispensing and, where necessary, application of product directly to the area of use. The tube is a perfect package for viscous products such as dentifrice, pharmaceutical creams and ointments, cosmetic creams and gels, and household and industrial products.

The tube definitely is a package for food products where the contents can be conveniently used in precise amounts when required. Examples of food products contained in tube abound in the European and Asian markets. Examples such as tomato paste, fish and meat paté, garlic paste, and dessert toppings can be found in gourmet shops around the world. But other food products in tubes may include preserves, mustards, chocolate sauces, mayonnaise, mustard, and cheese spreads. In short, the tube is ideal for delivering the product to the consumer's toothbrush or dinner table, given creative application and packaging technology.

The Tube Council of North America reported that Americans purchased nearly 15.0 billion tubes in 2003. The market for products packaged in tubes continues to grow fueled by new materials and the consumers hunger for convenience in their life.

The first tubes, manufactured back in the mid-1800s, were for artist colors. Shortly thereafter, in 1893, a dentist by the name of Dr. Sheffield saw the convenience his patients could enjoy if the tube could contain dental cremes, replacing powders and the use of a rather unsanitary common jar—hence, the toothpaste tube with all the benefits. The original tubes were produced from soft metals, mostly tin or lead or an alloy of these. The aluminum tube was introduced in the mid-1950s and has been consistently improved in the years that followed. Today, the metal tubes are predominantly aluminum. The only tin tubes are for special pharmaceutical applications, mostly ophthalmic. The 1170 Aluminum Alloy used by tube manufacturers in North America is the highest purity available. The 99.7% pure aluminum is virtually free of trace substances and extrudes a seamless package. New, high barrier internal liners and specially sealed necks made the aluminum tube the package of choice for products requiring an absolute oxygen barrier. Additionally, aluminum tube decorations utilizing the metallic surface add unsurpassed luster to the appearance of the package (see also Decorating).

In the 1950s, metal tubes were joined by the plastic tube. The immediate appeal of plastic was obvious to every manufacturer of cosmetics and hair care products. The plastic tube kept its "just home from the store" look through its life in the bathroom or vanity. It could be extruded in clear or colored resins to enhance the package aesthetics. The plastic tube perfectly complemented the aluminum tube and allowed the launch of a whole new range of products not previously found in tubes.

In the early 1970s, laminate tubes joined their metal and plastic cousins. The barrier properties of laminate, coupled with the limited suck back of air accomplished by the inclusion of an aluminum foil layer, gave laminate greater product appeal for products such as toothpaste. In the ensuing years the laminate tube effectively captured the dentifrice market. It has now been selected to package products as diverse as mayonnaise and vaginal cream. The laminate tube surface may be printed on the web, allowing an eye-catching graphic presentation, even including scenic images or the human likeness.

THE METAL TUBE

The aluminum tube production process starts with an aluminum slug roughly varying in size from a dime to a silver dollar. The slug will be the approximate diameter of the tube and the slug thickness predetermined to minimize trimming to the length prescribed by the customer. The slug will either be a donut, having a center hole, or a solid. The solid slug is most often used to extrude a one-piece tube with an integral diaphragm forming the tamper-evident sealed neck feature. The tube manufacturer may elect to use flat or dished slugs, depending upon the design of their production equipment and tooling.

State-of-the-art aluminum tube production line commonly run at speeds varying from 200 to 500 tubes per minute. The slug is impact extruded one up; that is, one tube is made one at a time, three times per second. Aluminum tube lines are readily available from machinery suppliers in Europe, including Polytype and Hinterkopf.

The aluminum tube is formed by impact extrusion accomplished horizontally. The tube slug is first tumbled with a lubricant, generally zinc stearate, USP. It is then fed into position in from of the shaft, and the press moves forward with an impact forces of 80–100 tons, depending upon the diameter and, to a lesser extent, the thickness of the slug, which prescribes the length of the tube. A section of the typical tooling setup is shown in Figure 1. The male tool head matches the inside profile of the final tube. The largest diameter is only $\frac{1}{32} - \frac{1}{16}$ in. (0.8–1.6 mm) long, after which it tapers back to a diameter that runs around 0.008 in. (0.2 mm) smaller than the tip. The clearance between the male tool and the female cavity establishes the wall thickness of the tube sleeve.

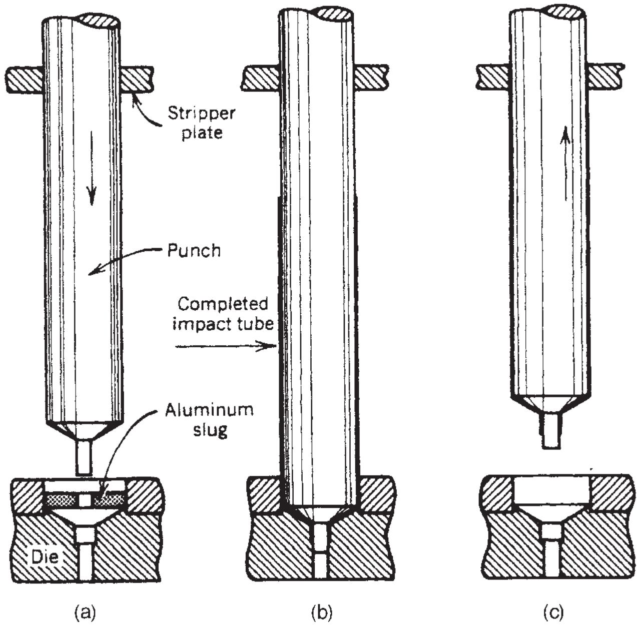

Figure 1. Impact extrusion of a metal tube: (**a**) beginning impact stroke; (**b**) bottom of stroke, (**c**) beginning to strip. (Courtesy of Herlan & Co.)

The slug is automatically fed into the cavity and is compressed by the male tool as it moves down. The first portion of the stroke seats the slug and takes up the bearing slack of the press. The balance of the stroke cold-works the slug, forming the head of the tube. As the plunger continues moving down, the excess metal is extruded out around the sides of the plunger, forming the body. Since the metal never reaches its melting point, the body is cold enough to maintain its shape and additional support from the tooling beyond the head area is not required. As the plunger moves back at the end of the stroke, the completed tube is stripped off, falling into a transfer conveyor, which takes it to the trimming operation. Here, the body is trimmed to exact length, cap threads are rolled onto the neck, and the mouth of the tube is trimmed.

By now the tube has been severely work-hardened and has the feel of an aluminum can. To relieve this hardness, it is annealed in an 1100°F (593 °C) oven and cooled, after which a spray application of a product-resistant lining is applied. A number of tough epoxy–phenolic or acrylic lacquers are available that not only resist the attack of the product but can be creased without chipping or peeling from the ???. “After the internal lining has been cured, ??? with either a white or colored base coat, usually enamel or, optionally, an acrylic, polyurethane, ??? gives an opaque printing base to the tube sidewalls. The shoulder of the tube may also be coated to complete the look desired. Another base sidewall coating involves the use of clear or translucent lacquers that utilize the aluminum surface to achieve a metallic appearance.”

Metal tubes are printed by a dry offset process (see Decorating; Printing) using either thermally or UV-cured inks (see Curing; Inks). The tube is pushed on a mandrel and rolled past a curved printing blanket, which applies up to six colors simultaneously. The tube now goes through a final drying cycle to cure the ink, after which the cap is applied and the tube is automatically packed in boxes for shipment, usually nested in a dividerless tray, for shipment to the customer.

PLASTIC TUBES

The first practical plastic-tube patent was issued in 1954 (1). The patent covered the process of making a thin plastic sleeve by an extrusion method (see Extrusion) and then injection-molding (see Injection molding) a head on one end to produce a tube. Modern equipment has improved but has not changed the basic Strahm concept.

Many plastics can be used to make plastic tubes; LDPE, MDPE, HDPE, LDPE are the primary materials used today (see Polyethylene, Low-Density). It has high-moisture-barrier properties, low cost, and good appearance. Its lack of oxygen and flavor barrier have been improved with barrier coatings. It was the development of a barrier coating by American Can Co. that made the plastic tube a practical container for general packaging.

HDPE (see Polyethylene, High-Density) is used for packaging some hydrocarbon-based products such as grease, and PP (see Polypropylene) is used for applications requiring nonstraining, better perfume barrier, or higher temperature resistance. Both HDPE and PP are much stiffer than LDPE for tube sidewalls and are not as popular.

COEX tubes, a coextrusion of EVOH and polyethylene, has been demonstrated to have excellent barrier properties enabling manufacturers of products that are adversely affected by air or moisture transmission the option of using the plastic tube. It was quickly adopted by toothpaste manufacturers where flavor loss in conventional plastic tubes was unacceptable. The COEX tube is often specified with a stand-up hinged cap. The COEX tube, otherwise, has all the functions of plastic.

The selection of a suitable plastic for producing a tube is critical to its performance. DuPont Alathon 2020T, a 0.92-g/cm^3-density resin with a melt index of 1.0, is the primary LDPE resin used by all tube manufacturers in the United States. It has good processibility, excellent stress-crack resistance to product attack, and an extremely low gel content, which reduces surface irregularities that would affect printing quality.

Plastic tubes are produced by two principal methods in the United States: the Strahm method and the Downs method. Both processes make excellent tubes.

Production of the tube begins with the extrusion of continuous thin-walled tubing (2). This has a wall thickness of 0.014–0.018 in. (0.35–0.46 mm), depending on the diameter. A standard extruder is used with a thin-walled tubing die. As the hot plastic emerges, it is corona-treated (2) (see Surface Modification) for later printing-ink adhesion. At the same time, it is drawn over a chilled internal forming mandrel and cooled on the outside with cold water. The tube cools and shrinks to an accurately controlled diameter as it is drawn off. After it has passed through the drive rolls of the haul-off unit, it is cut to exact length with a rotary knife cutter. This piece is called a sleeve to differentiate it from the completed container, which is called a tube.

Printing can be done before or after heading. The location is based on the layout and the relative scrap generated in printing and heading. All tubes are printed by dry offset printing. The same type of printer used for metal tubes is used for plastic sleeves. Thermally dried and UV-dried inks are available in a full range of colors. Good-quality process printing is possible, and for cosmetic applications, postdecoration with hot-stamp foils or silk screening is popular (see Decorating).

After the ink has cured, the sleeves are roller-coated with a high-gloss, oxygen- and flavor-barrier coating. High-barrier, two-component amine-cured epoxy coatings are available that reduce the overall tube permeability by a factor of 10. Special coatings more resistant to product staining or having lower coefficients of friction are also used. Most coatings are thermally cured, but UV-curable coatings are beginning to be used. These provide equally high barriers to oxygen and essential oils and cure more quickly. After the coating is cured, the completed sleeves are headed.

The head of a plastic tube must be compatible with the sleeve in order to produce a good bond. Sleeves made of LDPE can be headed with LDPE or HDPE, but PP sleeves must have a PP head. Head thickness is 0.030–0.065 in. (0.76–1.65 mm), depending on tube diameter and application.

The Strahm heading process traps the top end of the sleeve in an injection mold and injects plastic into the cavity to form the head and bond it to the sleeve. The process is done with multiple tools at each station. Slower machines have a female tool that remains in the injection station, and the tube is held there until it has cooled sufficiently before moving to the next position. The higher-speed machines have locked-die tooling, as shown in Figure 2. The male tool containing the sleeve is pushed up into the shoulder cavity. The end of the sleeve enters the shoulder cavity, rolling in slightly as it touches the radius of the shoulder. At the same time, the support sleeve, which moves with the male tool, contacts the shoulder cavity, lifting it up against the thread plates. This forces the plates together in the position shown in Figure 2. The injection nozzle now closes on the assembly, and molten plastic from a small reciprocating-screw extruder is injected to form the head and bond it to the sleeve. Injectioncavity pressures are low since excessive pressure causes "blowby," forcing plastic past the head area and down the sleeve wall. Melt temperature of the plastic is generally over 500°F (260 °C), high enough to ensure a good fusion seal to the sleeve wall. After the injection cycle, the nozzle retracts. The tooling remains locked together and continues to the next station. After the head cools, the male tool drops, the thread plates open, and the completed tube is released, remaining on the male tool. The die body and cavity support move off to one side to allow the completed tube to be extracted. A new sleeve is then placed on the tool, the female tooling moves over the top of the male tools, and the cycle is repeated.

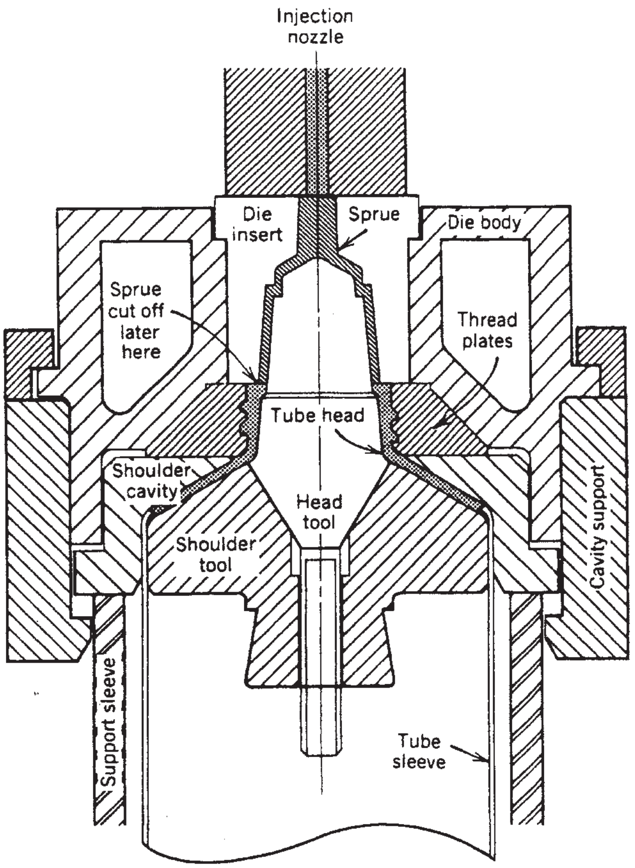

Figure 2. Strahm heading method.

After cooling, the completed tube is transferred to a snipper-capper. Here, the sprue is removed and a cap is applied, after which the tube is packed in unpartitioned trays for shipment to the customer.

In the Downs process (3, 4), the sleeve production is the same but the heading process is considerably different. As shown in Figure 3, the sleeve on its male tool enters a punch, which is placed just above a continuous strip of LDPE heated to well above its softening point. This strip is ~2 in. (51 mm) wide and $\frac{1}{8}$ in. (3.2 mm) thick. When the leading edge of the sleeve is about flush with the cutting edge of the punch, both parts move down into the semi-molten mass below. The punch forms a disk of plastic the diameter of the sleeve, and the sleeve inside the punch immediately adheres to it. The tool moves up, carrying the sleeve bonded to the hot plastic disk and indexes to the next station. Here, the female tool closes on the sleeve and head disk, compression-molding the head into its final shape. The compression-molding method eliminates the sprue and the snipping operation necessary with the Strahm process.

More recent commercial Downs machines have multiple heads at each station to make a number of tubes simultaneously.

A third process, developed by KMK (Karl Magerle AG Hinwil, Switzerland) (5), injects a "donut" of molten plastic in the female cavity before it closes on the male cavity. The head is formed by compression molding. The Magerle

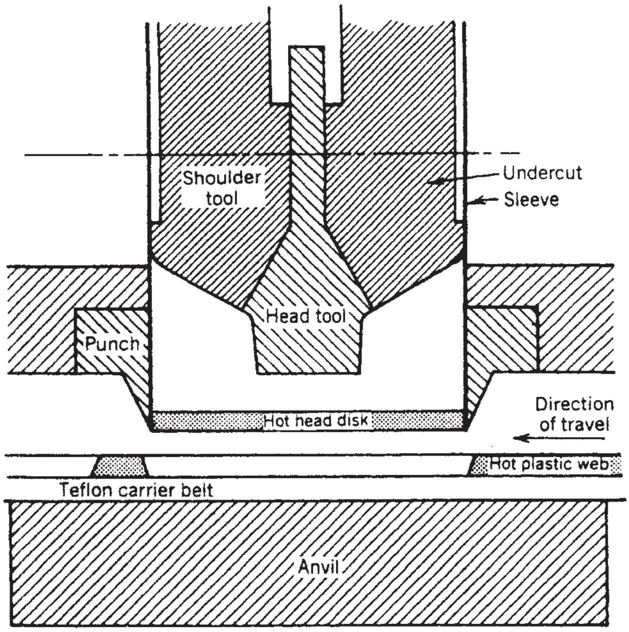

Figure 3. Downs process; head disk just after blanking out.

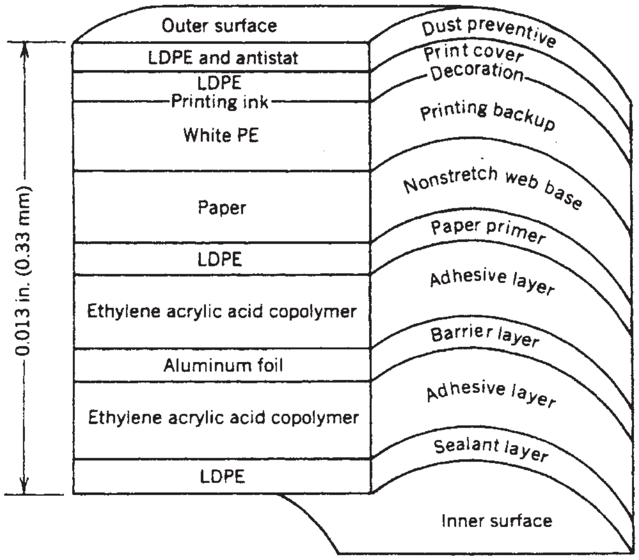

Figure 4. Typical structure of a laminate toothpaste tube.

machines are small, with only one tool per station, but they also incorporate capping on the same turret.

Although these are the most common methods, other processes have been developed. In Europe, the Valer Flax process (6) uses a premolded head that is spin-welded to the sleeve. Several companies have developed blowmolding methods (7) where the tube is blown as a bottle and the bottom is trimmed off. This approach generates a high amount of scrap that must be put back into the process, and care must be taken to maintain uniform wall thickness for the later printing step.

LAMINATED TUBES

In 1971 Procter & Gamble switched their Crest dentifrice to a laminate tube. The laminated material (see Laminating Machinery) consisted of seven layers with paper, plastic, and foil acting as the barrier. The foil was far superior to the plastic tubes then available and minimized flavor loss to acceptable levels. The laminate replaced the lead tube then being used by P & G for Crest.

The chief difference between this package and the plastic tube is the sleeve, made from preprinted laminate web (8, 9). It contains up to 10 layers, each contributing to the function of the structure. Figure 4 shows the material in each layer and describes its use. The complete laminate, 0.013 in. (0.33 mm) thick, is produced on an extrusion laminating line (10). This web is made in large rolls that are slit into the proper width for the tube being made. The slit rolls are shipped to the tube plant, where they are formed into sleeves. The sleeve has an impermeable aluminum layer, so the only permeation is along the seam overlap.

The seaming process takes the flat web, folds it into cylindrical form, and seams it to form a continuous tube (11). The seam must protect the raw edge of the foil; this is achieved by overlapping the edges of the sleeve, then heating and compressing the overlapped portion to squeeze some of the plastic out around the raw edge of the foil and paper. After the sleeve has been seamed, it is cut to length using the print registration marks on the web.

The presence of aluminum foil in the sleeve permits use of rf energy for induction heating (12). This is preferred in the seaming process because it permits better control of heat distribution.

To take full advantage of the vastly improved barrier properties of the laminated sleeve, an oxygen and flavor barrier is necessary in the head area. This is accomplished with a premolded insert (13) of polybutylene terephthalate (PBT), which has good oxygen- and flavor-barrier properties, can withstand the injection pressures and temperatures of the heading plastic, and does not crack in the head. Urea inserts are also used. The insert is placed on the heading tool before the sleeve is placed in position, and the head plastic locks the insert in position as it bonds to the sleeve. The resultant tube has some permeation windows along the sleeve seam and the area where the head bonds to the sleeve, but the result is still a very low gas and flavor permeability.

Alternative methods of producing laminated stock and tubes have also been developed, as well as alternative materials.

The American Can approach for seaming requires the axis of the tube to be parallel with the length of the laminated web (11). KMK has developed another system (14), where the axis of the tube is perpendicular to the web. In this process, the blank is cut from the web and wrapped around a fixed mandrel and sealed. KMK uses the heading process described under the plastic tube section above.

Another Swiss manufacturer, AISA (Automation Industrielle SA), has produced a machine using premoled heads that are bonded to the sleeve with rf induction (15). To ensure a good bond, a foil laminate disk, called a rondelle (16), is placed over the shoulder of the tube. The sleeve is butted against the rondelle, and the rf bond is made. This approach still requires a urea or PBT insert to act as a flavor barrier.

NEW TUBE CONCEPTS

The relatively recent appearance of ethylene–vinyl alcohol (EVOH) (see Ethylene–vinyl alcohol) as a clear barrier plastic has made possible the development of an all-plastic barrier tube (see Barrier Polymers). Coextrusion methods are available for producing laminates, and the Japanese have produced coextruded sleeves and blow-moled barrier tubes (7). The latter tubes have a continuous barrier; that is, there are no higher permeation areas such as side seams or head bonds. At present, the all-plastic barrier tube is not economically competitive with a laminated structure. EVOH costs about the same as aluminum foil, so there are no material cost savings involved. The advantage of being able to print flat web is an important factor in the cost of the laminated tube which would appear to limit the appeal of this new concept. However, a significant drop in the price of EVOH relative to aluminum foil or the development of a new market where higher-barrier properties are required could quickly change its importance. As well as the newest tube, polyfoil, made by Plastube of Canada.

VACUUM PACKAGING

Richard Perdue
Taylor, South Carolina

From World War II came plastics, the wide commercial application of mechanical refrigeration, self-service supermarkets, the superhighway system, and a growth economy. During the late 1940s, Dewey and Almy Chemical Company purchased the patent and brought a new and unique French packaging development to the United States. The first significant commercial application of this concept was for vacuum packaging of whole turkeys using rubber stretch bags. These were soon replaced with PVDC shrink bags. The concept led to the wide commercial use of vacuum packaging for perishable (refrigerated and frozen) food: the Cryovac (registered trademark) vacuum-packaging process. In the $\geq$45 years since, many individuals and companies have contributed to the technical advancement and wide successful commercial use of vacuum packaging for the preservation, distribution, and marketing of perishable foods. In future annals of history, vacuum packaging of perishable foods in flexible and semirigid plastic films should be ranked right up there with canning, pasteurizing, and quick-frozen foods as a technological breakthrough that contributed greatly to improving the quality of life for humankind!

Vacuum packaging involves the placing, either manually or automatically, of a perishable food inside a plastic film package and then, by physical or mechanical means, removing air from inside the package so that the packaging material remains in close contact with the product surfaces after sealing.

Packaging in this manner, depending on the product being packaged the barrier properties of the packaging material, the level of air removal, and storage temperature, can substantially retard chemical and/or microbial deterioration of the food product. In many instances, this dramatically extends eating quality life.

AIR-REMOVAL SYSTEMS AND PACKAGING EQUIPMENT

Nozzle Vacuuming. Using this method of air removal, a nozzle connected to a vacuum pump is inserted inside the open end of a preformed bag or pouch (see Figure 1). The vacuum or air removal level using the nozzle system is seldom high, as the packaging material (depending on its modulus) quickly collapses onto the product surface and blocks significant air removal. Today, nozzle vacuumizing is widely used for packaging whole fresh and frozen poultry, fresh-cut vegetables and bulk packaging of fresh meats, poultry, fish, processed meats, nuts, and so on.

For whole poultry, manual and high-speed rotary nozzle machines that provide an aluminum clip closure are used. The twisting of the bag neck and clipping provides for good whole-bird shaping and sealing under high-moisture conditions. Nozzle vacuumizing provides for good bag to product (bird) cling, without collapsing the body cavity as can happen with high-vacuum-chamber systems.

For cut vegetables and bulk packaging, manual and semiautomatic nozzle vacuumizing combined with heat sealing predominates.

Chamber Vacuumizing. Using this method, the product is placed inside the flexible plastic film package, which is loaded into the bottom section of a vacuum chamber (Figure 2). Such systems usually consist of a top chamber and a bottom chamber. The chamber is closed, and a high vacuum is [in both cubic feet per minute (cfm, i.e., mL/min) and inches of mercury (in. Hg)] drawn on the chamber both inside and outside the package. Some chambers are usually vacuumized to $\geq$29 in. Hg.

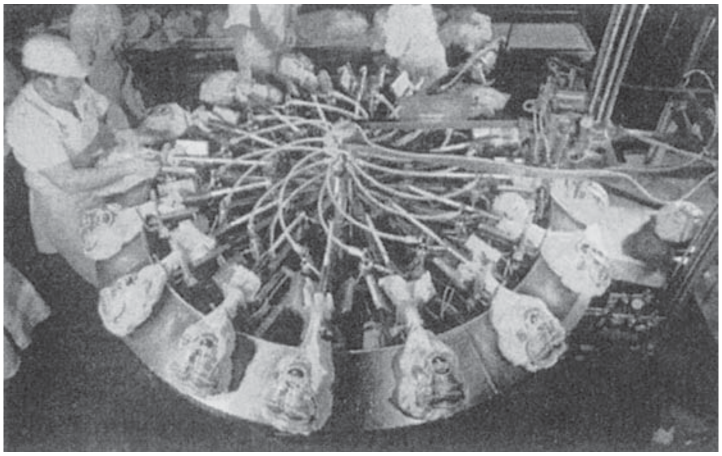

Figure 1. Nozzle vacuuming.

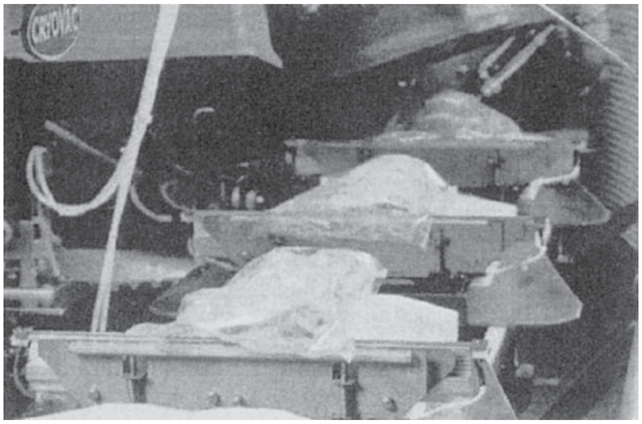

Figure 2. Chamber vacuumizing.

Chamber vacuumizing machines generally employ heat-seal closures and are available from manual through fully automatic rotary high-speed units. Such equipment uses shrink bags and laminate pouches. They are widely used to package fresh primal and subprimal meat cuts, smoked and processed meats, and natural cheeses. Some chamber units are also available that provide an aluminum clip closure inside the chamber.

Two other widely used chamber vacuumizing systems use rollstock films rather than preformed bags and pouches: thermoforming and vacuum skin packaging (VSP).

Thermoforming. Thermoforming vacuum-packaging machines dominate the packaging of consumer units of wieners, sliced luncheon meats, sliced bacon, smoked sausages, and some natural cheeses (Figure 3). Such machines operate using two rolls of multilayer (usually high-O_2-barrier) plastic film (top and bottom webs). The operation of a thermoforming machine involves feeding the bottom web into the machine by clamping the web by its edges and indexing it either (a) over a continuously moving train of thermoforming dies (pockets) or (b) in a parallel set of clamping chains that first indexes the bottom web over a thermoforming station. In both web-handling modes, the bottom web is heated, then vacuum and/or pressure formed.

The product is manually or automatically loaded into the formed pockets. The top web is then fed down over the bottom web between the two halves of the vacuum-sealing chamber. The two halves of the chamber close and a high vacuum ($\geq$29 in. Hg) is drawn on both sides of both webs and around the product. When the desired vacuum level is reached, the webs are heat-sealed together. The chamber(s) is (are) vented to atmosphere, opened, and the packages indexed out the machine and slit into individual units (see the Thermoforming article).

Vacuum Skin Packaging. There are great similarities between VSP (Figure 4) and thermoforming machines, with the primary differences involving how the forming web (bottom web in thermoforming and top web in VSP) is thermoformed and the plastic film structures used. Like thermoforming in an automatic VSP machine, the bottom web is fed through the machine by a parallel set of clamping chains. The bottom web may or may not be thermoformed slightly. It can be an oxygen barrier, nonbarrier flexible, or semirigid web. Again, as with thermoforming, the product is loaded onto the bottom web, a top web is fed down over the bottom web, and both are indexed between the two halves of a vacuum (skin) packaging chamber (see the Skin packaging article).

As the top web is fed down and into the VSP chamber, it is heated and may be partially thermoformed to fit over the product. When the chamber closes, the bottom web is pulled against the bottom of the VSP chamber with a high vacuum. The top web is either (a) suspended over the product by drawing an equal vacuum over both sides of the web and around the product or (b) is drawn against the heated surfaces of the upper half of the VSP chamber by a high vacuum, and the area around the product between the top and bottom webs is vacuumized. When the desired vacuum level is reached, the vacuum to the top of the chamber is vented to the atmosphere, and the heated top web instantaneously thermoforms to the shape of the product. At the same time, the two webs heatseal to each other wherever they come in contact. The bottom

Figure 3. Thermoforming.

Figure 4. Vacuum skin packaging.

chamber half is then vented, and the packages index out; they are slit into individual units as they do so.

Pressure. Probably the most simple means of producing a vacuum or negative-pressure package is through applying pressure to the outside of a bag or pouch that contains a product. Two methods have been used commercially. In the early days of fresh-red-meat vacuum packaging, a system of air removal involved holding a bag (with product) by its open end and lowering it into a tank of water so that the product was completely submerged with the open end of the bag still above the water, which forced air out. The open end of the bag was then gathered and closed with an aluminum clip.

Another pressure method used with bags and laminate pouches and today in packaging fresh cut vegetables is to squeeze the air out with sponges and heat seal the package prior to releasing the squeezing action of the sponges.

Hot Fill. This process is used to package pumpable prepared foods in flexible, oxygen-barrier plastic film packages. By hot filling, usually above 180°F, steam is present, which helps to exhaust air from the product and headspace of the package just prior to sealing. Such packages are then rapidly chilled, which creates a package with a negative pressure inside (Figure 5).

Following is a discussion of each perishable-food category with emphasis on why specific vacuum-packaging systems are used to preserve, distribute, and market each.

Poultry. Vacuum packaging of fresh poultry is done primarily to retard the growth of aerobic spoilage bacteria, and to provide an attractive leakproof (moisture) package (Figure 6). When packaging fresh poultry, care must be taken to avoid establishing conditions that support the growth of H_2S-producing bacteria. These bacteria are commonly present on fresh poultry and grow best above 34°F and under low-O_2 conditions. Therefore, fresh whole Rock Cornish, roasters, and turkeys are vacuum packaged using O_2-permeable shrink bags. Some cut-up fresh poultry is now being vacuum-packaged using thermoforming and O_2-permeable structures. Some boneless/skinless parts are being vacuum-skin packaged.

Figure 6. Vacuum packaging for poultry.

As for frozen whole and portioned fresh poultry, vacuum packaging in O_2 permeable shrink bags dominates. The bags are coextruded, multilayer polyolefin structures with a modified polypropylene (PP) outer layer to provide high gloss and freezer-case scuff resistance, and an electron-beam crosslinked polyethelene (PE) inner layer. This PE layer provides cold-abuse toughness, high hot-water shrinkability, and both heat and clip sealability. Good wrinkle-free film-to-product cling provided by the vacuumized shrink bag is essential for attractive, frost-free packages. A high oxygen barrier is not required as frozen fresh poultry does not develop significant oxidative rancidity during typical storage and distribution.

Fresh Red Meats (Beef, Pork, Veal, Lamb, and Venison). Today about 90% of the fresh beef primal and subprimal cuts shipped to food service and retail are vacuum-packaged in high-oxygen-barrier shrink bags (Figure 7). Such bags are made of coextruded materials consisting of an outer EVA or linear low-density polyethylene (LLDPE) layer, a PVDC barrier layer, and an electron-beam crosslinked EVA or LLDPE heat-sealable/clipable inner layer.

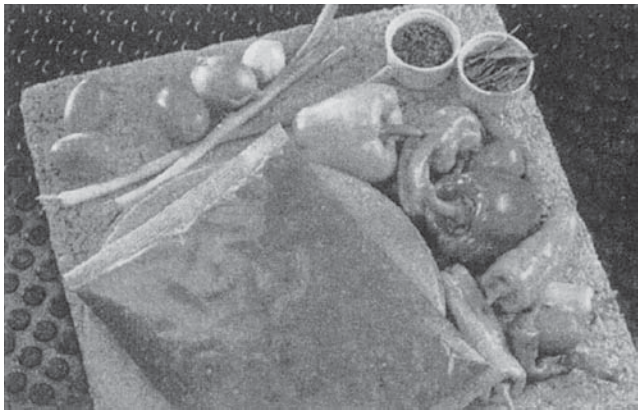

Figure 5. Hot fill.

Figure 7. Vacuum packaging for red meat.

Most fresh-red-meat (FRM) vacuum packages are produced on high-speed, high-vacuum, heat-sealing rotary chamber packaging machines. For bone-in FRM cuts, bags are available with bone-puncture-resistant patches laminated to the outside. Veal and lamb cuts are also vacuum packaged in this manner. The application of this technology was slow to develop for fresh pork. Several years ago the industry did start using this technology for boneless loins and tenders. With the advent of the "boneguard" shrink bag, bone-in loins were successfully packaged. The industry is now rapidly converting to shrink-bag vacuum packaging of bone-in pork loins for retail distribution.

The "aging" of beef is a tenderizing process that takes place as a result of naturally present enzymes. Vacuum packaging was first applied to beef by purveyors to age steaks and roasts for the food-service industry. Beef could be "aged" for up to 30 days without any significant shrink or trim loss. It was then applied to beef (later to veal, lamb, and pork) for retail, which dramatically improved the distribution and marketing. In fact, this development ultimately resulted in a total restructuring of the beef industry. The preservation aspects of FRM barrier shrink packaging are threefold: (a) retard the growth of aerobic spoilage microorganisms, (b) prevent the chemical degradation of myoglobin, and (c) minimize the loss of moisture.

As FRM is chemically alive and using some oxygen, oxygen permeability below $200\,\text{mL/m}^2$ will shift the microbial population from aerobes to facultative anaerobes (lactic acid producing). To minimize myoglobin degradation and provide adequate red-color (oxymyoglobin) regeneration and stability for retail display, oxygen permeabilities below $50\,\text{mL/m}^2$ are required. Most of the barrier shrink bags used today have O_2 permeabilities below $30\,\text{mL/m}^2$. As shrink bags are excellent moisture barriers, the moisture loss of major concern is "purge" (free liquid that separates from the meat). The cut of FRM packaged, temperature, and other product factors influence moisture separation.

From the package standpoint, the absence of minute negative pressure voids or cavities is critical. The application of high package vacuum to maximize film to product surface cling, and excellent hot-water shrink to minimize film wrinkles, provides for the least purge development.

Fresh ground beef and pork sausage are major FRM product categories. Although not truly vacuum packaged, they are pressure packaged in tubular oxygen-barrier packages. Today, most packages for these products are produced on vertical form/fill/seal machines that provide metal clip closures. The films used are coextruded structures. For ground beef: PE or EVA/nylon/EVOH, nylon/PE, or EVA with appropriate tie layers. For pork sausage: EVA/PVDC/EVA.

For individually cut fresh and frozen steaks distributed primarily to food service, thermoforming vacuum packaging and vacuum skin packaging are widely used.

For fresh steaks, oxygen-barrier structures are required:

Thermoforming: nonforming web-biaxially oriented nylon or PET/PVDC/LLDPE or Surlyn (DuPont)

Forming web: cast nylon/EVOH/LLDPE or Surlyn

Vacuum skin packaging: forming web—PVDC/Surlyn or coextruded, electron-beam crosslinked LLDPE/EVOH/LLDPE

Nonforming web, similar to the nonforming web used in thermoforming

For frozen steaks, structures are similar to those used for fresh except the PVDC or EVOH layers are left out.

Cured, Smoked, and Processed Meats. This category includes such products a wieners, bacon, hams, loaves, smoked sausages, sliced luncheon meats, and corned beef. Today such products are manufactured using both red meats and poultry. These products are vacuum packaged in high-oxygen-barrier materials to retard aerobic microbial growth, prevent cured color degradation, and loss or degradation of the cooked and smoked flavors and development of fat rancidity (Figure 8). As chemical changes are of greatest preservation concern, products in this category are chamber vacuumized to minimize residual O_2 within the packages. Wieners, sliced bacon, and sliced luncheon meats are packaged using materials with O_2 permeabilities below $15\,\text{mL/(m}^2\cdot 24\,\text{h)}$. To prevent curing-induced color degradation, they are generally packaged using high-speed laminate rollstock thermoforing machines. The forming web is a coextruded or extrusion structure consisting of nylon/PVOC or EVOH/Surlyn or LLDPE with appropriate tie layers if coextruded. The top layer will be polyester or oriented-nylon PVDC coated and reverse-printed if desired; also it could be adhesive or extrusion laminated to Surlyn or LLDPE sealant.

The larger units such as loaves, hams, and corned beef are usually packaged using high-barrier shrink bags—coextruded EVA, LLDE/PVDC/EVA, LLDPE (electron-beam crosslinked). The packages are vacuumized and heat sealed using high-speed rotary chamber machines.

Natural Cheeses. Vacuum packaging of cheeses for curing and for loaves and consumer units of cured cheeses (Figure 9).

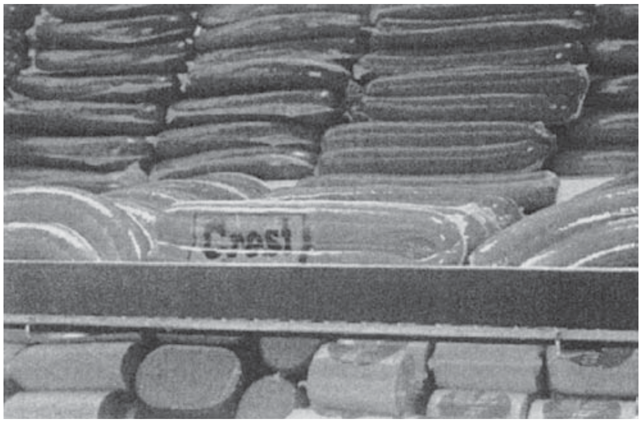

Figure 8. Vacuum packaging for cured, smoked, and processed meat.

Figure 9. Vacuum packaging for natural cheeses.

Curing. Cheddar cheese is formed into 40-lb rectangular blocks and vacuum packaged (chamber/heat sealed) using oxygen-barrier shrink bags and laminate pouches (nylon/LLDPE), then placed in strong, tight-fitting corrugated cartons for curing 90 days and longer. The vacuum packaging inhibits mold growth and moisture loss while allowing the non-gas-forming microbial curing to take place. After curing, the 40-lb blocks are cut into consumer units or used as manufacturing cheeses. Other non-gas-forming cheese varieties such as Gouda are also cured in this manner. More traditional shapes such as wheels, horns, and sticks of non-gas-producing varieties including Italian cheeses are cured using high-O_2-barrier shrink bags (see Figure 10).

For gas-producing cheeses (during curing) such as Swiss, high-CO_2-permeability shrink bags and nylon-based pouches are used. The O_2 permeability has to be kept below $250\,\mathrm{mL}/(\mathrm{m}^2 \cdot 24\,\mathrm{h})$ to retard mold growth during curing.

A unique application of shrink-bag vacuum packaging is for curing of wheels of Blue and Roquefort cheeses. After vacuum packaging and shrinking the barrier bag tightly around the uncured cheese wheel, which has been inoculated with the desired mold, long needles are forced through the wheel and removed to provide air channels to allow the mold to grow and develop the blue color.

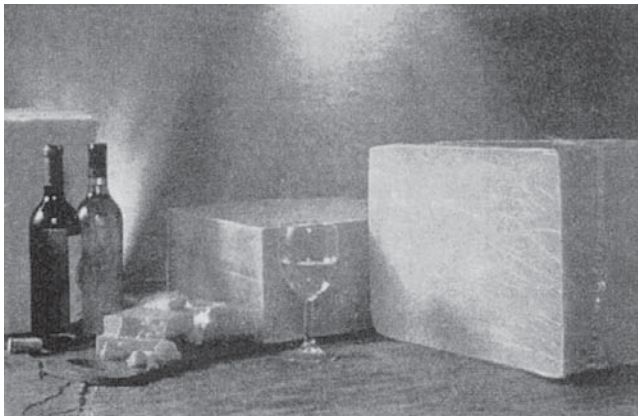

Figure 10. Curing.

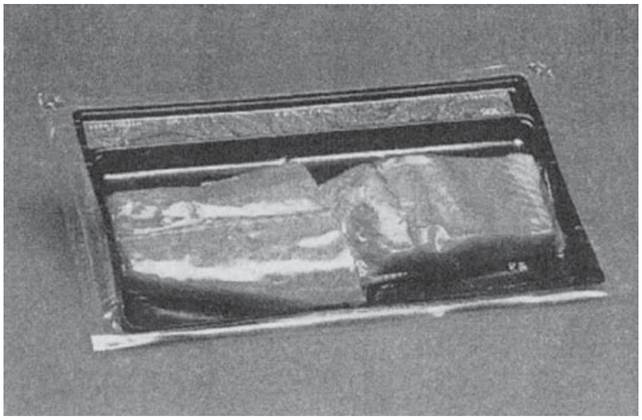

Figure 11. Vacuum packaging for fresh and frozen fish.

Retail Units. Chunks, sticks, blocks, loaves, and half moons of natural cheeses are vacuum packaged using O_2-barrier shrink bags and laminates using material structures and equipment systems very similar to previously described for smoked, cured, and processed meats. For cheese, such packaging is used to prevent mold growth, retard light-catalyzed oxidation of the butter fat on the surface, prevent surface color fading under display lights, and minimize moisture loss.

Fresh and Frozen Fish. With the growth of spoilage, bacteria can be retarded by vacuum packaging fresh fish in oxygen-barrier films. In the United States, doing so is looked on with disfavor by the U.S. Food and Drug Administration (FDA). *Clostridium botulin* type C, which is commonly found on fish, can grow under anaerobic conditions at temperatures as low as 39°F. This is well within the refrigerated distribution temperature ranges especially if abused. A vacuum-packaging system using O_2-permeable plastic films has been approved for improved shelf-life packaging of fresh fish.

Vacuum packaging using O_2-barrier shrink bags is being used successfully for frozen Alaskan salmon to replace ice glazing, to eliminate moisture loss (freezer burn) and rancidity, and for frozen tuna loin storage and transport to tuna-canning plants (Figure 11).

Fresh Produce. A new and rapidly growing end use for vacuum packaging is fresh-cut vegetables. Much of the food-service industry is on a fast track to remove the preparation of fresh vegetables from the back of the restaurant to central plants. The processing and extended-shelf-life packaging technology is now being applied to consumer packaging of such vegetables for retail supermarket sales. When the natural skin is removed from a vegetable or is cut in smaller segments (sliced, diced, etc.), extended shelf life can be provided through properly designed protective packaging. As fresh-cut vegetables are still alive and respiring, concern must be given to providing adequate O_2 and for release of the CO_2 produced. Fresh vegetables have been classified according to their respiration needs into three general groups as shown in the following table.

Respiration group	Vegetables	Film permeabilities [mL/($m^2 \cdot 24\,h$)]	
		O_2	CO_2
Light breathers	Carrots, potatoes, turnips	1000–3000	10,000–20,000
Medium breathers	Lettuce, celery, pepper	6000–7000	30,000–35,000
Heavy breathers	Broccoli, cauliflower, asparagus	15,000–20,000	75,000–100,000

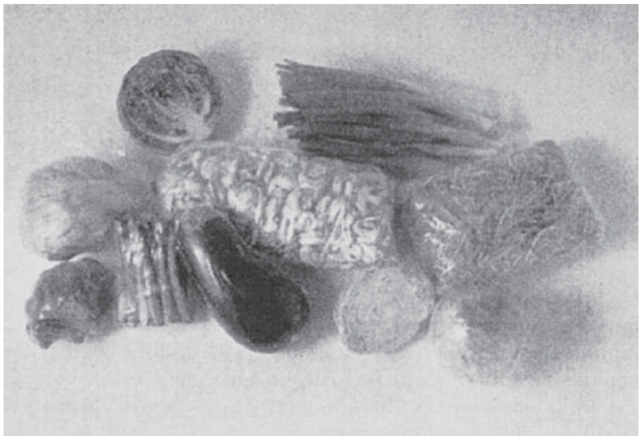

Figure 12. Vacuum packaging for fresh produce.

Such cut vegetables are packed in permeability modified polyolefin bags or film or vertical form/fill/seal machines (see the Form/fill/seal, vertical article). Bags are typically nozzle vacuumized and pressure squeezed to remove residual air from the package prior to heat sealing. For the various vegetables group, the polyolefin films are modified through resin variations and additives to achieve the desired O_2/CO_2 permeability.

The polyolefin films are adequate barriers to prevent significant moisture loss. The removal of the air from the package provides for the package quickly becoming a modified atmosphere. Under adequate refrigerated conditions, the O_2 will be maintained below 5% and the CO_2 in the 8–12% range. This slows down respiration and will significantly extend the eating-quality life of the cut vegetable. Large volumes of chopped lettuce, broccoli, and cauliflower florets are now being distributed to food service and retail in this manner. The vacuum or negative-pressure package also provides a good visual-quality measure of the package and product for both the producer and end user (Figures 12–14).

VACUUM-BAG COFFEE PACKAGING

The concept of vacuum-bag packaging for ground coffee was introduced in the U.S. market years ago. It had been developed in Europe years before, but except for nonhermetic paper bags still used in the southeastern states, ground coffee in the United States has remained in the three-piece sanitary can with plastic covercap that replaced the key-opening can about 40 years ago. The new vacuum-bag package has been described as a “flexible can,” because it delivers the same vacuum-packed fresh coffee that the consumer buys in the can, but that is where the similarity stops. The “vac-bag” is rectangular rather than round, and it can be shelved standing up, or lying on its side like a “brick,” which is one of its less-glamorous names.

Coffee Characteristics. Coffee has some unique characteristics. After coffee beans are roasted, they slowly evolve CO_2 amounting to over 1000 cm^3/lb (2200 cm^3/kg) of product depending on the blend and roasting color. During grinding, the volume of CO_2 is reduced to about half, and depending on the grind size, it requires varying holdup times before packing. Grind size varies greatly depending on the type of coffee-brewing equipment used and individual taste preference. Typical fine grind for most European countries is 500–600 μm; North American coarser grinds are 800–1000 μm. Vacuum-bag packaging of coarser grinds present more of a problem because of slower degassing. At 6–8 in. Hg (20–27 kPa), a vac-bag becomes soft and it can even balloon like a football (positive pressure) if it has insufficient degassing. Because rigid metal cans are capable of withstanding full vacuum as well as positive pressure, they require a relatively short holdup time even for coarse grinds. Because ground coffee also varies in density, the height of fixed-cross-section bags varies as well. This variation means that the equipment and materials must be adaptable to a limited automatic height change during a production run. In addition, coffee must be protected from oxygen to maintain the freshness. Vacuum packing eliminates most of the oxygen from the package by the nature of the process.

The Vacuum Bag. The first commercial “vac-bag” packages were made in the early 1960s, probably in Sweden. At that time the package was a bag-in-box style (see Bag-in-box, dry product) that later evolved to a lower cost, bag-in-bag style, which is still the most widely used type in Europe and Canada. A still lower cost style, the single-wall bag, is being used to some extent in Europe and by the major coffee producers in the United States. The bag-in-bag style and the single-wall style function equally well in protecting the product, but they differ in appearance. High-quality graphics on the paper or foil/paper outer wrap of a bag-in-bag package gives a smooth surface appearance. Most single-wall bags have a rough or “orange peel” surface when under full vacuum. As with any package concept with more than one style, there are pros and cons for each, but the current U.S. market is predominately single-wall vac bag and is likely to stay that way.

Equipment. Because Europe spawned the vac-bag’s popularity, it is no surprise that all the automatic high-speed equipment is made there. There are three major equipment suppliers who compete in the coffee-packaging area and are as follows: SIG, Hesser, and Goglio (1–3). All have automatic high-speed (40–120-boxes-per-minute (bpm)], 1-lb (0.45-kg)-size machines capable of forming bags from roll stock material, filling, evacuating, sealing, and folding the top of the bag to deliver a finished vac-bag. Bags can be made in different ways from rollstock. Mandrel- and tubeforming machines form the bag, which is carried horizontally into the filler. After filling it is transferred into a vacuum chamber where it is evacuated and sealed. It is then transferred out of the vacuum chamber to a trimmer and final folding of the top. Tape or hot-melt glue are two methods used to hold the top folds in place. The sealing of the bag is what keeps it hard and under vacuum.

Materials. Each of the major equipment suppliers provides basic information on what packaging material properties are essential for efficient vac-bag production. Some differences exist, but many similarities also are present for achieving a low level of defects from the machine. Each vac-bag must be durable enough to survive the rigors of transportation, warehousing, and retail distribution to remain vacuum-packed at point of purchase. Although many European packers use a three-ply structure made of 48-gauge polyester film (OPET)/35-gauge aluminum foil (AF)/300-gauge sealant (see Film, polyester; Foil, aluminum; Sealing, heat), most U.S. coffee roasters employ a more durable four-ply structure. This structure can be accomplished by the addition of one of several films, such as biaxially oriented polypropylene (BOPP) (see Film, oriented polypropylene) or biaxially oriented nylon (BON) (see Nylon). These structures can be constructed in various ways but most typically as follows:

48-ga OPET/75 ga BOPP/35 ga AF/300 ga sealant
48-ga OPET/35 ga AF/60 ga BON/300 ga sealant

When these structures are designed for a single-wall bag, the OPET is reverse-printed. Gravure printing (see Printing) on OPET provides excellent graphics, high gloss, and a scuff-resistant package. Vacuum-metallized films (see Metallizing vacuum) have been used successfully in Europe and Canada as lower-cost foil replacements. Because their oxygen barrier may be lower than foil, each coffee packer must determine if nonfoil structures provide adequate barrier.

Currently, the best method to joint these materials into a finished structure is by adhesive lamination (see Laminating; Multilayer flexible packaging). To produce a finished structure with uniform-gauge control, high internal bond strength, minimum curl, and a controlled coefficient of friction, adhesive lamination has proven to be an excellent converting system. Both solvent- and solventless-type adhesive laminators (see Adhesives; Coating equipment) are now converting materials in the United States and Canada for coffee packers. These new high-speed automatic packaging machines require consistently high-quality materials to operate efficiently. All of the material converters acknowledge the sometimes difficult learning experience on vac-bag films and the need to set up a very thorough quality-control system.

Valves and Sorbents. Gas-off of CO_2 from ground coffee is a problem for vac-bag packagers that can be handled in several ways. The simplest solution is to grind the coffee beans very fine, as in Europe. The fine grind evolves gas more quickly and requires only a short holdup time ($1\frac{1}{2}$–2 h). The North American markets require coarse grinds, however, that need up to 24 h of holdup time and considerable storage capacity. Two methods exist to eliminate all holdup time. One is the one-way coffee valve, which allows CO_2 out of the bag without allowing O_2 into the bag (see Valves). The bag, however, is soft. This concept was tested in the United States by two major roasters, but it was abandoned in favor of the hard vac bag that consumers seem to prefer. The other method involves a new technology from Canada, whereby a CO_2-sorbent pouch is placed in the coffee bag much like a desiccant pouch is used for moisture-absorbing applications. This new coffee vac-bag technology allows the roaster to package freshly ground coffee without any holdup time and still obtain a hard vacuum bag. This benefit is not possible with any other system.

A growing coffee market has been found in specialty and gourmet stores where whole beans are purchased. The beans are generally not hermetically packaged, so CO_2 gas-off is not an issue. In this case, the use of a one-way valve is an excellent way to achieve an airtight package and keep the beans fresh. The valve can be heat-sealed into the bag film as done by Goglio and SIG. It also can be attached to the outside surface using a pressure-sensitive valve concept developed by Hesser.

Advantages. Vac-bag is seen as a low-cost package compared with metal cans. For some coffee packers, this low-cost advantage may be true if bag packing line speeds are equal to or greater than those for cans. For others, where the reverse is true, the material-cost advantage is not as large. Current 1-lb-size (0.45-kg-size) metal cans that include plastic overcap cost about \$0.17–\$0.19. A high-quality four-ply vac bag costs about \$0.08–\$0.10, which provides a material-cost advantage of about 9 cents per 1-lb (0.45-kg) package. Additionally, advantages are present in storage, handling, and shelving a vac-bag because of its compact shape. The reduction in cube is dramatic (35%). This cube reduction is beneficial to both manufacturer and retailer, because warehousing and shelving space is always a premium. As vac-bags become more widely distributed, consumers will determine the future for this new package.

VIBRATION

Jorge Marcondes
San Jose State University,
San Jose, California

Vibration describes oscillation in mechanical systems. Packages, products, pallet loads, vehicles, machinery, and equipment are mechanical systems. They are subjected to vibration whenever there is movement. In packaging applications, vibration can be either desirable or undesirable, although often it is undesirable, because it can damage products. Examples of packaging applications of desirable vibrations are a filling machine and an ultrasonic heat sealer. Filling machines may have a vibratory tray feeder to dispense the product into a package; an ultrasonic heat sealing uses high-frequency mechanical vibrations to produce localized heat that melts the interface between the sealing materials only, without affecting the product or the rest of the package. However, vibrations encountered in vehicles during distribution are always undesirable. This article concentrates on vibrations in distribution only, or those that are undesirable.

Vibration always occurs in distribution because the operations of transport and handling always move goods. It can influence products to the point of causing physical damage or product spoilage. Studies have shown that vibration in vehicles can cause, for example, phase separation to emulsified products, bruising in fruit and vegetables, physical damage in mechanical and electronic products, and damage to labels because of friction (1, 2).

Both external and internal sources originate vehicle vibrations. Examples of external sources include road pavements, rail tracks, and ocean waves; internal sources include rotating parts such as unbalanced wheels and the engine itself (3). In a truck, for example, the wheels of the vehicle pick up the pavement up-and-down oscillations as mechanical vibrations; the suspension and structure of the vehicle transmit these, along with other internal vibrations, to the vehicle floor. Packaged products placed on the vehicle floor will then receive the vibrations.

Vibrations that occur in a vehicle floor may be decomposed in three perpendicular directions: vertical, lateral, and longitudinal. Several studies investigated the directions and locations in vehicles where highest vibration levels occur. On the basis of these studies, it is commonly accepted today that in trucks and semitrailers the highest vibrations occur on the rear axle and in the vertical direction (4, 5). Product damage caused by vibration is more likely to occur if packages are placed over the rear axle in trucks and trailers.

The role of the packaging engineer is to design packages that reduce vibrations. Cushions and other flexible-packaging systems are engineered in such a way that the package attenuates the vibrations that occur in vehicles. No package can completely eliminate vibration. Although still transmitted to products, a package designed for vibration attenuation may virtually eradicate the potential for damage.

FORCED VERSUS FREE VIBRATION

Vibrations are generally classified into two categories: *forced* (when there is a continuous input source) and *free* (input source discontinued). The type of vibration that occurs in packaging machinery is a forced vibration because a source continuously drives the system to vibrate. The vibration that occurs without external excitation is called *free vibration* (6). Both types, free and forced, occur in all vehicles during transport. As an example, the pavement roughness is a source of vibration that forces the wheels of a vehicle to move up and down, generating vibration. If the source of vibration stops, then the system will continually decrease its vibration level (free vibration now) until a full stop, when the energy is totally dissipated. Similarly, when the vehicle hits an obstacle such as a pothole, the vibration will be forced while the obstacle is in contact with the vehicle and free thereafter until the effect of that particular input ends. An example of free vibration occurs when a mass, placed on top of a spring, is pushed down and released, and then vibrates “freely” after its release. Whenever a system is vibrating freely, the movement will decrease and the vibration will eventually cease, because of *damping*. Damping is always present in mechanical systems (7), and it dissipates the energy that keeps the system vibrating.

FREQUENCY AND ACCELERATION

A state of vibration can be characterized by a frequency and an amplitude. The simplest harmonic motion of a mechanical system, such as of a mass placed on a spring that oscillates up and down, is defined by a *frequency* and a *peak acceleration*. The frequency is the number of times a cycle repeats itself in a unit of time, and the peak acceleration is the maximum value of the acceleration in the entire cycle. If a system is vibrating freely, it vibrates at its natural frequency (8). The natural frequency is mainly a function of the mass and the stiffness of the system. The relationship between peak acceleration, maximum displacement from the position of equilibrium, and frequency of a vibrating system is

$$a_{\mathrm{pk}} = \frac{d_{\max}(2\pi f)^2}{g} \tag{1}$$

where a_{pk} = peak acceleration in g (where $1g$ is equal to the gravitational acceleration), $d_{\max}$ = maximum displacement of the oscillating mass from the equilibrium position, f = frequency of oscillation, and g = gravitational acceleration, or $9.81\,\mathrm{m/s^2}$. In applying equation (1) to ideal, or linear systems, the equation shows that the peak acceleration is directly proportional to the maximum displacement and to the square of the frequency of vibration. In other words, if the maximum displacement is doubled, then the peak acceleration will also double (frequency kept constant); if the frequency is doubled (maximum displacement kept constant), the peak acceleration will quadruplicate. Figure 1 shows the relationship represented by equation (1), as applied to a spring-mass system undergoing free vibration. Equation (1) does not take into account the direction of vibration (up or down). In Figure 1, the mass is pushed down with the force F and then released. The situation depicted in Figure 1 does not show the effect of damping. For further information on damping effects on free vibration, the reader may consult Refs. (7–9).

The duration of one cycle of oscillation is shown as the period T. The frequency of oscillation f representing the number of cycles that occur in a unit of time is related to the period by

$$f = \frac{1}{T} \tag{2}$$

For example, if the period $T = 0.2\,\mathrm{s}$, and $d_{\max} = 0.5\,\mathrm{cm}$ ($0.005\,\mathrm{m}$), the frequency is $1/0.2\,\mathrm{s} = 5\,\mathrm{Hz}$ (using equation 2) and $a_{\mathrm{pk}} = 0.005\,\mathrm{m} \cdot (2\pi 5\,\mathrm{Hz})^2 / 9.81\,\mathrm{m/s^2} = 0.5g$ [using equation (1)]. This means that the system is vibrating with a peak acceleration of $0.5g$ and the mass is oscillating at five cycles per second (5 Hz). If the peak acceleration is $0.5g$, the acceleration at any instant will be somewhere between $+0.5g$ and $-0.5g$, inclusive.

When vibration levels in vehicles reach values above $1g$ (acceleration due to gravity) packages will start to bounce. Because packages are seldom attached to the vehicle floor, if the vertical vibration of the vehicle floor is higher than $1g$, the package would not follow the

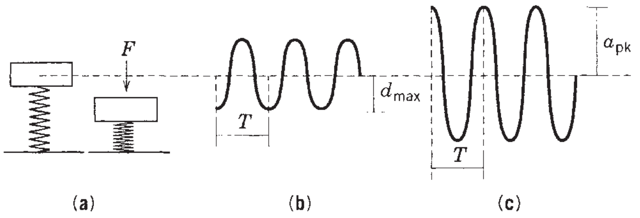

Figure 1. Spring-mass system in free vibration without damping: (**a**) force F causes displacement $d_{\max}$ and releases mass to vibrate freely; (**b**) displacement of mass varying with time; and (**c**) acceleration of mass varying with time.

vehicle floor when it is moving down and will be left suspended in the air momentarily, hitting the floor moments after. This will cause packages to receive impacts rather than only the vibration that occurs at the vehicle floor. Impacts have acceleration levels (G levels) much higher than vibrations (impact accelerations can get up $100g$ very easily) and are much more likely to cause damage to products during distribution.

SINUSOIDAL VERSUS RANDOM VIBRATION

Regarding the mode of vibration, there are two ways it can occur: *sinusoidal* and *random*. The displacement of the mass shown on the spring in Figure 1 characterizes a sinusoidal motion and it can be expressed mathematically as a function of the time only. For example, when time $t = 0$, the displacement is at its minimum, when $t = T/4$, the displacement is *zero*, and when $t = T/2$, the displacement is at its maximum. This pattern repeats itself every interval of duration T. Vibration encountered in distribution such as in a truck when it travels on the road is not like the periodic or sinusoidal vibration of a spring-mass system as represented in Figure 1; rather, it is complex (10). Vehicles vibrate at several frequencies simultaneously, with the displacement, and therefore the acceleration, varying at each instant and never repeating itself again in the same pattern. Figure 2 shows an example of a typical random signal measured on a truck floor.

Because of this complex characteristic, random vibration cannot be described in a deterministic manner, i.e., one cannot write an equation of acceleration versus time to describe this motion. Therefore, a statistical technique, or spectral analysis, is used to study such vibrations and to interpret the motions of the vehicle (9), which are covered in the next sections.

VIBRATION MEASUREMENT AND ANALYSIS

Most packaging-dynamics applications use *accelerometers* for measuring vibration. Accelerometers are sensors that produce an electrical output signal proportional to acceleration. These sensors are rigidly mounted on the surface of a truck floor or package item and are connected to data-recording devices. Manufacturers of accelerometers supply a calibration certificate with each sensor. One important information in this certificate is the *accelerometer sensitivity* (in output units per g). The sensitivity and the output voltage relate to the acceleration by

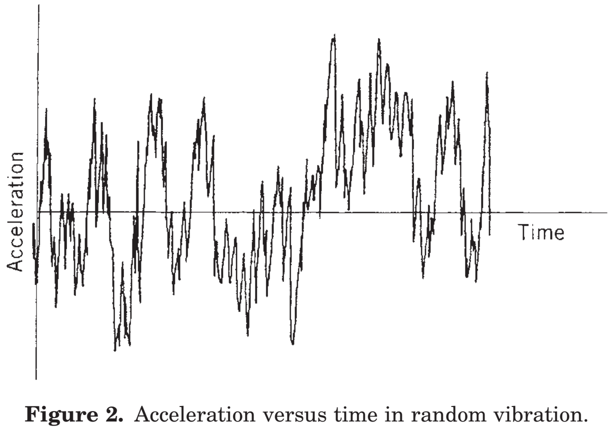

Figure 2. Acceleration versus time in random vibration.

$$\text{Acceleration} = \frac{\text{voltage output}}{\text{sensitivity}} \tag{3}$$

For example, consider an accelerometer with a $10\,\text{mV}/g$ sensitivity. If it senses a vibration with peak amplitude output of $6\,\text{mV}$, the acceleration is $6\,\text{mV}/(10\,\text{mV}/g) = 0.6g$. Accelerometers should be calibrated regularly to ensure accuracy of results acquired (11).

There are two basic ways to measure and store vibration data: *continuous* (or analog) and *intermittent* (or digital). The recording equipment defines the type of measurement and data storage.

In continuous recording, accelerometers are installed in strategic places in the vehicle and vibration data are recorded, without interruption, on a magnetic tape. A voice channel may be used to record a description of the events as they occur, such as the crossing of a rail track, the vehicle speed, or any other occurrence that may be of value for subsequent data analysis and interpretation. This technique requires the continuous presence of an operator, and the instrumentation used can be cumbersome, occupying as much space in a vehicle as one whole pallet load. After stored in the magnetic tapes, the acceleration recordings are transferred to additional instrumentation for analysis, interpretation and use.

Intermittent monitoring has grown substantially in the last few years with the availability of digital recording and storage instrumentation. Intermittent recording uses self-contained recording units to obtain and store acceleration either at predetermined intervals or above a preset triggering level. Recording units used for intermittent monitoring are usually small and contain a real-time clock and a battery to provide the operating power. After stored, the vibration is downloaded to a computer, analyzed, and summarized for subsequent use.

In random-vibration analysis, the complex signal is first decomposed into component sine waves of various frequencies either mathematically using Fourier decomposition (8) or electronically using *bandpass* filters. Whatever the technique used, the complex signal is analyzed in individual component frequency intervals determined by the *bandwidth*. For most packaging applications, the bandwidth has been traditionally set at 1 Hz.The random signal of a vehicle vibration has component sine waves that vary over time but have a zero average, and their peak amplitudes are distributed normally over time so that the Gaussian distribution and all its properties may be used to describe the process.

The acceleration level of any component frequency analyzed is represented by the power density (PD), which is calculated as

$$\text{PD}(f) = \frac{\sum_{i=1}^{n} (\text{Grms}_i)^2}{n \times BW} \tag{4}$$

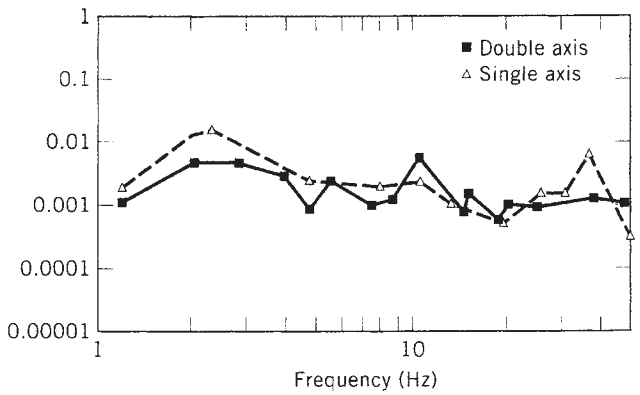

Figure 3. PSDs comparing vibration in single- and double-axle trailers (12). (Originally published in *IPENZ Transactions*.)

where PD(f) = power density at the frequency f, n = number of samples at the frequency f, Grms$_i$ = root mean square acceleration of the ith sample at the frequency f, BW = bandwidth (normalized to 1 Hz).

A power-spectrum density (PSD) represents the results of random-vibration analysis. The PSD is a graphic representation of the vibration intensity at each frequency. As an example, Figure 3 shows the results, in PSD format, of vibrations encountered in semitrailers in urban-area traffic at 60 km/h. This example shows that the single-axle trailer has an overall higher vibration force than the double-axle trailer, except for the frequencies in the range 9–22 Hz (12). Notice that the graphs are in a log–log scale for better clarity at the low-frequency range.

The PSD plots show the component frequencies in the horizontal axis and an indication of their amplitude in the vertical axis. High power-density levels at particular frequencies may indicate problems with the vehicle. This occurs because there are resonant reactions between the vehicle structure and the road surface in this frequency range. For example, for both vehicles represented in Figure 3, there are high power-density levels between 2 and 3 Hz. For the double-axle vehicle, there is another high power-density level at just above 10 Hz; for the single-axle vehicle, a high power density also occurs at 35 Hz.

The PSD plot is interpreted as a "signature" of the random vibration and is used to statistically represent vibrations that occur in vehicles. It can be used to determine the quality of the road or the vehicle, or both. The PSD plots of vehicles are important in the design of protective packages to attenuate how products receive the vibrations that occur in these vehicles. They are also widely used in the execution of laboratory vibration tests to simulate the transportation hazards encountered in these vehicles.

VIBRATION TESTS

In a laboratory, it is typical to perform two types of vibration tests: *sinusoidal* and *random*. Sinusoidal tests are used to identify resonant frequencies of a product, a packaging material, or a complete package. Random-vibration tests are usually performed to test finished-packages prototypes and packaging systems (13) but can also be used to test vibration transmissibility of cushioning materials using a frequency analysis technique (14).

Sinusoidal vibration tests should define (a) the upper and lower frequency of the test, (b) the level to be maintained at each frequency, (c) the rate at which frequency will sweep and whether it is logarithmic or linear, and (d) the number of sweeps or duration of the test. Random-vibration tests should define (a) the PSD to be used, (b) the duration of test at each PSD, and (c) the level sequences of each PSD. Both test types are performed using an electrohydraulic vibration tester mounted on a seismic mass (15), although mechanical shakers are still widely used, mainly for sinusoidal vibration tests with a narrow frequency range.

The purpose of a finished-package vibration test is to recreate in the laboratory the damage potential that the packages would encounter in distribution. These tests determine how effective a package system can be in providing product protection (2). ASTM standard D4169 recommends specific PSDs for each transportation mode (truck and rail). It also recommends that random-vibration tests last 3 h (13), although studies have shown that tests with durations as short as 20 min produce valid results (16). There is generally a tradeoff between test severity and test duration (17). Ideally, a test should be only long enough to impose on the packages events that have the same damage potentials of the events the test is supposed to reproduce.

TERMINOLOGY

The application of mechanical vibrations in packaging involves many terms that may not be familiar to some readers. For a definition of common terms used in vibration, refer to Harris and Crede (18). In addition, more specific terminology on distribution packaging may be found in ASTM standard D996-90a (19).

Updated by Staff

INTRODUCTION

Historically, in the United States, the use of wax-coated folding cartons to provide proper product protection has been a popular concept within the food-packaging industry. A wide assortment of refrigerated and frozen-food entrées have been packaged in this manner since the 1920s.

However, in the late 1950s, a new concept in the manner in which the wax coatings were applied to the folding-carton blank was commercialized. Coupled with the new, commercialized folding-carton waxers, a large number of new wax-based folding-carton formulations emerged. From the 1960s to the present, a large number of new wax-based folding-carton formulation concepts have been successfully commercialized and refined in order to fulfill the ever-changing packaging requirements of the specialty market.

Over the years, wax-based folding carton formulations have improved to provide the following properties:

1. Adequate protection against loss or gain of moisture by the food to the ambient environment
2. Effective bond strengths during heat-seal closing operations on packaging equipment
3. Ability to retain good bonds at low-temperature storage conditions
4. High initial gloss and excellent gloss retention
5. Adequate scuff and abrasion resistance
6. Adequate slip properties for high-speed handling on packaging equipment
7. Good grease resistance
8. Tamper-proof closures before sale, yet open easily at point of use
9. Economical costs commensurate with product protection

Today, a wide variety of specialty foods are now being packaged in wax-coated folding cartons. Wax-blend-coated folding cartons are especially suited for butter, margarine, ice cream, frozen vegetables, frozen pizzas, frozen shrimp, and frozen-dinner entrées, and prepared food specialties, to mention just a few of the limitless applications.

This article focuses on the past, present, and future applications of wax-based coated folding cartons. Waxes, in particular paraffin wax, are used in a great many packaging applications. The folding types include corrugated containers and folding cartons; the flexible types include wrappers, labels, bags, sacks, and pouches; the rigid types include bottles, jars, drums, and tubes. According to the paper and paperboard industry, container board is the largest single grade of paper produced and remains a growing grade. Corrugated containers for shipping manufactured goods make them one of the largest grade forms of packaging.

HOT-MELT WAX CARTON COATERS

From the early 1920s to the late 1950s there were two commercially accepted methods of coating folding carton blanks with wax: (a) the *hot-wax method*, which imparted a limited amount of protection and release to the carton—the wax coating did not enhance the appearance of the carton itself and, therefore, had very little shelf appeal; and (b) the *cold-water waxer*, which gave added surface protection and a reasonably glossy finish that increased the shelf appeal of the carton.

The coating used for both of these methods, wax, was initially nothing more than fully refined paraffin wax. As years went by, it was discovered that additives such as microcrystalline wax and small amounts of low-molecular-weight polyethylene could be added to the fully refined paraffin wax, slightly increasing the appearance and protective functional properties of the carton.

The hot-wax method and the cold-water waxer presented one major problem with the overall wax coating. With the exception of mechanically locked and tuck cartons, and except for those cartons where a dry strip could be left in the waxing operation, the other cartons had to be dewaxed before gluing. The dewaxing operation was time-consuming, very costly, and generated a large volume of wax waste.

In the late 1950s, recognizing the wax coating problem within the folding carton industry, the Oakland Paper Box Company developed the Oakland Hi-Gloss Pattern Coater. The Oakland Hi-Gloss Pattern Coater allowed wax coatings to be applied in any desired pattern, leaving voids in areas to be glued or printed.

The section where the wax is applied has two rubber-covered cylinders: One cylinder coats the underside of a carton blank, while the second waxes the top.

The waxing blanket favored is brass-backed 30–40 durometer neoprene. Like the cutting die or the printing plates, the blanket must be prepared to the needs of a specific carton. Like the cutting die or the printing plate, the blanket will be saved if repeats of the job are anticipated.

A rubber waxing blanket is prepared by stretching an uncut sheet over a cylinder of the same size as the cylinder on which it will be mounted. A template of the specific carton design is cut, and this serves as a pattern for cutting the blanket. Wherever wax is not to be applied, the rubber will be cut away. The result is a pad that is identical to a reverse-printing plate.

With the inception of the Oakland Hi-Gloss Pattern Coater, other machine manufacturers began to market similar wax coaters. In the United States, the majority of the carton coaters in operation are the IPBM GM Carton Coater and the 88-B Carton Center. The two IPBM wax coaters are capable of applying wax coating with viscosities approaching 1000 cP at 300°F (148.9°C).

The IPBM GM Carton Coater has two coating stations. The first station coats the inside (bottom) surface of the carton. The second station coats the outside (top) surface. This arrangement permits the application of different blends on the inside and outside surfaces, if desired. The wax coating weights are controlled by adjustment of the metering roll nip and the reverse or burnishing roll at each coating station. The second coating station is equipped with a weir-type curtain feed to ensure uniform distribution of the wax coating across the applicator roll. This is particularly important in applying high-viscosity wax coatings. Silicone rubber back-up rolls are used to prevent carton blanks sticking to the rolls.

The wax-coated cartons pass through a remelt section consisting of gas-fired infrared heaters. The temperature of the gas-fired infrared heaters is typically 250°F (137.1°C), and these heaters are rated at about 500,000 Btu. This exposure to the heat gives a smoother, more evenly dispersed flow to the wax coating and produces a high-gloss finish.

The wax-coated cartons are then passed through a refrigerated, chilled-water curtain and into a water-immersion tank. The temperature of the chilled water must be carefully controlled within a temperature range of 34–40°F (1.1–4.4°C). The purpose of the chilled water is to facilitate the setting of the wax coating without disturbing the surface. This process also enhances the high-gloss finish. If the chilled water is at a temperature above 40°F (4.4°C), the wax coating does not set properly and will produce a carton with a dull, uneven surface. The position of the heaters and the distance to the water-immersion section can be adjusted to obtain the maximum gloss for the particular wax coating being applied.

The waxed cartons are then passed through a set of squeeze rolls to remove the excess water. The waxed cartons are then deposited onto a slow-speed stacker apron.

The ideal wax-coating weight, per carton side, is approximately 3 lb/1000 ft^2 (14.6 g/m^2).

The machines are usually installed with three channels or lanes that automatically feed the folding carton blanks through the wax coater. Each single lane is capable of waxing 15,000 cartons per hour.

HOT-MELT WAX CARTON COATINGS

In the late 1950s, coupled with the development and commercialization of the "new" folding-carton coaters, new developments and refinements were also taking place in the area of "new" hot-melt wax carton-coating formulations. Specialty wax blends were being researched and developed for exclusive use with the "new" folding-carton coaters. The simple formulations are as follows:

1. Straight, fully refined paraffin-wax blend
2. Fully refined paraffin-wax/microcrystalline wax blend
3. Fully refined paraffin-wax/low molecular weight polyethylene blend

These gave way to sophisticated blends of carefully selected petroleum-derived waxes with carefully selected wax additives. Because of the significant changes made in the area of folding-carton coaters, a new era in formulating wax-based coatings for this specialty packaging industry began.

In early 1960, another series of products became commercially available that created an entirely new concept in hot-melt wax-based coatings. This new series of products were termed *copolymers* and consisted of various percentages of ethylene and vinyl acetate, or simply EVA. Other wax additives that became commercially available around the time of the EVA copolymers were polyterpene resins, stabilized ester gums, and a wide product diversification of low-molecular-weight and high-molecular-weight polyethylenes. The commercialization of these new wax additives gave compounders the tools to manufacture an almost limitless number of combinations or formulations of hot-melt wax-based folding carton coatings.

On the basis of the requirements of the folding carton industry, hot-melt wax-based folding-carton coatings are classified into the following two categories:

1. Non-heat-sealable folding-carton waxes
2. Heat-sealable folding-carton waxes

Non-heat-sealable folding-carton waxes are usually applied in a defined pattern onto the folding-carton blank, leaving unwaxed areas where a hot-meal adhesive (HMA) is applied to seal the folding carton closed. The wax coating is applied to both the outside (printed side) and the inside (unprinted side) of the folding carton.

Heat-sealable folding-carton waxes are applied onto the entire surface area of the folding carton blank, and they will seal the folding carton *without* the use of a HMA. The wax coating is applied to both the outside (printed side) and the inside (unprinted side of the folding carton). The use of a heat-sealable folding-carton coating is advantageous because the gluing operation is eliminated.

As the folding-carton industry developed, it became apparent that only four wax-based folding-carton coatings were necessary to fulfill the requirements of the industry. The wax-based coating product line consisted of the following:

1. Non-heat-sealable folding-carton waxes
    a. One economical coating
    b. One general-purpose coating
    c. One heavy-duty coating

2. Heat-sealable folding-carton wax
    a. One premium heat-sealable coating

The selection of the proper folding carton coating depends on the physical specifications of the formulation as well as the functional properties that the formulation must impart to the folding carton. Functional properties such as gloss, creased vapor barrier, grease resistance, scuff resistance, freezer-burn resistance, and heat sealability are some of the points to be considered in the section of the proper folding-carton coating. In most instances, the folding-carton coating must be nonflaking, exhibit no ruboff, and exhibit a high antiblock characteristic. These three properties are important when the waxed folding carton is processed through the folder/gluer. The wax coating cannot build up on the runners of the folder/gluer. When the wax coating builds up on the runners of the folder/gluer, subsequent waxed folding cartons stick and jam on the runners. The folder/gluer must then be shut down and cleaned (see also Sealing, heat).

The economical non-heat-sealable folding-carton coating provides minimal functional properties. The economical formulation is used in applications of generic folding cartons where minimum functional properties are required and the low cost of the wax coating is an important consideration. With a hot-melt wax carton coater containing two separate wax-coating stations, the economical formulation can be used on the inside (unprinted) of the folding carton, while the general-purpose formulation or the heavy-duty formulation can be used on the outside (printed) of the folding carton. This procedure is used for monetary consideration.

The general-purpose non-heat-sealable folding-carton coating offers improved functional properties over the economical coating. The general-purpose coating may be used on the outside (printed) area of the folding carton as well as the inside (unprinted) area of the folding carton.

The heavy-duty non-heat-sealable folding-carton coating imparts the optimum appearance, protection, and functional properties of the non-heat-sealable coatings. The heavy-duty coating may be used on the outside (printed) area of the folding carton as well as the inside (unprinted) area of the folding carton.

The premium heat-sealable folding-carton coating imparts the optimum appearance, protection, and functional properties to the folding and will seal the folding carton closed without the use of a HMA. This product will give a fiber-tearing seal over a wide range of sealing temperatures.

An additional consideration for all four products is that all ingredients and final products must fully comply with FDA (Federal Drug Administration) regulation as suitable for use in food packaging. The regulation cited most often is Paragraph 21, *CFR* 176.170 for "components of paper and paper-board in contact with aqueous and fatty foods."

With the new generation of hot-melt wax-based coatings and the commercialization of the new generation of hot-melt carton coaters, the folding-carton industry was well on its way to establishing itself as a strong specialty market within the food-package industry.

CURRENT USE

Many changes have occurred in the folding-carton industry since its modern conception in the early 1960s. A newer variety of boardstock required newer blends of wax coatings. At present, the most widely used of the petroleum waxes is paraffin wax, also called macrocrystalline wax. More than 50 companies produce petroluem waxes worldwide (1). It is extremely unreactive at normal temperatures. It remains cost-effective as a moisture and gas barrier. It can also be blended with microcrystalline wax or combined with polyethylene or ethyl vinyl acetate (EVA) to improve performance. The use of refined grades of petroleum wax are regulated by the FDA (21 *CFR* 172.886 and 21 *CFR* 178.3710) (2).

Petroleum waxes are now used to coat corrugated board as well. The most common methods used for applying wax are saturating or cascading and curtain coating. In saturating or cascading, a thick layer of wax is flushed or sprayed onto the finished board. The board will pick up 40–50% of its weight in wax. The wax is normally low melting. In curtain coating, the corrugated board is allowed to pass horizonatally through falling wax. The coating formulations contain paraffin wax, microcrystalline wax, and additves such as EVA copolymers, tackifier resins, and antioxidants. EVA increases the viscosity to produce a stable curtain. Tackifiers increase flexibility and antioxidants prevent the formation of odor and discoloration (3).

Folding cartons are made from heavy paper or papeboard. The carton is printed, folded into the basic carton shape, sealed and glued, and shipped to the user. The carton usually goes into an automatic filling line where it is popped open and filled with product. Waxing allows the board to sustain ply separation without splitting or failing when bent back.

FUTURE OUTLOOK

The current awareness of the environmental impact of products has consumers and manufacturers re-evaluating their existing materials. This is true for the packaging industry because much of its end product requires disposal.

Petroleum waxes have many properties that make it a barrier to gases and vapors. This is very desirable for the actual packaging, but makes it very difficult to recycle. Closed-loop recycling of paper products is called repulping. Packaging containing petroleum waxes requires special handling at recycling mills. The most severe problem is that the waxes combine with other contaminants, and clog the wires and felts of the paper machine, forming "stickies." Waxes can also delay the defibering in the pulper. Most existing plants are not equipped to remove the contaminants (4).

The International Group, Inc., a world leader in refining and marketing of petroleum waxes, is working with paper and equipment suppliers to develop new products that improve pulpability and to modify technologies to better handle contaminants (5). The industry is now developing wax alternatives, many of which have become commercial.

WRAPPING MACHINERY, STRETCH-FILM

Edwin Ho
OSI Industries
Lisle, Illinois

HISTORICAL OVERVIEW

The stretch-wrapper industry is over 30 years old in 2008. In 1976 there were only four or five manufacturers producing a wide-web model used to wrap standard-height pallet loads with a large 60-in. roll of stretch film. Soon after that the demand to wrap variable pallet load heights produced the *spiral* model, which used a smaller 20-in. roll of stretch film. Unlike the large roll of film, which was stationary when wrapping the entire pallet load, the smaller 20-in. roll traveled up and down on a motorized carriage, wrapping the entire load in a crisscross fashion. The spiral wrapper offered the primary advantage of wrapping a wide variety of load heights at minimal cost and dramatically reduced the use of the wideweb model.

Today the spiral wrapper (Figure 1), in both semiautomatic and fully automatic formats, represents approximately 90% of all wrapper production. Wrapper manufacturers in the United States now number over 20, ranging from small producers of lower-cost models to major producers offering a complete line of wrapper models to accommodate virtually every stretch-wrap application known.

THE DEMAND FOR STRETCH WRAPPERS

Prior to the energy crisis of 1974, the use of *shrink* film to unitize pallet loads of product was an increasingly popular packaging medium. The costly and excessive use of heat energy (gas, electric, or propane) to shrink film, however, along with the rising cost/availability of shrink resins, placed industry of all types in a cost-prohibitive situation.

Another unitizing method, using strapping (steel, nylon, polyethylene, or polypropylene) to unitize pallet loads, was recognized as labor-intensive; and an average pallet load could take up to 7 min to strap, depending on the nature of the product and the acceptable strapping pattern desired.

Still other unitizing mediums such as pressure-sensitive tape, twine, or spot adhesives did not provide inherent protection from the elements and would tend to loosen while in transit.

Stretch film offered a lower cost advantage of being applied by equipment that used only "on/off" electricity as a source of power and could be applied by a semiautomatic stretch wrapper. Significantly less labor time was involved and an average size product load could be wrapped in less than 2 min. As a result, many of the initial products

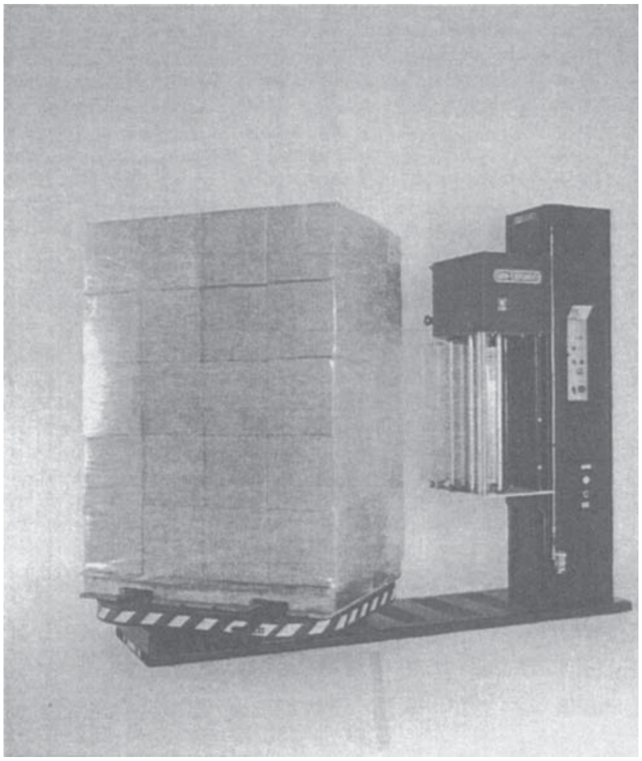

Figure 1. A semiautomatic, spiral wrapper (IPM 55UTS30F) equipped with Uni-Tension power prestretch. For unitizing up to 35 pallet loads per hour.

stretch-wrapped were packaged in multiwall paper bags, polyethylene bags, or cartons. The following is a list of very early stretch film product applications:

Product	Shipped in
Kitty (cat) litter	Multiwall paper bags
Dog and cat food	Multiwall paper bags and cartons
Detergent	Corrugated cartons
Chemicals	Multiwall paper bags and steel drums
Printed forms	Corrugated cartons
Injection-molded bottles	Corrugated cartons
Mortar mix	Multiwall paper bags
Concrete block and brick	Strapped (steel)
Potting soil and mulch	Polyethylene bags
Seed	Polyethylene bags
Canned and jarred food	Corrugated cartons
Liquids in polyethylene/ glass bottles	Corrugated cartons or trays

It should be noted that, even in 30 years later, these products are still being shipped on pallets and in some cases corrugated slip sheet via the stretch-wrap medium. Thus, the demand for stretch film continues to grow with over 2.2 billion pounds being produced annually in the United States. The demand for stretch film is projected to rise 4.7% annually for the next few years. It is estimated that more than 40,000 stretch wrappers are sold annually in the United States as this type of machinery continues to replace conventional packaging methods. In addition, virtually every type of product shipped today in a carton, paper/polyethylene bags, drums, or polyethylene containers is being stretch-wrapped. Products having been considered marginal as a stretch-wrap application are now being packaged or unitized with stretch film. Some of the once considered marginal product applications are as follows:

Aluminum/steel coils
Tires
Engine castings
Expanded styrofoam sheets
Doors
Coils of copper tubing
Batteries
Signatures
Perishable foods (produce and meat)
Windows
Furniture
File cabinets
Frozen fish in ice
Frozen foods
Recycled rubber in polyethylene bags
Hazardous chemicals and powders

PRESTRETCHING FILM

Wrapping a pallet product load with stretch film is generally accomplished by first placing the load on the turntable of the stretch wrapper. The turntable is activated, and rotates and draws film from the supply roll. Originally, film stretch was created by the film roll being gradually retarded from turning while the load pulled the film from the roll. Retarding the film roll was affected by an electromagnetic brake fixed to the film core or through a series of rollers bars. The effective maximum stretch, however, was no more than 120% and in most cases averaged 50–60%. Higher percentages of stretch would generally cause product cartons to crush and could even pull the load from the turntable unless otherwise held in place by an optional top compression platen (electric or air-operated).

Prestretching film, however, became instantly popular in the late 1970s as moderate-to high-volume shippers took advantage of the higher film yields offered by improved stretch films coming into the marketplace. These improved films utilized linear low-density polyethylene (LLDPE) resins either alone or combined with ethyl vinyl acetate (EVA) to enhance puncture resistance, reduce tear propagation, and extend film yield up to 400%. The prestretch method of stretching such films was found to reduce stretch film cost per pallet load by 20–45% as sophisticated prestretch machine assemblies became part of an upscale trend in stretch wrappers in the 1980s.

Unlike a stretch wrapper equipped with brake tension, a prestretch assembly stretches the film at the machine by routing the stretch film between two powered rollers prior to its application to the load. Because the two powered rollers are moving mechanically or electrically at different speeds, the film stretches between the rollers.

The percentage of stretch that can be attained through a fixed-ratio or variable-prestretch assembly can reach 300% with the appropriate film quality and gauge. Common or the most desirable level of prestretch is 200–225%, which allows for maximum film recovery (holding force) at an economical level of film usage. Excessive prestretch can cause stretch film to thin, reduce puncture/abrasive resistance, and diminish the “cling” or self-adhering property of the film. Without a reasonable amount of “cling,” the trailing segment of the film wrap (pressed against the side of the load at the end of the wrap cycle) can release itself allowing the wrapped load to partially unwrap.

Another advantage of prestretch is that most manufacturers have a method to apply tension of the film to the load immediately after the prestretch process occurs. Generally, an adjustable spring *or* air operated dancer bar is utilized to regulate film tension to the product load. One such system is the patented IPM Uni-Tension system (Figure 2), which provides constant and consistent film tension (adjustable) to the product load. As a result, many product loads, which could normally *not* be stretch-wrapped without the use of a top stabilizer platen, *can be wrapped* with power prestretch. Examples of these types of loads are as follows:

Mixed-Product Loads
Partial-pallet loads
Tall-pallet loads
Empty drums
Empty plastic bottles
Load weights of 150–500 lb

Prestretch is preferred by many volume shippers because it reduces the amount of stretch film received by their customers. Although stretch film *is* recyclable, prestretch minimizes the film disposal process.

WRAPPER MODELS AVAILABLE

The stretch-wrapper industry has come a long way since the original *wide-web* machine was introduced. The single-turntable wide-web machine (using a 45- to 80-in. film roll size) has been expanded to at least several additional models to include wide web prestretch. The *spiral* wrapper model has evolved into multiple models designed to accommodate a wide variety of applications and user preferences. The following is a list of the most popular models currently available—also noted is the average production rate for which that model would be applicable:

Wrapper Model	Production Rate
Hand wrapper	0–10 pallets/day
Power turntable with hand wrapper	0–10 pallets/day
Powered-turntable machine with manually operated film carriage (has mechanical powered carriage)	≤20 pallets/day
Semiautomatic, powered-turntable machine with adjustable programmable controls for number of wraps, speeds of turntable, film carriage, etc., and brake tension	≤35 pallets/h
Semiautomatic, powered-turntable machine with adjustable programmable controls for number of wraps, speeds of turntable, film carriage, etc., and fixed-ratio powered prestretch	≤35 pallets/h

(*Note:* These powered-turntable machines are available in a high-platform turntable design (for forklift use only) or a low-profile design with a loading ramp for hand/electric pallet jack and forklift use. These machines are also available in wide-web or spiral-type models.).

The machine models listed above continue to withstand the test of time, being the most popular and often manufactured with the following most common options to enhance the stretch-wrapping process, increase the production rate, or improve operator efficiency:

- *Photoelectric height sensor* (*for semiautomatic spiral models*)—located on the film carriage to automatically seek the top of the pallet load, halt the film carriage, and permit the top wrap cycle to occur.

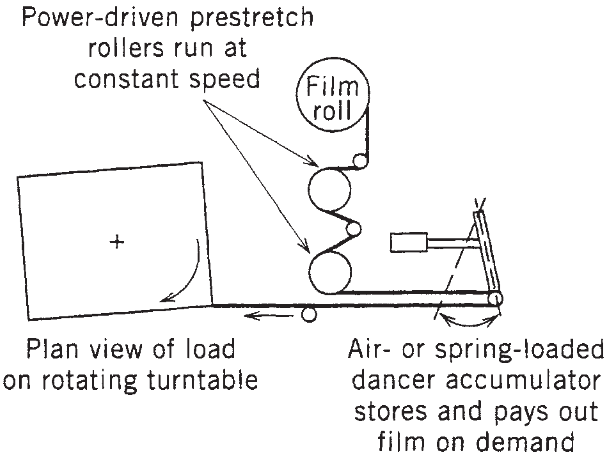

Figure 2. Powered prestretch.

- *Mast extension* to permit pallet loads in excess of 85 in. in height to be wrapped.
- *Top-compression platen* (*electric or air-operated*)—exerts an adjustable amount of stabilizing pressure on the top of a lightweight or unstable product load.
- *Additional turntable (dual-turntable model)*—increases production rate by 33%.
- *Conveyorized turntable* (*gravity roller*)—for in-line capability; that is, machine is installed into existing or new gravity roller production line.
- *Pit mount*—machine is installed into the floor with turntable virtually flush with floor; enhances use of pallet jacks.
- *Scale*—5,000- to 10,000-lb capacity scale integrated with and under the wrapper turntable eliminates double handling of pallet loads.

FULLY AUTOMATIC CONVEYORIZED MODELS

Shippers with moderate to high production (15–85 pallets/h) have generated an increased demand for fully automatic stretch wrappers. The most popular fully automatic has a powered conveyorized turntable for in-line powered-conveyor systems or for multiple forklift operations. Unlike a semiautomatic wrapper, the fully automatic wrapper eliminates the operator, who necessarily would first attach the stretch film to the load and then press a START button. At the completion of the wrap cycle, the operator would cut the film and adhere the trailing edge of the film to the side of the load. The automatic, however, operates through an electric programmable logic controller (or microprocessor) and a series of electronic photoelectric load sensors. The stretch film is held in a mechanical clamp between load wrap cycles and is cut and brush-wiped onto the pallet load automatically at the completion of the wrap cycle.

A fully automatic wrapper equipped with a power infeed and discharge conveyor can be integrated with an automatic load palletizer (which feeds loads to the wrapper). This same system can be used effectively by having a forklift operator set a load on the power infeed conveyor and then activate that conveyor with an overhead remote pendant control. As that load would feed into the wrapper module, the forklift operator would drive over to the discharge conveyor section to remove a completely wrapped load and place it into storage or a shipping vehicle. Automatics are generally equipped with a prestretch assembly for maximum utilization of the stretch film.

Common *optional* equipment to enhance higher-speed, fully automatic systems are as follows:

- Top-compression platen exerts an adjustable amount of stabilizing pressure on the top of a lightweight or unstable product load.
- Automatic top-sheet dispenser that automatically places a 2- to 3-mil polyethylene top sheet on top of the pallet load prior to the load being conveyed to the wrapping module. A top sheet is usually desirable to prevent the elements from damaging the product.
- The 90° index turntable is used primarily to direct the discharge of the pallet load 90° from which it was accepted onto the machine. This option is usually desired if there is a floor-space restriction.
- Mast extension to permit pallet loads in excess of 85 in. in height to be wrapped.

OTHER WRAPPER MODELS

In recent years, *new* stretch-wrapper designs have been created by different manufacturers to accommodate either the end user's specific product application or existing packaging line. One such model is the increasingly popular *overhead rotary-arm*-type stretch wrapper (Figure 3). With this model, the product load does not rotate on a turntable. The load sits on the floor or on conveyor, and the roll of stretch film travels on the overhead arm *around the load* wrapping it in a spiral fashion. The film stretch delivery system can be either the brake tension type or the powered prestretch type.

The overhead rotary-arm-type machine is advantageous for wrapping pallet loads when

- Loads are extremely heavy.
- The product on the pallet is subject to damage if rotated.
- Loads are unstable and not easily moved by forklift, pallet jack, or conveyor.
- Washdown is required—that is for use in poultry plants or facilities where the machinery and general work areas must be washed down periodically for sanitation reasons.

The overhead-arm-type machine is currently manufactured as a wall- or floor-mounted semiautomatic or can be upgraded and incorporated into a fully automatic conveyorized system for high-production use.

The *semiautomatic robotic wrapper* is a battery-operated, wheeled vehicle with a vertical mast and film-stretch delivery system. This wrapper is placed next to a product load and, when activated, travels around the perimeter of the load while the film carriage travels up and down stretch wrapping the load. A sensing device signals the wrapper to turn as it senses the corner of the load. This type of wrapper has been used to wrap longer-than-average product loads and requires ample floor space in which to operate.

Orbit stretch wrapping has become a popular method to stretch wrap large flat panels such as office dividers, locker-room partitions, and so on, in which the panel is conveyorized through a large ringlike assembly and a 10- to 30-in. roll of stretch film travels in a vertical plane with a circular motion around the entire panel wrapping it as it moves through the ring on the conveyor.

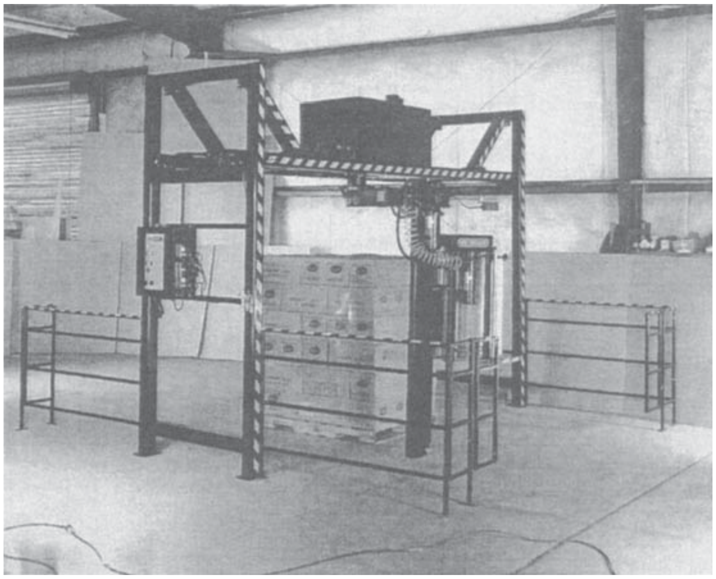

Figure 3. A semiautomatic overhead rotary-arm-type stretch wrapper.

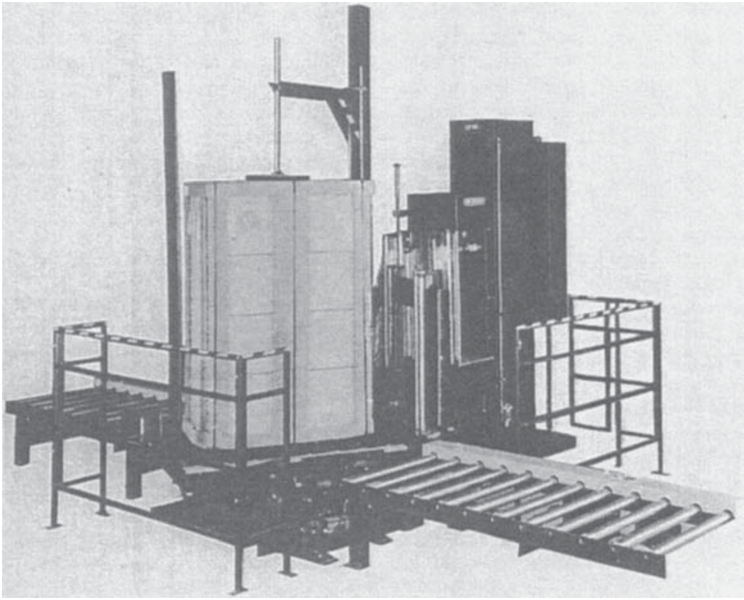

Figure 4. A down-sized fully automatic (IPM Bantam 88) wrapping F-Pack prepared file cabinets.

The orbital wrapper is also advantageous for wrapping long products either singularly or in bundles. Examples of such products would be rolls of carpet, PVC pipe, fencing, and shovel or rake handles. The orbital wrapper is available in several "ring" sizes to accommodate even small bundling applications such as a stack of blue jeans, bags of dog food, and like products. Orbital wrappers are largely manufactured as automatic equipment, although semiautomatic and manually operated orbital wrappers are available for low-production and individual-product-size applications.

Wrappers have been designed *for* stretch wrapping *doors, windows*, and similar products in the vertical plane. In most cases, the stretch wrapper of choice is a standard semiautomatic, low-profile model with power prestretch for maximum film economy. Wrapping doors on a pallet, however, requires an air-loaded clamp that locks the doors together at the very top of the load. Wrapping windows requires a top-compression stabilizer with an adjustable clamp and a similar adjustable clamp mounted on the turntable. Both clamps hold the window stationary during the wrap process.

Explosion-proof wrappers are required for many hazardous materials, flour, and similar powder-type products packaged in cartons, multiwall paper, or polyethylene bags. The manufacturing environment for such products demands that the stretch wrapper be designed as spark-free as possible. Static eliminators (for the stretch film) are often used on this type of equipment.

Produce and *perishable* wrappers have been designed to use stretchable and rigid stretch net that allows the wrapped load to "breathe." Produce items such as bananas, melons, peppers, and tomatoes are shipped in ventilated cartons so that damage causing gases generated from certain fruits and vegetables can escape from the carton during the cooling and shipping process.

Stretch net (used in the same way as stretch film on the wrapper) wraps the produce load securely and permits the ventilation to occur. Net, however, cannot be prestretched, and actual stretch is limited to 5–35%.

The product wrapper itself is usually a semiautomatic wrapper and is fitted with a brake-tension delivery system. This same wrap method is being used for perishable products such as cartoned meat, poultry, yogurt, and frozen foods.

A recent innovation to the wrapper is the *roper / bander*, an option that allows somewhat less expensive stretch *film* to be reduced in web size (from 20 to 3 in.) by having the film travel through a mechanical fixture as it is being dispensed from the feed roll under tension to the product load. Thus, a 3-in. rope (or band) of film is created that unitizes the load in the standard up/down, crisscross fashion yet does not inhibit the ventilation process. A standard brake tension system or a power prestretch system can be utilized with the roper/bander unitizing method.

Luggage wrappers have recently been designed to stretchwrap standard luggage at airport departure terminals. The stretch wrap acts as a theft deterrent as well as a preventive measure for tightening airport security.

FUTURE WRAPPING SYSTEM

The appearance and performance of the future stretch wrapper will likely be driven by specific product package designs as many regions of the world further their concept of source reduction:

Less packaging materials per package
Less actual labor involved per package
Less time to prepare the package
Less packaging materials to recycle
Less materials going to landfill
Less factory floor space consumed by packaging material inventory

Packaging engineers are working closely with stretch-wrapper manufacturers to marry the two concepts of source reduction in packaging and the stretch-wrapper design.

A primary example would be the development of the "*clear-view*" package (acronym for *F-Pack*) for products such as file cabinets, bedroom furniture, entertainment centers, and armoires. Driven by consignee resistance to the disposal problem of large corrugated cartons along with the increasing cost of corrugated cartons, product manufacturers have had to develop "abbreviated" package designs.

The F-Pack package design eliminates the use of the corrugated carton and replaces it with a stretch-wrap package utilizing protective corrugated corner posts and corrugated caps and trays. Polyethylene strapping is also used in some cases.

For low-volume producers, the standard semiautomatic stretch wrapper has been modified to accept and wrap F-Pack type packages. For moderate- to high-volume manufacturers, fully automatic stretch-wrapper models have been *down-sized* and significantly modified to accept the high-production volume and the specific individual package design. A down-sized Bantam 88, conveyorized fully automatic stretch wrapper (Figure 4) can be placed in-line to accept F-Pack prepared products like file cabinets. It is likely that additional products such as small appliances, air-conditioning units, and heat pumps will also shed their corrugated carton in favor of a clear-view package in the future.

Material improvments in terms of strength and stretch percentages will stimulate gains as greater stretchability and lower costs by enabling pallets and other products to be wrapped with less film. Stretch hoods will exhibit the fastest growth of all product categories due to their significant higher throughput compared to conventional unitization methods. In recent years, the stretch hood wrapping system (Cover-Pal 6000) manufactured by Arpack using Thimon patented technology offered reliable five-sided stretch wrapping of pallet load. Their machine covers pallet-held products on the top and sides, allowing for pallet load storage with strong environmental protection against dust, water, and shipping damage that occur during storage and transportaion. The packaging system is ideal for products for home centers, construction sites, and freight yards.

The Arpack COVER-PAL 6000® STRETCH, a stretch hood pallet covering system, offers numerous advantages over standard pallet wrapping, including:

- Higher production capacity—wraps pallets at speeds up to 120 pallets per hour with less film changeovers.
- Brand messaging can be printed directly onto the film, enhancing product recognition.
- Transparent pallet cover enables labels to be read without removing the film.
- Ensures stable pallet loads for transportation.
- Unlike stretch film used by conventional stretch wrap equipment, stretch hood films are recyclable.

A stretch hood pallet covering system can be a viable replacement of conventional stretch-wrapping machine for the specific product groups using corrugated containers in various industries in the near future. The challenge for the success is to make sure that the cost per pallet load offered by the stretch hood method is more cost competitive in terms of film material usage, capital investment, and operation efficiency compared to conventional unitization methods.

A few major stretch-wrapping equipment suppliers to the United States market are Arpac, Lantech, ITW Mima, and Seal-O-matic.

SUMMARY

The stretch wrapper continues to be the unitizing medium of choice for (a) palletized product loads, (b) slip-sheeted product loads, and (c) for products having new, lower-cost package designs. The use of stretch film (particularly prestretched) and stretch net offers significant savings for the shipper, carrier, and consignee. New stretch-film resins such as *metallocene* may enhance prestretch film yield and allow "down-gauging" for many applications.

Stretch-wrapper design and performance function should continue to be refined in the areas of manufacturing cost, prestretch assemblies, and ergonomics, resulting in additional benefits to the end user. Stretch hoods will exhibit the fastest growth of all product categories due to their significant higher throughput compared to conventional unitization methods.

CONVERSION FACTORS, ABBREVIATIONS, AND UNIT SYMBOLS

Selected SI Unite (Adopted 1960)

Quantity	*Unit*	*Symbol*	*Acceptable equivalent*
BASE UNITS			
length	meter[†]	m	
mass[‡]	kilogram	kg	
time	second	s	
electric current	ampere	A	
thermodynamic temperatures[§]	kelvin	K	
DERIVED UNITS AND OTHER ACCEPTABLE UNITS			
*absorbed dose	gray	Gy	J/kg
acceleration	meters per second squared	$\mathrm{m/s^2}$	
*activity (of ionizing radiation source)	becquerel	Bq	I/s
area	square kilometer	$\mathrm{km^2}$	
	square hectometer	$\mathrm{hm^2}$	ha (hectare)
	square meter	$\mathrm{m^2}$	
density, mass density	kilograms per cubic meter	$\mathrm{kg/m^3}$	g/L; $\mathrm{mg/cm^3}$
*electric potential, potential difference, electromotive force	volt	V	W/A
*electric resistance	ohm	Ω	V/A
*energy, work, quantity of heat	megajoule	MJ	
	kilojoule	kJ	
	joule	J	N · m
	electronvolt[x]	eV[x]	
	kilowatthour[x]	kW · h[x]	
*force	kilonewton	kN	
	newton	N	$\mathrm{kg \cdot m/s^2}$
*frequency	megahertz	MHz	
	hertz	Hz	1/s
heat capacity, entropy	joules per kelvin	J/K	
heat capacity (specific), specific entropy	joules per kilogram kelvin	J/(kg · K)	
heat-transfer coefficient	watts per square meter kelvin	$\mathrm{W/(m^2 \cdot K)}$	
linear density	kilograms per meter	kg/m	
magnetic field strength	amperes per meter	A/m	
moment of force, torque	newton-meter	N · m	
momentum	kilogram-meters per second	kg · m/s	
*power, heat flow rate,	kilowatt	kW	
radiant flux	watt	W	J/s
power density, heat-flux density, irradiance	watts per square meter	$\mathrm{W/m^2}$	
*pressure, stress	megapascal	MPa	
	kilopascal	kPa	
	pascal	Pa	
sound level	decibel	dB	
specific energy	joules per kilogram	J/kg	
specific volume	cubic meters per kilogram	$\mathrm{m^3/kg}$	
surface tension	newtons per meter	N/m	
thermal conductivity	watts per meter kelvin	W/(m · K)	

velocity	meters per second	m/s	
	kilometers per hour	km/h	
viscosity, dynamic	pascal-second	$\mathrm{Pa \cdot s}$	
	millipascal-second	$\mathrm{mPa \cdot s}$	
volume	cubic meter	$\mathrm{m^3}$	
	cubic decimeter	$\mathrm{dm^3}$	L (liter)
	cubic centimeter	$\mathrm{cm^3}$	mL

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

Multiplication factor	*Prefix*	*Symbol*	*Note*
10^{18}	exa	E	
10^{15}	peta	P	
10^{12}	tera	T	
10^{9}	giga	G	
10^{6}	mega	M	
10^{3}	kilo	k	
10^{2}	hecto	h[a]	
10	deka	da[a]	[a] Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.
10^{-1}	deci	d[a]	
10^{-2}	centi	c[a]	
10^{-3}	milli	m	
10^{-6}	micro	μ	
10^{-9}	nano	n	
10^{-12}	pico	p	
10^{-15}	femto	f	
10^{-18}	atto	a	

*The asterisk denotes these unite having special names and symbols.

†The spellings “metre” and “litre” are preferred by ASTM; however, “-er” is used in the *Encyclopedia*.

‡“Weight” is the commonly need term for “mass.”

§Wide use is made of “Celsius temperature” (t) defined by $t = T - T_0$ where T is the thermodynamic temperature, expressed in kelvins, and $T_0 = 273.15$ by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvins.

ˣThis non-SI unit is recognised by the CIPM as having to be retained because of practical importance or use in specialised fields.

Factors For Conversion to SI Units

To convert from	*To*	*Multiply by*
acre	square meter ($\mathrm{m^2}$)	4.047×10^{3}

GLOSSARY OF PACKAGING TERMINOLOGY AND DEFINITIONS

Paul Zepf
Zarpac, Inc.
Oakville, Ontario, Canada

GLOSSARY

The attempt of this glossary is to communicate, define, and clarify common words used in the packaging industry as they relate to machines and processes. This glossary has evolved over time and will continue to evolve and refine these definitions and terms and add new definitions and terms as required. Just because someone uses the same word or term as another individual does not mean that person understands it the same way. It has been found that miscommunication and misunderstandings are common in the packaging industry even when using the same word. The reader is encouraged to contact the author pertaining to clarifying an existing definition and/or adding more terms.

Wherever possible, definitions from other sources or associations have been maintained, such as terms and definitions from the canning trade, to achieve as much alignment as possible with the large diversity in the packaging industry.

Absolute humidity The actual weight of water vapor contained in a unit volume or weight of air. See Relative humidity.

Absorbent A substance that has the ability to soak up or retain other substances, such as sugar or salt absorbing water, when exposed to high relative humidity atmospheres.

Acid A substance, usually a liquid, that increases the concentration of hydrogen ions (H^+) in water and reacts with a base to form a salt. On a pH scale, an acid has a pH value of <5; a pH value of 7 indicates a neutral substance. As the pH value declines from pH<5, the substance becomes more acidic and is generally more corrosive.

Accumulation An accumulation apparatus is a device that deliberately amasses inputs or products into one place for the next required operation or process. Taking a single line of product and collating the products into multiple rows to go into an oven, cooler, or similar operation is an example of accumulation. Accumulation should not be confused with buffers. The definition of buffer is to shield or cushion (via conveyor length or off-loading areas such as tables or conveyors to let the inputs gather) an upstream machine from a downstream machine that stops. Generally, a buffer is a technique used as a positive modulating effect on utilization. The two definitions should not be used interchangeably.

Achievable run speed That speed or rate as tested during commissioning (which also verifies the packaging line design criteria of needs) to be the needed sustainable steady-state speed on a per minute or per hour basis with a wastage factor of<0.01. It is generally 20% less than the packaging line capacity and 50–70% less than the packaging line capacity for a true just-in-time (JIT) packaging line. The proposed run speed, the achievable run speed, and the design run speed can be used interchangeably, although the achievable run speed is the phase used in this book.

Action steps Specific, tactical activities you take to accomplish goals and objectives.

Activity An individual step or piece of work that is part of the total job being scheduled.

Activity-based costing The use of cost accounting tools that attempt to allocate indirect or overhead costs on the basis of related activities, rather than using surrogate allocation bases such as direct labor or machine hours, floor space, or material costs.

Actual set run speed That target speed or rate as set or fixed for a given package run cycle on a per minute or per hour basis that is subjectively set by the operator or management. It is generally equal to (ideal) or less than the achievable run speed (usually). It is the dialed run speed set by the operator or management. On dynamically controlled automated packaging lines, it is the instantaneous steady-state target output rate. Note that the effects of wastage rework and stoppages have not been considered.

Additive Any substance, the intended use of which results or may reasonably be expected to result, directly or indirectly, in its becoming a part of or otherwise affecting the characteristics of any input.

Adsorbent The material on whose surface adsorption takes place.

Adsorption The adhesion of a substance to the surface of a solid or liquid.

Adulterant (adulteration) Foreign materials in the product, especially substances that are aesthetically objectionable, hazardous to health, or indicate that unsanitary handling or manufacturing practices have been employed.

Aeration The bringing about of intimate contact between air and a liquid by bubbling air through the liquid or by agitation of the liquid.

Aerator A device for promoting aeration.

Aerosol The colloidal suspension in which gas is the dispersant. Dispersion or suspension of extremely fine particles of liquid or solid in a gaseous medium.

Affordable capital limits (ACLs) The specified cost or "cap" for a project to achieve maximum value. The ACL is based on the economic facts associated with a specific business need, not a "wish" or arbitrary "grab number."

Agglomerate To gather, form, or grow into a rounded mass, or to cluster densely.

Aftersales service Service provided after the sale, such as repair or warranty service, customer problem solving, or follow-up in canvassing customers as to their opinions, needs, quality of products, and quality of service (timely delivery) to ensure that the customer is and remains satisfied.

Allocated inventory Materials that are in inventory or on order but have been assigned to specific production orders in the future. These materials are therefore not available for use in other orders.

Anaerobes These are microorganisms that grow in the absence of oxygen. Obligate anaerobes cannot survive in the presence of oxygen. Facultative anaerobes normally grow in oxygen but can also grow in its absence.

Anaerobic Living or active in the absence of free oxygen.

ANSI American National Standards Institute.

Antimicrobial A compound that inhibits the growth of a microbe.

Apparent viscosity (see Viscosity) Viscosity of a complex (non-Newtonian) fluid under given conditions.

Appropriation An authorization by the appropriate executive or management committee for funding of capital projects in excess of a specific amount.

Approved-bidders list A list of prequalified contractors used for the purpose of soliciting competitive bids.

Aseptic processing and packaging The filling of a commercially sterilized cooled product into presterilized containers, followed by aseptic hermetical sealing, with a presterilized closure, in an atmosphere free of microorganisms.

Asset utilization Fraction of time of a 24-h day, 7 days a week potential time, that is actually used in producing quality packages until the package run cycle is completed (package run cycle start point to the next package run cycle start point). If the package run cycle (start to next start) takes exactly 3 days, then the total asset utilization time is $24 \times 3 = 72$ h, even though only one shift per day may be used.

Authorize To give final approval.

Authorized work Work that has been approved by higher authority.

Automation A technique of making industrial machinery, a process, or a system operate in an independent or self-controlling manner. This is the generic definition of automation. With regard to packaging, this definition should be adjusted to reflect the objectives of packaging, as follows: Automation is controlling the packaging line by using the optimum technique to cause the process to operate at a steady state pace in a self-controlling manner. Note that these definitions say nothing about eliminating labor or guaranteeing profitability, but they both imply that automation will optimize labor and give the potential of profitability.

Availability The total available time for which a machine or system is in an operable state or between failures divided by the sum of the mean time between failures plus the mean time to repair plus the mean preventive maintenance time. Simply put, it is the fraction of time the machine is in an operable state to the total time period defined. An operable state is the condition that allows the machine or system to function at its achievable run speed in a manner that produces an outcome or an assemblage of inputs within the stated specifications and conformance to customer's needs.

Available inventory Materials that are in inventory or on order that are not safety stock or allocated to other uses. This available inventory is on immediate call to sustain the needs of production on a timely bases without interruption.

Backcharge The cost associated with corrective action taken by the purchaser. This cost is chargeable to the supplier under the terms of the contract.

Baffle A partition or plate that changes the direction or restricts the cross section of a fluid, thus increasing the velocity or turbulence.

Base Alkaline substances ($pH > 7.0$) that yield hydroxyl ions (OH^-) in solution. As a general rule, as the pH value increases, the corrosive ability of the solution increases.

Benchmarking A comparison or scale of product, function, practice, or strategy between identical industry segments. There are four types of benchmarking:

Product benchmarking, which evaluates the current and future strengths and weaknesses of internal and external competitive products or packages.

Functional benchmarking, which can be a comparison of the functional process or manufacturing technique relating to product development, packaging-line design, machinery setup, packaging-line control, and logistics of inputs in and packages out. Utilization when set up correctly can be a form of functional benchmarking.

Best-practices benchmarking, which goes beyond the functional benchmarking by focusing on management practices.

Strategic benchmarking, which compares the goals, direction, and key performance measure of a company within an industry sector against their internal or external competitors.

The *performance index* is a benchmark of functional and best practices.

Bid-clarification management Meeting with potential suppliers to clarify contract and associated issues prior to a decision on selection of a contractor.

Bid evaluation Review of a supplier's ability to perform the work requested. The supplier's financial resources, ability to comply with technical criteria and delivery schedules, and past performance are considered.

Bid list A list of suppliers invited to submit bids for the specified goods or services.

Bid response A negative or positive response to an invitation to bid from prospective suppliers.

Bill of material (BOM) The list of all end items or products that is a major element of the material requirements planning (MRP) system. In addition, a bill of material contains a listing of all raw materials, parts, subassemblies, and assemblies that go into each end item or package, as well as how the components go together.

Biodegradability Susceptibility of a chemical compound to depolymerization by the action of biological agents.

Blanching Heating by direct contact with hot water or live steam. It softens the tissues, eliminates air from the tissues, destroys enzymes, and washes away raw flavors.

Breakdown maintenance Breakdown maintenance and emergency maintenance are basically the same, when the predominate method of maintenance is breakdown maintenance. Breakdown maintenance is doing no maintenance other than lubrication between breakdowns. Repairs and adjustments are done as a result of reduced or no production occurring. Emergency maintenance occurs when a technical person is called on to perform a repair at any time of the day without being forewarned. With most other types of maintenance, emergency maintenance should be the exception, not the rule, as in breakdown maintenance.

British thermal unit (Btu) The British engineering unit of heat quantity. It is approximately the quantity of heat that will raise the temperature of 1 pound of water 1 degree Fahrenheit. 1 Btu = 0.252 calories = 1054 J.

Buffer The definition of a buffer is to shield or cushion (via conveyor length or off-load areas to let the inputs gather) an upstream machine from a downstream machine that stops or slows down. Generally, a buffer is a technique used to maintain uptime and effect utilization. It should not be confused with accumulation. The definition of accumulation is a device that deliberately amasses inputs or products into one place for the next required process. The two definitions are similar but different.

Bulk density Weight per unit volume of a quantity of solid particles that depends on the packing density.

Bursting strength The strength of material in pounds per square inch, measured by the Cady or Mullen tester.

Business strategy The organization's reason for being, including purpose, mission, operating principles, objectives, and goals.

CAD Computer-aided design. This term implies the use of a computer and drafting software such as AutoCAD (trademark) to produce and store prints for layout, installation, machining, assembly, and fabrication. Another definition is the use of computers in interactive engineering drawings and the storage and retrieval of designs.

Caliper The thickness as related to paperboard, of a sheet measured under specified procedures expressed in thousandths of an inch. Thousands of an inch are sometimes termed "points." The precision instrument used in the paperboard industry to measure thickness. To measure with a caliper.

Calorie A unit of heat or the amount of heat necessary to raise the temperature of a gram of water 1 degree Celsius. Nutritionists use the large Calorie or kilo-Calorie (spelled with a capital C), which is 1000 calories. One Calorie (kilo-calorie) = 4184 J or 3.968 Btu.

Computer-aided manufacturing (CAM) This term implies the use of a computer and postprocessing or linking software (such as Smartcam or Mastercam) to manipulate and compile data into a machine language for a machine(s) to execute the desired function. Another definition is the use of computers to program, direct, and control production equipment.

Can, cylinder A can whose height is relatively large compared with its diameter. Generally called a "tall can."

Can, flat A can whose height is equal to or smaller than its diameter.

Can, key-opening A can opened by tearing off a second strip of metal around the body by means of a key, or any can opened by means of a key.

Cap (see also Closure) Any form or device used to seal off the opening of the container, so as to prevent loss of its contents.

Cap, lug A cap closure for glass containers in which impressions in the side of the cap provide a grip when the cap is given a quarter turn, as compared to the full turn necessary with a screw cap.

Cap, screw A cylindrical closure having a thread on the internal surface of the cylinder capable of engaging a comparable external thread on the finish or neck of a container, such as a glass bottle or collapsible tube.

Cap, snap-on A type of closure for rigid containers. The sealing action of a snap-on cap is effected by a gasket in the top of the cap that is held to the neck or spout of the container by means of a friction fit on a circumferential bead. Material of construction is either metal or semirigid plastic.

Cap, two-piece vacuum Standard CT (continuous-thread) or DS (deep-screw) caps, equipped with a separate disk or lid that is lined with sealing for vacuum-packing processes.

Capability (schedule) In simple terms, *capability* is the relative measure of how capable or how effective is the actual packaging process to produce the appropriate volume of needed packages within the planned plant operational time period or schedule. Capability or, more correctly the *schedule capability*, relates to the ratio of the scheduled run cycle time available divided by the actual package run cycle time used. This definition is valid only if the actual time taken is greater than the scheduled time. If the actual time is less than the scheduled time, the capability is the actual package run cycle time divided by the scheduled run cycle time. Capability is always equal to or less than 1.

Capacity Capacity for a given packaging line and product is the *upper possible sustainable limit* of packages passing a point just before warehousing or shipping in a given amount of time (usually one minute or one hour or one shift). *Sustainable* refers to the ability to maintain consistent production of quality packages at a given speed.

One could argue that it is the speed at which the percentage of rejects and/or jams begins to rise in a nonlinear manner. Capacity is usually expressed as a rate (packages/minute, etc.). Typically, a line will operate at a somewhat lower speed, called the *actual set run speed*. For just-in-time (JIT) processing, all machines and systems in the packaging process as well as making must have excess capacity.

Capacity requirements planning (CRP) The process of reconciling the master production schedule to the labor and machine capacities of the production departments over the planning horizon. This process is generally used in conjunction with material requirements planning (MRP) systems.

Case A nonspecific term for a shipping container. In domestic commerce, "case" usually refers to a box made from corrugated or solid fiberboard. In maritime or export usage, "case" refers to wooden or metal box.

Cash flow The net amount of actual inflows and outlays generated by a project or business unit.

Cash-flow analysis The process of determining monthly and overall total cash flow for projects. The cumulative total is used as a measurement of actual versus budget costs. This activity helps monitor projects and costs.

Catalyst A substance that increases the rate of chemical reaction and remains unchanged at the end of a reaction.

Celsius (°C) The temperature on a scale of 100° between the freezing point (0°) and the boiling point (100°) of water.

Centimeter (cm) One-hundredth of a meter. Equivalent to 0.3937 in. One inch equals 2.54 cm.

Centipoise (cP) Unit of viscosity equal to $\frac{1}{100}$ dyn/($s^2 \cdot cm^2$).

Changeover time (or period) The time to complete the following items:

1. Exchange of changeover parts or tooling for all line elements.
2. Recalibration and/or adjustment of all line elements.
3. Run the first 1000 packages or 15 min of production, whichever comes first

At the end of this procedure, the line and all machine elements are expected to perform the desired functions to produce quality packages at the required output rate.

Clean in place (CIP) A machine's (such as a filler's) ability to be cleaned and sanitized in place on the packaging line without dismantling any components and minimizing time, product loss, cleaning solutions, cleaning procedures, and volume of water required.

Cleanup time or (period) The time required to (*1*) remove change parts from the previous package run cycle and (*2*) clean and/or flush out and inspect areas of the machine and line.

Closure The joint or seal that is made in attaching the cover to a glass container. Also, the type of closure, such as friction, lug, and screw top.

Computer numerically controlled (CNC) This term implies the use of a computer or processor on board the machine that is controlled by compiled program and/or data in APT or ASCII or G codes or other machine languages derived from software (such as Smartcam or Mastercam) to manipulate and instruct the machine in an exact manner.

Commissioning Commissioning is the act of sequentially and systemically starting up and testing a machine or machines or systems to ensure that they function as specified and that it can meet the needs of production. All components are tested and evaluated as to fit, function, vibration, alignment, integration, control, ergonomics, input flow, installation, and safety.

Commissioning, qualifying, and verifying (CQV) Commissioning, qualifying, and verifying (CQV), or more simply, "get up and stay up" (GUSU), is basically a management structure to ensure that a new or modified packaging line and all its machinery and systems are tested properly, the operators and maintenance personnel are adequately trained, and the results of the testing and training are verified or observed in the production runs without special assistance of any kind. Some companies restrict CQV to the machinery and systems and keep people and training separate.

Commissioning is the act of sequentially and systematically starting up and testing a machine or machines or systems to ensure that they function as specified. All components are tested and evaluated as to fit, function, vibration, alignment, integration, control, ergonomics, input, flow, installation, and safety.

Qualifying is the act of setting up and administering a training program that ensures the people who will be interfacing with the packaging line are given a thorough overview of the packaging line and a detailed program on what they need to know to complete their tasks without hesitation or guessing. All training must address the following questions:

When should training be done?
What training should be done?
How should we do training?
Where should we do training?
How much is enough training?
Manuals and other self-help tools?
Performance reviews and continuing improvement?
Company standards and policy?

Verifying is the act of being able to determine without hesitation that the machine testing and training of personnel is not only thorough but also effective in the day to day production of the packaging line without senior staff, consultants, and/or machinery service personnel being involved in any manner.

Training of all line and maintenance personnel is critical to the performance of any packaging line. Training must be thorough, to the extent that all personnel working on the line are knowledgeable in the overall operation and be the technical expert in their specific task(s). Management people must be experts in the overall operations of the line, and knowledgeable about the tasks and performance of each person working on the line.

Complete kit (CK) The complete kit (CK) is a managerial method or concept. It suggests that no work should start until all the items required for the completion of the job are available. These items such as components, tools, drawings information, and samples constitute the kit.

Computer-integrated manufacturing (CIM) The integration of the total manufacturing enterprise through the use of integrated systems and data communications coupled with new managerial philosophies that improve organizational and personnel efficiency. In other words, the business enterprise is dependent on human knowledge and information flow in order to operate efficiently. Companies that have implemented CIM successfully tend to say that they get the right information to the right people or devices in the right places at the right times to make the right decisions. CIM uses such a broad spectrum of technologies that it is best to think of CIM as a goal or strategy or philosophy as outlined by the company's needs and direction.

Computerized maintenance management system (CMMS) A computerized maintenance program is sometimes called a *computerized maintenance management system* (CMMS), which can form the central part of a TMM program. There are many computerized maintenance programs in use today. One or several can be an effective tool for your operation. Always remember that the software has to fit your needs, not the other way around. The main function of the computerized system is to make life easier and faster for maintenance to do their job.

Components Components can be either input items or product items. Example of components are labels, caps, containers, seals, cartons, cases, and the product such as liquids, pastes, pills, hardware, and powders.

Confidential-disclosure agreement (CDA) A legal agreement between two parties that establishes terms and conditions for protecting the security of specified information.

Consistency Resistance of a fluid to deformation. For sample (Newtonian) fluids, the consistency is identical with viscosity; for complex (non-Newtonian) fluids, identical with apparent viscosity.

Contingency plan Alternative strategies to accomplish a project's objectives.

Contract award Tne award of the contract to one prospective supplier. Acceptance is usually followed with a purchase order or a signed contract.

Contract manufacturer An outside company contracted to manufacture or package a product.

Control The authority or ability to regulate, direct, or dominate a situation or series of events. For any packaging line, whether manual, semiautomatic, or automatic, control is critical.

Cop Clean-out-of-place.

Criteria A document that provides objectives, guidelines, procedures, and standards that are to be used to execute the development, design, and/or construction portions of a project.

Critical activity Any activity on a critical path.

Critical path The longest path or chain of activities in the project that determines the shortest period of time in which the project can be completed.

Critical-path method (CPM) A scheduling technique using arrow, precedence, or PERT (program review and evaluation technique) diagrams to determine the length of a project and to identify the activities and constraints that are on the critical path.

Culture Observable work habits and priorities of an organization. It explains how the organization really works.

Customer The individuals, companies, or their representatives that receive a company's product, use a company's services, or purchase a company's product for resale (trade).

Cycle rate The cycle rate is the number of machine cycles per minute. We denote the number of cycles as N, so the cycle rate is dN/dt. It is not necessarily equal to the run speed of the machine. Over an 8-h period, the cycle rate of any machine in the packaging line is always higher than any set run speed. Most original equipment manufacturers (OEMs) specify their machine speeds based on cycle rates not output and therefore the OEM's speeds are the theoretical or design speeds that are possible.

Data-exchange format (DXF) Electronic format used to exchange CAD files from one software brand to another.

Deliverable A product that satisfies one or more objectives and must be delivered to meet contractual obligations.

Design The application of process engineering, machine design engineering, or power and controls engineering and the production of detailed engineering documentation, such as drawings and specifications, that explain how the technology defined in the design basis will be embodied in equipment and how the equipment will be constructed, assembled, and installed.

Design basis A document defining the project scope for designers and communicating how the engineering packages must be structured to fit construction requirements.

Design for manufacture (DFM) A general approach to designing products that can be more effectively manufactured. Often used in conjunction with databases. Includes such concepts as design for assembly, design for serviceability, or design for test.

Design speed The theoretical capacity obtained in a perfect operating environment. All adverse operating conditions are neglected, and all machinery is assumed to be in optimum operating condition. The design speed usually does not take into consideration the natural handling difficulties or stability of the inputs *(K value)*, environmental concerns, or training. This is usually the machinery builders advertised maximum functioning cycle speed for a given range of optimum inputs under ideal conditions. The concept of line speeds is not well understood in the packaging industry; thus there is a lot of confusion and disappointment over the actual results achieved. The following is a summary of the speed hierarchy from highest to lowest:

1. *Design speed* (usually the OEM's maximum cycle rate)
2. *Capacity* (highest sustainable cycle rate—about 80–90% of design speed)
3. *Achievable run speed* (target set speed or required steady-state condition)
4. *Actual set run speed* (actual packaging line set speed or dial speed)
5. *Output rate* (what goes to the warehouse or shipping per time period)

Note that the actual run speed will be set and its result will equal the output rate plus losses from rework, wastage, and stoppages.

Detergent Surface-active material or combination of surfactants designed for removal of unwanted contamination from the surface of an article.

Dew point The temperature at which air or other gases become saturated with vapor, causing the vapor to deposit as a liquid. The temperature at which 100% RH is reached.

Direct labor The labor expended in directly adding value to the package. For simplicity, it could be looked at as "touch" labor since direct-labor employees usually physically touch the product or inputs.

Disturbance Any anomaly in the flow of product, inputs, or packages in the packaging process that may or may not cause production to cease or slow down.

Disturbance frequency The number of disturbances for a specific output (quantitative amount) as determined by the set or actual run speed of the line.

Disturbance-frequency analysis (DFA) A production process tool that tracks and eliminates disturbances and their source(s). It is an excellent troubleshooting method for the analysis of small or large sections of the packaging process. DFA states that when the causes of disturbances are eliminated the downtime disappears, so why worry about time.

Disturbance-frequency period The minimum number of outputs allowed for one disturbance. The minimum number of outputs is determined mathematically from the actual set speed of the packaging process. As the actual set speed increases, the minimum number of outputs required increases exponentially.

Downtime The amount of time a machine or system is not functioning due to stoppages in a given shift or time period. Downtime should not include idle time or time the machine or system is waiting for inputs. Therefore downtime depends on stoppages and company policies.

Downtime analysis (DA) A production process tool that tracks the amount of time a given machine or system ceases production. Since it is time-based and monitors symptoms, not causes, its effectiveness is limited to specific applications. Historically, downtime analysis has been applied in an ineffective manner.

Drawings and specifications Engineering details for projects, packages, equipment, systems, and facilities.

Drop test A test for measuring the properties of a container by subjecting the packaged product to a free fall from predetermined heights onto a surface with prescribed characteristics.

Duration A unit measure of time for the time interval of a given stoppage.

DXF See Data-exchange format

Efficiency (*n*) A fundamental engineering term that is broadly defined as the ratio of benefits/penalties or, for packaging, the ratio of output/input. In keeping with this engineering definition, we define it as the average ratio of packaged output multiplied by the number of components over the sum of input components. Unfortunately, in the packaging industry, efficiency has become a generic catch-all term whose definition varies depending on the political needs of the organization, not its real needs.

Elemendorf test A test for measuring the tearing resistance of paper, paperboard, tape, and other sheet materials.

Element utilization The fraction of time a given machine or element is actually producing output at a set run speed divided by the total time available for production. Note that changeover, cleanup, and prep work are not included. This definition usually relates to machinery and/or components.

Elements Any machines, equipment, conveyors, or mechanical components by which the product and/or inputs are manipulated, assembled, transferred, collated, or brought into contact with each other. Examples of elements are fillers, cappers (with sortation), labelers, unscramblers, case packers soap presses, calenders, meat grinders, wrappers, packers, banders, and conveyors. For the purpose of clarification, all elements are considered or designated as machines. For example, we assume that all types of conveyors, collators, or buffers are elements.

Emergency maintenance Emergency maintenance occurs when a technical person is called on to perform a repair at any time of the day without being forewarned. With most other types of maintenance, emergency maintenance should be the exception not the rule as in breakdown maintenance. Breakdown maintenance and emergency maintenance are basically the same, when the predominate method of maintenance is breakdown maintenance. Breakdown maintenance is doing no maintenance other than lubrication between breakdowns. Repairs and adjustments are done as a result of reduced or no production occurring.

Equipment A capital-cost-estimating category for hardware used in manufacturing, including manufacturing support.

Equipment acceptance Criteria for approving equipment for use.

Estimate A statement of the probable capital appropriation scope and cost associated with changes needed to achieve a specified goal.

Excess capacity (EC) A managerial concept or approach advocating that a system's or process's capacity or limit should exceed the average demand (throughput or output). This position has been developed by Dr. Abraham Grosfeld-Nir from the University of Waterloo. The author agrees strongly with this concept. This concept is in contrast to the "lean and mean" approach where any attempt to have a capacity that exceeds the demand is viewed as wasteful ("fat") and any system or process having a capacity equal to the demand is perceived as ideal. Added to this is the traditional accountants' advise to cut extra capacity, in particular the work force, to force a balance between capacity and demand. In other words, the packaging process capacity is equal to the customer's demand and no more. It is very likely that, at times, EC will recommend to buy more capacity under given conditions, while an accountant would recommend a cut. The need for excess capacity arises from the presence of randomness in demand, processing time, quality, etc. (In a deterministic world, EC would, indeed, be wasteful.) Benefits of operating with EC are small WIP (work in process), quick response time, and increased quality. In observing JIT multistage systems it is clear that each stage is utilized only to a fraction of its capacity as it relates to the speed potential. Each stage is idle some of the time as a result of stoppages. Thus stages of a properly designed JIT system operate with excess capacity. Experience indicates that typically in the automotive industry, stages are utilized 60–80% of their capacity. To use JIT in packaging, it can be argued (because of the speeds involved) that "speed utilization" or the set run speed of 50–70% of the capacity speed are proper for JIT to be effective.

Extrusion The process of forcing a material in plastic condition through an orifice.

Factory end Bottom or can manufacturer's end.

Failure analysis A formal analysis that assumes failure and attempts to define the paths leading to failure and what should be done to prevent it.

Failure rate The ratio of the total number of failures to the cumulative operating time for a stated period of time. We denote this by the symbol λ, and its units are failures per unit of time.

Feasibility studies Experimental studies on a process or equipment to access what results are achievable and/or what will be required to produce a desired result.

Flow sheet (FS) A schematic presentation of a process.

Flowchart A graphic representation of a work process in which each step in the process proceeds from start to finish.

Fluidity Reciprocal of viscosity.

Freight on board (FOB) The term used to signify that the seller is required to bear all costs required to place the goods aboard equipment of the transporting carrier. The stated FOB point is usually the location where title to the goods passes to the buyer. The buyer is liable for all charges and risks after passing of title.

Frequency The number of occurrences in a given period of time.

Funding The process that leads to a specific amount of money and resources being set aside for or committed to a specific object.

Gantt chart A graphic presentation (bar chart) of project activities shown by time-scaled bars with the length of the bar equal to the duration of the activity.

Gelometer Instrument used to measure the time required for a fluid to gel. Also, instrument used to determine the firmness of a gel.

General terms and conditions A package of standard requirements included with all purchase orders.

Good manufacturing practices (GMP) A document that describes agreed-to best or optimal procedures for manufacturing.

Headspace The vertical distance between the level of the product (generally the liquid surface) and the inside surface of the lid in an upright, rigid container.

Hermetically sealed container A container designed and intended to be secured hermetically against the entry of microorganisms and to maintain the commercial sterility of its contents after processing.

High-performance products Products with clearly superior attributes such as taste, styling, speed, smell, comfort, and effectiveness with results in the packager receiving a premium price and/or dominate market share more than the perceived normal product.

Hydrometer densimeter Device used for the measurement of specific gravity or density.

Impact strength The ability of a material to withstand mechanical shock.

Indirect labor Any labor, including supervision and management, that is not direct labor or directly connected to the production or manufacturing process. Overhead activities such as material handling, stockroom, inspection, all engineering functions, maintenance, supervision, cost accounting, and personnel are usually included.

Input (*X*,*x*) Input for a given packaging line is the specific item or part required for the package assembly operation or packaging process to form part of the complete package. Examples of input items are bottles, cartons, caps, labels, cases, pallets, tubes, and so on. Inputs are not product entities, but product entities can be classed as inputs. In general, inputs are discarded items that are trashed or recycled after product use. Since we use the symbol X for systems input, we will use x_i for the ith machine as the input for a machine. Note that several types of inputs may be required by a machine (and certainly by a line), but in general, only one output is produced. Minimizing input losses reduces cost, increases the performance index, and reduces the waste headed to landfills. From the economic point of view, reducing input item losses, as well as the number of different types of inputs, makes business sense. Minimizing the types of inputs maximizes performance and quality.

Input rate The input rate for a given packaging line is the amount of a specific item or part (required to form part of the complete package) processed or consumed in a given amount of time.

Integration *Integration* as it relates to the packaging process is defined as the mechanical, pneumatic, hydraulic, and/or electrical method of physically (mechanically or electronically) connecting machinery and input handling systems to ensure a smooth harmonized throughput operation. It should not be confused with automation and control. Usually control or automation cannot solve or correct poor or faulty integration.

Integration principles for input and product handling

1. Once you have it, don't let go. Having it means complete physical or electronic engagement so that the mechanism motion and the input motion are identical or within a tolerance range that is smaller than the functional requirements.
2. Eliminate or minimize input and package manipulations or change of direction, velocity, and/or inertia.
3. Always interface using complete integration or hand-shaking pass off within a defined boundary, not at a point. The interface position tolerance must be smaller than the operational functional window.
4. If manipulations are required because of overall design constraints, always match motions (intermittent to intermittent, continuous to continuous). Incompatible motions (continuous to intermittent and intermittent to continuous) always yield the highest unreliability.
5. For cycles $>60\,\mathrm{min}^{-1}$, continuous is superior to intermittent.

Keep it rugged and simple, meaning the fewer moving parts, the better.

Interfunctional communication Communications and understandings between manufacturing and other functional areas in a business.

Islands of automation Pieces of equipment or systems that are not integrated with the packaging line. They can be considered independent and not controlled by the packaging process directly. The output from each island of automation does not affect the other directly.

ISO 9000 Series Protocol An international set of documents written by members of a worldwide delegation known as the ISO (International Standards Organization)/Technical Committee 176. Its primary purpose is to harmonize the large number of national and international standards adopted by many countries. This series is also intended to be driven by market and customer needs. The ISO series consists of five main documents:

- Three core quality system documents that are models of quality assurance: ISO 9001, ISO 9002, and ISO 9003.
- Two supporting guideline documents: ISO 9000 and ISO 9004.

Following is a brief outline of each document.

ISO 9000 (ANSI/ASQC Q90-1987): *Quality Management and Quality Assurance Standards: Guidelines for Selection and Use*.

ISO 9001 (ANSI/ASQC Q91-1987): *Quality Systems—Model for Quality Assurance in Design/Development, Production, Installation and Servicing*. Applicable to contractual arrangements, requiring that design effort and the product requirements are stated principally in performance terms or they need to be established. Confidence in product conformance can be attained by adequate demonstration of certain supplier's capabilities in design, development, production, installation, and servicing.

ISO 9002 (ANSI/ASQC Q92-1987): *Quality Systems—Model for Quality Assurance in Production and Installation*. The specific requirements for the product are stated in terms of an established design or specification. Confidence in product conformance can be attained by adequate demonstration of a certain supplier's capabilities in production and installation.

ISO 9003 (ANSI/ASQC Q93-1987): *Quality Systems—Model for Quality Assurance in Final Inspection and Test*. The conformance of the product to specified requirements can be shown with adequate confidence, provided certain supplier's capabilities for inspection and test conducted on the product supplied can be satisfactorily demonstrated on completion.

ISO 9004 (ANSI/ASQC Q94-1987): *Quality Management and Quality System Elements Guidelines*.

Justification For most industries a justification is a written request for action that consists of

1. Acquisition of valid data
2. Presentation of the problem, need and data
3. A logical course of action with options and alternatives
4. Cost profiles
5. Benefits of undertaking a specific course of action

Just-in-time (JIT) First used by Toyota in Japan as the "Kanban system," it has been successful in reducing inventory while maintaining high throughput and increased quality. Kanbans are cards authorizing production or shipment of material. Mondem in 1981 defined JIT as a production system to produce a kind of units needed, at the time needed and in the quantities needed. Schonberger in 1982 defined JIT as goods produced just in time to be sold and only purchase materials just in time to be transformed into the product. Sohal in 1988 defined JIT as more of a philosophy than a series of techniques, the basic tenet of which is to minimize costs by restricting commitment to expenditure until the last possible moment.

Groenvelt in 1991 defined JIT as a management philosophy that fosters change and improvement through inventory reduction. To have the ideal situation of exactly the necessary amount of material available where it is needed and when it is needed. From the book *Benchmarking Global Manufacturing, 1992*, just-in-time is both a philosophy of eliminating waste and a toolset for pacing and controlling production and vendor deliveries on time, with short notice and with little or no inventory. According to JIT, multistage systems as found in packaging lines should be a pull (produce only in response to demand) and not a push (produce as long as there is raw material to be processed). In simple terms, JIT means that regardless of what disasters happen in my packaging process, you have the excess capacity to guarantee the highest probability of attaining the exact delivery window required by the customer with quality packages.

Kraft A term derived from a German word meaning strength, applied to pulp, paper, or paperboard produced from virgin wood fibers by the sulfate process.

Label Any display of written, printed, or graphic matter on the container of any consumer commodity, affixed to any package containing a consumer commodity.

Lag Specified time increment between the start or completion of an activity and the start or completion of a successor activity.

Lid Can end applied to open end of can in a cannery. Also known as top, cap, or packer's end.

Liner Generally, any liner material that separates a product within a container from the basic walls of the container.

Logic The description of how the activities in a schedule are related to one another.

Logic diagram Drawings using logic symbols that tell how a piece of equipment or system is to operate.

Lost-time accident (LTA) frequency One of the most widely used accident statistics. LTA frequency is a measure of the number of disabling injuries per year.

Lug A type of thread configuration, usually thread segments disposed equidistantly around a bottle neck (finish). The matching closure has matching portions that engage each of the thread segments.

Lump sum A method of paying for equipment fabrication and construction work in which the buyer pays the vendor a single lump sum for all the work involved.

Machine A *machine* can be defined as a system of components arranged to transmit motion and energy in a predetermined fashion. Another definition is that a machine typically contains mechanisms designed to provide significant forces and transmit significant power.

Machine downtime Machine (or element) downtime is the total amount of time a given machine in the packaging line stopped or ceased production during the run period.

Maintainability or mean time to repair (MTTR) *Maintainability* is the average time required to repair a device or system. This includes preparation time, active maintenance time, and delay time associated with the repair. It is quantified as the mean time to repair.

Maintenance The physical act of ensuring that all machinery and systems are in operable condition at all times, especially during scheduled periods of demand. Maintenance can also be defined as the ability to keep all mechanisms and machines required for optimum production available to not only produce but also maintain a steady flow of quality packages without interruption. Types of maintenance programs to maximize operational readiness and sustainability: (*1*) breakdown, (*2*) preventive, and (*3*) predictive.

Manufacturing costs Raw and packing materials, manufacturing expenses, processing costs, and variations.

Manufacturing lead time (MLT) The cumulative time from the beginning of the production cycle until an item is finally finished. Time spent in inventory as work in process, setup times, move times, inspection, and order preparation time are included.

Manufacturing overhead costs (MOC) Those costs that are allocated to unit product costs, including the cost of indirect labor as well as indirect purchased services and supplies but excluding unallocated period costs such as sales and marketing and R&D.

Master production schedule (MPS) The main or overriding schedule of the number and timing of all end items to be produced in a manufacturing plant over a specific planning horizon. An important input to the MRP computer program.

Material requirements planning (MRP) MRP is more of a computerized information system than a managerial philosophy that determines how much of each material, any inventory item with a unique part number, should be purchased or produced in each future time period to support the master production schedule (MPS). It is designed to contain information required for efficient decision making. MRP is mainly used by large industrial organizations but as more improved computer software and hardware emerge, smaller organizations will find MRP advantageous in their operations. Input to MRP is information from the MPS and the "bill of materials" (BOM). The MPS determines starting times for future jobs, while the BOM is a detailed description of all inputs (material and work) required for each job. MRP also monitors all in-stock inventory and outstanding purchase orders. On the basis of information about jobs in progress and waiting jobs, MRP regulates the purchase of material from internal and external suppliers. It also provides information about jobs behind schedule, for potential expediting. Methods such as the "economic order quantity" (EOQ) and "reorder point" (ROP) control material requirements, without taking into account information about job scheduling from the MPS. In contrast, MRP recognizes the handling material is more efficient when the information from the MPS is incorporated. MRP also aggregates requirements from different sources and sets timing for arrivals considering overall system performance, rather than aiming at local satisfaction. In other words, unlike EOQ and ROP, MRP takes advantage of dependent demand. MRP assumes all operations to be deterministic, which is unrealistic. One consequence of this assumption is the frequent need for expediting jobs. MRP requires dealing with an enormous amount of information that needs continuous update. It turns out that when details are required, MRP is unreliable. Maybe this will be taken care of as technology and advanced software are developed.

Mean The average value of several observed data.

Mean time between failures (MTBF) The cumulative operating time divided by the number of failures. This is the reciprocal of the failure rate.

Mean time to failure (MTTF) The average life of nonrepairable items. This does not apply to most machinery in the packaging industry, but it does apply to certain components (e.g., seals, bearings).

Mean time to repair (MTTR) *Mean time to repair* (or *maintainability*) is the average time required to repair a device or system. This includes preparation time, active maintenance time, and delay time associated with the repair. It is quantified as the mean time to repair (MTTR).

Mechanism A system of components arranged to transmit motion in a predetermined fashion. Another definition is that a mechanism is a device that transform motion to some desirable pattern and typically develops very low forces and transmits little power.

Melting The change from the solid to the liquid state. Also the softening of harder compounds.

Methodology The sequence or manner in which events are made to occur or a logical thinking process to achieve an end result.

Milestone A key network event that is of major significance in achieving the program, project, or contract objectives.

Mission Statement of purpose or reason for the existence of the organization. It answers the question who we are and why we exist. It expresses the distinctive competence or unique contribution of the organization.

Model A mathematical model consists of one or more equations that describe some idealized form of a system. The idealized form is rendered from the real form by making one or more simplifying assumptions. It is an attempt to explain or predict a portion of reality using mathematics.

Monitoring Following the progress of the project. This phase follows the preparation of the CPM plan and schedule.

Mylar A synthetic polyester fiber or film.

NFPA National Fire Protection Association.

Neck The part of a container where the bottle cross section decreases to form the finish.

Occupational Safety and Health Act Federal organization responsible for health and safety on construction sites and in plants.

Occurrence Any anomaly or action in the packaging process that actually stops that process. A *stoppage* and an *occurrence* are the same.

Optimized production technology (OPT) A philosophical approach that maximizes throughput through the modification or elimination of bottlenecks. Claiming that (only) throughput or output translates into sales, OPT aims at maximizing throughput. Improvements that do not render increased output are viewed as negligible. OPT concentrates on "bottlenecks" or critical resources. This aged manufacturing concept is still quite common in many packaging plants. Typically OPT can lead to extremely large inventory levels, which is contrary to JIT. OPT can give substantial gains in short time periods of 3 to 6 months.

Original equipment manufacturer (OEM) A manufacturer who produces equipment to be sold by another company.

OSHA See Occupational Safety and Health Administration.

OSHA No. 200 Log and Summary The OSHA recordkeeping form used to list injuries and illnesses and to note the extent of each case.

Output (Y, y) Output for a given packaging line and product is the exact quantity of quality packages produced in a package run cycle as required by the customer and shipped to the customer. It is denoted by the symbol Y. Similarly, we define the output for a machine or output rate as the number of items (of acceptable quality) leaving a machine in a given amount of time. We denote this by, y_i for the ith machine. The word *throughput* has the same definition as output, but this *Encyclopedia* uses the word output, which is the more correct term.

Output rate The output rate for a machine or system is the number of items (of acceptable assembled quality) leaving a machine or system in a given amount of time. We denote this by y_i for the ith machine. It is always less than the machine cycle rate and/or the actual set run speed, due to the effects of wastage, rework, and stoppages.

Package A metal can, glass bottle, plastic bag, or pouch which serves the functions of containing and protecting the product, as well providing convenience and communicating to the consumer.

Packaging Changeout (t_{pc}) Packaging change out is the sum of the changeover time, cleanup time, and prep work time. The package changeout is the total interval between finishing one run of a given package and starting another run with a different package.

Package-changeout utilization (U_c) The fraction of the package run cycle time the packaging line has available for producing output at a set run speed after changeover, cleanup, and prep time have been completed.

Package run cycle (PRC) The duration of specific events needed to produce a given amount of quality packages. It consists of the total end of the first production run to end of next production run period, which involves change out and the entire run or producing period.

Packaging line An assemblage of specialty-function machinery or systems and/or manual workstations from depalletizing to palletizing integrated together to carry out a process in which a given product is combined, inspected, and transported with inputs or media. The inputs themselves protect, control, and identify the product: (*1*) bottling lines for liquid products such as beverages, (*2*) canning lines for products such as precooked foods, or (*3*) box-packaging lines for materials such as powered detergents.

Packaging process The combined execution of specialty-function machinery or systems and/or manual workstations in order to carry out a process in which a given product is combined an/or assembled with inputs or media. Basically the *packaging process* has the same definition as a *packaging line* but is more encompassing because it makes people part of packaging line. Some companies, by nature of their operations, may include the making as part of the packaging process.

Paneling Distortion (sidewall collapses) of a container caused by development of a reduced pressure (too high to vacuum) inside the container.

Paper, water-resistant Paper that is treated by the addition of materials to provide a degree of resistance to damage or deterioration by water in liquid form.

Paper, wet-strength Paper that has been treated with chemical additives to aid in the retention of bursting, tearing, or rupturing resistance when wet.

Parallel elements Parallel elements (i.e., machines) perform the same type of operation in a system. The main line is split into two to feed each machine with consistent product and/or inputs. The elements need not be identical, and the speeds of each can be a factor of the total main-line output. Parallel machines provide system redundancy; the failure of any one of them will not stop the line but only reduce output by a factor. Usually, the combined capacity of the two parallel elements should equal over 125% of the total output plus wastage, rework, and stoppage losses.

Pasteurization A relatively mild heat treatment of food, intended to destroy all organisms dangerous to health, or a heat treatment that destroys some but not all microorganisms that cause food spoilage or that interfere with a desirable fermentation.

Percent complete A comparison of the actual status to the current projection. The percent complete of an activity in a program is determined by inspection of quantities placed as effort hours expended and compared with quantities planned or effort hours planned.

Performance *Performance* can be defined as the level or effectiveness of carrying out an action or execution of a sequence of events according to a prescribed functional description. A better definition for performance for the packaging industry can be as stated below.

> Performance in the packaging industry is a widely used term such as effectiveness that means different things to many people. Therefore the word *performance* is relative and qualitative. The only understanding that may be common to all is that it is a reflection of productivity, output, or effectiveness of time. Unless it is rigorously defined and understood, the word performances has limited value to decision makers, other than projecting a sense of being or desire. The author defines performance as a measure of profitability based on the ability to produce the needed quantity of quality packages in the time required to fulfill customer needs at the lowest per unit cost over a sustained long period of time (>1 year). To many people, performance is the best bang for the buck based on up-front costs or capital costs only, not on the best value, which is based on capital and ongoing operational costs. If one buys a system based on up-front costs or lowest costs to get in without working out operational costs over a 1-, 3-, or 5-year period, then their anticipated profits (based on marketing targets) will rarely materialize. Too many people are hooked on this false sense of performance that will only contribute to the long-term uncompetitiveness of the company. Short-term or no planning leads to long-term disasters. Anyone can demonstrate excellent performance hour by hour or even day by day, but performance can truly be judged only quarter by quarter and year by year, which translates into consistent steady-state production under complete control (manual or automatic) at all times and under all conditions.

Performance Index (PI) A method of evaluating, benchmarking, tracking, and verifying a company's packaging processes. It gets rid of the old confusing notion of line efficiency and establishes a new framework that establishes a level playing field, especially among multiple corporate plants running the same or similar products. The performance index can also be used to evaluate dissimilar types of packaging lines that are internal or external to the organization. The effectiveness of a packaging operation that relates directly to the profit of the product is the objective of the performance index. The PI also utilizes the most effective ideas an/or techniques used in OPT, JIT, TQM, TPM, and MRP and applies them to the packaging process. As such, the PI can be considered an operation's tool but only a tool in the benchmarking sense, because it is the tip of the pyramid from which everything else expands out to explain the PI value. As a benchmark, it can evaluate the functional and best practices of a company against itself or competitors. The performance index is a mathematical model that projects the overall rating of a packaging line. Technically, the PI is a composite measurement of the productivity of a given packaging line. In mathematical terms, the performance index is the efficiency multiplied by the utilization multiplied by the capability multiplied by the speed factor. Equal weighting is usually given to efficiency and utilization. Under ideal conditions, the PI value would be 1. A typical high-PI packaging line, such as a soft-drink line, should have a value greater than 0.8. Other lines will yield PIs ranging from 0.10 to 0.70. Locating and eliminating the source of low PI will improve productivity. Common symptoms of low PI are a low speed factor or high wastage on the line. Solving the problem is often easier than finding the problem. Note that the index excludes the number of people running the packaging line. When maximizing PI, labor will move to its optimal level, which is minimal labor input Management must avoid labor replacement and consider instead labor optimization, given the environment and the package. For a given packaging line and package, it is possible to determine the profit to be gained for each point gain in the PI. With this information, one can justify changes very quickly.

Permeability The passage of a gas, vapor, or liquid through a barrier without physically or chemically affecting it.

PERT Program evaluation and review technique.

pH The effective acidity or alkalinity of a solution; not to be confused with the total acidity or alkalinity. The pH scale is where pH 7 is the neutral point (pure water). Decreasing values below 7 indicate increasing activity, whereas increasing values above 7 indicate increasing acidity, while increasing values above 7 to indicate alkalinity. One pH unit corresponds to a 10-fold difference in acidity or alkalinity; hence, pH 4 is 10 times as acid as pH 5 and pH 3 is 10 times as acid as pH 4 and so forth. The same relationship holds on the alkaline side of neutrality, where pH 9 is 10 times as alkaline as pH 8, and so on. Most meat and fish products have pH values between 6 and 7, vegetables have pH values between 5 and 7, and fruits have pH values between 3 and 5.

Acid solutions	Neutral	Alkaline solutions
0 1 2 3 4 5 6	7	8 9 10 11 12 13 14

Planned maintenance A type of maintenance in which a company has a given period or periods of production idle times each month in which maintenance activities can be undertaken. In periods of heavy production demands, this type of maintenance breaks down into simple breakdown maintenance.

Planning The establishment of the project activities and events, their logical relations and interrelations to each other, and the sequence in which they are to be accomplished.

Predictive maintenance A type of maintenance that utilizes an array of sensors and/or monitoring equipment to determine the status and condition of critical wear components in machinery and systems so that proactive procedures or replacement can be undertaken at a convenient time period before the failure of the component could cause any unscheduled downtime.

Premium time An allowance to cover the premium portion of overtime pay, that is, the cost differential between straight time and overtime work.

Prep work time or (period) The time required to bring inputs to the line, load and stage ready for production. Some companies may combine change over with clean up and prep work.

Present value The cash value today of the difference between a project's investment and the related return over the project life.

Preventive maintenance A type of maintenance determined by historical data and life-cycle testing to determine optimum time of part life and therefore by extension lead to a program of part changeout prior to the anticipated part failure. Carried to its extreme, it can be a costly venture to a company, and therefore most preventive programs are tempered by budgets and other constraints.

Primary spoilage (see also Secondary spoilage) That spoilage caused by bacterial or chemical action of product packed within the can.

Process The succession of actions (filling, capping, labeling, palletizing, etc.) undertaken to make a package. Some companies may include the making, if it is essentially part of or integral to the packaging operation.

Procurement The acquisition (and directly related matters) of equipment, material, and nonpersonnel services (including construction) by such means as purchasing, renting, leasing (including real property), or contracting.

Procurement lead time The cumulative time from the beginning of the procurement order cycle (order commitment) until the procured item is delivered. It includes vendor lead time, transportation, receiving, and inspection time.

Product Those items used or consumed by the customer. They are usually items made or modified by human industry. Take shampoo as an example; the consumer uses the shampoo and throws away its container, cap, and labels. The product is the shampoo and the input items are the container, cap, and labels. (The term *product*, as a collective noun, can have a plural sense.)

Product amenities The extra product features that enhance the basic product and make it easier to use or more enjoyable. For example, a finger pump spray on a bottle versus a pull-and-squeeze cap.

Product run cycle (PRC) The duration of time needed to produce a given amount of quality packages based on the designed or historical output. It is the same as the package run cycle. The word *package* is more applicable than product in most industries and is used in this *Encyclopedia*.

Product specifications The written description of the products to be manufactured.

Product stability (*K* value) The ability of the product to be handled in a stable and consistent manner. A beer bottle, for example, has all the features necessary to make it a stable and consistent product:

- Cylindrical parallel shape
- Relatively low center of gravity
- Heavy, smooth base for stability and low friction
- Relatively hard to break
- A shape that remains stable throughout the packaging cycle

Generally, a stable product is a product that gives a packaging line the least amount of handling problems. This stability can be defined as a value *K*. A more rigorous definition of *K* value is left for future development. As a packaging line increases its level of automation, the *K* value becomes critical.

Product support Those activities that support the customer in the use of a product, such as customer education, information about related products, or services and information hotlines.

Productivity The level of ability or effectiveness in marketing, manufacturing, distributing, and servicing a package.

Project The overall work being planned. It will have one specific start point and one finish point in time.

Project manager The person on a project team responsible for the engineering process and appropriation management.

Psychrometer An instrument for measuring the humidity (water-vapor) content of air by means of two thermometers, one dry and one wet.

QA Acronym for quality assurance.

QCP (quick-change process) A new common phase used to describe the techniques used to design and operate a packaging line that is always prepared to change from one product to another within a minute notice. This encompasses quick changeover (QCO), clean-in-place (CIP), eradication of all possible adjustments, matchmark position settings for remaining adjustments, flexible crewing, tooling readiness, and a streamlined results-oriented management A similar phrase is quick changeout.

Qualifying The act of setting up and administering a training program that ensures that the people who will be interfacing with the packaging line are given a thorough overview of the packaging line and a detailed program on what they need to know to complete their tasks without hesitation or guessing. All training must address the following questions:

Whom should be trained?
When should training be done?
What training should be done?
How should we do training?
Where should we do training?
How much is enough training?
Manuals and other self-help tools?
Performance reviews and continuing improvement?
Company standards and policy?

Quality circles Teams of employees used to diagnose and solve quality problems relating to fulfilling the needs of the customer. It also includes the use of the work team concept for solving other problems related to productivity improvement, safety, and so on.

Quality control A system for assuring that commercial products meet certain standards of identity, fill of container, and quality sanitation and adequate plant procedures.

Quality function deployment (QFD) A set of techniques for determining and communicating customer needs and translating them into product and service design specifications and manufacturing methods.

Quality package A package that meets all design specifications and is manufactured in compliance is ISO 9001 or ISO 9002. Take a bottle of shampoo as an example of a quality package:

- The content must comply with internal and government weight and/or volume regulations.
- The print documentation must be clear, readable, accurate, and acceptable to the end customer and comply with government regulations at point of manufacture to point of end use.
- The container must be clearly coded and identified using industry-standard codes such as UPC and comply with customer and government regulations at point of manufacture to point of end use.
- The seal on the package must be seated correctly to a specified torque and/or form a protective seal against leakage, spoilage, contamination, and/or tampering.

In short, a quality package is the end product envisioned by the marketing group that will fulfill all the design criteria and packaging standards, either internal, governmental, or required by the customer.

Quick-change process (QCP) A new common phase used to describe the techniques used to design and operate a packaging line that is always prepared to change from one product to another within a minute's notice. This encompasses quick changeover (QCO), clean-in-place (CIP), eradication of all possible adjustments, matchmark position settings for remaining adjustments, flexible crewing, tooling readiness, and a streamlined results-oriented management. A similar phrase is quick changeout.

Quick changeout The total downtime between production runs of different packages or the end of first production run to end of the next production run time. It encompasses the same time-period definition as the quick-change process involving preparation time, cleanup time, and changeover time.

Quick changeover (QCO) A new common phase used to describe the technique of effective tooling used to change a packaging line over from one product to another using no tools and can be done in minutes or less.

Relative humidity The ratio of actual humidity to the maximum humidity that air can retain without precipitation at a given temperature and pressure. Expressed as percent of saturation at a specified temperature. See also Absolute humidity.

Reliability The probability that a device or system will not fail within a given time frame under given conditions. Quantitatively, this is expressed as a true mathematical probability.

Requisition A form used to transmit purchasing information to the Buying Department regarding needs.

Reschedule The process of changing the duration and/or dates of an existing schedule in response to externally imposed conditions or progress.

Resource Any consumable, except time, required to accomplish an activity.

Return on equity (ROE) An accounting ratio used to evaluate the overall financial performance of an entire company. ROE compares the net earnings generated by a company to the shareholders' equity (net worth) of that business.

Return on investment (ROI) An accounting return measure (similar to RONA) that includes an inflation adjustment to the historical accounting value of the physical assets. ROI approximates the internal rate of return calculated on a computer.

Return on net assets (RONA) An accounting ratio used to evaluate the overall financial performance of an established business. RONA compares the net earning generated by a business with the net book value of the physical assets employed in that business.

Rework (Q) Components or packages produced that are of unacceptable quality but are acceptable for reprocessing (denoted by Q and q_i). Furthermore, the product is reclaimable and some input items are reusable. If the product cannot be restored to an acceptable quality, then it becomes wastage. In packaging, one could argue that the cost of selling off seconds is greater than the value received. Costs associated with rework are less than those associated with wastage, because rework does not cause large amounts of lost product, only lost time. Some costs incurred in the rework process are input item cost(s), overhead cost, and opportunity cost. Even assuming wastage is negligible, a decrease in rework will, in turn, lower production costs and increase output. In general, rework is an indicator of a process out of control.

RFP Request for proposal.

RFQ Request for quotation.

Rheology Study of the deformation and flow of matter.

Risk A perceived probability of failure or not achieving the target(s) or goal(s) as *originally* established at the start of the project as well as its consequences. Since we do not live in a perfect world, no project or decision is risk free. There are technical and political risks.

Risk, technical Risk strictly related to a new process, machine, or component used in packaging a known product, or a new untried product or package design. It is logical to assume that additional money and time will be expended in a direct relationship to the shortfalls that occur in the first attempt. Sometimes, management will deem a project that is partly successful to be satisfactory because the costs and time to correct the shortfall are not economical. In this case, although the project is technically a failure, politically it was approved. As a guideline, more than 70% of all projects fail to reach the original technical targets or goals. And less than half of all projects that have shortfalls are completely corrected. In some cases where the consequences are death, a low probability is of little comfort and must not be traded off. *Political risk* is a perceived probability of management's ability of not understanding the basic technical and marketing techniques and philosophies in order to make clear timely, and profitable decisions and to accept their consequences in the marketplace. It is also related to management's ability to admit to their mistakes quickly, change direction and to learn from the experience. Finally it relates to ego and power, elements of which make up humanity and the complexity of life. In some cases where the consequences are death, a low probability is of little comfort and must not be traded off.

Run speed The run speed of a machine is the instantaneous operating rate at some point in time. It is derived in terms of the output rate at that time. For example, if a machine is outputing at a rate of 300 (not necessarily quality) containers per minute (cpm) at a given point in time, then that is the run speed. As the time interval increases, the output rate is always lower than the run speed, because of stoppages, wastage, rework, and so on. When the output approaches the run speed for any given time period, then the line is approaching the steady-state condition. In a perfect world, the output and the run speed would be equal.

Run utilization The fraction of time the packaging line is producing output at a set run speed divided by the total time available for production. Note that changeover, cleanup, and prep work are not included. This factor can be considered the uptime during the producing time period.

Runup period The time required after the package changeout has been completed to get the given interval actual run speed (or output rate) to exceed the 80% of achievable run speed. The more correct term is transient period. If the packaging process cannot move out of the run up period quick enough, the loss in potential production can be staggering.

Sales and use taxes Taxes imposed on vendors or contractors and passed on to the purchaser on all applicable expenditures as required by state and local law.

Sanitize To reduce the microbial flora in or on articles such as food-plant equipment or eating utensils to levels judged safe by public-health authorities.

Sanitizer A chemical agent that reduces the number of microbial contaminants on food-contact surfaces to safe levels from the standpoint of public-health requirements. Sanitizing can also be done by heating.

Schedule The plan for completion of a project based on a logical arrangement of activities, resources available, imposed dates, or funding budgets.

Schedule capability (C_p) In simple terms, the schedule capability is the relative measure of how capable or how effective the actual packaging process is in producing the appropriate volume of needed packages within the planned plant operational time period or schedule. The schedule capability relates to the ratio of the scheduled run cycle time available divided by the actual package run cycle time used. This definition is valid only if the actual time taken is greater than the scheduled time. If the actual time is less than die scheduled time, the capability is the actual package run-cycle time divided by the scheduled run-cycle time. The schedule capability is always equal to or less than 1. The term *schedule capability* is sometimes shortened to just *capability*.

Scheduled package run cycle (SPRC) The *scheduled package* (or *product*) run cycle refers to the time that management allots the packaging line to yield a required quantity of quality packages. It can also be defined as the total plant asset available time based on a 24-h clock. If this definition is used, it should be defined as the asset package run cycle (APRC). In an ideal system, the scheduled package run cycle and the package run cycle are equal. Normally, the scheduled product run cycle is far longer than the product run cycle, based on the designed or historical output. For an optimized packaging process, PRC is usually more than 90% of the SPRC.

Scheduling The assignment of start and finish to all activities belonging to a project that indicate when the activities are expected to be performed.

Secondary spoilage Consists of those cans rusted or corroded as a result of bursting or leaking cans. May occur during warehousing.

Series elements Those machines connected in-line that perform unique functions so that the operation of each element is vital to the system. For example, if a line has one filler connected to one capper, these may be represented as series elements, because the failure or jam of either one will stop production almost immediately if no buffers exist.

Setup This is basically the same as the changeover but relates only to a given machine not the packaging line. It is defined as the completion of the following items:

1. The exchange of change over parts or tooling
2. The recalibration and/or adjustment of the machine
3. The preliminary test with samples

At the end of the procedure, the machine is expected to perform the desired function to produce a quality package at the achievable run speed.

Shelf life The length of time that a product will maintain market acceptability under specified conditions of storage. Also known as merchantable life.

Simulation The modeling or effect by computer, scaled models, or mathematics to play out a scenario or sequence of events that would give the appearance or outcome that approximates as close as possible the real world. A computer simulation is a means of representing the behavior of real life systems over time, using some combination of models, initial conditions, and discrete time steps. Real-time computer simulation is always the optimal condition.

Single minute exchange of die (SMED) As developed by Dr. Shigeo Shingo of Japan, this is a time and motion evaluation using industrial engineering techniques to facilitate the quick exchange of dies as used in the automotive stamping industry. There are some people who are attempting to use this technique and other similar techniques to acquire a quick change over capability for packaging lines. Extensions of these ideas are no tools, no time, no talent concept and quick changeover (QCO) as well as the rapid exchange no tool components developed by specialized companies such as Septimatech in Waterloo, Canada and enlightened and progressive OEMs.

SKU See Stockkeeping unit.

Solvent A substance which dissolves or holds another substance in solution such as common salt in water. Solvents are used in some foods as carriers for flavors, colors, stabilizers, emulsifiers, antioxidants, and other ingredients.

Speed factor (S_f) The actual average output rate or actual run speed of a packaging line divided by the achievable run speed of the packaging line, for a given package run cycle and time period. It does not include changeover, prep time, and cleanup that are already in utilization.

Standard practice A written description of the minimum necessary to meet the intent of policy and standards. To the extent possible, standards should describe the "what" and not the "how."

Statistical control The state of predictable stability.

Statistical process control (SPC) A statistical method of using control charts to monitor whether a process is in or out of control. It is a method that requires planning teamwork, methodology of measurement, knowledge of measurement techniques, and acute knowledge of the process. In most causes, the packaging process must be improved first before control charts can be use effectively.

Statistical quality control (SQC) The use of statistical techniques for process control or product and package inspection. It also includes the use of experimental design techniques for process improvement.

Stockkeeping unit (SKU) An industry term that details the assortment or variety of items shipped in "one" physical case.

Stoppage A short time occurrence that causes the packaging line or any portion of the packaging line to cease production of a quality package. A stoppage is made up of frequency and duration.

Surfactant Surface-active agent.

System A collection of one or more elements (e.g., machines) that are combined to perform some overall function. A packaging process (line) and a given section of a line having more than two elements or functions are examples of systems.

System downtime The total amount of time the packaging line stopped or ceased production during the run period. System downtime is generally less than the total sum of all machine and conveyor downtimes, because of buffers and idle machine factors. It is best measured after the last operation in the packaging process, which usually is palletizing. System downtime normally should not include changeover, cleanup, and prep time periods. These times should be documented separately.

System utilization In general, *system utilization* refers to how effectively time is used during production. With regard to packaging lines, utilization is the fraction of the total package run cycle that is actually used to produce a needed quantity of quality packages. With regard to machines or subsystems, system utilization quantifies the fraction of productive time that remains after factoring in the effects of wastage, rework, changeover, breaks, restraints, stoppages, and so on. *System utilization* refers to how effectively time is used during the production period. With regard to packaging lines, system utilization is the fraction of the total package run cycle that is actually used to produce a needed quantity of quality packages at a set run peed rate. In this *Encyclopedia* the word *utilization* is used to refer to system utilization, except with respect to machine elements. Another way is to say the system utilization is a fraction that quantifies the amount of productive time that remains after factoring in the appropriate effects of downtime over the package run cycle. Some people call this "uptime."

Target cost The estimated cost to accomplish the project contract as defined by the estimate design basis and the project objectives. The target cost assumes that project execution during design, construction, and initial startup will meet the normal performance standards of the company. The sum of all direct and indirect costs. By definition, the target cost is a tight but realistic figure that should have an equal chance of being overspent or underspent. It excludes "management reserve."

Target date The date an activity is desired to be started or completed, imposed, or requested by client or program management.

Team approach Basically, this means using teamwork to accomplish goals. Teamwork is the dedicated work of a team or number of associated persons of different talents and abilities acting together in a joint action or endeavor with reference to coordination of effort and collective efficiency. The team should be made up of internal and external resources, management, operators, and maintenance personnel.

Temper A measure of the ductility and hardness of steel plate.

Thermocouple A bimetallic device used to measure temperatures electrically.

Tolerance A specified allowance for deviations in weighing, measuring, and so on from the standard dimensions or weight.

Total quality management (TQM) "Quality" is made up of conformance to specifications as well as conformance to the customer's expectations. Expectations are extremely difficult to measure, because this includes perceived elements. Total quality management is a philosophy of how to bring about quality. Deming and Derant agree that quality is not the problem, it is the solution. Improving quality entails low upfront costs while returns are extremely high. Typically, in the 1980s, 25% of the workforce was busy doing rework. It is estimated that reducing defectives or wastage by 5% increases revenue by 25–85%. The following are TQM milestones:

Quality is achieved by working on the process, striving to eliminate variability, and not by reworking or wasting products or packages.

It is the line operators and maintenance that should control the process, not the QC department. Quality is everyone's job.

Instead of directions, explain intent; take advantage of workers' talents, do not view them as machines or items to be replaced. Workers should be trained for flexibility. Workers should be trained to use "statistical quality control" and other tools such as PRC, DFA, and CCS.

When a problem arises, or a defective product is found, it should be viewed as an opportunity to learn about the process, not as an excuse to blame someone. Learn from your customers by getting their ideas, concerns, and recommendations.

Strive for evolution and innovations, not revolutions and inventions.

Total productive maintenance (TPM) A philosophy or management tool that view maintenance not as a necessary evil, but a vital operation that contributes to the productivity and profitability of the company. For JIT to work, one of the keys is to ensure the process availability to produce is maximized. A coordinated maintenance program with integrates QCP, TQM, preventive maintenance, predictive maintenance, and DFA is what is needed to have a successful TPM program.

Throughput Throughput for a given packaging line and product is the exact quantity of quality packages produced in a package run cycle as required by the customer and shipped to the customer. It is denoted by the symbol Y. Similarly, we define the throughput for a machine or throughput rate as the number of items (of acceptable quality) leaving a machine in a given amount of time. We denote this by y_i for the ith machine. The word *throughput* has the same definition as *output*.

Training *Training* is the same as *qualifying*. Training is the act of setting up and administering a training program that ensures the people who will be interfacing with the packaging line are given a thorough overview of the packaging line and a detailed program on what they need to know to complete their tasks without hesitation or guessing. All training should address the following points:

1. Whom should be trained?
2. Why should training be done?
3. When should training be done?
4. What training should be done?
5. How should we do training?
6. Where should we do training?
7. How much is enough training?
8. Manuals and other self-help tools.
9. Performance reviews and continuing improvement.
10. Company standards and policy.
11. Equipment effectiveness analysis.
12. Retrofits, adjustments, and additions to new, modified, or existing packaging lines.
13. The team approach.

Training prerequisites The skills and knowledge that a learner should have before training starts on a new technology.

Training qualification A test for learners that is both written and hands on.

Training resources Training experts such as teachers, photographers, technical writers, and illustrators.

Transient period The time required after the package changeout has been completed to get the given interval actual run speed (or output rate) to exceed the 80% of achievable run speed. This is sometimes called the "runup period." If the packaging process cannot move out of the transient period quickly enough, the loss in potential production can be staggering.

Translucent Descriptive of a material or substance capable of transmitting some light but is not clear enough to be seen through.

Transparent Descriptive of a material or substance capable of a high degree of light transmission (e.g., glass).

Uptime The time a machine or process is available to produce a quality product during the run period of the package run cycle.

Utilization (*U*) The fraction of a defined time period that is actually used to produce quality packages. There are many definitions of utilization, but there are five main types of utilization:

1. System utilization
2. Run utilization
3. Package changeout utilization
4. Element or machine utilization
5. Asset utilization

System utilization is the fraction of the total package run cycle that is actually used to produce a needed quantity of quality packages at a set run speed. In this *Encyclopedia* when we use the word utilization, we refer to system utilization. Another way is to say that system utilization is a fraction that quantifies the amount of productive time that remains after factoring in the appropriate effects of downtime over the package run cycle. Some people call this "uptime." *Run utilization* is the fraction of time the packaging line is producing output at a set run speed divided by the total time available for production. Note that changeover, cleanup, and prep work are not included. This factor can be considered the uptime during the producing time period. *Package changeout utilization* is the fraction of the package run cycle time the packaging line has available for producing output at a set run speed after changeover, cleanup, and prep time have been completed. *Element utilization* is the fraction of time a given machine or element is actually producing output at a set run speed divided by the total time available for production. Note that changeover, cleanup, and prep work are not included. This definition usually relates to machinery and/or components. *Asset utilization* is the fraction of a 24-h-per-day clock that is actually used in producing quality packages until the package run cycle is completed. If the package run cycle takes exactly 3 days, then the total asset utilization time is $24 \times 3 = 72$ h, even though only one shift per day is being used. When calculating performance index (PI), only the system utilization is used that considers the entire package run cycle with changeover, cleanup, prep work, and run utilization. Run utilization is used to get an overview of the integration, control, and elements that make up the total packaging line. Element utilization is used to get an overview of a given Machine, conveyor, or equipment. It can be used as a general guideline for acceptance of a vendor's machine. But for a specific specification for acceptance of a vendor's machine, the disturbance frequency (DF) should be used with the element utilization. In this *Encyclopedia* the word *utilization* refers to system utilization.

Vacuum packaging Packaging in containers, whether rigid or flexible, from which substantially all gases have been removed prior to final sealing of the container.

Value analysis A systematic approach to simplification and standardization of products so that they provide needed value at minimum cost. Usually applied to existing products to reduce input counts or amount of packaging.

Value engineering A corporate engineering tool used in meeting a sharply defined objective that is capable of measurement and control by corporate managers. Most objectives of value engineering are often associated with cost-reduction programs. Value engineering uses the systematic job plan consisting of the following steps:

1. Stating the problem
2. Forming the hypothesis
3. Observing and experimenting
4. Interpreting data
5. Drawing conclusions or solutions

The test for value functions are

Reliability
Performance
Quality
Weight
Packaging
Maintenance and servicing
Appearance
Initial costs
Lead time
Human factors
Productivity
Capital investment

Variables Quantities that describe the current operating state of a machine or system. Output rate, wastage rate, and cycle rates are examples of variables.

Verifying The act of being able to determine without hesitation that the machine testing and training of personnel is not only thorough but also effective in the day to day production of the packaging line without senior staff, consultants, and/or machinery service personnel being involved in any shape or form.

Viscometer An instrument to measure viscosity.

Viscosity Internal friction or resistance to flow of a liquid. The constant ratio of shearing stress to rate of shear. In liquids for which this ratio is a function of stress, the term *apparent viscosity* is defined as this ratio.

Wastage (*W*) Components or packages produced that are of unacceptable quality. The quantity of such items is denoted by the symbol W for a system and w_i for the ith machine. This items of unacceptable quality cannot be reused or recycled back into the system. As a general policy, food and pharmaceutical products that fall onto the production floor are discarded and are therefore wastage. In other industries, wastage may be reworked. Usually, employees use their discretion to decide on wastage items, unless company policy or government regulations clearly define wastage. Wastage increases manufacturing costs. Some basic costs relating to wastage are as follows:

1. Initial cost for the product and/or inputs
2. Overhead cost
3. Opportunity cost
4. Disposal cost
5. Recycling cost

A decrease in wastage will, in turn, lower production costs and increase output. In general, wastage is an indicator of a process out of control.

Working capital The estimated cash investment in inventories and accounts receivable, minus accounts payable.
