List of Entries

Absolute Pitch
Acoustics and Concert Halls
Action and Vision
Aesthetic Appreciation of Pictures
Aftereffects
Afterimages
Ageing and Chemical Senses
Ageing and Hearing
Ageing and Touch
Ageing and Vision
Agnosia: Auditory
Agnosia: Tactile
Agnosia: Visual
Air Quality
Amblyopia
American Sign Language
Ames Demonstrations in Perception
Amodal Perception
Animal Chemical Sensitivity
Animal Color Vision
Animal Depth Perception
Animal Eye Movements
Animal Eyes
Animal Frequency and Pitch Perception
Animal Motion Perception
Aphasias
Aromatherapy
Art and Perception. *See* Pictorial Depiction and Perception
Assistive Technologies for the Blind
Atmospheric Phenomena
Attention: Cognitive Influences
Attention: Covert
Attention: Cross-Modal
Attention: Disorders
Attention: Divided
Attention: Effect of Breakdown
Attention: Effect on Perception
Attention: Object-Based
Attention: Physiological
Attention: Selective
Attention: Spatial
Attention: Theories of
Attention and Consciousness
Attention and Emotion
Attention and Medical Diagnosis
Attention and Memory
Attractiveness
Audiology
Audition
Audition: Cognitive Influences
Audition: Disorders
Audition: Loudness
Audition: Pitch Perception
Audition: Temporal Factors
Auditory Frequency Analysis, Neural
Auditory Frequency Selectivity
Auditory Illusions
Auditory Imagery
Auditory Localization: Physiology
Auditory Localization: Psychophysics
Auditory Masking
Auditory Processing: Central
Auditory Processing: Peripheral
Auditory Receptors and Transduction
Auditory Scene Analysis
Auditory System: Damage Due to Overstimulation
Auditory System: Evolution of
Auditory System: Structure
Auditory Thresholds

Bayesian Approach
Binding Problem
Binocular Vision and Stereopsis
Bistable Perception
Body Perception
Body Perception: Disorders

Reader's Guide

The Reader's Guide is provided to assist readers in locating articles on related topics. It classifies articles into 18 general topical categories: Action; Attention; Audition; Chemical Senses; Cognition and Perception; Computers and Perception; Consciousness; Disorders of Perception; Illusory Perceptions; Individual Differences (Human) and Comparative (Across Species); Methods; Perceptual Development/Experience; Philosophical Approaches; Physiological Processes; Sense Interactions; Skin and Body Senses; Theoretical Approaches; and Visual Perception. Entries may be listed under more than one topic.

Action

Action and Vision
Corollary Discharge
Echolocation
Effort: Perception of
Embodied Perception
Event Perception
Eye and Limb Tracking
Eye Movements: Behavioral
Eye Movements: Effects of Neurological and Mental Disorders On
Eye Movements and Action in Everyday Life
Eye Movements During Cognition and Conversation
Feature Integration Theory
Film (Cinema) Perception
Guidance Systems for Blind People
Haptics
Human–Machine Interface
Kinesthesia
Mirror Neurons
Motion Parallax and Structure From Motion
Motion Perception
Motion Perception: Social
Multimodal Interactions: Visual–Haptic
Navigation Through Spatial Layout
Perceptual Development: Imitation
Perceptual Development: Touch and Pain
Perceptual Development: Visually Guided Reaching
Perceptual-Motor Integration
Prism Adaptation
Reaching and Grasping
Response Time
Self-Motion Perception
Speech Production
Tool Use
Unconscious Processes
Vestibular System
Video Games
Visually Guided Actions
Visual Search
Weight Perception

Attention

Attention: Cognitive Influences
Attention: Covert
Attention: Cross-Modal
Attention: Disorders
Attention: Divided
Attention: Effect of Breakdown
Attention: Effect on Perception
Attention: Object-Based
Attention: Physiological
Attention: Selective
Attention: Spatial
Attention: Theories of
Attention and Consciousness
Attention and Emotion
Attention and Medical Diagnosis
Attention and Memory

Bistable Perception
Cell Phones and Driver Distraction
Change Detection
Consciousness
Eye and Limb Tracking
Eye Movements During Cognition and Conversation
Film (Cinema) Perception
Magic and Perception
Perceptual Development: Attention
Rapid Serial Visual Presentation
Top-Down and Bottom-Up Processing
Video Games
Visual Search

Audition

Absolute Pitch
Acoustics and Concert Halls
Ageing and Hearing
Agnosia: Auditory
American Sign Language
Animal Frequency and Pitch Perception
Aphasias
Audiology
Audition
Audition: Cognitive Influences
Audition: Disorders
Audition: Loudness
Audition: Pitch Perception
Audition: Temporal Factors
Auditory Frequency Analysis, Neural
Auditory Frequency Selectivity
Auditory Illusions
Auditory Imagery
Auditory Localization: Physiology
Auditory Localization: Psychophysics
Auditory Masking
Auditory Processing: Central
Auditory Processing: Peripheral
Auditory Receptors and Transduction
Auditory Scene Analysis
Auditory System: Damage Due to Overstimulation
Auditory System: Evolution of
Auditory System Structure
Auditory Thresholds
Causality
Cochlear Implants: Controversy
Cochlear Implants: Technology
Computer-Generated Speech, Perception of
Computer Speech Perception
Echolocation
Evoked Potential: Audition
Guidance Systems for Blind People
Hearing Aids
Language
Lightning and Thunder
Melody Perception
Mirror Neurons
Multimodal Interactions: Tactile–Auditory
Multimodal Interactions: Visual–Auditory
Music Cognition and Perception
Music in Film
Otoacoustic Emissions
Perceptual Development: Hearing
Perceptual Development: Infant Music Perception
Perceptual Development: Intermodal Perception
Perceptual Development: Speech Perception
Sound Reproduction and Perception
Sound Stimulus
Speech Perception
Speech Perception: Physiological
Speech Production
Speechreading
Statistical Learning
Synesthesia
Timbre Perception
Tinnitus
Unconscious Processes
Virtual Reality: Auditory
Word Recognition

Chemical Senses

Ageing and the Chemical Senses
Air Quality
Animal Chemical Sensitivity
Aromatherapy
Common Chemical Sense (Chemesthesis)
Constancy
Electronic Nose
Flavor
Fragrances and Perfume
Multimodal Interactions: Color–Chemical
Multimodal Interactions: Thermal–Chemical
Olfaction
Olfaction: Evolution of
Olfaction: Feature Detection and Integration
Olfaction and Reproductive Behavior
Olfactometry
Olfactory Adaptation
Olfactory Bulb: Functional Architecture

Cognition and Perception

Computers and Perception

Consciousness

Disorders of Perception

Prostheses: Visual
Recovery of Vision
  Following Blindness
Sensory Rehabilitation
Sensory Restoration and Substitution
Speechreading
Taste: Disorders
Tinnitus
Vision: Developmental Disorders
Visual Disorders: Blindness

Illusory Perceptions

Aftereffects
Afterimages
Atmospheric Phenomena
Auditory Illusions
Change Detection
Contrast Enhancement at Borders
Contrast Perception
Hallucinations and Altered Perceptions
Impossible Figures
Nonveridical Perception
Phantom Limb
Pictorial Depiction and Perception
Visual Illusions

Individual Differences (Human) and Comparative (Across Species; Not Including Ageing, Disorders, and Perceptual Development)

Absolute Pitch
Animal Chemical Sensitivity
Animal Color Vision
Animal Depth Perception
Animal Eye Movements
Animal Eyes
Animal Frequency and Pitch Perception
Animal Motion Perception
Cultural Effects on Perception
Echolocation
Electroception
Emotional Influences on Perception
Individual Differences in Perception
Nature and Nurture in Perception
Pain: Cognitive and
  Contextual Influences
Perceptual Expertise
Private Nature of Perceptual Experience
Taste: Genetics of
Taste: Supertasters
Taste and Food Preferences
Video Games

Methods

Brain Imaging
Evoked Potential: Audition
Evoked Potential: Vision
Magnetoencephalography
Microstimulation
Neural Recording
Neuropsychology of Perception
Phenomenology (Psychology)
Physiological Approach
Priming
Psychophysical Approach
Psychophysics: Detection
Rapid Serial Visual Presentation
Receptive Fields
Recognition
Response Time
Reverse Correlation
Scaling of Sensory Magnitude
Selective Adaptation
Signal Detection Theory and Procedures
Transcranial Magnetic Stimulation
Tuning Curves
Visual Search

Perceptual Development/Experience

Ageing and Chemical Senses
Ageing and Hearing
Ageing and Touch
Ageing and Vision
Cultural Effects on Perception
Infant Perception
Infant Perception: Methods of Testing
Nature and Nurture in Perception
Perceptual Development: Attention
Perceptual Development: Color and Contrast
Perceptual Development: Face Perception
Perceptual Development: Hearing
Perceptual Development: Imitation
Perceptual Development: Intermodal Perception
Perceptual Development: Object Perception
Perceptual Development: Taste and Olfaction
Perceptual Development: Touch and Pain
Perceptual Development: Visual Acuity
Perceptual Development: Visually Guided Reaching
Perceptual Development: Visual Object
  Permanence and Identity

Perceptual Expertise
Perceptual Learning
Prism Adaptation
Statistical Learning
Vision: Developmental Disorders

Philosophical Approaches

Causality
Color: Philosophical Issues
Computer Consciousness
Consciousness
Content of Perceptual Experience
Indirect Nature of Perception
Intentionality and Perception
Inverted Spectrum
Mary the Color Scientist
Mind and Body
Modality (Philosophy)
Molyneux's Question
Naïve Realism
Perceptual Representation (Philosophy)
Phenomenology (Philosophy)
Philosophical Approaches
Philosophy: Access and Report
Philosophy: Attention and the Size of the Conscious Field
Private Nature of Perceptual Experience
Qualia
Seeing As
Visual Filling In and Completion

Physiological Processes

Aftereffects
Binding Problem
Contrast Enhancement at Borders
Cortical Organization
Cortical Reorganization Following Damage
Experience-Dependent Plasticity
Feedback Pathways
Lateral Inhibition
Loss of a Sense, Effect on Others, Psychological
Mirror Neurons
Modularity
Multimodal Interactions: Neural Basis
Neural Prosthetic Systems
Neural Recording
Neural Representation/Coding
Neuropsychology of Perception
Oscillatory Synchrony
Physiological Approach
Receptive Fields
Speed of Processing in Sensory Systems
Tuning Curves

Sense Interactions

Action and Vision
Attention: Cross-Modal
Cortical Reorganization Following Damage
Cross-Modal Transfer
Extrasensory Perception
Flavor
Loss of a Sense: Effect on Others, Psychological
Molyneux's Question
Motion Perception: Social
Multimodal Interactions: Color–Chemical
Multimodal Interactions: Neural Basis
Multimodal Interactions: Pain–Touch
Multimodal Interactions: Tactile–Auditory
Multimodal Interactions: Thermal–Chemical
Multimodal Interactions: Visual–Auditory
Multimodal Interactions: Visual–Haptic
Perceptual Development: Intermodal Perception
Perceptual-Motor Integration
Sensory Restoration and Substitution
Synesthesia
Taste and Food Preferences

Skin and Body Senses

Ageing and Touch
Agnosia: Tactile
Body Perception
Body Perception: Disorders
Braille
Constancy
Cutaneous Perception
Cutaneous Perception: Physiology
Electroception
Embodied Perception
Haptics
Itch, Tickle, and Tingle
Kinesthesia
Migraine
Molyneux's Question
Multimodal Interactions: Pain–Touch
Multimodal Interactions: Tactile–Auditory
Multimodal Interactions: Thermal–Chemical
Multimodal Interactions: Visual–Haptic

Out-of-Body Experience
Pain: Assessment and Measurement
Pain: Cognitive and Contextual Influences
Pain: Neuromatrix Theory
Pain: Physiological Mechanisms
Pain: Placebo Effects
Pain: Treatments for Chronic
Perceptual Development: Touch and Pain
Phantom Limb
Proprioception
Reaching and Grasping
Surface and Material Properties Perception
Tactile Acuity
Tactile Map Reading
Temperature Perception
Texture Perception: Tactile
Tool Use
Vibratory Perception
Virtual Reality: Touch/Haptics
Visceral Perception
Weight Perception

Theoretical Approaches

Bayesian Approach
Computational Approaches
Direct Perception
Ecological Approach
Embodied Perception
Evolutionary Approach
Evolutionary Approach: Perceptual Adaptations
Gestalt Approach
Indirect Nature of Perception
Information Theory
Physiological Approach
Psychophysical Approach
Theoretical Approaches
Theory of Mind

Visual Perception

Action and Vision
Aesthetic Appreciation of Pictures
Aftereffects
Afterimages
Ageing and Vision
Agnosia: Visual
Amblyopia
American Sign Language
Ames Demonstrations in Perception
Amodal Perception
Animal Color Vision
Animal Depth Perception
Animal Eye Movements
Animal Eyes
Animal Motion Perception
Assistive Technologies for the Blind
Atmospheric Phenomena
Attention: Cognitive Influences
Attention: Covert
Attention: Cross-Modal
Attention: Disorders
Attention: Divided
Attention: Effect of Breakdown
Attention: Effect on Perception
Attention: Object-Based
Attention: Physiological
Attention: Selective
Attention: Spatial
Attention: Theories of
Attention and Consciousness
Attention and Emotion
Attention and Medical Diagnosis
Attractiveness
Binding Problem
Binocular Vision and Stereopsis
Bistable Perception
Camouflage
Causality
Change Detection
Color: Genetics of
Color: Philosophical Issues
Color Constancy
Color Deficiency
Color Mixing
Color Naming
Color Perception
Color Perception: Physiological
Computer Graphics and Perception
Computer Vision
Constancy
Context Effects in Perception
Contrast Perception
Corollary Discharge
Depth Perception in Pictures/Film
Digital Imaging
Direct Perception
Dyslexia
Ecological Approach
Embodied Perception
Event Perception

About the Editor

E. Bruce Goldstein is Professor Emeritus of Psychology at the University of Pittsburgh and Adjunct Professor of Psychology at the University of Arizona. He has received the Chancellor's Distinguished Teaching Award from the University of Pittsburgh for his classroom teaching and textbook writing. He received his bachelor's degree in chemical engineering from Tufts University, his PhD in experimental psychology from Brown University, and he was a post-doctoral fellow in the Biology Department at Harvard University before joining the faculty at the University of Pittsburgh. Dr. Goldstein has published papers on a wide variety of topics, including retinal and cortical physiology, visual attention, and the perception of pictures. He is the author of *Sensation & Perception,* 8th edition (Wadsworth/Cengage, 2010), and *Cognitive Psychology: Connecting Mind, Research and Everyday Experience,* 2nd edition (Wadsworth/Cengage, 2008), and is the editor of the *Blackwell Handbook of Perception* (Blackwell, 2001).

Introduction

The Field of Perception

The field of perception is concerned with explaining the operation of the senses and the experiences and behaviors resulting from stimulation of the senses. The senses are vision, hearing, the cutaneous senses (touch, pain, tickle, itch), chemical senses (taste, smell, flavor), proprioception and kinesthesia (awareness of body positions and limb position and motion), and the vestibular sense (balance).

One of the characteristics of perception is that it involves more than is apparent. This statement reflects the following paradox: Perceptual experiences such as recognizing objects; seeing light, color, and spatial layout; hearing pitch and music; perceiving the locations of sounds; and experiencing smells, tastes, touch, cold, and pain represent the actions of extremely complex, and still not completely understood, mechanisms. Yet for all the underlying complexity of these mechanisms, we perceive easily, usually with little effort or conscious awareness of the mechanisms involved. One way to appreciate the fact that there is more to perception than may be apparent to the perceiver is to consider the following examples.

- A person looks out over a visual scene dotted with houses, trees, and other objects. Although this scene creates a two-dimensional image on the person's retina, the person sees the scene as stretching into the distance, and the objects as volumetric shapes.
- Bacon simmering and coffee brewing release hundreds of different types of molecules into the air. The molecules from the bacon and coffee become indiscriminately mixed in the air and across a person's olfactory receptors. Despite this random mixing of molecules, the person perceives just two olfactory objects, "bacon" and "coffee." This feat is particularly impressive because many of the individual molecules, when considered individually, have their own odors, which do not necessarily resemble the odors of bacon or coffee.
- It is very easy for people to perceive and recognize objects in a scene ("that's a chair in the corner," "that's Sandra's face"). However, the most powerful computers can accomplish this task only with difficulty and cannot begin to approach the speed and accuracy of human performance, especially under "real-world" conditions when objects are seen at different distances and from different angles, and are sometimes partially obscured by other objects.
- A woman's arm was amputated after she was injured in a car accident. Although her arm and hand are no longer there, she still feels as if they are. In fact, she sometimes has the disconcerting experience of feeling the missing hand as tightly clenched, with fingers digging painfully into her palm.
- All of these examples and everything else we perceive are created by electrical signals in the brain, which in themselves have no color, sound, taste, hot, or cold. Yet somehow these electrical signals become transformed into perceptual experience.

This encyclopedia provides an overview of the field of perception through authoritative 1,000- to 4,000-word essays by leading researchers and theoreticians in the field. These essays are supported by nearly 180 figures and tables, 39 of which are in color.

The research and theory reported here involves two parallel and interacting approaches, the psychophysical approach and the physiological approach. The psychophysical approach involves determining the relationship between stimuli in the environment and perception. This approach has measured basic operating characteristics of perception, which involves determining things such as thresholds for qualities associated with each sense (for example, detecting light, motion, sounds, taste, and smell stimuli) and how stimulus characteristics influence perception of these qualities (for example, how wavelengths of light are associated with color perception, frequency of sound with pitch, chemical structures with taste and smell). This approach is also important for uncovering underlying mechanisms of perception and has provided the basis of various theoretical approaches to perception.

The physiological approach is concerned with determining the biological mechanisms responsible for perception. These physiological mechanisms begin when receptors sensitive to specific kinds of stimuli (light for vision, sound for hearing, for example) are activated and trigger electrical signals that eventually result in activation of neurons in a large number of structures, both before reaching the brain and then within the complex architecture of a large number of interrelated brain areas.

The physiological approach has determined how stimuli in the environment are represented by the firing of neurons and activation of the brain, and has demonstrated connections between specific areas of the brain and the perception of specific types of stimuli (for example, visual patterns such as faces, complex sounds, and chemical compounds with specific structural components have been linked to specific brain areas). The complexity of the brain processes that cause perception is reflected by the finding that although brain areas have been identified that process information about specific types of stimuli, these stimuli also cause activity in many other areas of the brain, as well.

Perception is not, however, determined only by receptors sending signals to the brain. Other factors such as the context within which perception is experienced, individual differences across perceivers, and a person's expectations and prior knowledge can also influence what is perceived. In addition, "perceptual experience"—seeing a tree, smelling the scent of a rose, feeling pain from an injury—is not the only outcome of stimulating sensory receptors. Once an object is perceived, it is usually "recognized," by placing it in a category ("that's a cup," "that's the smell of a rose"), and then in some cases the person interacts with stimuli in some way. This can involve using perceptual landmarks to help navigate through the environment, deciding to pick up a coffee cup, or accepting or rejecting a particular food based on its taste or smell.

Thus, although many of the entries in these volumes are about sensing stimuli, many other entries illustrate how the field of perception extends to "recognizing," "taking action," and other areas as well. Perception is, for example, linked to processes such as memory (memory can be enhanced for experiences rich in perceptual detail; perception can be influenced by past experiences), thinking (perception can both aid thinking and involves processes similar to those involved in thinking), emotion (perceptual experiences can create both positive and negative emotions; emotional states can influence perceptual behavior), and motivation (perceptions such as smell and pain are associated with approach and avoidance behavior; a person's goals and intentions guide looking behavior and tactile exploration).

Are there processes that are *not* associated with or influenced by perception? Surely there are—but the pervasiveness of perception is truly impressive, and the phenomena of perception and the mechanisms underlying these phenomena are what this encyclopedia is about.

Goals of the Encyclopedia

Three basic goals guided the creation of this encyclopedia: (1) broad coverage, (2) authoritative entries, and (3) accessibility to a general audience. The brief overview of the field at the beginning of this introduction describes the field of perception as involving (a) many different sensory qualities and physiological systems; (b) two broad approaches, each of which makes use of a wide variety of methods; and (c) links to many areas outside the field. Thus, in deciding how to represent the field of perception, my guiding principle was to include as varied and broad a list of topics as possible, and to include not only the basic research that accounts for most of the entries, but also descriptions of methods, theoretical approaches, and real-world applications of perceptual research. Although the primary emphasis is on explaining human perception, much animal research is included, both because of its importance in its own right and because of what the results of this research tell us about human perception.

Given the goal of casting a broad net, it is not surprising that researchers represented in this volume come from a wide range of backgrounds. For example, the list of contributors beginning on page xix includes people in departments of anatomy, behavioral science, biology, biophysics, cognitive science, computer science, neuroscience, ophthalmology, optometry, philosophy, physiology, psychology, statistics, and zoology.

The second goal, presenting authoritative state-of-the-art information, has been achieved by inviting recognized experts to write the entries. But having experts write entries is useful only to the extent that these entries are accessible to our readers. Thus, the third goal was to be sure that the experts wrote entries that could be understand by the target audience for encyclopedia—general readers with no previous background in perception, which includes anyone with an interest in perception—undergraduates, college graduates, and members of the general public. But even though entries have been written with the goal of accessibility to a wide audience, there is information here for specialists as well. Even though I have a broad background in perception, I learned quite a bit in the process of reading these entries.

Content and Organization

As indicated, the content of this encyclopedia includes topics that span the field of perception. This scope can be appreciated by consulting the List of Entries beginning on page v, which lists the 367 headwords in the alphabetical order in which they appear in the encyclopedia. Another resource is the Reader's Guide, beginning on page xi, which includes the following 18 headings with relevant headwords listed under each heading:

Action
Attention
Audition
Chemical Senses
Cognition and Perception
Computers and Perception
Consciousness
Disorders of Perception
Illusory Perceptions
Individual Differences (Human) and Comparative (Across Species; Not Including Ageing, Disorders, and Perceptual Development)
Methods
Perceptual Development/Experience
Philosophical Approaches
Physiological Processes
Sense Interactions
Skin and Body Senses
Theoretical Approaches
Visual Perception

Although headwords appear alphabetically in the encyclopedia (that is, they are not grouped by the headings listed), these headings serve as a guide to the topics that are relevant to each heading. The fact that a particular topic may appear under a number of headings reflects the interrelatedness between areas of perception. Additional evidence for this interrelatedness is the list of related topics ("*See also*" cross-references) that appears at the end of each entry. Also, Further Readings at the end of each entry provide a starting point for further, more detailed study of a topic.

One of the key features of the encyclopedia is the 16-page section of color illustrations and photos at the front of each volume, beginning on page xxxiii. Each is linked to specific entries and, at the appropriate points in the text, the entries send the reader to examine the figures. The interrelationship between the art and entries helps the encyclopedia to be useful for all readers.

Finally, a word about the headwords. Headwords were assigned lengths from 1,000 to 4,000 words based on the generality or broadness of the topics, with more general topics being assigned more words. However, even many of the shortest entries could be expanded to fill a book (and in many cases, our contributors are authors of such books).

A few of the longest entries are intended to provide an overview of an area, so the authors of these entries were asked to provide perspective regarding the history and scope of the topic and not to be concerned with details that would be covered by other entries. Some of these "overview" entries are

Audition
Consciousness
Consciousness: Disorders
Cortical Organization

Cutaneous Perception
Infant Perception
Nature and Nurture in Perception
Neuropsychology of Perception
Olfaction
Philosophical Approaches
Physiological Approach
Psychophysical Approach
Taste
Theoretical Approaches
Vision

How the Encyclopedia Was Created

The creation of this encyclopedia, which spanned two years from initial conception to publication, followed these steps:

1. I invited internationally recognized experts in the field to serve on the advisory board, with the understanding that their main task would be to play the crucial role of suggesting headwords and possible contributors to write the essays for the headwords.

2. I created a list of headwords by consulting textbooks, professional journals, handbooks, and other encyclopedias (although it is important to note that there was no encyclopedia of perception to consult because one has not existed until now). "Scope" statements were also created for each headword to indicate the intended content.

3. The advisory board reviewed the headword-scope list, suggesting additions and deletions and making comments regarding the content for each entry.

4. The advisory board suggested possible contributors for the headwords in their areas of expertise. A list of potential contributors was created based on these suggestions (giving preference to people getting more "votes" from the advisory board).

5. Invitations were sent to potential contributors for each headword. When the "first choice" was unavailable, usually because of time issues, additional people were contacted until there was a contributor for each headword.

6. I read all of the entries (some in collaboration with Carole Maurer, Sage's developmental editor for the encyclopedia) and returned them for revision when necessary. Revision was requested for two reasons: (1) need for additional coverage, or in some cases less, if there was too much overlap with another entry; (2) need for improved readability. Because accessibility of the entries was one of the major goals of the encyclopedia, some entries needed to be simplified from what would appear in the research literature, and one of the main reasons for requesting revision was the need to define technical terms. In addition, the use of concrete examples was encouraged. In a few cases, entries were sent to a member of the advisory board for a second opinion.

Using the Encyclopedia

This encyclopedia can be used both to answer specific questions about perception and to obtain an overview of the field. Two excellent starting points are the List of Entries and the listing of topics in the Reader's Guide. It is often useful to check an entry's related topics ("*See also*" cross-references) for more breadth and the Further Readings for additional information and sources.

If, as is likely, you were drawn to the encyclopedia in searching for information about a specific topic, I invite you to extend your search beyond that topic. Take some time to browse. You may be surprised by unexpected revelations about specific topics and might gain some insight into the vast scope of the field of perception. After all, perceiving is something we are doing constantly, and understanding perception can enhance this experience. I've found that studying perception has made me more observant of my environment, and more appreciative of the miraculous process that transforms energy falling on receptors into the richness of experience. I hope that reading selections from this book helps you appreciate both the complexity and the beauty of the mechanisms responsible for perception.

Acknowledgments

I am especially indebted to three people. I thank James Brace-Thompson (whom I have always known as JBT) for broaching the idea that I edit this encyclopedia, for being willing to wait until I had time to do it, and for providing the support I needed to be able to handle the logistics involved in this rather huge undertaking.

The major support JBT provided were the two people without whom I simply wouldn't have been able to make this book happen. Eileen Gallaher, my editorial assistant, sent out invitations and follow-ups, answered contributor's questions, and kept things organized (not a trivial task!) as the encyclopedia took shape. I worked with her for more than a year, sometimes on almost a daily basis, and she always came through. Thank you, Eileen!

The other person, Carole Maurer, Sage's developmental editor for the encyclopedia, helped evaluate entries, gave me advice, made revisions when necessary, and perhaps most important, provided emotional support. Working with Carole, which felt like a true collaboration, was a pleasure! Thank you, Carole.

Once all the entries were in and Carole had transformed them into the correct format, she handed the manuscript off to Kate Schroeder, the production editor, who assigned Amy Freitag and Robin Gold to copyedit the manuscript. Thank you Amy and Robin for your excellent copyediting. Also a special thanks to Kate for everything you did during the challenging process of transforming the manuscript into this book.

There are two groups of people, without whom this book wouldn't exist—my advisory board and the contributors. I thank the members of the advisory board, whose names are listed on page iv. Their major job was to help get the project off the ground by suggesting headwords, scope statements, and contributors. Only with their help was I able to cast the net out into the field of perception that made it possible for me to recruit the distinguished list of contributors who wrote the 367 entries. I especially thank Mark Hollins, Don Wilson, and Bill Yost, who provided sample entries to post on the Web site, and a special thanks to Don Wilson for being willing to provide advice on an ongoing basis as the project progressed.

And finally, I thank the hundreds of contributors, whose names are listed beginning on page xix. Everyone who wrote an entry was extremely busy with other projects but somehow made time to write her or her entries. But what impressed me the most about the contributors was the graciousness with which they responded to my requests for revision. Much to my surprise, some of them even thanked me for my suggestions! In addition, I had some interesting and intellectually stimulating e-mail conversations with a number of the contributors. Thank you all for making the journey from agreeing to edit the encyclopedia to seeing the completed book a positive one for me, and for making the final product useful to our readers, and, I hope also to the field of perception.

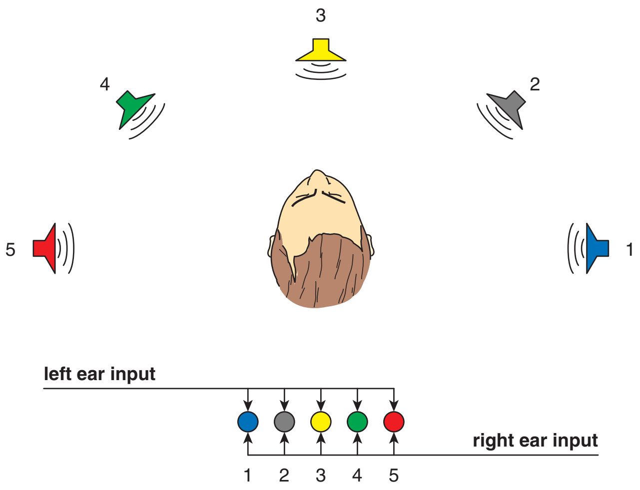

Figure 1 *Auditory Localization: Physiology*—Axonal Delay Lines

Note: Each neuron in the array is contacted by axons from each ear. See page 168 in the Auditory Localization: Physiology entry for additional information (pp. 167–170).

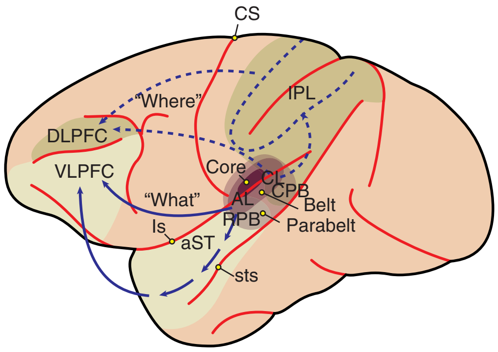

Figure 2 *Auditory Processing: Central*—Schematic Illustration of Hierarchical Processing in the Auditory Cortex of the Rhesus Monkey and Processing Streams for "What" and "Where"

Notes: Auditory signals arrive first in the core areas (consisting of the primary auditory cortex, A1, and two rostral areas) from subcortical inputs in thalamus and brainstem. Activity then propagates to the belt (AL, CL, among others) and parabelt areas (rostral and caudal, RPB and CPB, respectively), which give rise to two pathways projecting to two largely segregated regions in the prefrontal cortex (PFC): the ventrolateral and dorsolateral (VLPFC and DLPFC) regions, respectively. The ventral processing stream is also relayed through the anterior superior temporal (aST) cortex, where regions or patches specialized for the processing of voices and communication sounds have been found in both monkeys and humans. The dorsal stream, in addition to its projection to the DLPFC, is relayed also through the inferior parietal lobule (IPL) of the posterior parietal cortex (PPC, particularly the ventral intraparietal region, VIP). Rich back-projections exist from the prefrontal cortex to the PPC as well as to the aST (not shown). See the Auditory Processing: Central entry for additional information (pp. 176–180).

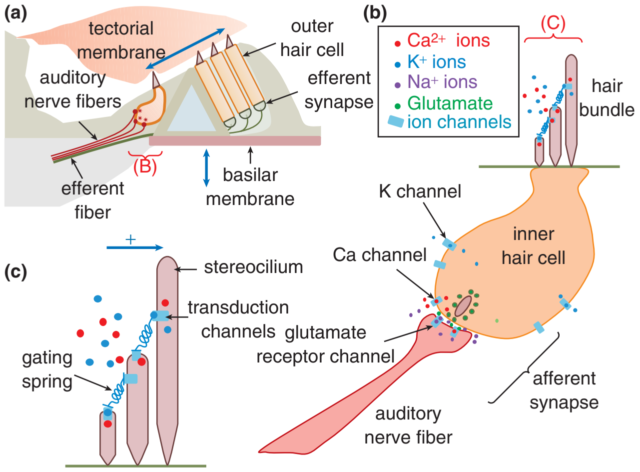

Figure 3 *Auditory Receptors and Transduction*—Hair Cells of the Mammalian Cochlea

Notes: (a) Cross-section through the sensory epithelium (organ of Corti) in the middle chamber of the cochlea. (*Blue arrows*) Sound moves the basilar membrane up and down, bending the hair bundles of inner and outer hair cells against the tectorial membrane. (b and c) Ion channels involved in the afferent flow of electrical signals from the ear to the brain: (b) is a higher-magnification view of the inner hair cell in (a), and (c) is a higher-magnification view of the hair bundle in (b). Deflection of the hair bundle toward its tall edge (+, *blue arrow*) opens mechano-electrical transduction channels, through which potassium (K^+) and calcium (Ca^{2+}) ions enter the stereocilium and make the hair cell more positive. The voltage change activates voltage-gated channels that are selective for K^+ or Ca^{2+} ions. Entry of Ca^{2+} through Ca channels activates release of glutamate by the hair cell onto the afferent nerve ending. Binding of glutamate to glutamate-receptor channels opens the channels, producing an influx of positive ions, which triggers action potentials. See the Auditory Receptors and Transduction entry for additional information (pp. 183–186).

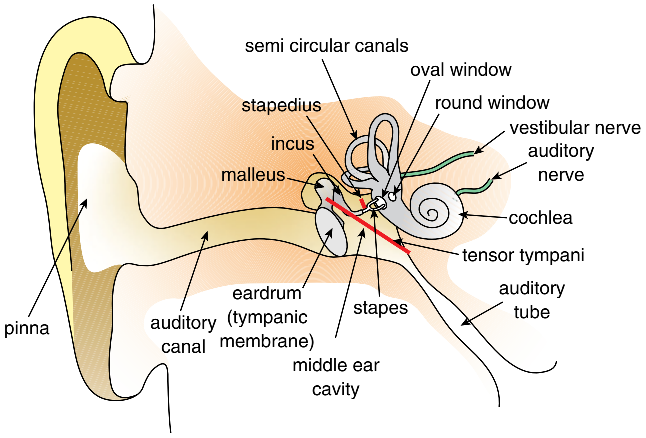

Figure 4 *Auditory System: Structure* (1)—Structure of the Ear

Source: Modified from a Wikipedia illustration by Dan Pickard, with permission.

Notes: Muscles are shown in red and nerves in green. See the Auditory System: Structure entry for additional information (pp. 194–197).

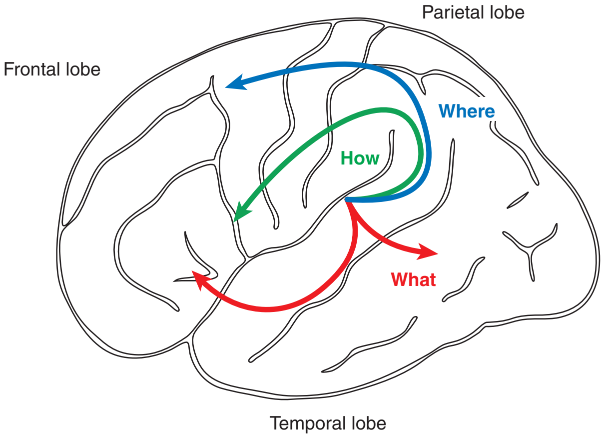

Figure 6 *Speech Perception: Physiological*—Auditory Processing Streams Important for Speech Perception

Source: Adapted from Scott, S. K. (2005). Auditory processing—speech, space and auditory objects. *Current Opinion in Neurobiology, 15,* 197–201.

Note: See the Speech Perception: Physiological entry for additional information (pp. 923–926).

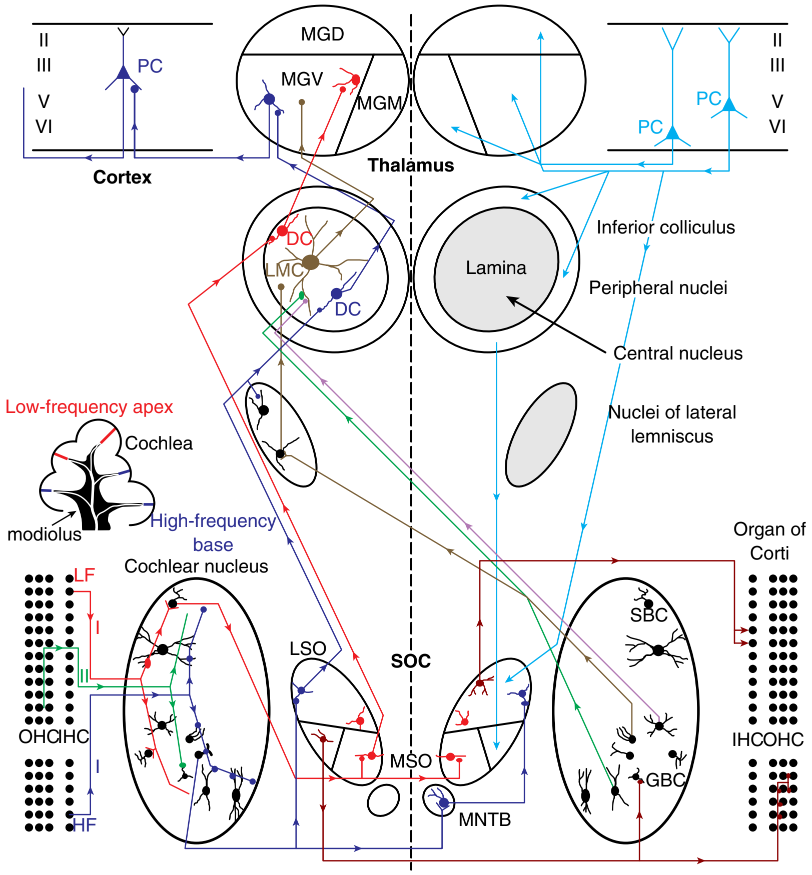

Figure 5 *Auditory System: Structure* (2)—Cell Types and Major Connections Within the Nervous System Processing Auditory Input

Notes: Ascending pathways are mainly shown on the left and descending pathways are mainly shown on the right. The dashed line represents the midline. See the Auditory System: Structure entry for additional information (pp. 194–197).

Cutaneous

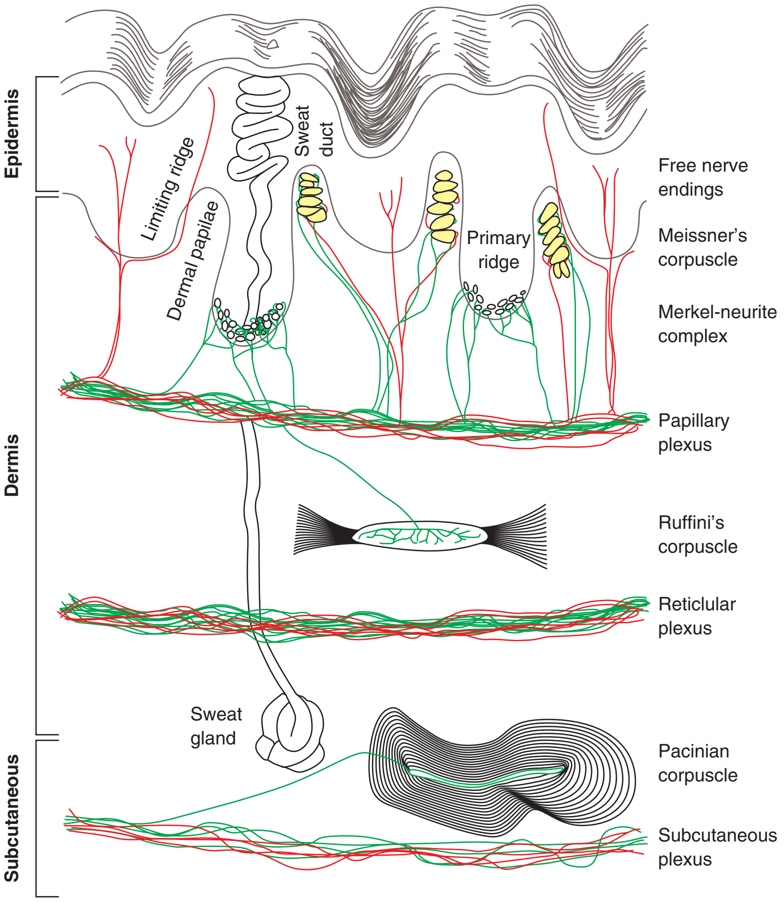

Figure 7 *Cutaneous Perception: Physiology*—Cross-Section Diagram Showing the Different Kinds of Afferent Receptors Innervating the Glabrous Skin of the Primate

Source: Adapted from Johnson, K. O. P. (2002). Neural basis of haptic perception. In H. Pashler & S. Yantis (Eds.), *Steven's handbook of experimental psychology: Vol. 1. Sensation and perception* (3rd ed., pp. 537–583). New York: Wiley.

Notes: The receptor endings that are associated with cutaneous processing are the Meissner's corpuscle, which is the receptor ending for the rapidly adapting afferents (RA); the Merkel-neurite complex, which is the endings for the slowly adapting type 1 afferents (SA1); the Pacinian corpuscle, which is the ending for the Pacinian afferents (PC); and the Ruffini's corpuscle, which was once thought to be the ending for the slowly adapting type 2 afferents (SA2). The free-nerve endings provide the inputs for the pain, temperature, and itch afferents. See the Cutaneous Perception: Physiology entry for additional information (pp. 348–353).

Olfaction

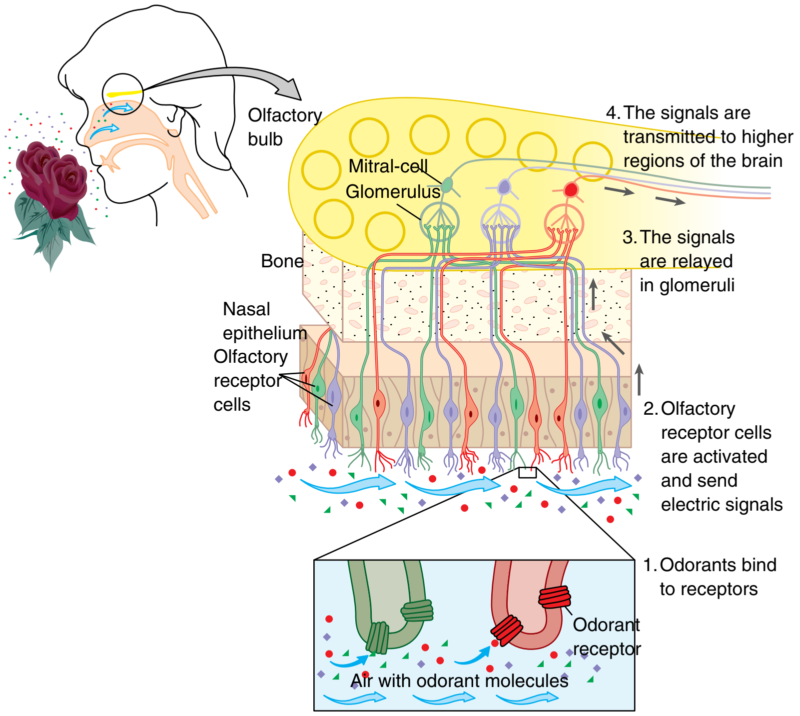

Figure 8 *Olfaction*–Olfactory Epithelium and Bulb

Notes: Schematic of the olfactory epithelium showing how the axons of the olfactory receptors cells that express the same receptors project to common glomeruli within the olfactory bulb. See the Olfaction entry for additional information (pp. 657–661).

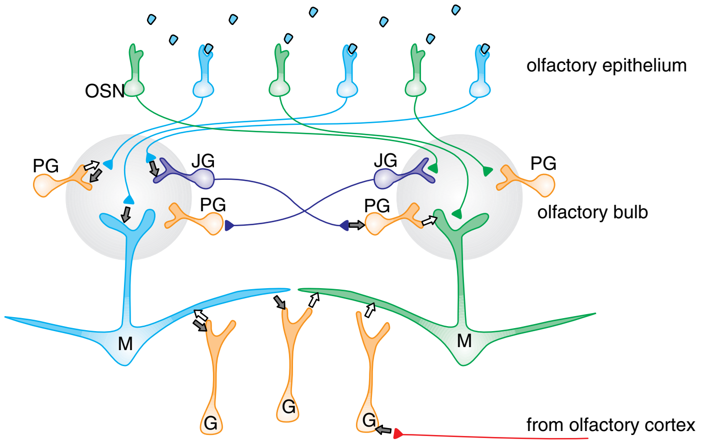

Figure 9 *Olfaction: Feature Detection and Integration*—Basic Circuit Outlining the Flow of Excitation and Inhibition in the Olfactory Bulb

Notes: When excited by odorants, OSNs activate a network of intrinsic and output neurons associated with a single glomerulus. This circuit makes use of both feedback and lateral inhibition to enhance the contrast between similarly responding glomeruli. Abbreviations: OSN = olfactory sensory neuron; PG = periglomerular cell; JG = juxtaglomerular cell; M = mitral/tufted cell. Black arrows indicate excitatory synapses and white arrows indicated inhibitory synapse. See the Olfaction: Feature Detection and Integration entry for additional information (pp. 668–671).

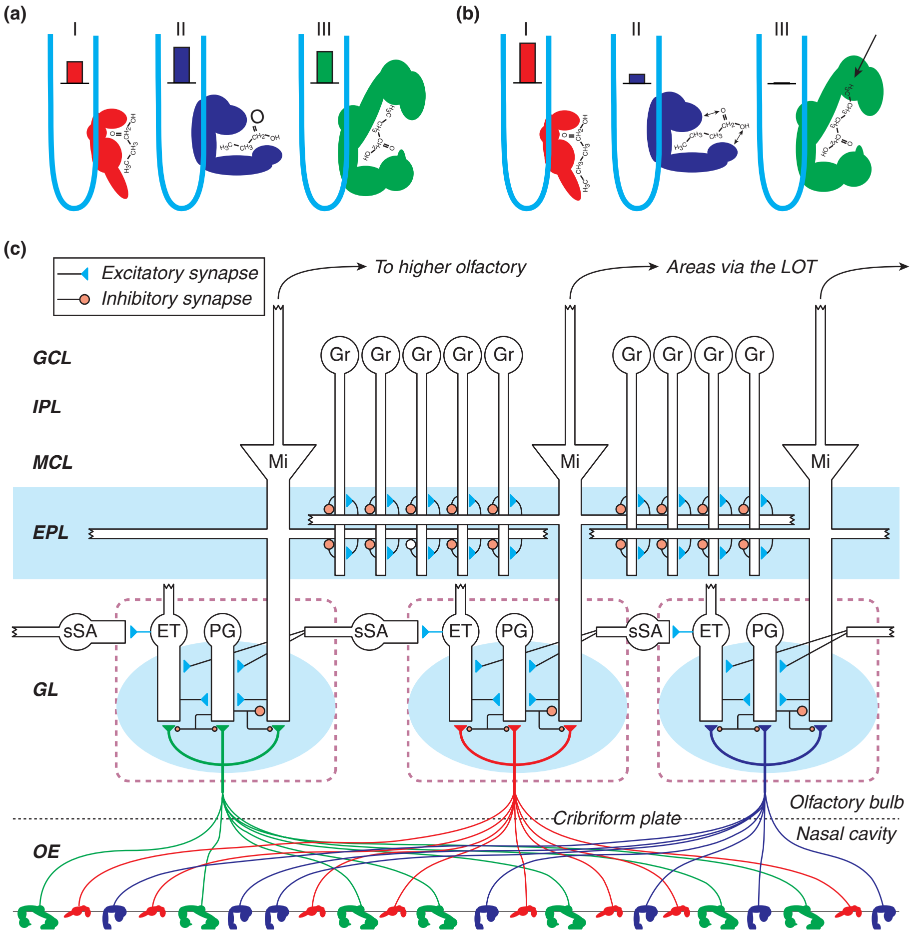

Figure 10 *Olfactory Bulb: Functional Architecture*—Coding and Anatomy of the Olfactory System

Note: See pages 680–681 in the entry Olfactory Bulb: Functional Architecture for a complete description.

Vision

Figure 11 *Atmospheric Phenomena*–Some Atmospheric Phenomena

Sources: Figure 1(a) was kindly supplied by Dr. Urte Roeber, who retains its copyright. Figure 1(b) © Photograph by "Σ64." Retrieved January 16, 2009, from http://commons.wikimedia.org/wiki/File:Brocken-tanzawa.JPG. This file is licensed under the GNU Free Documentation License, Version 1.2 or any later version published by the Free Software Foundation (http://commons.wikimedia.org/wiki/Commons:GNU_Free_Documentation_License); with no Invariant Sections, no Front-Cover Texts, and no Back-Cover Texts.

Notes: (a) Aerial perspective makes distant objects appear to be lighter and to have less contrast than near objects, here seen in the two slopes, both of which are covered in essentially identical vegetation and are identically illuminated. (b) Four antisolar phenomena: The shadow of the photographer is a *spectre*. It is surrounded by a bright *halo* from back-scattered sunlight. The halo is surrounded by a *glory*, the colored rings. The photographer's shadow also shows *anticrepuscular* rays. (c) Two antisolar phenomena: The fan shape of shadow rays are anticrepuscular rays. These arise from parallel light from the sun being blocked by clouds in the west, creating parallel shadows that receding from the viewer in the east. The rainbow arises from refraction and total internal reflection of sunlight in raindrops. This display of anticrepuscular rays and rainbow is called *rainbow spokes*. See the Atmospheric Phenomena entry for additional information (pp. 67–71).

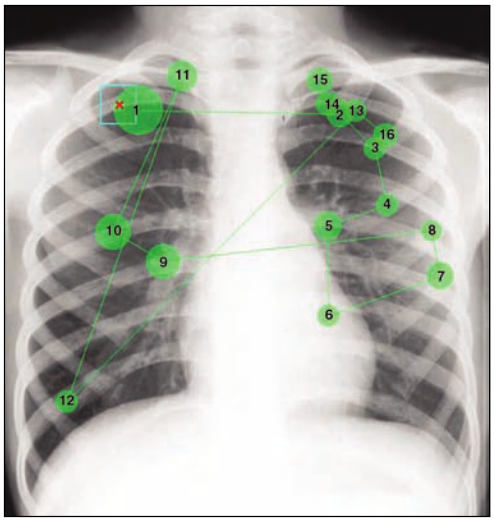

Figure 12 *Attention and Medical Diagnosis*—Expert's Scanpath

Notes: A lesion has been identified by a mouse click (red cross in blue box) at fixation 1 in the image. The first fixation is at the location of the nodule, which suggests the lesion must have been identified in the global look. The size of the green circle is proportional to the length of time of each fixation, with the first fixation being 1.8 seconds. See the Attention and Medical Diagnosis entry for additional information (pp. 119–121).

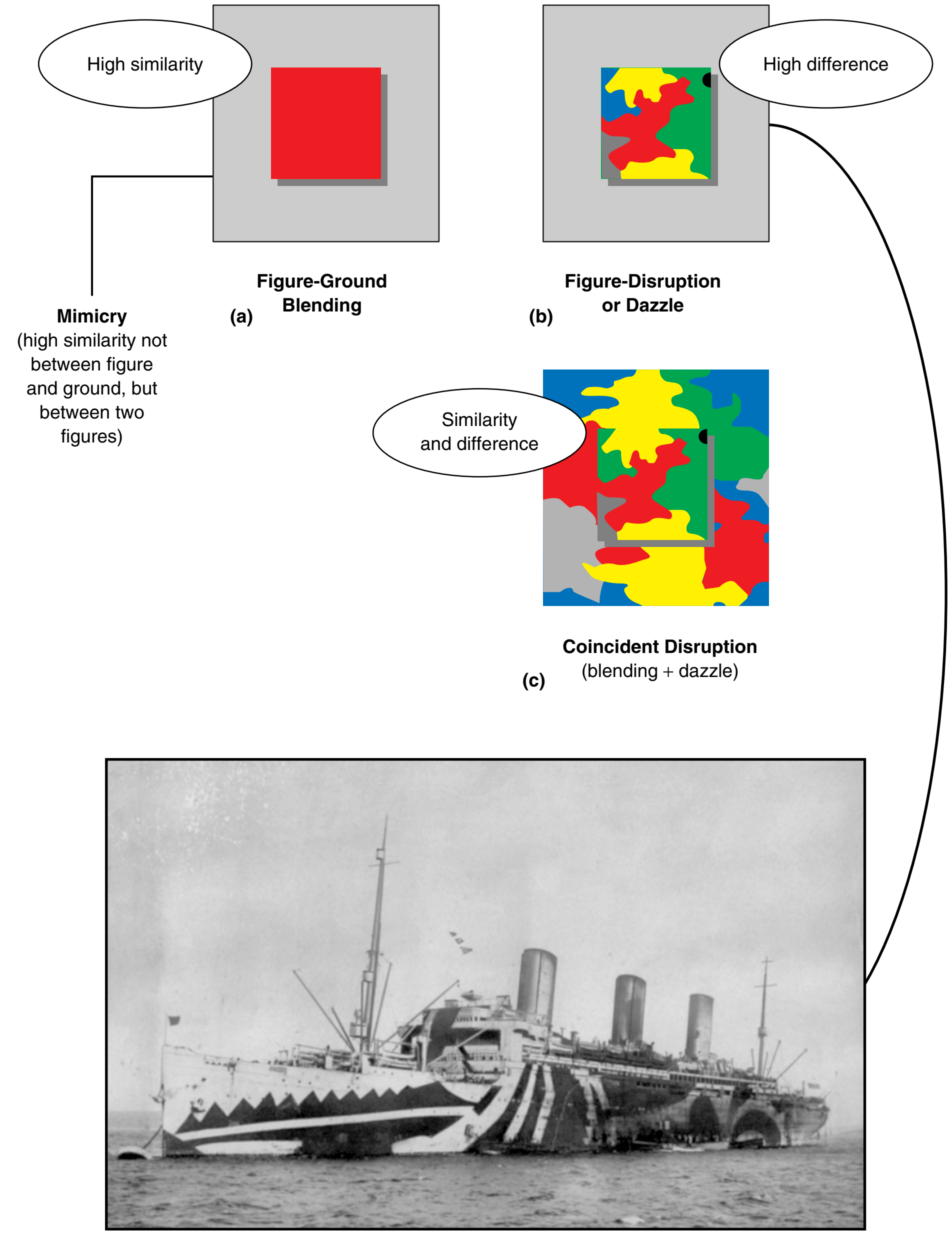

Figure 13 *Camouflage*—Three Major Categories of Camouflage

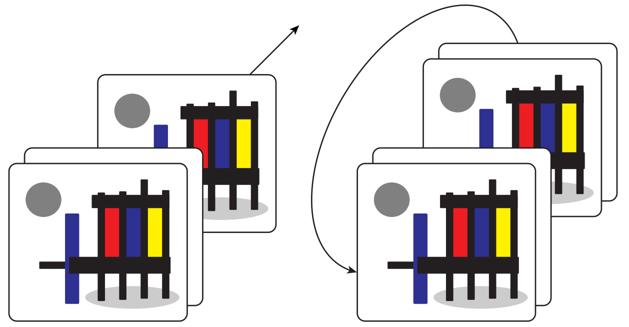
Source: Illustration © by Roy R. Behrens, 2008. Reprinted with permission.

Notes: Although there are any number of ways to categorize examples of camouflage, perhaps the three most common kinds are figure-ground blending (a), in which an object blends in with its setting (also sometimes known as crypsis); figure disruption (b and photo below it), in which the surface of the figure is broken up by highly contrasting components, a method that was used widely for ship camouflage during World Wars I and II; and coincident disruption (c), in which the figure is broken up, but parts of it blend in with the background. In the system shown here, mimicry is said to be a subcategory of blending or high similarity camouflage. See the Camouflage entry for additional information (pp. 233–236).



(a) One-shot paradigm **(b)** Flicker paradigm

Figure 14 *Change Detection*—Example of Method Used to Study Change Detection

Notes: Here, a gap-contingent technique makes the change at the same time a brief blank appears. Two ways of measuring performance are illustrated. (a) One-shot paradigm. The observer views a single alternation of the stimuli; performance is measured by the accuracy of detection (or identification) of the change. (b) Flicker paradigm. The observer views a continual cycling of stimuli; performance is measured by the time taken until the change is detected (or identified). Both measurement paradigms can also be applied to other techniques, such as changes made during an eye movement or a shift in the image. (The change between the front and back images is in the width of the horizontal black bar under the colored panels.) See the Change Detection entry for additional information (pp. 241–244).

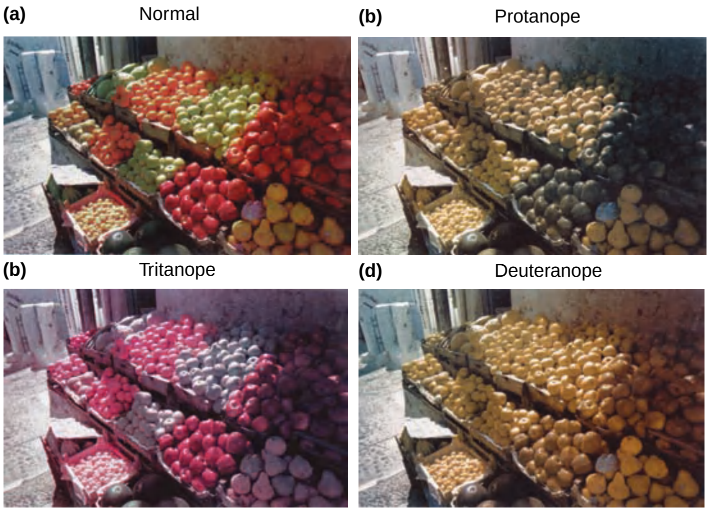


Figure 15 *Color Deficiency*—Perceptual Consequences of Color Vision Defects

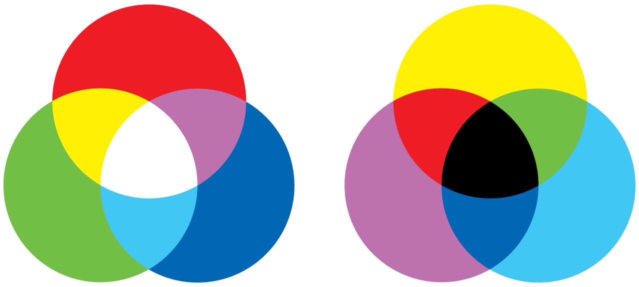
Source: Gegenfurtner, K. R., & Sharpe, L. T. (1999). *Color vision: From genes to perception*. New York: Cambridge University Press. Reproduced with permission of Cambridge University Press.

Notes: Here is a simulation of how a scene from a fruit market is perceived by (a) a normal trichromat, (b) a protanope, (c) a deuteranope, and (d) a tritanope. Each color vision deficiency shows greatly reduced chromatic discrimination compared with that of a normal trichromat. See the Color Deficiency entry for additional information (pp. 257–261).



Additive color mixing Subtractive color mixing

Figure 16 *Color Mixing*—Additive and Subtractive Color Mixing (1)

Notes: The left panel simulates the additive combination of red, green, and blue lights. The right panel simulates the subtractive combination of yellow, purple, and cyan pigments. See the Color Mixing entry for additional information (pp. 262–264).

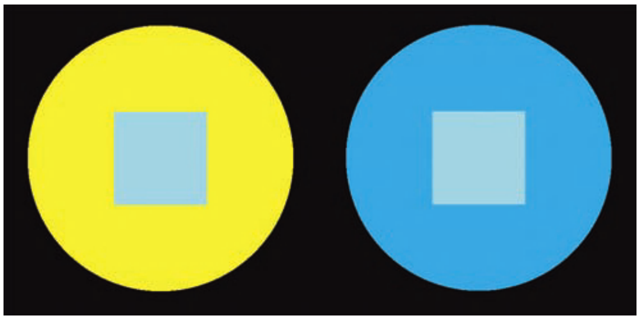


Figure 17 *Color Mixing*—Color Appearance (2)

Notes: The smaller squares are physically the same (i.e., they are printed with the same ink), but their colors appear different. The differences arise because of the surrounding colors, which induce color changes in the appearance of the central squares. See the Color Mixing entry for additional information (pp. 262–264).

Figure 18 *Color Perception*—Image Decomposed Into Its Luminance or Chromatic Components (1)

Notes: The grayscale image (left) retains much of the fine spatial detail, depth, and shading information in the scene. The chromatic images (center and right) captures the material differences between the objects much better and more clearly delineates the objects in terms of these differences and despite variations in shadows and shading. Thus, adding color helps viewers perceive both what the objects are and where they are. See the Color Perception entry for additional information (pp. 266–270).

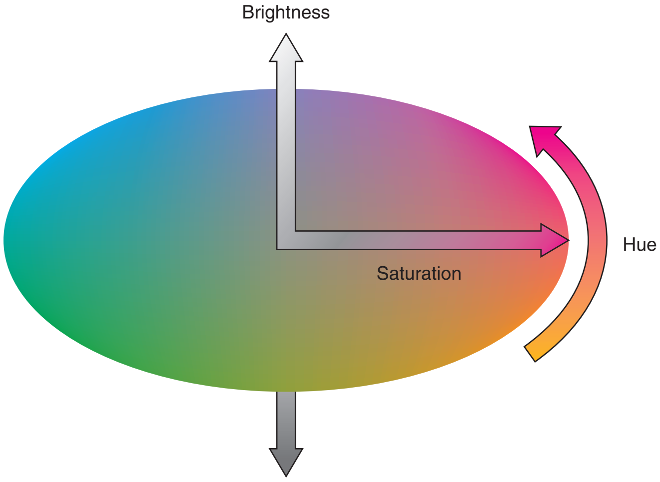

Figure 19 *Color Perception*—The Appearance of an Unrelated Color Can Be Described by Its Brightness, Hue, and Saturation (2)

Notes: These three attributes are arranged in perceptual color spaces to represent colors according to how they differ from a neutral gray. See the Color Perception entry for additional information (pp. 266–270).

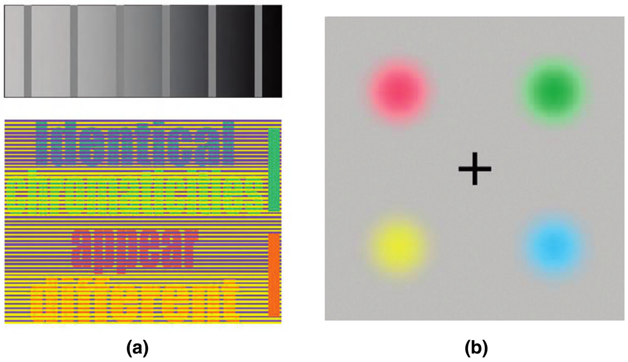

Figure 20 *Color Perception*—Examples of Contextual Effects in Color Appearance (3)

Notes: (a) The thin bars in the upper image are all the same printed gray but appear darker or brighter because of the contrast difference with the neighboring background. Similarly, in the lower figure, the top two and bottom two words are the same physical chromaticity (green and orange, as shown by the bars on the right), yet they appear dramatically different when they are interleaved with either the purple or yellow lines (image courtesy of Patrick Monnier, Department of Psychology, Colorado State University). In (b), as you stare directly at the cross in the center, the colored patches will fade away and may disappear entirely. This occurs because each area of the retina adapts over time to the color falling on it, a process that keeps color appearance centered around the average stimulus we are exposed to. See the Color Perception entry for additional information (pp. 266–270).

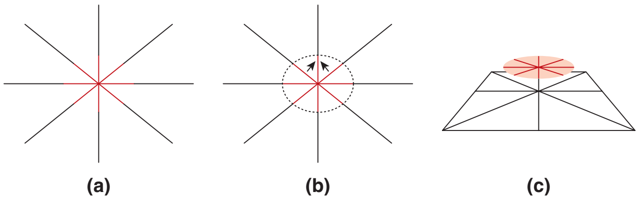

Figure 21 *Computational Approaches*—Neon Color Spreading

Notes: (a) An image that shows the perceptual effect of neon-color spreading. (b) Construction of the invisible fence (dotted line) based on cue discontinuity and border linking. Diffusion spreads the red hue over the surface (arrows) but is contained by the invisible fence. (c) Presumed mental interpretation of a tinted red surface on top of a surface with black lines. See the Computational Approaches entry for additional information (pp. 278–283).

Figure 22 *Digital Imaging*—Color Filter Array (CFA) Overlaid Onto a Charge Coupled Device (CCD) Sensor

Notes: Each CCD element records a limited range of wavelengths, corresponding to either red (gray), green (light gray), or blue (dark gray). A full three-channel RGB color image is created by interpolating the missing color pixels by, for example, averaging the recorded values. See the Digital Imaging entry for additional information (pp. 362–366).

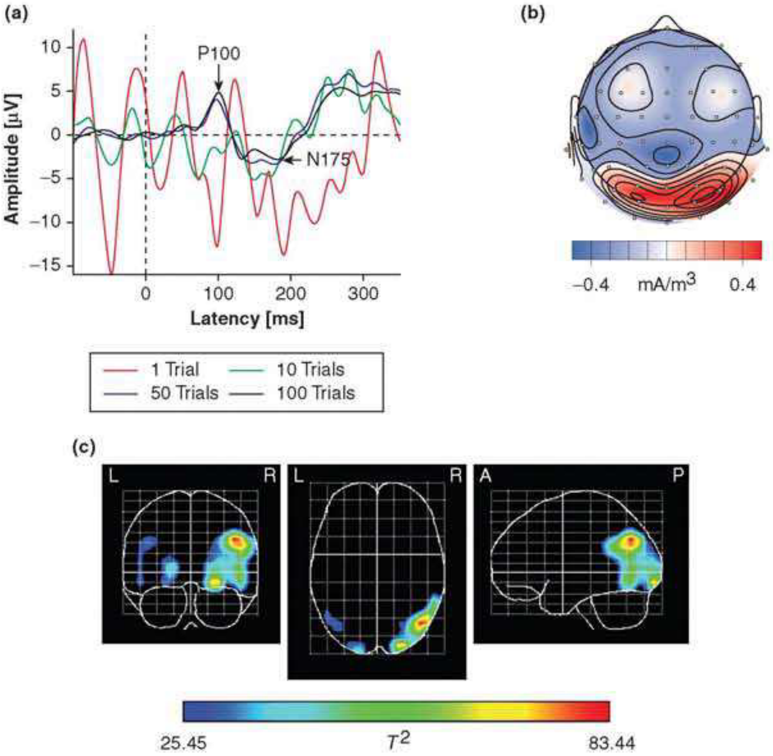

Figure 23 *Evoked Potential: Vision*—Visual Evoked Potential Records

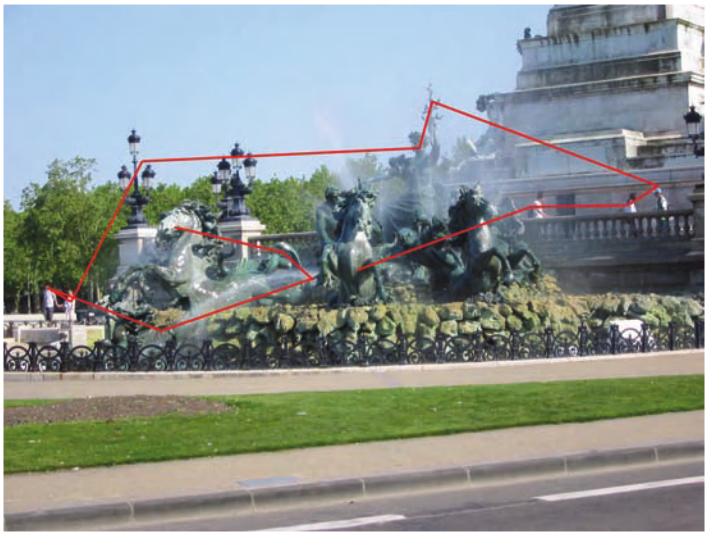
Source: This figure is based on data from Roeber, U., Widmann, A., Trujillo-Barreto, N. J., Herrmann, C. S., O'Shea, R. P., & Schröger, E. (2008). Early correlates of visual awareness in the human brain: Time and place from event-related brain potentials. *Journal of Vision, 8*(3), 1–12.

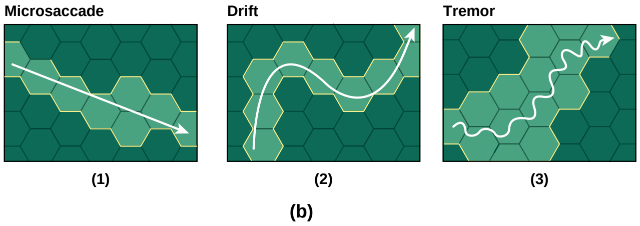
Notes: (a) A person's EEG activity averaged from three electrodes over the right parieto-occipital scalp as a grating presented to one eye changed its orientation (at time 0) from being perpendicular to an identical grating presented to the other eye to being the same as the grating in the other eye. The VEP requires averaging of many EEG records from many trials showing the same visual event. After one trial (the red trace), the EEG activity is essentially random, the VEP being obscured by other activity in the brain. After 10 trials (green trace), the average EEG activity is still essentially random, although its variance is much reduced as the random activity on one trial tends to cancel out the random activity on another. After 50 trials (blue trace), the average EEG activity is quite regular, and the VEP is clearly evident, the random activity having been largely averaged out. After 100 trials (black trace), the VEP is clearly revealed. (b) The scalp current densities computed over 61 scalp electrodes from 12 participants in the same experiment. Changes evoke larger currents over the right occipital area. (c) The sources of the electrical activity computed by VARETA (variable resolution electromagnetic tomography), shown in a "glass brain." It occurs mainly in the right ventrolateral occipital area. See the Evoked Potential: Vision entry for additional information (pp. 399–401).

Figure 24 *Eye Movements and Action in Everyday Life*—The RIT Wearable Eyetracker, Showing the Scene Camera and Eye Camera Mounted on a Lightweight Glasses Frame

Source: M. Hayhoe and D. Ballard, 2005.

Notes: (a) The backpack carries a battery and video camera, which tracks eye position relative to the scene the person is observing. (b) Composite image of a scene from the head-mounted video camera while the subject makes a peanut butter and jelly sandwich. The images from the camera were integrated over different head positions. The fixations are indicated by the yellow circles in the color insert. Circle diameters reflect the duration of the fixation. See the Eye Movements and Action in Everyday Life entry for additional information (pp. 430–433).





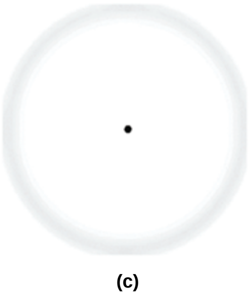


Figure 25 Eye Movements During Fixation

*Sources: (*a) Henderson, J. M. (2009). Used with permission. (b) E. Bruce Goldstein, 2009. (c) Modified from Martinez-Conde, S., Macknik, S. L., & Hubel, D. H. (2004). The role of fixational eye movements in visual perception. *Nature Reviews Neuroscience, 5,* 229–240.

Notes: (a) Eye movements to a picture of a fountain. Each line is a saccadic eye movement. Each saccadic eye movement ends in a fixation, where the eye rests briefly before the next saccadic eye movement. (b) Three types of fixational eye movements: movements of the eye that occur during fixation. (c) Troxler fading. In 1804, Swiss philosopher Ignaz Paul Vital Troxler discovered that deliberately fixating on something causes surrounding stationary images to fade away. To elicit this experience, stare at the central dot while paying attention to the surrounding pale ring. The ring soon vanishes, and the central dot appears set against a white background. Move your eyes, and it pops back into view. See the Eye Movements During Fixation entry for additional information (pp. 438–439).

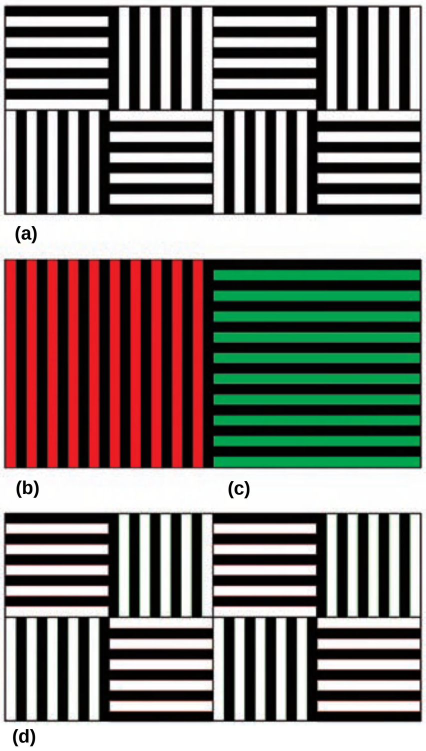

Figure 26 *McCollough Effect*—McCollough Effect Stimuli

Notes: To see the effects illustrated in this figure best, view it from seven times the height of panel (a). (a) The test figure for the McCollough effect. Vertical and horizontal lines look, and are, black-and-white. (b, c) Induction stimuli. Look at the center of (b) for about 10 seconds, then the center of (c) for about 10 seconds; continue looking between (b) and (c) for about five minutes. When you look back at (a) you might see something similar to (d): all of the lines, including the white space between them, appear tinted with faint complementary colors. This stimulus is the same as (a), largely black and white, except that very fine lines of red and green have been added to the edges. These fine lines can be seen by looking closely. See the McCollough Effect entry for additional information (pp. 547–549).

Notes: (a) An inferior mirage on a road: there is an (inverted) image of the blue sky on the road and a distorted, inverted image of the trees. (b) A superior mirage: The superior mirage is the inverted image above the erect image of the ship. Above that is another, narrow, erect image of the ship, also a superior mirage. (c) A fata morgana: This mirage, shown in four panels, involves numerous alternately inverted and erect superior mirages. In the top panel is the fata morgana. In the next panel is the same scene without any mirage. The next two panels show magnified versions of the first two. (d) The flattened sun: As the sun sets, it becomes flattened vertically. (e) The green flash: The upper panel shows an overview of the sun almost completely set showing only a green part. The small lower panels show a magnified view of the sun in sequence as it disappeared below the horizon. (The diagonal cloud is from a contrail.) (f) A mock mirage giving a paper-lantern sun. See the Mirages entry for additional information. (pp. 555–557).

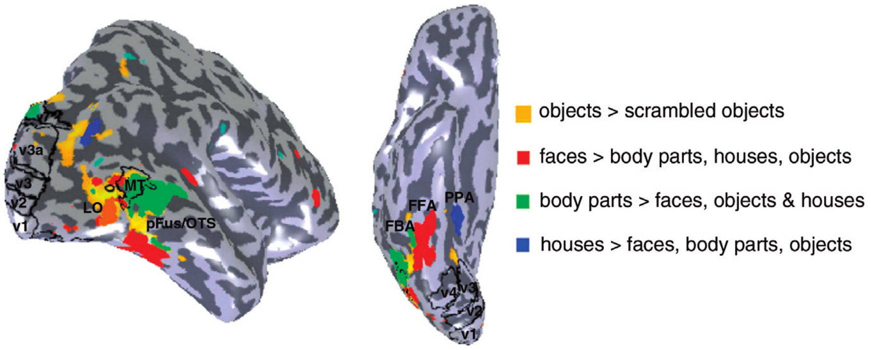

Figure 28 *Object Perception: Physiology*—Functional Magnetic Resonance Imaging (fMRI) Responses to Various Stimuli

Notes: Object (yellow), face (red), body part (green), and house (blue) selective regions presented on an inflated cortical surface of a right hemisphere of a representative subject. Dark grays indicate sulci and lighter grays indicate gyrii. *Left:* lateral view. *Right:* ventral view. Orange indicates regions that are both face and object-selective. Abbreviations: LO = lateral occipital; pFus/OTS = posterior fusiform/occipitotemporal sulcus; MT = mid-temporal motion selective region; FBA = fusiform body part area; FFA = fusiform face area; PPA = parahippocampal place area. Boundaries of early visual areas V1, V2, V3, V3a, and V4 are shown in black. See the Object Perception: Physiology entry for additional information (pp. 648–653).

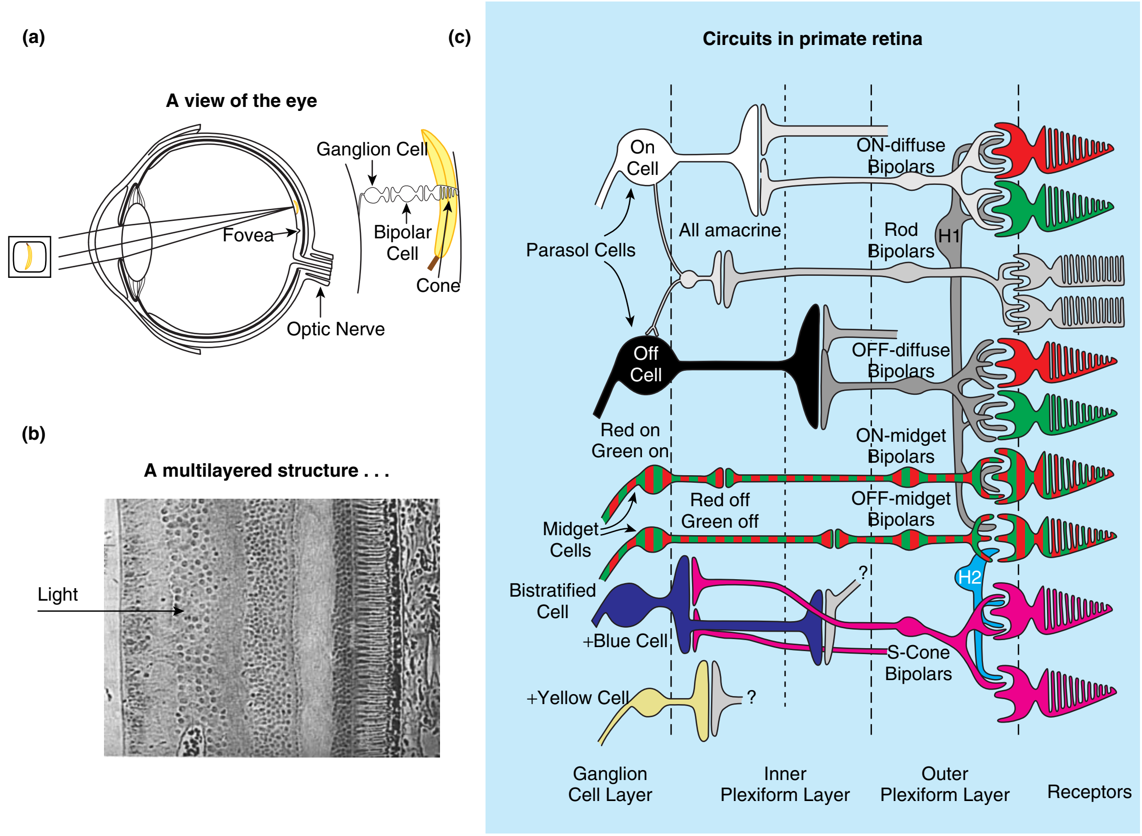

Figure 29 *Retinal Anatomy*—The Eye and Retina

Notes: (a) Sketch of the eye. The retina lies at the back of the eye. The fovea is the region of central vision. The basic retinal circuit (inset) consists of photoreceptors (anchored to the pigment epithelium) that give their output to the bipolar cells that give their output to the ganglion cells, which send their output to the brain. (b) The retina shows a regular structure with different lamina; light must pass through them to reach the receptors. (c) A wiring diagram of the different channels in primate retina. Different channels mediate achromatic, red-green, and blue-yellow signals. Each has the same pattern—cone to bipolar cell to ganglion cells, but there are differences in detail. See the Retinal Anatomy entry for additional information. (pp. 868–871).

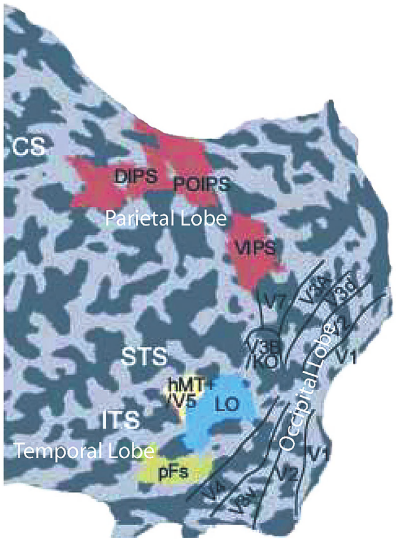

Figure 30 *Visual Processing: Extra-Striate Cortex*—Areas in Extrastriate Cortex

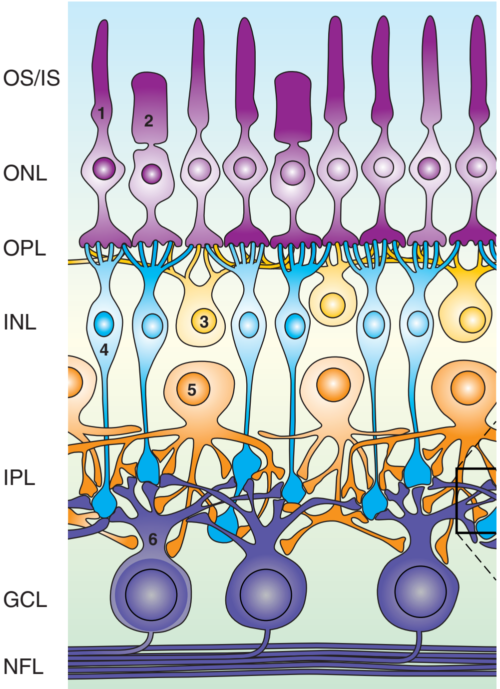
Notes: Activation maps on a flattened cortical surface showing retinotopic areas (V1, V2, V3, V4, V7, V3B/KO), the human motion complex (hMT+/V5), the lateral occipital complex (LOC with subregions: LO = lateral occipital; pFs = posterior fusiform sulcus), and 3-D shape-related areas in the parietal cortex (VIPS = ventral inferior parietal sulcus, POIPS = junction of posterior occipital and inferior parietal sulcus, DIPS = dorsal inferior parietal sulcus). Left hemisphere is shown. Sulci are coded in darker grey than the gyri. Major sulci are labeled as follows: STS = superior temporal sulcus; ITS = inferior temporal sulcus; CS = central sulcus. See the Visual Processing: Extra-Striate Cortex entry for additional information. (pp. 1096–1099).



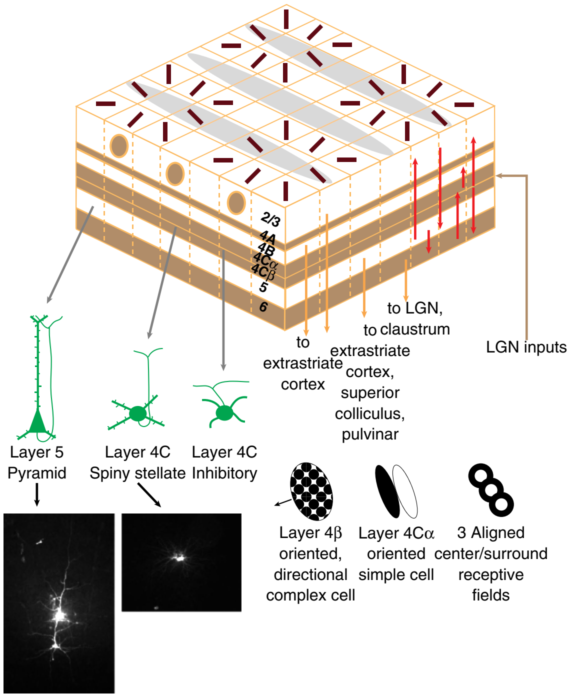


Figure 31 *Visual Processing: Primary Visual Cortex*—Functional Organization of the Primary Visual Cortex, V1

Notes: V1 is a three-dimensional structure containing six main layers. Within these layers, three major cell types—pyramidal cells, spiny stellate cells, and inhibitory cells (shown in green; example intracellular fills of a pyramidal and stellate neuron are illustrated below each)—provide a specific organization of intrinsic connections (red arrows) and extrinsic connections (orange arrows). The organization of lateral geniculate nucleus (LGN) inputs and intrinsic connections underlie the construction of cortical receptive fields (bottom right illustrates a progression from aligned center/surround receptive fields to an oriented simple cell receptive field and a direction selective complex cell receptive field). Dashed orange lines illustrate the boundaries of cortical columns, which contain neurons with similar response properties (e.g., all neurons in a column are tuned to the same stimulus orientation, illustrated here by oriented black bars drawn on the surface). Across the cortex, columns are organized in a precise fashion to form maps of visual space (retinotopy), ocular dominance (illustrated by grey stripes on the cortical surface), and orientation preference (illustrated by oriented bars). See the Visual Processing: Primary Visual Cortex entry for additional information. (pp. 1099–1101).

Figure 32 *Visual Processing: Retinal*—Neuroanatomy of the Retina

Source: Wassle, H. (2004). Parallel processing in the mammalian retina. *Neuroscience Nature Reviews, 5,* 747–757.

Notes: Cell types: Cones (#1), rods (#2), horizontal cells (#3), bipolar cells (#4), amacrine cells (#5), ganglion cells (#6). Abbreviations: OS/IS = outer segments and inner segments; ONL = outer nuclear layer; OPL = outer plexiform layer; INL = inner nuclear layer; GCL = ganglion cells; NFL nerve fibers. See the Visual Processing: Retinal entry for additional information. (pp. 1101–1104).

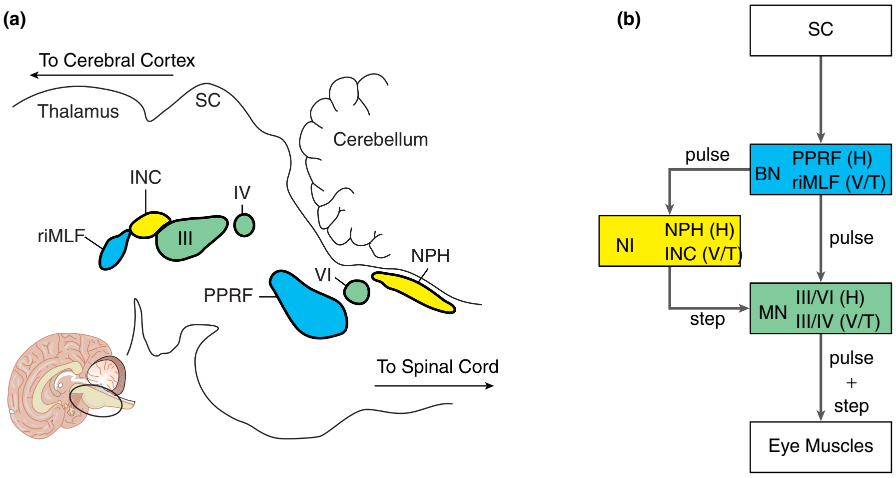

Figure 33 *Visual Processing: Subcortical Mechanisms for Gaze Control*—Brain Stem Pathways for Gaze Control

Sources: (a) V. Henn, J. A. Buttner-Ennever, and K. Hepp, 1982. (b) Author.

Notes: (a) Midsagittal view of the primate brain stem. Burst neurons are shown in blue, neural integrators in yellow, and motoneurons in green. The superior colliculus (SC), thalamus, and cerebellum are also shown. Inset shows the location of the brain stem. (b) A schematic of gaze shift commands traveling through the brain stem. Color scheme same as in (a). Horizontal components are indicated by (H), while vertical/torsional components are indicated by (V/T). SC = superior colliculus; BN = burst neurons; NI = neural integrator; MN = motoneurons; III = oculomotor nucleus; IV = trochlear nucleus; VI = abducens nucleus. See the Visual Processing: Subcortical Mechanisms for Gaze Control entry for additional information (pp. 1104–1107).

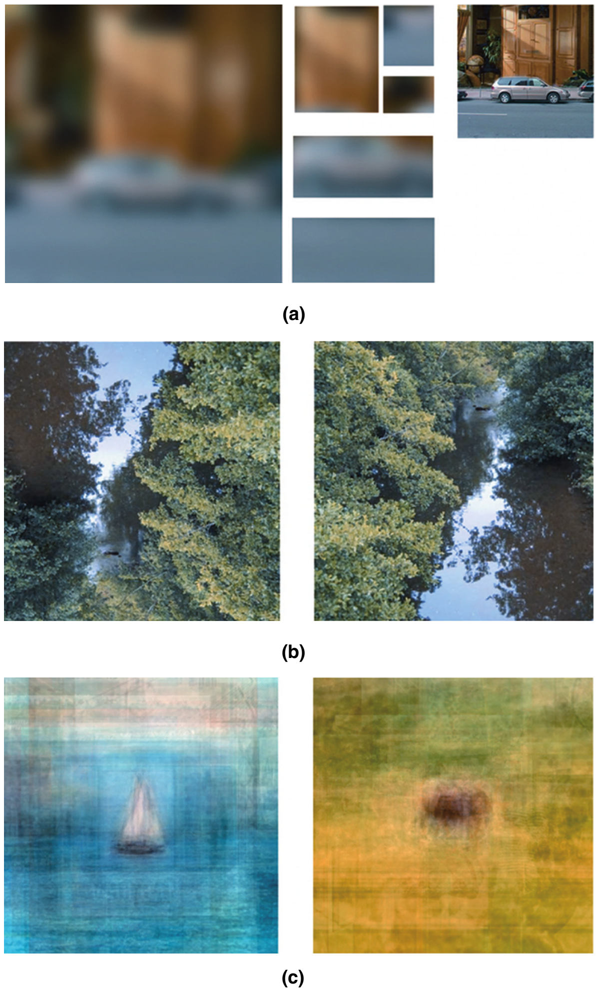

Figure 34 *Visual Scene Perception*—Perceiving Visual Scene Stimuli

Source: Courtesy of Antonio Torralba, MIT.

Notes: (a) The blurry image looks like a street scene, even if the objects cannot be recognized in isolation. (b) A forest scene that changes interpretation with image orientation. (c) Average images centered on pictures of sailboats (left) and cows (right). See the Visual Scene Perception entry for additional information (pp. 1111–1116).

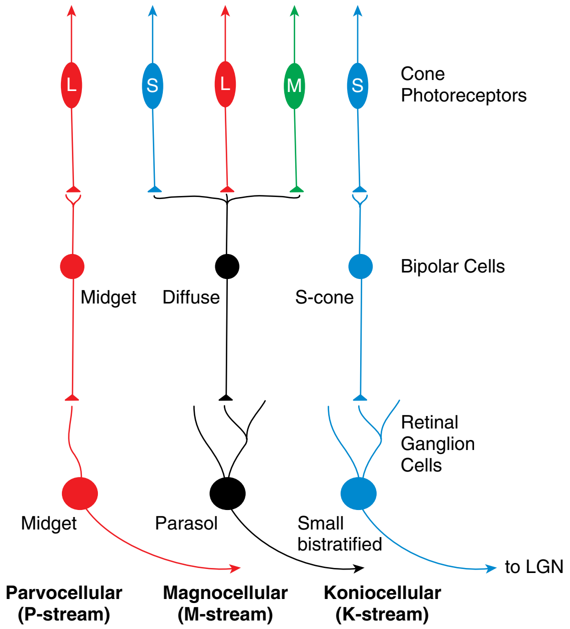

Figure 35 *Visual System Structure* (1)—Foveal Retinal Circuitry

Notes: Three types of cone photoreceptors synapse onto specialized bipolar neurons, which connect to distinct types of retinal ganglion cells depending on their participation in the parvocellular, magnocellular, or koniocellular processing streams. See the Visual System Structure entry for additional information (pp. 1130–1134).

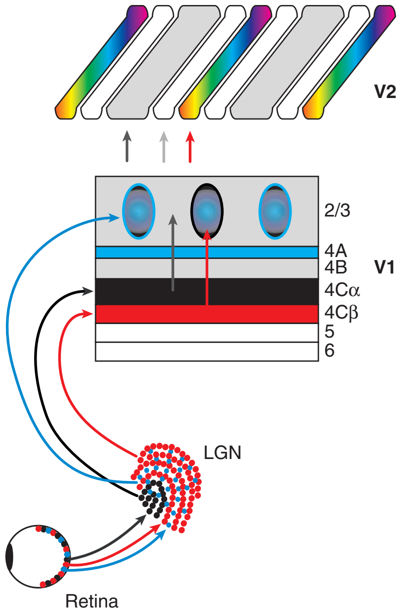

Figure 36 *Visual System Structure* (2)—Parallel Processing Streams of the Early Visual System

Notes: The magnocellular stream illustrated in black, parvocellular stream illustrated in red, koniocellular stream illustrated in blue. Retinal ganglion cells project to lateral geniculate nucleus (LGN) neurons, which project to specific layers within V1. V1 sends motion information to thick stripes in V2 and color/form information to thin and pale stripes in V2. Numbers on the right indicate cortical layers. See the Visual System Structure entry for additional information (pp. 1130–1134).

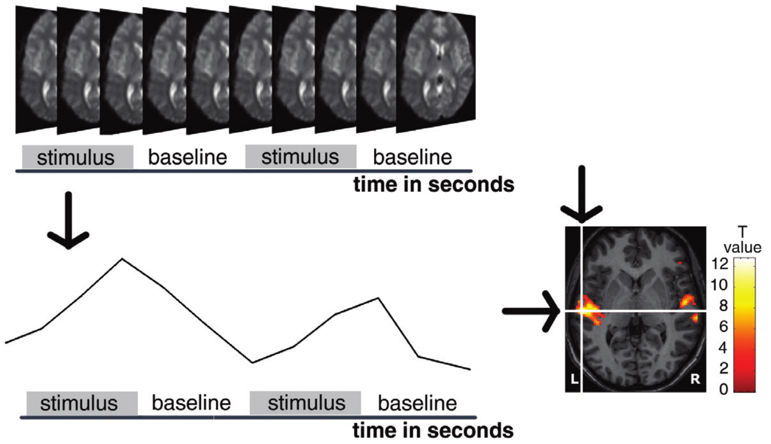

Figure 37 *Brain Imaging*—Several Key Aspects of an (Auditory) fMRI Experimental Design and Image Analysis

Source: Original figure created by D. A. Hall.

Notes: The upper time line represents a segment of the experiment showing how repeated scans are acquired at regular intervals over time, while the participant listens to an alternating sequence of sound stimulation and baseline conditions. Each scan is represented by one horizontal slice through the brain. In this example, each stimulus condition lasts about 9 seconds, with scans occurring every 3 seconds. The lower time line presents a schematic diagram of the stimulus-correlated variability in the MR signal measured in arbitrary units. Such a time course is representative of a voxel (individual point) that responds strongly to the sound stimulus. The spatial distribution of the activated voxels is shown in the right panel, with the most significant voxel highlighted by the crosshairs. The color scale reflects the statistical significance of the activation across the auditory cortex. Note that the activation is overlaid onto the anatomical scan, which has a finer spatial detail than the functional scans shown in the upper time line. In this figure, the activation reflects the greater contralateral auditory cortical response to a sound stimulus that was presented to the right ear (pp. 227–231).

General Perception

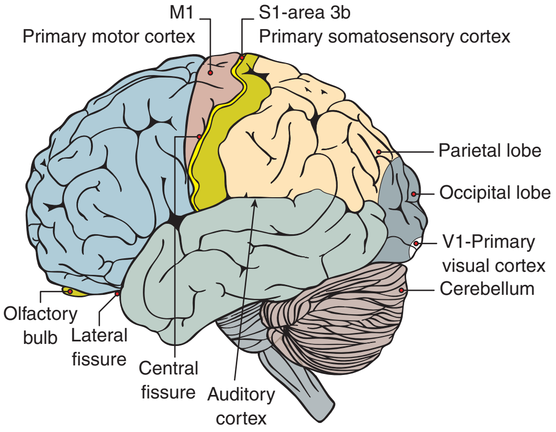

Figure 38 *Cortical Organization* (1)—The Cerebral Cortex of the Human Brain

Notes: The four lobes of the cortex are indicated, as well as parts of primary motor and sensory areas. Because areas extend into the central fissure, only parts of the primary motor cortex (M1 or area 4) and primary somatosensory cortex (area 3b) are visible. The primary auditory cortex is deep in the lateral fissure, and most of the primary visual cortex (V1 or area 17) is hidden in the calcarine fissure on the medial wall of the hemispheres. The human brain has many other cortical areas. See the Cortical Organization entry for additional information (pp. 327–333).

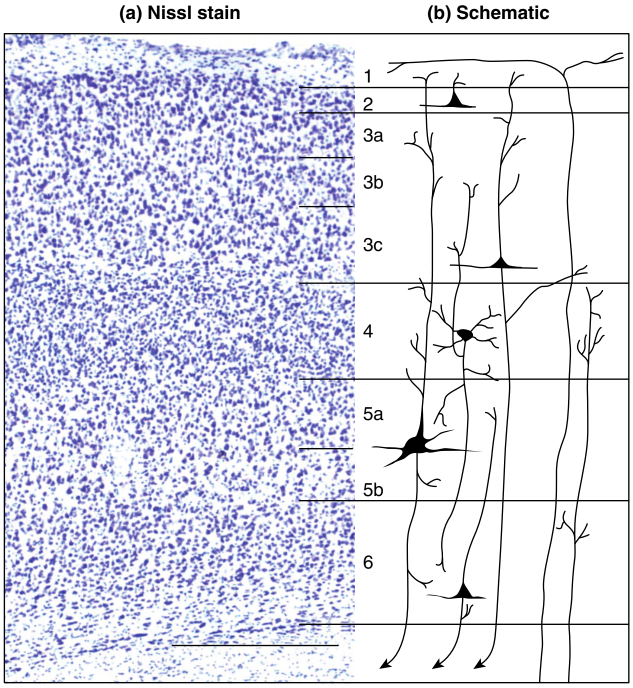

Figure 39 *Cortical Organization* (2)—The Laminar Organization of the Cortex

Notes: (a) A thin section through the thickness of the cortex from the surface above to the fibers (axons that connect the cortex to other regions of the cortex and the brain) below. The Nissl stained section through V1 of a squirrel shows the locations of small, individual neurons as dark dots. Layers (1–6) are distinguished by differences in the arrangements, sizes, and shapes of neurons. (b) A drawing of enlarged neurons (for visibility) and their local connections illustrates how vertical arrays of neurons are densely interconnected. Neurons have large cell bodies, and thin dendrites and axons. Axons entering the cortex and terminating in layers 6, 4, and 1 are shown on the far right side in (b). See the Cortical Organization entry for additional information (pp. 327–333).

A

ABSOLUTE PITCH

Absolute pitch (AP) is the rare ability some people have to instantly and effortlessly name the pitch of musical tones, as readily as most of us name the colors we see. Others are said to possess AP if they can produce (such as by humming, whistling, or singing) a tone given its name. Suppose you are at a concert by your favorite rock group and the guitarist begins to play the opening strains of one of the group's biggest hits. Within a few notes, the entire audience recognizes the song and they jump to their feet. But you overhear someone sitting in the next row complaining, "They've changed the key to C—I can't believe they did that, it sounds so wrong!" The annoyed concertgoer in front of you probably has AP. This entry describes the nature of absolute pitch, its acquisition, and current controversies.

A common misconception is that people with AP are more skilled at being able to notice when a tone is played or sung out of tune, or at being able to sing perfectly intonated tones. Although such differences certainly exist among people, this is a separate phenomenon and not associated with AP. (The fact that there is no agreed-upon name for superior "in tuneness" skills may feed the confusion.) What AP possessors do is notice the pitches (and by extension, the keys) of pieces of music, something that most of us do not. Sing "Happy Birthday" at a birthday party three times, and you may well be singing it in three different keys, and not be at all bothered by it. This is because the identity of a melody is defined by the *intervals,* not by the actual tones used.

Part of a long-standing fascination with AP is that it is so rare (some estimates put it at fewer than 1 in 10,000 people) and that among musicians it is often regarded as the ultimate in musical endowment. Although nearly all musicians can name tones if they are given a reference tone to start with (using their knowledge of intervals to calculate tone names relative to this reference), those with true AP can do so without any external referent, relying instead on an internal template. Some musicians have acquired a stable, long-term memory representation for a single musical tone (typically their tuning note) and can use their knowledge of intervals to "calculate" the names of other tones; this is called quasi-absolute pitch. For this reason, an important methodological consideration in screening for AP possession is that reaction times must be collected.

Why do so many more of us learn to name colors than pitches? Tone labels lack the ecological salience that color labels do, most parents don't teach them, and appreciation of music generally requires that one focuses attention on patterns, intervals, and relations, rather than on the actual pitches of tones. The preponderance of evidence suggests that AP must be acquired early in life, generally before the ages of 8 to 12. There is no documented case of an adult acquiring true absolute pitch. What seems necessary is the early and systematic pairing of tone sensations with verbal labels, whether acquired through explicit or implicit exposure. Gottfried Schlaug found enlargement of the planum temporale in musicians with AP, but the implications of this remain unclear.

Robert Zatorre has shown that similar regions of the dorsolateral prefrontal cortex are activated when musicians with AP name tones, and when musicians with only relative pitch name intervals; this strongly suggests that AP is fundamentally a cognitive operation (of labeling) rather than a perceptual operation (of improved discrimination).

Geneticists have found familial clusters of AP ability, providing evidence that there may exist an allele underlying AP ability. Skeptics counter that AP most certainly has to be learned (no infant automatically knows the names of notes, nor the association between these names and the perceptual input of particular sounds), and therefore even if AP was an entirely learned ability, it would still run in families because only those parents who have it or value it would teach it to their children.

A current controversy concerns the distribution of AP ability across the general population. An online study of 2,000 individuals with AP found the ability to be bimodal: Some people had it, others didn't, and there were no respondents found to possess only partial AP. Other studies have found that the ability is distributed along a continuum. For example, some individuals score 75 or 80% correct on AP tests, indicating that they have AP for only some of the tones in the scale, or that they are performing well above chance, but inconsistently for reasons not yet known. Latent AP has been demonstrated even in nonmusicians who tend to sing their favorite pop songs in the correct key, leading to a two-component model of AP: that it consists of pitch memory separate from pitch labeling.

Another controversy concerns the extent to which infants have a pre-linguistic form of AP, and research findings are contradictory. Diana Deutsch has argued that AP is more prevalent among speakers of tone languages (such as Mandarin), but methodological questions concerning appropriate experimental controls have made this claim controversial. Finally, anecdotal claims that special populations (e.g., individuals with autism or Williams syndrome) show a higher prevalence of AP are not yet widely accepted by the scientific community.

ACOUSTICS AND CONCERT HALLS

When sound travels from a source to a listener in a room, the environment will shape the sound considerably, mainly through the reflections from boundaries. There are a number of qualities of received sound, and each is linked to the characteristics of sound reflections in certain ways. Although in the evolution of Greek and Roman theatres, the acoustics was already considered and gradually improved with increased reverberation and loudness, the subject of architectural acoustics was only established after W. C. Sabine's pioneering study on reverberation early in the 20th century. He carried out quantitative measurements of reverberation, and it was then possible to relate objective qualities of sound to perception.

The perception of music in a concert hall is multidimensional. In the past few decades, a large number of subjective attributes have been introduced for the acoustic quality of concert halls, mainly through questionnaires and interviews. Some of those attributes are interrelated, and some could be combined or subdivided to form more attributes. Correspondingly, to design concert hall acoustics, several objective indices have been developed. This entry examines the meaning of some subjective attributes and their relationships with the objective indices.

Sound Field

Imagine an acoustic impulse is generated in a hall. The first sound to arrive at the listener will be the sound that travels in a straight line from the source, namely the direct sound. This is followed by a series of sounds that have traveled by paths including one or more reflections from room surfaces. The reflection could be specular, namely the incidence angle equaling the reflection angle, if a surface is large and acoustically smooth (i.e., surface roughness significantly smaller than the wavelengths), or diffuse if the surface is irregular. Compared with the direct sound, the amplitude of a reflected sound is always less because part of the sound energy is absorbed by the reflected surfaces and it travels farther. Reflections that arrive at the listener immediately after the direct sound are called *early reflections*. The late reflections are called the *reverberant sound*.

Reverberance

Reverberance is arguably the most important attribute for the acoustic perception of concert halls. It can be measured by the *reverberation time* (RT), which is defined as the time taken for a sound to decay 60 decibels after a continuous sound source is stopped, although actually it is obtained from the 5- to 35-decibel decay and then extrapolated to correspond to a 60-decibel decay because a signal to background noise ratio of 60 decibels is difficult to achieve in practice. It is a function of the volume of the room and of the amount of sound absorption within it. The perception of reverberance is well correlated to the early slope of a sound decay, so the early decay time (EDT) is often used. EDT is obtained from the initial 10 decibels of the decay slope, and then multiplied by a factor of 6. In an ideal diffuse sound field, the decay curves are perfectly linear, and thus, EDT equals RT.

Reverberation is related to liveliness. With a longer reverberation, especially at middle (e.g., 500 Hz–1 kHz) and high frequencies, people feel a concert hall is more lively, and a hall with a short reverberation is perceived as deadly or dry. If a hall is reverberant at low frequencies, say below 350 Hz, it will sound "warm." At middle frequencies, the recommended occupied reverberation time is 1.5 seconds for chamber music, 2 to 2.4 seconds for symphony music, and more than 2.5 seconds for organ music.

Clarity

To enable musical details to be appreciated, a good clarity, or definition, is required. The clarity is usually measured by C, namely the ratio of early sounds (direct sound and early reflections) to the energy in the later reflections. The early reflections are normally defined as those arrived within 80 milliseconds of the direct sound because the ear will perceive the reflections within 50 to 80 milliseconds and the direct sound as one sound. A similar objective measure of clarity is the center time, which is essentially the center of gravity along the time axis of the squared impulse response, where the use of continuous time weighting avoids a sharp time limit between early and late energy. The speed of music (i.e., tempo) also affects the clarity in a concert hall. The subjective feeling of texture, such as something missing in the music, probably relates to the number and nature of early reflections.

Intimacy

Acoustic intimacy is related to the perception of the space size where the music is performed, indicating whether the listener feels acoustically involved or detached from the music. If the music played in a concert hall gives the impression of being played in a small hall, this hall is regarded to have acoustic intimacy, particularly for music originally associated with small halls such as chamber music. Although it is likely that intimacy depends on a number of objective measures, it seems that when the initial time delay gap (ITDG)—namely the time interval between the arrival of the direct sound and the first reflection—is more than 45 milliseconds, the hall has no intimacy.

Spaciousness

The spaciousness of a concert hall has two contributing components: the apparent source width (ASW), which is the impression that the music is from a source wider than the visual width of actual source, and the listener envelopment (LEV), which is the impression of being surrounded by the reverberant sound field. The former increases when there are more early lateral reflections, and the latter will be stronger when the level of late lateral reflection is high. The apparent source width can be measured by the lateral energy fraction (LEF), which is the ratio of lateral sound energy recorded using a "figure-of-eight" microphone (i.e., receiving sounds from the front and back) compared with that recorded using an omnidirectional microphone (i.e., receiving sounds from all directions), all within 80 milliseconds after the direct sound. For the listener envelopment, the late lateral strength (LG) is an objective measure, which relates the lateral energy arriving after 80 milliseconds to the direct sound at 10 meters from the source. Although at the two ears, the lateral reflections could be different, the interaural cross-correlation coefficient (IACC) is used to evaluate spaciousness through measuring their signal dissimilarity, with the listener facing the performing entity.

Loudness

Although the preferred loudness depends on the type of music and many other factors, an experiment with a piece of orchestral music showed that about 60% of the listeners preferred a listening level of 80 to 85 decibels (A-weighted), and others preferred lower or higher levels. An objective measure of loudness in a concert hall is the strength factor (G), which is the difference between the sound level in the hall and that in a free field at a source-receiver distance of 10 meters, using an identical sound source. In an ideal diffuse sound field, where the sound level is uniform across a hall, the strength depends only on reverberation time and hall volume, but in actual halls, the loudness also depends on the source-receiver distance and reflection patterns. In most existing concert halls, the averaged strength in the seating area is about 3 to 5 decibels at middle frequencies, which is a clearly perceivable level.

Timbre

The perception of music in a concert hall in timbre or tone color, such as warm, bright, or harsh, can be related objectively, to a certain degree, to the room influences on the balance between low, middle, and high frequencies. The bass ratio (BR) is the ratio of low (125 and 250 Hz) to middle (500 Hz and 1 kHz) frequency reverberation time, and the treble ratio (TR) is the ratio of high (2 and 4 kHz) to middle (500 Hz and 1 kHz) frequency reverberation time. Although BR and TR are associated with warmth and brightness, respectively, no clear relationship exists between perceptual dimensions and the objective measures. Similarly, the BR and TR could be based on the early delay time or strength values.

Ensemble

The acoustic quality of a concert hall should be judged from the viewpoints of performers as well. Ensemble is a subjective measure of the ability of the musicians to hear their colleagues in an orchestra, and it is strongly affected by the amount of sound reflections. An objective indicator of ensemble is the support factor (ST), namely the difference between the direct sound and reflections, measured on a stage or in a pit, with a source-receiver distance of 1 meter. Two support factors are used, one considering reflections between 20 to 100 milliseconds, called early support, and the other considering reflections between 100 to 1,000 milliseconds, called late support. A concert hall should also give performers an appropriate feeling of immediacy of response (attack), which is mainly determined by the early reflections from the hall to the performer's ears. Moreover, various sections of an orchestra should be balanced and different instrumental groups should be well blended, thus perceived as being tightly coupled as an integrated body.

Acoustic Defects

An echo can be perceived when a reflection arrives at least 50 milliseconds after the direct sound and its amplitude is considerably higher than that of the reflections arriving in the neighboring times. Flutter echoes often occur between two parallel, acoustically smooth, and reflective walls, where a characteristic twang is created by regularly repeated reflections. Sound focus occurs when concave surfaces reflect sound to certain areas, causing high loudness but leaving others with too little reflected energy. Tonal distortion, which makes the perceived sounds different from the originals as a result of the strengthening or weakening of certain frequencies, could be caused by selective sound absorption by room surfaces or seating areas, or resonance of certain architectural elements such as suspended panels. Acoustic glare refers to early reflections of brittle or hard or harsh quality, often caused by large, acoustically smooth reflectors. Finally, it is important to control background noise level, such as from external noise and vibration sources, ventilation systems, and audience movement, to a required level, generally specified using noise criterion (NC) or noise rating (NR) values.

Design

Conventionally, the shoebox shape has been often used for concert halls, but successful examples can also be found with other forms including fan-shaped, vineyard, and arena. Normally, the seat number should be limited to 3,000 and the maximum seat-stage distance 40 meters for concert halls. Other key design considerations include ceiling height, volume per seat, seating layout and arrangement in section, balcony configurations, suspended reflectors, surface conditions in absorption and diffusion, and stage size, layout, and materials. The absorption of seating areas should be carefully designed, so that the sound quality under occupied and unoccupied conditions is similar, which is important for rehearsal.

The use of computer simulation techniques to predict various objective indices in concert halls started from the 1960s. Auralisation techniques recently have been developed to listen to music in three dimensions at the design stage as if it is played in the actual hall, so that the design can be adjusted if needed. Physical models, usually at a scale of 1:8 to 1:50, are also often used.

Ranking

Unlike speech, for which the quality can be assessed by simply conducting articulation tests, the perception of music in a concert hall depends on multiple attributes, and there are often low mutual correlations between those attributes. For a given attribute, people's preference could vary significantly, although the normal distribution is usually followed. Moreover, the importance of different attributes varies considerably between listeners. Furthermore, the variation in objective indices at various seats in a hall sometimes exceeds that between different halls. Although all these factors make it difficult to exactly rank every concert hall, there is a general consensus about which halls have excellent acoustics, based on subjective attributes or objectives indices.

ACTION AND VISION

Vision is so fundamental to our experience of the world that we sometimes forget that the visual system also plays a critical role in the control of the movements we make in that world. Consider what happens, for example, when we perform the deceptively simple act of reaching out and picking up our morning cup of coffee. After identifying our cup among all the other objects on the table, we begin to reach out toward the cup, choosing a trajectory that avoids the box of cereal and the glass of orange juice. At the same time, our fingers begin to conform to the shape of the cup's handle well before we make contact. As our fingers curl around the handle, the initial forces we generate to lift the cup are finely tuned to its anticipated weight—and to our predictions about the friction coefficients and compliance of the material from which the cup is made. From the beginning of the movement to the final grasp, vision is the main source of information that the brain uses to carry out the required computations.

Many traditional accounts of vision, though acknowledging the role of vision in motor control, have simply regarded such control as part of a larger function of the visual system—that of constructing an internal model of the external world. In most of these accounts, there is an implicit assumption that, in the end, vision delivers a single representation of the external world—a kind of simulacrum of the real thing that serves as the perceptual foundation for all visually driven thought and action. But during the last two decades, it has become increasingly clear that vision does not deliver a single general-purpose representation of the external world. Instead, it appears that two separate visual systems have evolved in the primate brain, each system specialized for a different purpose. This entry describes those systems, the evidence for them, different metrics and frames of reference, and interactions between the two systems.

Two Visual Systems

One system, *vision-for-perception,* allows us to recognize objects and their relationships, enabling us to build up a knowledge base about the world. This is the system we are more familiar with, the one that gives us our conscious visual experience—and allows us to see and appreciate objects in the world beyond our bodies. The other system, *vision-for-action,* provides the visual control we need to move about and interact with those objects. Vision-for-action does not have to be conscious, but it does have to be quick and accurate.

Although there are many different pathways over which visual information is conveyed from the eyes to the brain, the distinction between vision-for-perception and vision-for-action has been mapped onto two anatomically separate "streams" of visual projections that arise from early visual areas in the cerebral cortex of the primate brain (see Figure 1). The ventral visual stream, which projects to higher-order visual areas in the ventral part of the temporal lobe, mediates vision-for-perception. The dorsal visual stream, which projects to visuomotor areas in the posterior parietal lobe, mediates vision-for-action. Importantly, the dorsal stream also gets visual inputs directly from subcortical visual structures that bypass the early visual areas in the cortex.

The ventral stream, which plays the critical role in vision-for-perception, transforms incoming visual information into perceptual representations that embody the enduring characteristics of objects and their relations. These representations allow us to perceive the world beyond our bodies, to share that experience with other members of our species, and to plan a vast range of different actions with respect to objects and events that we have identified. This constellation of abilities is often identified with consciousness, particularly those aspects of consciousness that have to do with decision making and reflecting on our own thoughts and behavior. The perceptual machinery in the ventral stream that has evolved to do this is not linked directly to specific motor outputs, but instead accesses action plans via cognitive systems that rely on memory, semantics,

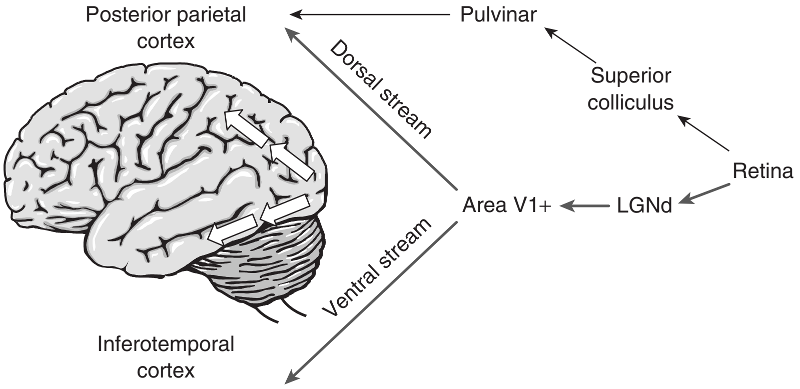

Figure 1 Schematic Representation of the Two Streams of Visual Processing in the Human Cerebral Cortex

Notes: The retina sends projections to the dorsal part of the lateral geniculate nucleus in the thalamus (LGNd), which projects in turn to the primary visual cortex in the occipital lobe of the cerebral cortex. Within the cerebral cortex, the ventral stream arises from early visual areas (V1+) and projects to regions in the ventral parts of the temporal cortex. The dorsal stream also arises from early visual areas but projects instead to the posterior parietal cortex. The posterior parietal cortex also receives visual input from the superior colliculus via the pulvinar, a nucleus in the thalamus. On the left, the approximate locations of the pathways are shown on an image of the brain. The routes indicated by the arrows involve a series of complex interconnections.

spatial reasoning, and communication with others. Once a course of action has been selected, however, the visual control of the constituent movements of that action is mediated by the dorsal stream, whose visuomotor modules are intimately linked with motor areas in the cerebral cortex and other (older) motor systems in the basal ganglia and brainstem. Thus, the structural and spatial attributes of a goal object are processed by both streams, but for different purposes. This is not to say that the distribution of visual inputs does not differ between the two streams but, rather, that the main difference lies in the nature of the transformations that each stream performs on those two sets of inputs. In the case of the ventral stream, information about a broad range of object parameters is transformed for perceptual purposes; in the case of the dorsal stream, many of these same object parameters are transformed for the control of actions. But even though the two systems transform visual information in quite different ways, they work together in the production of adaptive behavior. In general terms, one could say that the selection of appropriate goal objects depends on the perceptual machinery of the ventral stream, whereas the visual control of the goal-directed action is carried out by dedicated online control systems in the dorsal stream.

Neuropsychological Evidence

Much of the evidence for the distinction between vision-for-action and vision-for-perception comes from work with neurological patients. One of the most compelling cases is that of D. F., a young woman whose ventral stream was selectively damaged as a consequence of hypoxia from carbon monoxide poisoning. D. F. shows no visual awareness of the form and dimensions of objects (visual form agnosia) and cannot recognize common objects or the faces of her friends and relatives. Indeed, D. F.'s deficit is so profound that she cannot discriminate between simple shapes such as a triangle and square, and cannot tell a horizontal from a vertical line. Brain imaging has revealed that she has bilateral damage in that part of the ventral stream that is involved in processing the geometrical structure of objects. Nevertheless, when D. F. reaches out to grasp objects, the posture of her hand and fingers is exquisitely tuned in flight to the size, shape, and orientation of the object in front of her, just as it is in a person with normal vision. For example, when she is presented with a series of rectangular blocks that vary in their dimensions but not in their overall surface area, she is unable to say whether or not any two of these blocks are the same or different. Even when a single block is placed in front of her, she is unable to indicate how wide the block is by opening her index finger and thumb a matching amount. Nevertheless, when she reaches out to pick up the block using a precision grip, the opening between her index finger and thumb is scaled in flight to the width of the block, just as it is in people with normal vision. Similarly, even though she cannot indicate the orientation of elongated objects placed in a table in front of her, she rotates her hand appropriately when she reaches out to grasp the same objects.

Patients who have suffered selective damage to the dorsal stream show a pattern of deficits and spared abilities that are the mirror image of those seen in D. F. Such individuals are unable to use visual information to guide their hand movements as they reach out to grasp objects, even though they can see the object and can describe where it is and what it looks like. At the same time, these patients typically have no difficulty using input from other sensory systems, such as touch or audition, to guide their movements. In other words, their deficit is neither "purely" visual nor "purely" motor but is instead a visuomotor deficit. The clinical name for this neurological disorder is *optic ataxia*.

Different Metrics and Frames of Reference

The evidence from neurological patients points to a clear dissociation between the visual pathways supporting perception and action. But why did two separate streams of visual processing evolve in the primate brain? Or, to put it another way, why couldn't one general-purpose visual system handle both vision-for-perception and vision-for-action? The answer to this question lies in the different computational requirements of the two kinds of vision. Simply put, perception and action require quite different transformations of the visual signals. To be able to grasp an object successfully, for example, the brain must compute the actual size of the object, and its orientation and position with respect to the grasping hand of the observer (i.e., in egocentric coordinates).

The time at which these computations are performed is equally critical. Observers and goal objects rarely stay in a static relationship with one another and, as a consequence, the egocentric coordinates of a target object can often change radically from moment to moment. For these reasons, it is essential that the required coordinates for action be computed in an egocentric framework at the moment the movements are to be performed. In other words, vision-for-action works largely in an "online" mode. Unlike our visual percepts, the visual information that is used to control actions such as grasping is not accessible to conscious scrutiny.

Perceptual processing needs to proceed in a quite different way. Vision-for-perception does not require the absolute size of objects or their egocentric locations to be computed. In fact, such computations would be counterproductive because we almost never stay fixed in one place in the world. For this reason, it would be better to encode the size, orientation, and location of objects relative to each other. Such a scene-based frame of reference permits a perceptual representation of objects that transcends particular viewpoints, while preserving information about spatial relationships (as well as relative size and orientation) as the observer moves around. Indeed, if the perceptual machinery had to deliver the real size and distance of all the objects in the visual array, the computational load would be prohibitive. It is far more economical to compute just the relational metrics of the scene, and even these computations do not always need to be precise. The reliance on scene-based frames of reference means, for example, that we can watch the same scene unfold on a small television or on a gigantic movie screen without being confused by the changes in scale. These differences in the frames of reference and metrics used by vision-for-perception and vision-for-action can give rise to striking differences in the sensitivity of the two systems to visual illusions. Thus, the scaling of grasping movements is often insensitive to size-contrast illusions, which (by definition) affect our perception of object size (see Figure 2).

Evidence also suggests that our perception of an event takes longer to emerge than does our ability to act upon that event. Thus, we are often able to react to the change in the trajectory of a moving target well before we perceive that change.

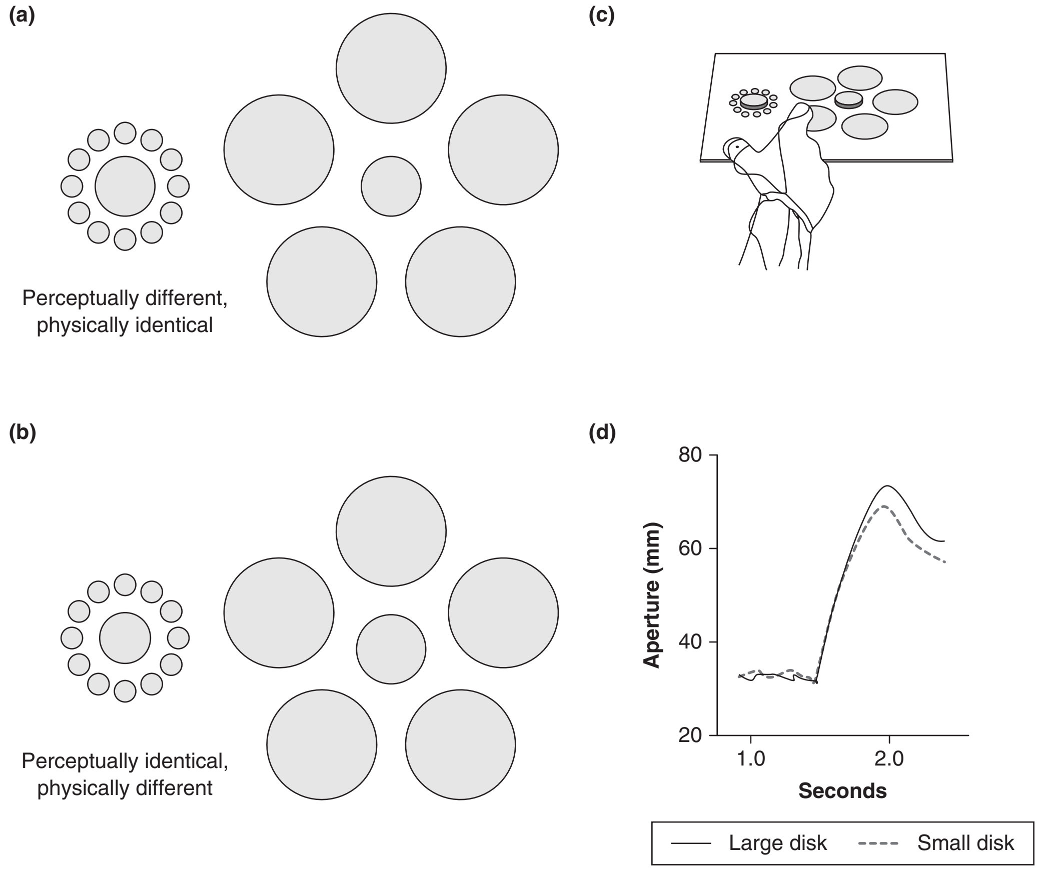

Figure 2 The Effect of a Size-Contrast Illusion on Perception and Action

Notes: (a) The traditional Ebbinghaus illusion in which the central circle in the annulus of larger circles is typically seen as smaller than the central circle in the annulus of smaller circles, even though both central circles are actually the same size. (b) The same display, except that the central circle in the annulus of larger circles has been made slightly larger. As a consequence, the two central circles now appear to be the same size. (c) A 3-D version of the Ebbinghaus illusion. People are instructed to pick up one of the two 3-D disks placed either on the display shown in panel A or the display shown in panel B. (d) Two trials with the display shown in panel B, in which the person picked up the small disk on one trial and the large disk on another. Even though the two central disks were perceived as being the same size, the grip aperture in flight reflected the real rather than the apparent size of the disks.

Moreover, the products of perception also need to be available over a much longer time scale than does the visual information used in the control of action. We may need to recognize objects we have seen minutes, hours, days—or even years before. To achieve this, the coding of the visual information has to be somewhat abstract, transcending particular viewpoint and viewing conditions. By working with perceptual representations that are object- or scene-based, we are able to maintain the constancies of size, shape, color, lightness, and relative location, over time and across different viewing conditions. Although there is much debate about the way in which this information is coded, the identity of the object and its location within the scene, rather than its disposition with respect to the observer is of primary concern to the perceptual system. Thus, current perception combined with stored information about previously encountered objects facilitates the recognition of objects and contributes to the control of goal-directed movements when we are working in off-line mode (i.e., on the basis of our memory of goal objects and their location in the world).

Interactions Between the Two Streams of Visual Processing

So let us see how the two streams of visual processing work together in the example introduced earlier: the (deceptively) simple act of picking up a cup of coffee. The initial identification of our cup among the other objects on the table (including the cups of other people) depends on processing in the ventral stream. Areas in this ventral "perception" stream are undoubtedly recruited for identifying the cup—and the handle on the cup. But by virtue of identifying the handle as the goal for the intended action, the ventral stream (together with associated cognitive machinery in other brain regions) also determines the functional grasp to be used. But once the cup has been identified and the intended grasp posture selected, the job of using visual information to program and control the constituent movements for that grasp are carried out by dedicated visuomotor modules in the dorsal "action" stream. These dorsal-stream modules compute the real size of the handle and its location and disposition with respect to our hands and fingers so that our grasp is directed toward the handle in the correct orientation and the opening of fingers is scaled to its size. Moreover, in most cases, all of this is done "automatically" without any conscious supervision.

But what happens when the hand actually reaches its goal? Once the hand and fingers make contact with the handle, the initial grip and load forces required to pick up the cup are exquisitely well matched to the cup's weight, compliance, and surface friction—and to the amount of coffee left in the cup. (When we get that last computation wrong, as we sometimes do, we can end up spilling our coffee all over the table!) The calculation of these forces depends on learned associations between the material properties of the cup and its appearance (as well as our updated memory of its contents). It seems likely that areas in the ventral stream that process object shape and surface cues play a critical role in recognizing the cues associated with the material properties of the cup and other objects we interact with. This leaves unanswered how the ventral and dorsal streams coordinate their computations. Whatever complex interactions might be involved, goal-directed action is unlikely to be mediated by a simple serial processing system; instead, multiple iterative processing across many levels of the brain is almost certainly required.

Final Thoughts

The idea of two visual systems in a single brain might seem initially counterintuitive. Our visual experience of the world is so compelling that it is hard to believe that some other quite independent set of visual information is guiding our movements. After all, it seems obvious that the perceptual representation that allows us to recognize our coffee cup is the same one that enables us to pick it up. But evidence from observations of neurological patients and other studies suggests that this belief is an illusion. The visual processes that lead to our perception of the cup are *not* the same as those that guide our hand as we reach out and pick up it up! The illusion arises because the former but not the latter are associated with conscious visual experience.

AESTHETIC APPRECIATION OF PICTURES

Viewing visual art can be a dramatic, richly rewarding yet wholly personal event. In discussing the aesthetic appreciation of pictures within the bounds of perceptual research, an attempt is made to cross a significant chasm between a detailed cellular and cortical understanding of lower-level visual objective properties such as color and shape, and a less clear understanding of higher-level visual phenomenology or subjective experience. Over the centuries, both the definition and content of an aesthetic experience has meant many things to many people; however, perceptual research has tended to define aesthetic appreciation in terms of some measure of *preference* based on the perceived *beauty* of the image in question. In this respect, perceptual research provides echoes of both David Hume's and Immanuel Kant's approaches to aesthetics in terms of their discussion of taste and beauty, respectively. The factors that are thought to influence an individual's aesthetic response to pictures include both the physical properties of the picture itself that exist "inside the frame," as well as the role of contextual influences such as the labeling and presentation of art that exist "outside the frame." Although perceptual research continues to use group data (or a nomothetic approach) as a way of tackling aesthetics, others have argued that individual data (or an idiographic approach) should serve as the unit of currency if we are to have the fullest appreciation of appreciation. This entry describes how aesthetics are measured, objectivist and subjectivist approaches to aesthetics, and how researchers use these.

Measuring Aesthetics

The origins of empirical aesthetics are generally attributed to Gustav Fechner in his book *Elementary Aesthetics,* whereas Daniel Berlyne is typically credited with the resurgence of interest in linking the scientific method with aesthetics in the 1970s. These early experiments were characterized by assessing individuals' preferences for large sets of artificially constructed stimuli such as polygons that differed according to a number of quantifiable properties labeled *collative* (e.g., complexity), *psychophysical* (e.g., color), and *ecological* (e.g., meaning) variables. According to Berlyne's psychobiological account, aesthetic experience should be higher for intermediate levels of arousal, with arousal being calculated as summed activation of the these features: Many-sided polygons should contain less color than polygons with fewer sides, for example. This early work set the trend for the measurement of aesthetic appreciation using a simple numeric (also referred to as a Likert) scale, where individuals were invited to sort or rate pictures from the least preferred/beautiful (e.g., 1) to the most preferred/beautiful (e.g., 5). Although it is easy to criticize such measures on the basis that individuals may not use the whole range of scores available to them, such subjective measures remain at the heart of perceptual research on aesthetics. Over time, however, self-report measures of aesthetic experience have been augmented with additional objective measures such as looking time and blood oxygenation levels in the brain to provide converging evidence in understanding the aesthetic experience.

Aesthetics Inside the Frame

These first steps in understanding aesthetics via perceptual research reveal what is essentially a reductionist approach. Although not of primary interest to Berlyne, the assumption here is that it should be possible to arrive at an understanding of the genesis of beauty within an actual work of art by studying individuals' responses to the building blocks of visual perception. In this way, preference for certain pictorial images is decomposed into the study of preference for particular conjunctions of colors, line orientations, sizes, and shapes. Common to many psychological domains, there is a tension here between the control that one is able to exert on so-called pictorial art within the laboratory and the ability to generalize this data to the much richer examples of pictorial art found in the real world. On the one hand, the development of self-produced abstract visual stimuli means that individuals will have had no prior exposure with the images. This makes the aesthetic experience a primitive one, where influences of schema or memory are reduced and the image is assessed in a stimulus-driven or bottom-up manner. On the other hand, these types of stimuli are far removed from the actual stimuli of interest and ecological validity is weak: Can the study of polygons really tell us anything about Picasso?

However, an intersection between low-level and high-level visual experience is provided by the work of Piet Mondrian, whose painted elements specifically map onto basic visual features such as line orientation and color. Consequently, researchers have been able to manipulate the line spacing, line thickness, orientation, and placing of color within the painting to assess the extent to which individuals judge an original Mondrian composition to be more aesthetically pleasing than a manipulated Mondrian. Evidence has accrued to suggest that even individuals untrained in the visual arts can give higher ratings to the original paintings, suggesting that variation in aesthetic experience is driven partly by the arrangement of the visual elements presented to the viewer. Other researchers have shown that aesthetic preference for original rather than manipulated paintings also apply to representational artwork, although success in establishing preference for the original image often relies on major rather than minor spatial changes in the piece. These observations suggest that an aesthetically pleasing painting will be one that has established *the* best arrangement (or balance) of elements, and that these preferred arrangements deliberated over by the artist are then readily perceivable by non-artists. These findings align well with the principle of Prägnanz found in Gestalt psychology (also referred to as "visual rightness") and provide evidence for universalism in aesthetic experience.

Aesthetics Outside the Frame

In contrast to an objectivist approach to the empirical study of aesthetics in which the beauty of the picture is thought to be somehow engrained within the organization of the visual elements themselves, subjectivist approaches emphasize the role of external variables in deciding what is beautiful and what is not. The need for a subjectivist component to aesthetics will be clear to anyone who has had the misfortune to accompany a lover of Renaissance painting around a modern art gallery. That individuals can have different responses to identical visual stimulation therefore implies that attitudes toward and experience with art can have significant influences on aesthetic appreciation. Comparisons between art novices and art experts are often employed within the literature, although the determination of what it means to be an "art expert" or "what constitutes an art expert" can range from a median split within a given sample to the achievement of (at least) graduate-level training. On the basis of previous distinctions between figurative and abstract art, and original color or manipulated black-and-white images, art novices' aesthetic preferences tend toward color images of figurative art, whereas art experts tend to have much broader preferences.

The labeling of a picture is also thought to have an influence on an individual's aesthetic response. However, the outcome of labeling depends on both the content of the label and the type of picture to which it is applied. For example, the provision of a descriptive title to a representational picture may be redundant (e.g., William Turner's *The Shipwreck* [1805]), but when applied to a more abstract work (e.g., Marcel Duchamp's *Nude Descending a Staircase* [1912]) such information may help the individual unlock the ambiguous elements on view. Moreover, elaborative comments related to the genesis, style, or interpretation of the piece can also influence an individual's reaction to it. For example, informing the viewer that in Edvard Munch's *The Scream* (1893) the character at the forefront of the painting is not actually screaming but rather trying to protect the self from the scream of Nature, may radically affect the viewer's perception and aesthetic appreciation of the image. Although the effect of labeling does not seem to be consistent for all images, studies which have manipulated the presentation of no label versus descriptive or elaborative labels across artworks have shown that descriptive labels are often useful for increasing the understanding associated with a picture, but elaborative labels consistent with the artwork are more likely to lead to a greater aesthetic reaction.

Other external influences on aesthetic appreciation stem from exactly where the picture is viewed. In the interests of control, individuals taking part in studies on empirical aesthetics are likely to view images on a computer screen for a prescribed period. This is quite different from the natural viewing conditions of an art gallery, in which the original size of the picture is preserved, the viewing distance is often carefully controlled, and the viewing time is essentially self-paced. Consequently, images viewed in aesthetic appreciation studies are likely to be substantially reduced in both size and viewing time, relative to the original viewing of the artwork. Although the limited data that examines the comparison between original and reduced size images reveals little substantive difference between the two forms of presentation, some optical effects or effects of scale intended by the artist could potentially be lost by the manipulation of size to suit ease of presentation in the laboratory. For example, the large color-field paintings of Mark Rothko could be judged quite differently if there were no preservation of the size of the image itself. Limiting the presentation time of a picture from a self-paced average of around half a minute can also restrict the types of pictorial analyses conducted, with short presentation times leading to aesthetic judgments based on only the global properties of the image itself.

Is There Any Account for Taste?

In examining objectivist and subjectivist approaches to the aesthetic appreciation of pictures, a consolidation of both approaches (termed *interactivist*) has begun. In the defense of objectivist models, both representational and nonrepresentational art can elicit aesthetic responses and, as such, the relationship between these judgments should be in the form of the picture rather than its content. In defense of subjectivist models, identical visual stimulation can lead to different aesthetic preferences between individuals. However, it is also necessary to consider alternatives to the nomothetic approach to empirical aesthetics. Even with the paring down of complex pictorial stimuli to their basic-level components, researchers have found it difficult to develop a group model of aesthetic appreciation that adequately represents the individual. Moreover, clinical applications of aesthetics have tended to adopt an idiographic approach. For example, the palliative benefit derived from the display of artwork in healthcare settings may well rest with personal rather than institutional selection. Further, although patients in the early stages of Alzheimer's differ between themselves in their categorization of pictures, aesthetic preferences for the pictures can remain stable over a two-week period whereas their explicit memory does not. Finally, in systematically varying pictorial representations of male and female bodies as a way of evaluating both own and ideal body image, individual aesthetic judgments of the images depend heavily on a number of psychosocial factors at the time of selection. Understanding aesthetics at either an individual or a group level promises the tailoring of more intense and more beautiful experiences in our environment. The study of empirical aesthetics has shown that it is indeed possible to begin to account for taste, although some of the most crucial aspects of the aesthetic experience remain at a distance.

AFTEREFFECTS

A perceptual aftereffect can be said to occur when an inducing stimulus (typically presented for a prolonged period) affects subsequent perception of another stimulus. As described in this entry, aftereffects are a seemingly maladaptive consequence of the processes of sensory adaptation by which our sensory systems are continually matching their response properties to the prevailing environment. In the normal course of events, our perception of the world does a remarkable job of "telling us what's there," and it is hard to appreciate just how much work our sensory systems are doing to support this feat. Aftereffects represent instances when there is a clear mismatch between our perception and our surroundings and can thus provide insight into the mechanisms underlying our perceptual experience.

As a specific example, imagine that you have just turned your car onto a busy highway. As you accelerate up to speed, the world outside seems to be rushing past at an alarming rate. As you drive along, your perception quickly adapts to this high-speed environment and speeds that just minutes ago seemed alarmingly fast are now the new norm. However, you must be careful when you leave the highway and return to the ordinary road because your adaptation to fast highway speeds can have a pernicious aftereffect. Specifically, adaptation to high speeds causes an aftereffect in perceived speed whereby subsequent slow speeds appear even slower than they should, potentially leading you to drive too fast after leaving the highway and to underestimate the time required for braking.

In addition to affecting the perception of speed, adaptation to visual motion can also cause static objects to appear in motion. Consider what happens, for example, after prolonged viewing of water rushing down a waterfall. If you transfer your gaze from the falling water to the nearby rocks, you can experience the illusion that the rocks are moving in the opposite, upward, direction: the *waterfall illusion.* Paradoxically, this illusory perception of motion entails little or no change in the apparent position of the rocks; although the rocks appear to be moving upward, they never seem to get to a new position. This dissociation between the perception of motion and location during the waterfall illusion indicates that it is a consequence of adaptation of sensory mechanisms specific to the processing of motion.

Analogous Aftereffects in Vision, Touch, and Hearing

The waterfall illusion has analogues both in hearing and in touch. In all these sensory modalities, prolonged exposure to a moving stimulus biases subsequent perception in the opposite direction: a "negative" aftereffect. The auditory analogue, for example, can be induced by prolonged exposure to a sound source sweeping horizontally from left to right. A subsequently presented static sound is then perceived to move in the opposite direction, right to left. The existence of analogous aftereffects across different sensory modalities is evidence that they reflect common strategies of sensory processing. A motion aftereffect has even been reported across modalities, such that after a few minutes of viewing a square moving in depth, a steady sound is perceived as changing loudness in the opposite direction. For example, after prolonged viewing of a square increasing in size to simulate motion toward the observer, a subsequent steady test tone can be heard to decrease in loudness as though it were moving away from the observer.

Adaptation and its consequent aftereffects are by no means restricted to motion. Actually, they are nearly ubiquitous in sensory processing. For example, after a period of adaptation to a tilted grating, an objectively vertical grating appears to take on a marked tilt opposite to the tilt of the adapting grating. You can experience the tilt aftereffect yourself by following the instructions in the legend to Figure 1.

How Can We Tell Where Aftereffects Are Generated?

Staring at a bright light can saturate the photoreceptors in our retinas, leading to the perception of afterimages. Perceptual afterimages are characteristically monocular. This means that after staring at a bright light with the right eye covered or closed, the afterimage can only be seen with the left eye and does not transfer to the right. However, aftereffects produced by adaptation of neurons in the visual cortex, where signals from the two eyes converge, typically transfer from one

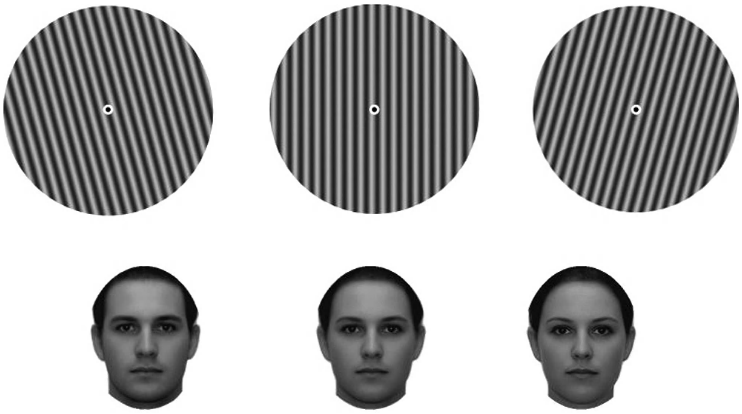

Figure 1 Experiencing Aftereffects

Notes: Experience aftereffects for yourself using these images: (Top) The tilt aftereffect; (bottom) an aftereffect of facial gender. *Tilt aftereffect:* The procedure for inducing a tilt aftereffect is as follows. First, satisfy yourself that the middle grating stimulus is oriented vertically. Then transfer your gaze to the fixation marker at the center of one of the tilted gratings. Count to 50 while keeping your eyes on the fixation marker. There is no need to stare too fixedly or the light and dark bars of the grating will induce differential adaptation at the retina leading to an afterimage. Instead, just let your eyes wander a little over the white annulus of the fixation marker. You might want to cover the other gratings during this adaptation phase as they can be a little distracting but it is not necessary for getting the effect. Once you have counted to 50, transfer your gaze to the center of the middle grating. It should now appear to be tilted away from vertical in the direction opposite to the adapting grating—a tilt aftereffect! If you now adapt to the other tilted grating you can reverse the effect. Adapting to one of the tilted gratings with one eye covered then looking at the middle grating with the other eye should still produce an aftereffect. This inter-ocular transfer of the tilt aftereffect indicates that it is mediated by adaptation of neurons in the visual cortex, where signals from the two eyes converge, rather than earlier in the visual pathway. *Gender aftereffect:* The procedure for inducing an aftereffect of facial gender is as follows. First, look at the middle, androgynous face and decide whether it looks male or female to you. If it looks male, you should adapt first to the male face to get the best effect. If it looks female to you, adapt to the female face. To adapt, look at the appropriate face with the other two faces covered and count to 50. Once you have counted to 50, uncover the middle face. It should appear to have changed gender! If you now adapt to the other face, the gender of the middle face should appear to change back.

eye to the other. For example, the magnitude of the tilt aftereffect is only slightly reduced by presenting adaptor and test in different eyes—you can see this for yourself by putting your hand over your right eye while adapting to one of the oriented gratings in Figure 1, then moving your hand to your left eye to view the objectively vertical middle grating.

Behavioral studies with human observers have demonstrated high-level perceptual aftereffects to properties of faces such as their identity, gender, ethnicity, emotion, and attractiveness. For example, after prolonged viewing of a male face or set of male faces, a face that previously appeared androgynous (gender neutral) will now be perceived as opposite in gender to the inducer(s), that is, female. These effects transfer to a large extent between faces of different size, position, and orientation. This invariance to low-level image properties indicates that face aftereffects are generated at a high level of the visual processing hierarchy. To witness an aftereffect of facial gender, follow the instructions in the legend to Figure 1.

Contingent Aftereffects

The motion aftereffect following prolonged exposure to moving colored (e.g., red) dots appears stronger when the subsequently viewed static dots are the same color (red) than when they are a different color (green). This color selectivity allows the direction of the motion aftereffect to be made contingent on the color of the dots. For example, after prolonged exposure to red dots moving up and green dots moving down, colored static dots will tend to appear to move in the opposite directions: down if they are red and up if they are green.

Similarly, in auditory perception, the motion aftereffect can be made contingent on whether the sound is rising or falling in pitch. For example, an auditory motion aftereffect contingent on direction of pitch change can be induced by prolonged exposure to a rightward-moving sound with falling pitch alternating with a leftward-moving sound rising in pitch. A subsequent stationary test sound with falling pitch can then seem to move to the left, and a stationary test with rising pitch is heard to move rightward.

The existence of contingent aftereffects is an indication of the dynamic nature of the way that neural representations of different sensory attributes can become associated with one another to reflect complex relationships in the environment. A fuller understanding of mechanisms underlying contingent aftereffects should allow us to appreciate how different sensory attributes are bound together to bring about our unified perceptual experience of the world.

AFTERIMAGES

Nearly everyone has experienced seeing the flash from a camera for several seconds or even minutes after the flash occurred. This is an example of the phenomenon known as an afterimage. Not everyone is aware, however, that it is just one of the more noticeable effects of visual mechanisms that underlie all visual experience.

An afterimage is a spatial pattern that is seen when a stimulus that produced it is no longer present and resembles the stimulus. Its properties depend on the intensity, color, and duration of the stimulus and on the stimuli that follow it. It can last a fraction of a second or several minutes. It takes two forms: *positive,* if the colors and luminances (the light and dark regions) correspond to those in the stimulus, and *negative* if they are opposite. (Opposite colors here are complementary colors, such as red and green or yellow and blue.) These two forms are related to two separate causes of afterimages, *visual persistence* and *adaptation,* which are described in this entry.

Visual Persistence

Visual persistence results from the inability of the nerve cells in the visual system, especially the photoreceptors, to follow changes of stimulation instantaneously: A finite amount of time is required for them to respond to the onset of the stimulus and, more important for present purposes, to respond to its cessation as well. As long as the nerve cells are responding to and therefore signaling the presence of a stimulus, one continues to see it, just as one continues to see the flash of the camera if one's surroundings are otherwise dark or if one closes one's eyes. One can also observe such persistence by placing a white spot on a dark disk and spinning the disk. The spot appears to have a tail, like that of a comet. The faster the disk spins, the longer the tail. If the tail just barely extends all the way around the disk, the time required to complete one full rotation is a measure of the duration of the visual persistence. Visual persistence produces positive afterimages, and this allows us to see the images in movies and television as though they were stable, moving objects instead of a succession of still images.

Adaptation

An animal's survival depends on sensing changes in its environment, and sensitivity to such changes is fostered by keeping sensory excitation at intermediate levels and by damping the response to stimuli that do not change. Negative afterimages are a by-product of the processes that accomplish this.

The process of light adaptation reduces the effect of light much as light-sensitive sunglasses do. Suppose that the light level increases tenfold, and that as a consequence, the sunglasses darken so that only 30% of the light passes through. Then a tenfold increase in light ends up increasing excitation only threefold. Light adaptation accomplishes the same thing as darkening the sunglasses, except that the change in effectiveness of the light occurs not by absorption but by changes in the physiology of the cells of the retina, the thin layer of light sensitive receptor cells, and associated nerve cells on the inside surface of the eye.

However, light affects the sensitivity of only the receptor cells that absorb it and the neurons downstream in the visual pathway to which they are connected. If the camera flash mentioned previously temporarily reduces the effectiveness of light falling on the receptors stimulated by the flash, then during subsequent viewing of a uniform surface such as a white wall, the effectiveness of the light falling on the array of receptors will not be uniform, and the effect of the light falling on the receptors previously stimulated will be reduced. As such, light is less effective; it has the same effect as if a dark pattern on the wall were imaged specifically on the adapted receptors, and so that is what one sees: a dark pattern in the shape of the camera flash. The pattern is dark instead of light, so it is called a *negative afterimage.*

Color

If more of the light in the stimulus is absorbed by the photoreceptors sensitive to red light than, say, the photoreceptors sensitive to green light, then the red-sensitive receptors will be more adapted (desensitized) than the green-sensitive receptors will. Subsequent exposure to white light, which contains a mixture of all colors, will excite the green-sensitive receptors more than the red-sensitive receptors, and so the white light has the same effect as it would have if the light had more green light than red light; consequently, in the areas of the retina adapted to red light, white light looks green. As the resulting color appearance is approximately that of the complement of the color to which the retina is adapted, it also is called a negative afterimage.

Temporal Factors

Even a weak stimulus, if viewed steadily for several seconds or a minute, can accumulate strong, negative afterimages. Conversely, even an extremely brief stimulus, if intense enough, can create strong positive or negative afterimages. These images can last for several minutes, although they pass through alternating phases of disappearance and reappearance. This is partly because maintaining visibility of an image requires movement between the image and the retina. Even when one tries to fixate steadily on one spot, the eye makes small, involuntary movements that ordinarily are both necessary and sufficient to keep images visible, but afterimages move with the retina and thwart the sustaining effect that the eye movements would otherwise have. Blinking or other changes in stimulation usually restores visibility of the afterimage. Long-lasting afterimages also pass through a succession of intense colors, called the *flight of colors,* even when the stimulus itself was white. Weak afterimages that would normally last only a few seconds can be permanently obliterated by brief superimposition of a pattern rich in contours.

AGEING AND CHEMICAL SENSES

Reading glasses and hearing aids are accepted accoutrements of the elderly: It is common knowledge that the visual and auditory senses dim with age. What about the chemical senses of smell and taste? A decline in the ability to appreciate ("taste") food and drink in old age was recognized thousands of years ago and noted in the Old Testament of the Bible (2 Samuel 19:34–35). But in what ways do our perceptions of the volatile and water-soluble molecules we smell and taste change with age? How pronounced is that change? And how early in life does it begin?

This entry addresses these questions, but it is important to recognize first that smell (olfaction) and taste (gustation) are distinct physiological systems. They have different receptor types and peripheral neural pathways, and they respond, largely, to different types of chemical stimuli. However, central nervous system responses to many smell and taste stimuli overlap. Thus, when food is eaten—simultaneously releasing some molecules that stimulate taste receptors in the oral cavity and some that flow from the mouth to the nasal cavity and stimulate olfactory receptors—it is perceptually difficult to distinguish which components of the resulting flavor perception are smells and which are tastes. Actually, however, these two aspects of food flavors are not equally affected by ageing: Diminutions in olfactory sensitivity are more pronounced than are diminutions in gustatory sensitivity.

Olfaction

Olfactory receptors are found on primary olfactory receptor neurons (ORNs) located in a relatively small patch of tissue high in the nasal cavity. These neurons extend cilia along the epithelial surface and, thus, are uniquely exposed to the external environment and subject to a constant barrage of potentially toxic chemicals and particulates, as well as being susceptible to direct injury from microbes. Although ORNs are also highly unusual in that there is ongoing replacement of these neurons throughout life, this is a complex process requiring reinnervation of the olfactory bulb (the first brain relay in the olfactory pathway), and it is often imperfect. Degeneration of the olfactory neural epithelium, and patchy replacement by respiratory epithelium, is seen even in young adults and becomes more pronounced with aging.

Olfactory function is most often assessed via tests of threshold sensitivity (the lowest concentration of an odorant that can be detected) or of the ability to identify suprathreshold concentrations of odors (e.g., is this orange, licorice, grass, or banana?); less frequently, ratings of the perceived intensity of suprathreshold odors are obtained. Almost uniformly, studies using all of these measures have shown a significant decline with age, typically beginning in the seventh or eighth decade of life. Age-related olfactory loss appears to develop gradually and is rarely complete, except in extreme old age. Nonetheless, it is often of sufficient magnitude to render older people vulnerable to chemical hazards such as gas leaks and to greatly diminish olfactory food flavor perception, reducing food enjoyment.

Despite extensive documentation of age-related decline in average olfactory sensitivity, debate continues regarding the uniformity of that decline, both across different odors and across individuals. Although there is little variation in the degree of loss reported for different odors, most studies have simply contrasted the performance of an elderly group with that of a group of young adults. As a result, possible differences in the onset or rate of decline in sensitivity to specific odors have not been examined. In addition, at the individual level, extreme differences among elderly subjects in olfactory abilities have frequently been noted, with some older individuals performing as well as the average young person. However, specific genetic, medical, and environmental factors that underlie this variation have not been identified, and some have questioned the reliability of apparent overlaps between the young and elderly in measures of olfactory ability.

Gustation

Taste receptors (responding to sweet, salty, sour, bitter, and umami, or "savory," stimuli) are also subject to damage from the chemicals they are designed to detect, as well as from viral, bacterial, and fungal species that often find a home in the oral cavity. However, taste receptors are not expressed on neurons, but on modified epithelial cells that turn over rapidly (approximately every two weeks). Moreover, these receptors are scattered over a large portion of the tongue dorsum, as well as being found on the soft palate, esophagus, pharynx, and epiglottis, and their responses are transmitted to the brain by multiple branches of three cranial nerves. These characteristics protect the taste system against extensive damage.

Actually, taste appears to be relatively stable across the life span. The measures used to assess gustatory function are similar to those used in studies of olfactory function, although few studies have included an assessment of the ability to identify the qualities of suprathreshold taste stimuli, at least partly because taste quality confusions (sour-bitter, sour-salty, and salty-bitter) are common even in healthy young subjects. Some age-related declines in both taste threshold sensitivity and the perceived intensity of suprathreshold tastes are typically observed; however, these declines are quality-specific and, in the case of bitter, compound-specific, and they are not always observed in both threshold and suprathreshold measures within a quality. Most modern studies have found no age-related decline in sensitivity to sweet (as exemplified primarily by sucrose), and declines in sensitivity to salty, sour, and bitter tastes, at either threshold or suprathreshold levels, are modest relative to those observed in smell. Because umami has only recently gained wide acceptance as a fifth basic taste, only a few studies have examined how it is affected by age. There are also few large, life-span studies of taste, but as is the case in smell, average declines appear to be significant only in the seventh and eighth decades.

All of these findings, however, are based on the whole-mouth presentation of taste stimuli. Several studies suggest the elderly are particularly prone to spotty losses of function affecting circumscribed areas of the tongue. In general, this has little impact on the whole-mouth experience of taste because other areas appear to compensate, but it may render elderly individuals more vulnerable to taste dysfunctions that lead them to seek medical assistance, including both whole-mouth loss of taste and the development of chronic, phantom taste sensations.

AGEING AND HEARING

A common complaint of older adults is difficulty hearing and understanding speech, which can result in problems following conversations, using the telephone, and detecting and locating alerting sounds. Approximately one third of adults ages 65 to 74 and nearly one half of adults 75 and older have impaired hearing. When loss of hearing for higher frequency sounds is included, nearly all individuals older than 80 have significant hearing loss. Indeed, hearing loss is among the most common chronic conditions of ageing, ranking first among men and fourth among women, after arthritis, cardiovascular disease, and cataracts. In the next few decades, the number of individuals with hearing loss will substantially increase as the population ages, as this entry describes.

Hearing loss in older adults is known as *presbyacusis* and results from genetic influences and the combined effects of ageing, long-term exposure to noise, ototoxic drugs, diet, trauma, and otologic and neurologic diseases. Additional risk factors may include smoking, cardiovascular disease, high blood pressure (hypertension), diabetes, and hyperlipidemia (high cholesterol). Presbyacusis can be narrowly defined as hearing loss that increases with age and is caused by the ageing process, which likely has a genetic basis. Because environmental and disease effects on hearing accumulate over a lifetime, hearing loss caused specifically by ageing is difficult to isolate in older humans. Older animals raised

Source: Medical University of South Carolina, Longitudinal Study of Age-Related Hearing Loss.

without exposure to noise or drugs nevertheless show unique age-related anatomic and physiologic changes in their auditory peripheral and central nervous systems (CNS). These include deterioration of tissues and blood supply in the cochlear lateral wall (inner ear), some degeneration of auditory neurons, and reductions in the resting potential that supplies power to the sensory (hair) cells.

Age-related hearing loss in the United States has been described by several community-based epidemiological and clinical studies. Figure 1 shows the systematic increase in hearing thresholds with increasing age in women and men, beginning with reduced ability to hear high-frequency and then mid-frequency sounds, which are important for understanding speech. Thresholds for women show the progression of a generally constant hearing loss at lower frequencies to a gradually sloping loss at higher frequencies; thresholds increase steadily with age more in higher than lower frequencies. Thresholds for men show similar patterns, but with more high-frequency hearing loss, which may relate to increased noise exposure.

Epidemiological surveys also suggest a strong genetic component in age-related hearing loss, which has been confirmed by results of twin studies and data from various strains of mice. Heritability coefficients indicate that as much as 55% of the variance in hearing thresholds of older persons is genetically determined, which is similar to heritability reported for hypertension and hyperlipidemia. The genetic component is reported to be stronger in women than men, which may be caused by a larger environmental component in men related to noise exposure. These results, along with studies of hearing in nonindustrialized societies, are consistent with the view that hearing loss in older adults results from environmental and disease factors superimposed on a genetically determined ageing process.

Along with declines in the ability to detect sounds (Figure 1), older adults have poorer abilities to detect small changes in intensity, frequency, and timing of sounds, which are important for using information carried by fluctuations in speech. The strongest evidence is from older adults whose thresholds are normal, which separates age-related effects from those resulting simply from poorer hearing. Differences between older and younger adults are larger at lower frequencies and decrease as frequency increases. This suggests a mechanism related to processing of timing information (e.g., detecting fast fluctuations or silent periods), which may degrade with age.

Many older adults complain of difficulty understanding speech, especially in noisy environments with many talkers. Declines in understanding of simple speech presented to one ear are largely explained by reduced speech audibility. Age-related differences not resulting simply from hearing loss are those for temporally distorted speech (such as rapid speech), speech presented binaurally with other sounds that are separated in space or fluctuating, or tasks requiring divided attention. Although behavioral measures of hearing and speech understanding are consistent with declines in processing timing information, it remains unclear whether these represent age-related changes in the auditory periphery, which provides impoverished signals to the CNS, or the combined effects of an ageing periphery, an ageing CNS, and cognitive factors.

Along with poorer communication abilities, untreated hearing loss in older adults can have negative effects on quality of life, contributing to social isolation, depression, and loss of self-esteem. Regrettably, no current medical treatment can prevent, delay, or reverse age-related hearing loss. The most widely used treatment is amplification provided by hearing aids and, for adults with severe-to-profound hearing loss, a cochlear implant, which is an electronic device implanted in the inner ear. Despite advances in hearing-aid technology, surveys report that more than 75% of individuals likely to benefit from a hearing aid do not own one (a gap of about 20 million people in the United States). Reasons are varied and include attitudes toward hearing loss and hearing aids, background noise and distortion, cost, adaptability, comfort, maintenance, tactile sensitivity, manual dexterity, and vision loss that may reduce benefits of speech reading.

AGEING AND TOUCH

Common wisdom indicates that sensory processes lose efficiency in old age. Glasses and hearing aids are a kind of standard aid for elderly people. Yet, in contrast to vision and hearing, the dramatic age-related deterioration of the sense of touch goes mostly unnoticed because there are no conditions such as reading newspapers or obtaining a driver license that would disclose an impairment of senses. As a result, the sense of touch and its vital role for coping with activities of daily living is widely underestimated. This entry discusses age effects on receptors and tactile perception, haptic perception, and treatability of age effects on touch.

Age Effects on Receptors

Touch perception is built on sensing through receptors, transmission through neurons at various stations along the sensory pathway, and central processing by the brain. As aging affects all components, multiple factors are involved in the age-related decline of the sense of touch.

Skin conformance undergoes alterations in old age. There is a loss of dermal receptors, which provide the senses of touch, pressure, and vibration. The morphology of Meissner's and Pacinian corpuscles, which detect vibrations and changes in texture change in old age, whereas Merkel-neurite touch receptors, which detect sustained touch and pressure, appear to be less affected.

Age Effects on Transmission and Central Processing

Transmission of touch information is affected by slowing of nerve conduction with increasing age and reduction of action-potential amplitude. In contrast to eyes and ears, which are close to the brain, the distances of skin receptors from the brain vary greatly across the body. Accordingly, skin receptors located on the feet are particularly vulnerable to a slowing down of conduction, which can amount to as much as 20 or 30%. It is believed that slow conduction emerging during aging results in greater temporal dispersion of incoming afferent information, which harms central processing thus contributing to perceptual impairment. At a central level, there is now agreement that neuron loss is a rare event. However, at a subcellular level, cortical sensory processing is affected through manifold age-related alterations of ion channels and receptor composition. Imaging studies in aged humans using magnetic resonance imaging indicated that gray matter density is reduced as a function of age, often starting as early as about 40 years of age; however, the time course of aging effects varies considerably over cortical areas. Thus, a major question is, what are the functional and perceptual consequences of these age-related changes, and how do these changes cause degradation of touch perception, which is discussed in the next paragraph.

Age Effects on Tactile Perception

At a perceptual level, a simple measure of tactile perceptual performance is tactile acuity, which describes the ability to resolve fine spatial details. Usually, measures of tactile acuity are obtained by testing two-point discrimination, gap detection, or grating orientation. Whatever technique is used, tactile acuity is significantly reduced during aging. For example, tactile acuity declined much more vigorously on some body regions than on others. According to one study, deterioration of acuity in the great toe averaged about 400% between young and elderly subjects (aged 65 to 87 years) compared with an average decline of 130% observed on the fingertip, meaning that acuity threshold is, depending on the body part, severalfold greater in older subjects (see also Figure 1, where spatial discrimination thresholds are plotted as a function of age).

Against intuitive thinking, the relation between receptor density and tactile acuity is far from being one-dimensional. Although the density of Meissner's corpuscles in the index and ring fingers does not differ, the acuity does. On the other hand, although males have lower density of Meissner's corpuscles compared with females, their acuity is not different. The reason for the lack of a simple relation between receptor density and perceptual outcome is that central somatosensory representations are not a mere mirror of the afferent input signals, but extract additional information through active computation based on the interaction of inhibitory and excitatory processes. In respect to the processing of touch information, there is a controversy about the role of peripheral versus central aspects that determine perception.

Haptic Perception

Providing tactile acuity information is only one among many functions the sense of touch subserves. Haptic perception, the ability to identify common objects by exploration with hands and fingers without sight, depends on accessing cutaneous information. For example, if afferent sensory information of the fingers is suppressed by wearing a glove or by local anesthesia of the fingers, motor control of the hand is severely impaired. In a study, both acuity thresholds and manual dexterity were assessed using a pegboard test that revealed a strong correlation between threshold and manual dexterity. As a result, age-related impairment of touch processing has far-reaching consequences on haptic and motor performance and may translate into great difficulties in tasks requiring fine manipulations. In addition to a reduction in tactile acuity, elderly people undergo a significant impairment in haptic perception.

In most cases, however, age-related decline of the sense of touch develops slowly and as part of a normal, that is, nonpathological, aging process over decades. As a result, elderly progressively adapt to the loss of high-level tactile performance and learn to compensate by developing behavioral strategies such as relying more on visual control to overcome the decrement in the sense of touch.

Treatability of Age Effects

Neuroplasticity is the ability of brains to adapt to new experiences and constraints of the environment during the entire life span. During the past few decades, such use-dependent plastic capacities of somatosensory systems have been intensively studied demonstrating that practice and training determine to a large extent perceptual abilities of an individual even at high age. This notion has been corroborated by recent findings demonstrating that the typical age-related decline in tactile performance is not inevitable, but that despite the accumulation of degenerative processes during aging, performance can be recovered by learning and training.

The impact of age, training, and sensory stimulation on tactile acuity is illustrated in Figure 1. Overall, discrimination performance is progressively impaired with increasing age. However, blind subjects who read Braille do not show the age-related changes, suggesting that maintained use of the fingers might play a role in preserving intact acuity. Furthermore, applying a brief period (3 hours) of tactile coactivation on the tip of the fingers, a procedure known to induce plastic changes in the somatosensory cortex, results in a significant amelioration of the age-related decline in elderly subjects, suggesting that age-related decline of tactile acuity is not irreversible. These results suggest that mechanoreceptor density may play a minor role in determining tactile acuity performance at old age but that acuity is rather controlled by cortical mechanisms. This view is also supported by recent imaging data that demonstrated a close correlation between tactile spatial resolution and the size of the area in the cortex devoted to processing of touch information. In conclusion, cortical processing, which is subject to alterations through practice and training, appears to be a crucial factor shaping the quality of touch-related performance even at high age.

AGEING AND VISION

Age-related changes in vision can profoundly affect the quality of life for seniors, decreasing independence and mobility and increasing physical injuries, such as hip fractures. But what aspects of vision change with age? And what produces those changes? Despite the critical importance of vision for functioning in everyday life, much still remains to be learned about the effects of healthy ageing on vision. This entry provides a brief overview of some of the most important aspects of ageing and vision researchers have learned.

Age-Related Effects

As people age, their vision is affected by changes both to their eyes and their brains. The average pupil size decreases with age, so that less light enters the eye, and this reduction in light is compounded by changes in the structure of the lens. Through the normal ageing process, even in the absence of cataracts (clouding of the lens), the lens becomes less transparent, blocking additional light from entering the eye, and changing the color of the light that does get through. Changes to the lens and intraocular media also increase light scatter, reducing the contrast of the retinal image. These structural changes to the lens also make it more difficult to focus on close objects as we age; this change in accommodative ability—the ability to change the optical power of the eye to focus on objects at different distances—is known as presbyopia, and is a normal part of the ageing process. The inability to focus on close objects without wearing glasses typically occurs between about 40 and 50 years of age, and the "near point" (the closest point on which one can focus) continues to move further away throughout our lifetimes. As young adults, people typically can focus clearly on objects about 10 centimeters away; by the time they reach 60 years of age, the near point has moved away to about 1 meter. Fortunately, by wearing appropriate optical corrections (glasses), seniors can overcome many of the difficulties associated with presbyopia.

These optical changes adversely affect vision, but research has shown that the most profound age-related effects on vision stem from changes in neural, rather than optical, processing. Blurring of the optics would lead to an inability to see fine details, resulting in a decrease in visual acuity. But ageing also decreases our contrast sensitivity—defined as the inverse of the lowest contrast needed to see different sized targets—even for mid-sized objects, although the most pronounced effects are seen for objects with more fine details. For example, the general shape and features of a face would remain visible throughout our lives, but it becomes more difficult to discriminate individual eyelashes around the eye, or fine wrinkles on a face. Based on behavioral techniques that can tease optical and neural factors apart, and based on studies in which stimuli are projected directly onto the retina, bypassing the optics, the age-related reduction in contrast sensitivity is largely the result of changes in neural processing, rather than of changes in the optics of the eye. Regardless of what causes a change in our acuity and contrast sensitivity, the net result is that the world appears a bit more blurry and washed out in the elderly.

Ageing affects many stages of neural processing of visual information, beginning with a reduction of sensitivity in cone photoreceptors (the cells that enable us to discriminate color) in the retina. Interestingly, however, although the relative sensitivity of the cones changes continuously from adolescence through our senior years, color perception remains relatively constant, suggesting that the neural systems encoding color engage compensatory mechanisms, although the precise nature of such mechanisms remains unclear. Recent physiological studies have also suggested that the intrinsic level of noise in visual neurons is increased and the selectivity of visual neurons to visual attributes such as direction of motion and orientation decreases in senescent monkeys. Such changes may be because, throughout the brain, there are changes in the quantity and function of certain neurotransmitters. For example, the efficacy and production of the brain's primary inhibitory neurotransmitter (gamma-aminobutyric acid, or GABA) decreases with age, at least in some cortical areas.

Implications for Task Performance

As might be expected from the neural changes in the selectivity of motion mechanisms, older adults are impaired on many motion perception tasks. For example, older observers can detect only about a 10% difference in speed of a cluster of moving dots or other targets, whereas younger observers can detect speed differences half that size (5%). Similar age-related effects are seen for direction discrimination, although there is some indication that these basic motion deficits mostly affect "senior-seniors" (observers older than 70 years of age), rather than for "junior-seniors" (60–69). In some unusual circumstances, older observers can even outperform younger observers. For example, seniors are better able and faster than young observers to detect the direction of motion for large high-contrast targets. Although this result seems counterintuitive, it may be a by-product of reduced intra-cortical inhibition (e.g., GABA levels) in the visual cortex. Inhibition in the brain typically highlights objects on backgrounds, and "tunes out" large, uniform patterns, resulting in decreased sensitivity to motion for large, high-contrast targets in young observers. If inhibition declines with age, large, high-contrast targets would not be suppressed as much in seniors, and, consequently, detection of motion of such targets should improve with age. In general, however, seniors consistently have difficulties in perceiving more complex forms of motion such as shape from motion, optic flow (the way objects and scenes move across the retina as they or the observer move), biological motion (e.g., the ability to discern the presence of a person walking when viewing only a sparse array of dots on the locations of a person's joints), and motion defined across different visual attributes. Evidence also suggests that older women are more impaired in a range of motion tasks than are older men, although the extent of this sex difference and the mechanism underlying it are unknown.

The effect of stimulus and task complexity on ageing is not limited to motion perception. In general, age-related deficits appear to grow with increasing stimulus or task complexity. For example, ageing seems to impair our ability to integrate information across space, even when our perception of local elements remains intact. A good example of this is seen in the perception of oriented contours. Older observers have little if any difficulty in discriminating localized, oriented targets; indeed, in humans, the behaviorally estimated neural selectivity of orientation mechanisms seems unaffected by age (a result that stands in contrast to the finding from single-cell physiology in monkeys suggesting that ageing may decrease orientation selectivity, at least in anesthetized animals). However, integration of local orientations into larger, more spatially distributed contours appears to be impaired. For example, young adults have no difficulty grouping several small oriented lines together to form a curve, but seniors appear not to be able to integrate those local orientations together to form a global shape as well as younger observers can. Other aspects of visual integration, including the perception of symmetry, are similarly impaired with age, and older observers are also impaired on perceptual tasks that require observers to divide their visual attention across space or to detect a target in a cluttered environment (evidenced in the lab by relatively poor performance by seniors on visual search tasks in which observers have to find a specific object hidden among a number of other objects).

Why might age have a larger impact on visual processing for complex rather than for simple stimuli and tasks? One possibility is that compensatory mechanisms are active in older brains, but that there are limits to the extent of that compensation. Recent advances in neuroimaging techniques shed some light on this hypothesis. Researchers now know that even when younger and older observers perform identically on a simple visual discrimination task, the neural systems engaged in younger and older brains may be quite distinct. For example, in one study, whereas the visual cortex was of primary importance for a visual discrimination task in younger observers, older observers performing the same task appeared to recruit parts of the hippocampus (normally associated with memory) and prefrontal cortex (normally associated with attention).

Overcoming Limitations

Fortunately, the visual system remains tremendously plastic throughout our lifetimes, so that seniors can continue to learn new visual tasks and can learn to improve performance on more familiar tasks. For example, as mentioned earlier, seniors typically are less able to divide their attention across space than younger observers (e.g., in a multitasking, divided attention task, in which observers must name a central letter while detecting a spot in the periphery). With about a week's worth of training, however, seniors can learn to divide attention as well as younger observers do. Effects of training can be seen for lower-level aspects of vision as well, including the discrimination of moving stimuli. In some cases, such learning can last for months, even with no intervening training. Important questions for future research include determining ways in which learning can be optimized, what the effects of learning on the brain are, and how age-related changes in vision (and improvements based on learning) affect seniors' ability to function in the everyday world.

So, although the visual world of the senior may be more of a "blooming, buzzing confusion" than is that of the young adult, older brains can learn new tricks and can compensate in a variety of visually challenging situations. That, combined with glasses that can correct many optical problems, enables seniors to overcome many of the limitations in vision that accompany healthy ageing.

AGNOSIA: AUDITORY

Auditory agnosia is the loss of auditory recognition in the absence of deafness. It is often associated with lesions of the auditory cortex, but the definition does not require a cortical lesion. It also is possible to have auditory agnosia resulting from disorders of the auditory nerve, brainstem, and midbrain. Acquired agnosia following brain insult is rare because it often, but not always, follows damage to both sides of the brain, which is usually fatal. The assessment of auditory agnosia requires the assessment of both discrimination and recognition. Problems with discrimination occur in *apperceptive agnosia* (caused by loss of perception), when there will also be deficits in recognition. In *associative agnosia,* discrimination (and therefore perception) is intact, but there will be a deficit in recognition caused by a deficit in the attribution of semantic labels to sounds. The two general types of auditory agnosia are therefore disorders occurring at different levels in auditory object analysis. Apperceptive and associative forms of agnosia for word recognition (pure word deafness) and voice recognition (phonagnosia) are both described in this entry. Agnosia for music (amusia) can be characterized as an apperceptive agnosia. Environmental sound agnosia has also been described.

Causes

Auditory agnosia is most commonly caused by strokes on both sides affecting the upper temporal lobe. It can also occur after temporal lobe damage resulting from herpes simplex encephalitis. Many cases of auditory agnosia reported after cortical lesions do not actually meet a strict definition of agnosia based on the presence of normal hearing. This may reflect the evolution from cortical deafness to auditory agnosia that is observed in a number of cases. In addition, many patients with auditory agnosia caused by stroke are from an elderly population in which deafness resulting from abnormal cochlea function is common.

Lifelong (congenital) forms of agnosia have also been described. In particular, the disorder commonly known as tone deafness or tune deafness can be characterized as a congenital agnosia called congenital amusia.

Overlap Between Apperceptive Agnosias

In apperceptive forms of agnosia, there is often an overlap between the domains of perception that are affected. Deficits in the recognition of single words (word deafness), environmental sounds (environmental-sound agnosia), and music (amusia) commonly coexist, especially in patients with agnosia resulting from damage to the upper temporal lobe on both sides. This reflects overlap in the aspects of auditory perception required for the analysis of these different sounds, where the profile of specific deficits depends on the particular aspect of auditory analysis that is affected by the cortical lesions. The degree of overlap between domains affected by agnosia is likely to be underestimated in view of the practical difficulty of carrying out a comprehensive and rigorous assessment of all of these, and that it is unusual for patients to undergo a systematic assessment of complex sound analysis.

Some studies of patients with apperceptive forms of agnosia have examined temporal aspects of complex sound perception, especially in patients with word deafness, using approaches that include click counting and discrimination of tone sequences or rhythms. Many of the reported patients with word deafness in which such temporal deficits have been described also suffered deficits in other domains, as would be predicted on the basis of an apperceptive agnosia caused by a deficit in temporal analysis. Deficits in examining the frequency structure (spectrum) of sound have not been systematically explored in agnosia, but might be relevant to deficits in musical perception, in particular, which is less robust than speech is to degraded spectral structure.

The damage associated with auditory agnosia commonly affects the primary and secondary auditory cortex in Heschl's gyrus in the uppermost part of the temporal lobes and the association cortex behind Heschl's gyrus in a region called the planum temporale. Studies of normal subjects using functional imaging suggest that different aspects of time analysis and spectral analysis occur in different regions of the auditory cortex, and different distributions of damage in different patients can cause different types of deficits in complex sound analysis and therefore different differential effects on speech, music, and environmental sound perception. Attentional effects in association with such damage are also common and will contribute to the clinical defect observed.

Agnosia for Words and Voices

The distinction between acquired apperceptive and associative agnosia has been emphasized in the word-deafness literature. Associative forms of word deafness, where word discrimination is intact but word recognition impaired, can occur with damage to the left temporal lobe, although left-side lesions have also been reported to produce an apperceptive agnosia. A similar distinction has been made in the case of phonagnosia: agnosia for voices. Reports of symptomatic deficits in voice recognition are rare in the case literature, but in series of asymptomatic patients with damage to the right or left temporal and parietal lobes, apperceptive phonagnosia has been reported resulting from right or left temporal lobe damage and associative phonagnosia resulting from right parietal lobe damage.

Agnosia for Music

Musical agnosia (amusia) has been studied in a number of patients following unilateral or bilateral temporal lobe stroke. It can be argued that musical deficits resulting from stroke can be considered relative to the components of music in the pitch or rhythm domain. In the pitch domain, for example, deficits can occur in the perception of the pitch of individual notes, simple pitch patterns such as pitch-interval direction between pairs of notes, contour (the patterns of "ups" and "downs" in a melody), and tonal structure. Neuropsychological models suggest that these are successive levels in a hierarchy of pitch and pitch-pattern analysis, and normal functional imaging suggests that the substrate for such analysis becomes increasingly distributed (involves areas increasingly distant from the primary and secondary auditory cortex) when moving up the perceptual hierarchy. The disorder commonly coexists with a deficit in the perception of prosody in speech at a similar level of temporal structure to the critical level in music: prosody involves changes in pitch, stress, and rhythm within a temporal "window" that is also at the level of hundreds of milliseconds. The disorder is best characterized as an apperceptive agnosia before the level of deficits in tonal analysis, when learned associations with pitch patterns are made and a form of associative deficit might be argued.

In the pitch domain, there is a tendency for deficits at higher levels in the pitch hierarchy to be caused by lesions that are more remote from the primary and secondary auditory cortex. Right-hemisphere lesions causing deficits are more commonly reported and therefore emphasized in the literature but left-hemisphere lesions *can* produce deficits in mechanisms for the analysis of pitch and pitch pattern. In part, this might reflect an ascertainment bias. Cases of acquired amusia resulting from left-hemisphere damage may be associated with aphasia, making behavioral assessment more difficult.

There has been recent interest in lifelong disorders of musical perception, known as tone deafness, tune deafness, or congenital amusia. Lifelong disorders of singing have been recognized for more than a century, and recent work using a schedule called the Montreal Battery for the Assessment of Amusia (MBEA) demonstrates that the deficit is commonly associated with a deficit in musical perception that can be demonstrated by impaired discrimination of novel melodies. The disorder can therefore be characterized as a congenital form of apperceptive agnosia and is particularly associated with deficits in the pitch domain. Rhythm deficits can also occur, but only if these occur in the context of a melody. Behavioral studies have demonstrated deficits in pitch discrimination and pitch-direction analysis, suggesting a fundamental deficit in the analysis of pitch pattern. Based on lesion data from a number of studies and consideration of the normal cortical mechanisms for pitch-pattern analysis demonstrated by functional imaging, a cortical basis for the disorder would be predicted. Although abnormalities of brain structure are not seen at the individual level, group studies of brain structure using magnetic resonance imaging provide evidence for cortical disorder abnormalities that particularly affect mechanisms in the right temporal lobe and frontal lobe for the analysis of pitch pattern and pitch working memory for pitch: the mechanism by which we hold notes in mind when we listen to musical phrases.

AGNOSIA: TACTILE

Everyday object recognition involves contributions from all of our senses. We recognize objects not only by their shape and color, but also by their sounds, textures, and temperatures. Our brains are organized to integrate information across senses, but each sense has its own separate neural object recognition system. To understand how the brain achieves multisensory object recognition, researchers examine how brain damage leads to the selective failure of recognition by an individual sensory system. This entry focuses on how impairments of tactile object recognition, or tactile agnosia, contribute to our understanding of normal object recognition. The entry reviews issues regarding different types of tactile agnosia, brain regions involved in tactile agnosia, sensory and motor contributions to tactile agnosia, and the existence of tactile agnosia separate from visuospatial disorders.

Agnosia is defined as the impaired recognition of familiar objects, faces, or sounds, despite adequate perceptual and intellectual capabilities. *Tactile agnosia,* or *somatosensory agnosia,* refers to a deficit in recognizing common objects by touch following brain damage, despite sufficiently intact tactile sensation, memory, and general intellectual function. Tactile agnosia is distinct from *tactile aphasia,* an inability to verbally label a felt object, or tactile inexperience in which the patient is not familiar with the object.

Tactile agnosia is modality specific: Patients who have difficulty recognizing objects by touch can still recognize objects by vision, audition, taste, or smell. Patients describe their condition as feeling like their hand is "numb" or "stiff," that the feeling is not distinct or strong enough to identify the objects by touch. Patients with visual agnosia have similar complaints saying their glasses appear "dirty" or "don't work."

Patients with tactile agnosia usually have unilateral lesions (i.e., brain damage on only one side of the brain). The hand that is contralateral to the lesion (on the opposite side of the lesion) is the hand that is "agnostic." A patient with a left hemisphere lesion will have difficulty recognizing objects with his or her right hand. The unilateral nature of tactile agnosia provides an advantage to investigating tactile agnosia: patients provide their own control comparisons because patients' ability to recognize felt objects with their non-agnostic, ipsilateral hand (i.e., on the same side of the lesion) can be compared directly with their inability to recognize the same objects and perform the same tasks with their contralateral agnostic hand. Thus, difficulties recognizing objects with their agnostic hand cannot be attributed to labeling problems or a lack of knowledge about the objects.

Types of Tactile Agnosia

To identify different types of tactile agnosia, researchers consider stages of processing for tactile object recognition. Tactile object recognition is assessed by asking patients to feel objects that they cannot see or hear, and identify them. When feeling objects, patients usually explore the object with one hand; this active touch is called *haptic perception.* Patients may also recognize patterns passively, without hand movement. Identification of felt objects includes verbally providing a name or label for an object (e.g., cup), pointing to a visually presented object or picture, and matching the felt object with another object.

In theories of tactile object recognition, perceptual input information is transformed through a series of processing stages before object identification. The first stage of processing involves the extraction and processing of the properties and features of the felt object. For example, to recognize a dime, one must first apprehend its small size, cool temperature, round shape, and rough edges. Exploratory procedures, or hand movements, integrate input from cutaneous, kinesthetic, and proprioceptive receptors to extract information about the object's texture, hardness, shape, size, weight, part relations, and temperature. Next, these properties must be combined or integrated into a common modality-specific representation or object description. The integrated tactile object description is then used to access information about object meaning and function (i.e., semantics). These descriptions contain semantic information from multiple senses that permit object recognition.

Object recognition deficits can be associated with earlier or later stages. If the property integration stage (tactile attributes cannot be combined with each other) is disrupted, then patients will be able to perceive the object's features but will not be able to draw the objects or describe how the various features relate to each other. If patients cannot associate the current perception of the object with its stored meaning (i.e., the access to semantic representation stage is disrupted), then patients can describe the object and draw it, but not be able to identify it. This division corresponds to the two major types of deficits revealed in case studies of both visual and tactile agnosia: apperceptive and associative.

Apperceptive tactile agnosia refers to tactile object recognition deficits in higher-level tactile perception. Patients with apperceptive tactile agnosia have relatively intact basic tactile perception in that that their abilities to discriminate two points on their hands, feel pressure, light touch, and finger movement are within the range of non-brain-damaged individuals of the same age. They can distinguish between different tactile textures, compliant surfaces, temperatures, and sizes. However, they have difficulty forming a perceptual representation, or percept, that integrates the individual tactile object properties, especially object shape and part relations. When feeling a combination lock, a patient with apperceptive tactile agnosia may describe its hook on top, its rounded shape, its moving dial, and its raised number ticks on the dial, but will be unable to put the parts together to identify the object. Further, if the patient is asked to draw the felt object, the drawing tends to have the wrong proportions or numbers of the object's parts (e.g., a cassette tape with twelve instead of two holes) or to only capture a vague outline of the object that lacks interior detail (e.g., no ticks on the dial of a combination lock).

Associative tactile agnosia refers to deficits that occur when patients cannot use the integrated tactile percept to access their knowledge of the object. In contrast to apperceptive tactile agnosia, patients with associative tactile agnosia can verbally describe the material and shape of felt objects. They can make drawings of tactually presented objects as well as match two- and three-dimensional shapes. Despite these capabilities, they cannot recognize the objects, determine whether two felt objects are from the same category (e.g., they are both necklaces), or both perform the same function (e.g., a cork screw and a church key both open bottles). As a result, their inability to recognize objects by touch is interpreted as disrupted connections between incoming perceptual information and stored object knowledge or semantic representations. Although apperceptive and associative agnosias provide an important distinction, current case studies refine these distinctions by studying the precise stage of processing at which the specific deficit occurs.

Cortical Bases for Tactile Agnosia

Case studies implicate the parietal lobe as the critical neural region for tactile agnosia. Patients with tactile agnosia often have lesions in the second somatosensory cortex (SII) and inferior parietal regions (Brodmann areas 39 and 40). The primary somatosensory cortex (SI) processes individual attributes such as values texture, hardness, vibration, and temperature on a particular body part, but these regions appear to integrate object attributes. Recent neuroimaging studies of non-brain-damaged individuals have confirmed these parietal regions as important for the initial, somatosensory-specific stages of tactile object recognition; later stages of tactile object recognition processing appear to follow the ventral temporal pathway used by the visual object recognition system. Thus, the initial stages of tactile object recognition are specific to tactile processing and the later stages are shared at least by the visual system, suggesting that information from individual object recognition systems may converge in the ventral or "what" pathway of the temporal lobe.

Sensory and Motoric Contributions

Similar to the study of visual agnosia, researchers debate whether tactile agnosia can exist without sensory impairment, and if so, how sensory and motor deficits influence the recognition process. The current consensus is that tactile object recognition can be disrupted without clinically demonstrated somatosensory loss. Supporting this view, some patients with tactile agnosia have shown comparable performance with non-brain-damaged individuals on basic and intermediate somatosensory functions despite severe tactile object recognition deficits. Tests of basic somatosensory functions include light touch (with a wisp of cotton), vibratory sensation (on a joint), proprioception (determine the direction the experimenter moved a joint), superficial pain (pin prick), temperature (cold/warm object applied to skin), and two-point discrimination (distance that two touches can be distinguished on the skin). Intermediate somatosensory functions include determining an object's texture, size, weight, hardness, and simple shape judgments (long or short). Thus, tactile agnosia is a higher-level processing problem that cannot be attributed to perceptual problems.

To examine the extent to which somatosensory and motoric inputs influence the tactile object recognition process, researchers have examined individuals with sensory and motor deficits. Patients who have damage to their hands or peripheral nervous system and patients with lesions in SI do not always show tactile object recognition deficits in their contralesional hand. Likewise, patients with hand paralysis do not necessarily have significant deficits in tactile object recognition. Touch differs from other senses because it interacts directly with objects themselves and most people perform exploratory procedures to actively investigate an object. For example, to determine an object's texture, they tend to rub the object; to determine its hardness, they squeeze it; and to determine an object's shape, they grasp it or run their fingers around the edge of it. Because the hand uses both tactile inputs and hand movements to extract somatosensory information, these patients probably are using the motions of object parts or hand movement cues to extract relevant object information that they cannot obtain through purely tactile perception. In sum, there are sensory and hand movement contributions to tactile agnosia, but they cannot explain the overall deficit.

Spatial Contributions

Researchers have also questioned whether tactile agnosia exists independently of a more general, supramodal (not specific to a particular modality) spatial impairment. This question arose from the result of a large study that compared the performance of brain-damaged World War II veterans with non-brain-damaged patients on a variety of tests of tactile and spatial function. Tactile tests include two- and three-dimensional pattern recognition. Spatial tests included a map-following task in which people were given a map and room with markers on the floor; they were asked to walk the path indicated by the map. Results showed that brain-damaged patients who were impaired on the tactile tests were also impaired on the spatial tests, suggesting that the two abilities had common neural sources. However, recent research has documented that tactile agnosia can exist without concurrent spatial deficits. A patient with documented tactile agnosia was assessed on visual spatial tests designed to assess the same spatial integration process assumed to be taxed by tactile object recognition, including the same map test used in the earlier study. Despite a severe tactile object recognition deficit, the patient performed at above-average levels on all spatial tests, both tactile and visual. This case study indicated that tactile object recognition problems may be specific to the touch and are not caused by general spatial deficits such as the inability to manipulate complex spatial images or to imagine how object parts fit together. Consistent with this conclusion, neuroimaging research has confirmed that the parietal regions involved in tactile object recognition are different from those involved with spatial localization. This functional dissociation in the somatosensory system of object recognition ("what") and spatial processing ("where") is similar to what is found in the visual system. The conflict between the results of these two studies may be resolved by the fact that the locations and extent of the lesions were unknown in the older study. The lesions of those patients may have involved both functional regions of the parietal lobe.

Significance

The study of tactile agnosia reveals that our brains have neural systems specialized for tactile object recognition that are independent of visual and auditory object recognition systems. Nonetheless, there are commonalities in the tactile and visual stages of object recognition at both functional and neural levels. These similarities provide a basis for the interaction of the two systems that permits our normal, multisensory recognition of common objects.

AGNOSIA: VISUAL

Visual agnosia refers to a class of disorders in the domain of visual recognition, in which the affected person cannot arrive at the meaning of some or all categories of visual stimuli. In such cases, knowledge of the shape, form, or other stored knowledge of the physical attributes of an object cannot be accessed, with the result that the stimulus is not successfully identified. The failure to recognize the object occurs under a whole range of conditions and independent of whether the stimulus is presented as a real three-dimensional object, as a black-and-white line drawing, or as a photograph. Dramatically, these perceptual failures occur despite the individual exhibiting normal or near-normal elementary visual functions such as acuity, brightness discrimination, and color vision, along with normal or near-normal semantic and memory functioning. These individuals also have intact alertness, intelligence, and language, thus setting aside questions about whether agnosia is simply a manifestation of reduced elementary visual function and intelligence.

Visual agnosia may result from a lesion (e.g., as a consequence of a stroke or tumor or other form of brain damage) sustained by an adult who possessed normal premorbid perceptual abilities, or it may be apparent in a child who sustained a brain lesion early in life, a disorder usually referred to as *developmental agnosia.* Visual agnosia may also occur in the context of a progressive deterioration of perceptual skills, as in the visually selective progressive posterior cortical atrophy, and finally, it may be evident in individuals who are apparently impaired at recognition (predominantly of faces) from birth in the absence of any obvious neurological concomitant (see Table 1).

Not surprisingly, patients may fail to recognize objects if they have a deficit in semantics (knowledge or meaning of objects and their properties such as what an object might be used for). Interestingly, however, and the focus of this short review, agnosic patients typically retain the long-term representation of the object but still fail to recognize the stimulus presented. Thus, several investigators have reported data from visual imagery tasks that demonstrate that stored visual knowledge may be at least relatively preserved in patients with severe visual agnosia and that, despite this, the patients do not recognize the presented object; for example, patients may be able to visualize in their mind's eye a particular object but, presented with the same object, may fail to identify it. Consistent with this, these patients usually demonstrate normal recognition of objects through modalities other than vision (touch, audition, verbal definition, or description of its function), further indicating that the deficit is not simply a difficulty in retrieving names or in accessing the necessary semantic/knowledge information. In short, the problem appears to be one of accessing meaning from visual input.

Visual agnosia can be general, affecting the recognition of all visual stimuli, or it can be more specific: for example, some agnosias are (relatively selective) for objects, for faces or *prosopagnosia,* for words or *pure alexia,* for body parts, for colors, and for environmental scenes, including landmarks. Finally, the disorder of simultanagnosia—an

Table 1 Classification of Types of Visual Agnosia, Their Underlying Neuropathology, and Clinical Manifestation

	Neuropathology	*Clinical Manifestation*
Apperceptive agnosia	Stroke, anoxia, carbon monoxide poisoning affecting occipital, parietal, or posterior temporal regions bilaterally	Unable to copy, match, or identify visual stimuli
Associative agnosia	Usually bilateral infarction of the posterior cerebral arteries but unilateral occipitotemporal damage may suffice	Able to copy and match stimuli, may even be able to provide verbal description of aspects but still not recognize the object
Integrative agnosia	Extensive extrastriate damage bilaterally or to the right hemisphere	Fails to piece the components of an object together so oversegments or perceives in segmental fashion
Prosopagnosia	Acquired form: bilateral infero-mesial visual association cortices (lingual and fusiform gyri) and subjacent white matter	Failure to recognize faces
Agnosia for words	Left occipitotemporal cortex	"Pure" alexia—fails to read words normally given normal language and sensory visual function
Agnosia for scenes	Bilateral or right posterior artery infarction involving the fusiform and lingual gyri, extending to the parahippocampal gyrus	Failure to recognize landmarks or known scenes
Developmental agnosia	No obvious neural concomitant on clinical scanning	Difficulty in acquiring mastery over word or face recognition (developmental dyslexia or developmental/congenital prosopagnosia)
Posterior cortical agnosia	Focal right temporal or occipital lobe atrophy or both	Progressive decline in complex visual functions and recognition

inability to "see" more than one object at a time—is also regarded as a type of visual agnosia. Some cases evince fairly "pure" forms of one of these agnosias, but there are many reported cases in whom some subset of the specific forms can co-occur. Some of the more common subtypes of visual agnosia are described in this entry.

Visual Object Agnosia

The term *visual agnosia* was coined by Sigmund Freud to refer to the problems observed in some individuals with object recognition problems, but is classically divided into two broad categories: *apperceptive mindblindness* and *associative mindblindness*. A person with apperceptive agnosia is impaired at constructing a perceptual representation from the visual input and, consequently, is unable to copy, match, or identify a drawing based on the impoverished visual representation derived from the image. Apperceptive agnosia corresponds to the breakdown at the stage of visual processing at which the elementary features of the stimulus are processed and its structural description is achieved—a relatively early stage of the visual recognition system (see Table 1 for description of all agnosia types as well as neuropathologic basis and clinical manifestation). In contrast, a person with associative agnosia cannot use the well-specified perceptual representation to access stored knowledge of the object's functions and associations—such an individual is able to copy and match the object (or a drawing/rendition of it) even though unable to identify it (this disorder is often described as *perception stripped of meaning,* to borrow the phrase from Hans-Lukas Teuber). Whether the derived percept is truly normal in associative agnosia and simply cannot be used to access meaning or whether it is still not sufficiently well derived is a topic of much contention.

One reason that the visual agnosias are so intriguing a class of clinical phenomena is that they have important implications for current theories of high-level vision. In the service of elucidating normal perception, then, more fine-grained neuropsychological accounts as well as computational accounts have fractionated the classical distinction between apperceptive and associative agnosia further because of the growing understanding that visual object recognition comprises a number of distinct steps, in transforming the retinal input into representations that reflect invariant properties of objects in the real world. In the course of doing so, these authors have identified agnosias that arise at different stages of object processing. One such addition is *integrative agnosia.*

Patients with integrative agnosia appear to have available to them the basic features or elements in a display but are unable to integrate all aspects into a meaningful whole. These patients operate in a piecemeal manner to identify objects, sometimes over-segmenting the single input object into several different objects (e.g., identifying the handle of a fork as one object and the tines as a second). These individuals may perform normally on visual matching and copying tasks but perform poorly when required to bind visual elements in a spatially parallel fashion across a field containing multiple stimuli. The failure to integrate the disparate elements occurs equally with displays of two- and three-dimensional stimuli and with black-and-white and chromatic displays; in some cases, however, the presence of depth, color, and surface cues may be of some assistance to the patients in segmenting the display. These integration/segmentation problems are most clearly demonstrated when there are multiple items present, such that there is competition in assigning elements between shapes, as in displays with overlapping shapes or when boundary assignment is required. Interestingly, in some patients, the presence of local information is so captivating that it reduces the efficiency of visual recognition; in contrast with normal perceivers, some patients with integrative agnosia identified silhouettes better than line drawings, whose internal details apparently led to incorrect segmentation. Figure-ground segregation and other forms of perceptual grouping, such as deriving a unified whole based on Gestalt heuristics, may be especially challenging for such individuals. The rapid and efficient access to the local information may impede the patients' ability to gain access subsequently to the global information.

Visual object agnosia, especially of the integrative or associative type, can be fairly specific to a semantic category, affecting predominantly living or animate objects or affecting mainly recognition of nonliving or inanimate objects with the latter form being the less frequent manifestation. Interesting theoretical exchanges about the type of information (whether functional versus perceptual) tapped for the recognition of living versus nonliving objects as well as questions about differential lesion localization in these two cases abound in the literature.

Prosopagnosia

Individuals with prosopagnosia are unable to recognize individual faces although they are clearly capable of detecting whether a face is present in the input. The disorder may be so profound that the affected individual may fail to recognize himself or herself from photographs and may fail to recognize family members and close friends too. In many instances, these patients can describe the face in detail, including the age and gender of the person, but still be unable to say whose face it is. The ability to extract information about emotional expression is preserved in some cases but impaired in others. Invariably, these patients rely on nonface characteristics such as gait or voice to recognize the individual. The deficit is typically perceptual in nature, rather than arising from a memory (although there are prosopamnesic cases for whom this is the core of the deficit) or semantic deficit, or from a failure to label the face (an anomia). In most cases, the affected individual also performs poorly at discriminating between two faces, even novel faces and even under conditions in which they are given unlimited time in which to make the discrimination decision. Many studies suggest that these patients process faces differently than do controls following the lesion, focusing more on individual features than on the holistic or second-order relations between the features. The lesion that gives rise to prosopagnosia is usually secondary to occipitotemporal lesions, affecting the fusiform and lingual gyri, and the growing consensus is that a unilateral right lesion to these regions is sufficient to give rise to this disorder.

Agnosia for Words

This is also known as pure alexia, alexia without agraphia, or pure word blindness. Although this phenomenon is usually discussed in the context of language impairments, it is an agnosic symptom because subjects who suffer from this deficit show a language impairment limited to visually presented stimuli (e.g., reading), but not to auditorily presented stimuli. These patients may be able to spell words out loud and to write well but fail to read their own handwriting subsequently. This disorder has also been called ventral simultanagnosia to indicate the failure to process multiple letters simultaneously, and this failure manifests most dramatically in word reading where individuals laboriously and sequentially process one letter at a time (giving rise to the label "letter-by-letter" reading). Pure alexia is one of the more common forms of agnosia and can be severely debilitating, with some patients requiring 1.4 seconds to process each letter in a string. Whether this form of agnosia is entirely limited to word recognition or whether other classes of visual objects are also affected, perhaps to a lesser degree, remains controversial. The lesion site is typically in the left ventral occipitotemporal cortex, sometimes, but not always, involving the splenium of the corpus callosum.

Agnosia for Landmarks and Environment

An impairment in recognizing landmarks or scenes, referred to as topographic agnosia, can co-occur with prosopagnosia or it can also occur in isolation. As with other forms of agnosia, these patients perform well on a wide range of memory and basic perception tasks. In these topographic cases, familiar landmarks and buildings lose their familiarity to the patients. Unsurprisingly, these patients get lost and are unable to learn new routes. They show undue reliance on street names and numbers of buildings to identify the landmarks. Topographic agnosia can be differentiated from other disorders affecting spatial orientation in a large-scale environment and a taxonomy. The lesion giving rise to topographic agnosia most commonly follows bilateral or right posterior artery infarction, and the lesions (as in prosopagnosia) may implicate the fusiform and lingual gyri, extending to the parahippocampal gyrus. Neuroimaging studies provide converging evidence for topographic-specific representations in these cortical regions, such as in the so-called parahippocampal place area.

Developmental Forms of Agnosia

The taxonomy and illustration of some forms of agnosia described earlier refer to the object recognition failures in individuals who were premorbidly normal. There is growing interest in some forms of agnosia that appear to be present from childhood. These childhood agnosias may be subdivided into two subgroups: *developmental agnosia* in which individuals are born normal and then become agnosic following a lesion, such as stroke, sustained during childhood, and *congenital agnosia* in which the disorder is present from birth or, at a minimum, lifelong, in the absence of any obvious neurological concomitants. Developmental dyslexia, or at least one subtype thereof, may be a form of childhood agnosia, and although some individuals appear to have an obvious underlying neural concomitant, this is not the case for all individuals. Recently, there have been several reports of individuals who are congenitally prosopagnosic and reports of individuals who are congenitally agnosic for color. Much research remains to be done with the individuals with the congenital variants to characterize the disorder fully and to uncover the underlying neural mechanism that may give rise to these disorders. There also appears to be a familial hereditary aspect associated with these disorders, and this promises a fruitful avenue for further genotype studies in these individuals and their family members.

Progressive Posterior Cortical Atrophy

Just as there appear to be forms of agnosia that arise in childhood, so there appear to be forms of agnosia that can occur relatively selectively as a form of progressive cortical deterioration associated with aging. Posterior cortical atrophy refers to the progressive decline in complex visual processing ability along with relative sparing of other cognitive and perceptual function. It is associated with occipitoparietal atrophy and hypometabolism on single photon emission computed tomography (SPECT) or positron emission tomography (PET) scans and can be independent of Alzheimer's disease. Progressive prosopagnosia is a degenerative disorder in which there is a progressive impairment in the recognition of faces. This syndrome is part of the fronto-temporal dementias (FTDs), which may present as focal atrophy in any combination of the right and left frontal or temporal cortices and is rather uncommon. Other forms of progressive agnosia may include agnosia for words and agnosia for objects but further description of such cases and systematic data collection are required in such cases.

AIR QUALITY

Residents who live near refineries or pig farms may be exposed to air that is of reduced quality, a situation that will rarely go unnoticed. They may perceive the air as unpleasant, unacceptable, and not appropriate for inhaling—all of which connotations are implied by the term *quality*—and they are well equipped by their senses to make such judgments. This entry provides an outline of the sensory systems and measurements involved in air quality evaluation, the health effects of exposure to bad air, and guidelines established to protect humans from exposure to bad air.

Senses Involved in Air Quality Judgment

Our sense of olfaction contributes to our evaluation of air quality by imparting sensations of intensity, (un)pleasantness, character (e.g., whether the odor smells solvent-like or putrid), and identity ("This is diesel fuel"). In addition, many airborne chemicals give rise to feelings of burning and stinging in the eyes, nose, or upper airways associated with the *common chemical sense (chemesthesis).* Both senses contribute to a person's evaluation of air quality. For example, air quality will be judged as bad when a person smells ammonia while feeling a sting up the nose during work.

Health Effects and Contributing Factors

We distinguish between indoor air quality and outdoor air quality. The air quality out of doors can be bad near highways, in industrial areas, and near animal operations. Indoor air quality may be jeopardized in offices as a result of bad ventilation, in the workplace when working with organic solvents, or at home and in schools because of fumes from carpet glue or building materials.

Depending on the chemical and its concentration, people may experience health effects from exposure such as sensory irritation of the eyes, nose, and throat; respiratory problems; or even central nervous system effects such as losing consciousness. Exposure to toxic substances at work can damage the olfactory epithelium—where the odor receptors are located—and diminish a person's sense of smell. On the other hand, decreased odor sensitivity to chemicals as a result of occupational exposure may also be the result of adaptation. Often, the situation reverses after exposure has discontinued.

We speak of *direct* health effects, such as described earlier, when people report health effects that are in line with toxicological models concerning the relation between health effects and chemical concentration. Yet, complaints about air quality and associated symptoms cannot always be explained scientifically. This may be the case when chemical concentrations cannot be measured with detection instruments, or are too low to account for the reported effects. This may be explained by individual variability in sensitivity because some people can pick up certain smells at much lower concentrations than other people can—or detection instruments—and yet others are sensitive because of allergic conditions or asthma.

Health effects may also be *indirect* consequences of chemical exposure, in the sense that the effects are mediated by the perception or interpretation of the odor. For example, when people smell an unpleasant odor near a factory, they may interpret that odor as a warning signaling harm, and react accordingly. Such reactions may involve a stress response, which causes physiological changes in the body leading to increases in blood pressure, heart rate, and sweating. In this manner, health effects that were really brought on by stress associated with perception of odor as threat can be mistakenly attributed to the chemical composition of the odorous air.

To better understand how air quality is perceived in the latter scenario, psychological factors need to be considered. Many studies have focused on annoyance experienced from exposure to malodorous air as an indicator of bad air quality. Being worried about the environment, or potential health effects, as well as endorsing certain beliefs such as that unpleasant odors can threaten your health, contribute to this annoyance. Furthermore, intensity of the odor, frequency and duration of exposure, and unpleasantness are all predictors of annoyance.

The discrepancy between subjective perceptions of air quality and objective air quality can become quite extreme, as in *multiple chemical sensitivity (MCS)*. MCS is a syndrome of still unexplained causes, characterized by subjective symptoms such as nausea, muscular pain, memory difficulties, and fatigue following low levels of chemical exposure.

Measuring Air Quality and Setting Standards

To protect workers from adverse health effects related to bad air quality at work, occupational exposure limits (OELs) have been formulated by government agencies and professional organizations. These define the highest levels of chemicals to which a human may be exposed without experiencing adverse health effects. For a number of substances, irritation of the nose, throat, and eyes provides the base for the OEL, whereas for some other (obnoxious) odors, odor effects provide the base. To assess the levels where chemical substances start to irritate or smell, human odor or irritation detection thresholds (i.e., how strong the chemical needs to be before it is noticeable as either odor or irritation) have been determined using *olfactometry*. Irritation thresholds can also be measured directly at the eyes instead of the nose. More objective assessments of sensory irritation include the electrophysiological *nasal mucosal potential,* which refers to the summed electrical response of the trigeminal chemoreceptors in the nasal mucosa, or ocular hyperemia (“red eye”), which can be assessed by comparing photographs of the eyes pre- and post-exposure.

Standards for outdoor air typically aim to keep annoyance from odor at acceptable levels. Annoyance and related complaints are assessed via surveys or resident diaries in the area as indicators of effects of odor exposure. Olfactometric assessments of threshold or pleasantness evaluations of air sampled near the source and evaluated by a trained panel of judges in a lab, or by a “sniffing panel” at various distances from the source itself, are examples of methods used to index odor dose. Formulating guidelines employing dose-effect relationships based on the previous, while considering economical and financial interests of the involved parties, can present a major challenge to the (local) governmental bodies involved in standard setting.

So far, emphasis has been on perception of bad air quality to alert a person to a health hazard. However, air quality can also be good and promote health. Lemon scent, for example, has been shown to enhance both positive mood and physiology.

AMBLYOPIA

The most common cause of vision loss in children of the developed world is a developmental disorder called *amblyopia,* sometimes called lazy eye. The term *amblyopia* is used to refer to a heterogeneous group of conditions that present to the ophthalmologist as reduced visual acuity in one eye despite normal ocular health and optimal refractive correction (not correctable with glasses). The fellow (unaffected) eye demonstrates normal clinical visual acuity. Amblyopia usually begins in infancy and becomes acute in childhood. It is associated with multiple conditions, such as a monocular cataract, or more commonly a deviated eye or a difference in near- or far-sightedness between the two eyes. The typical result is poor vision in one eye and severely impaired binocular vision. These abnormalities usually persist into adulthood. Many people know someone affected, given its prevalence of 2 to 4% in the general population. This entry describes types of amblyopia, visual loss, etiology, neural substrates, and treatment of amblyopia.

Types

Most specialists distinguish *anisometropic* amblyopia, which refers to conditions of unequal refractive error (focus) between the two eyes, from *strabismus,* which refers to a deviated eye that may or may not involve loss of acuity. Depending whether the eye deviates toward the temple or toward the nose, the strabismic condition is called exotropia or esotropia. In the United States, esotropia is the more common presentation. In the case of exotropia, some subjects adopt the strategy of moving their head to alternate left and right eye viewing, thus acuity is preserved in both eyes, but binocular integration does not develop normally.

Visual Loss

The visual deficits seen in anisometropic and strabismic amblyopia are different in many respects, yet they share some common characteristics. Numerous studies have compared the monocular performance of amblyopic and fellow eyes in both subtypes. The impaired eye in both types of amblyopia generally exhibits decreased visual acuity and reduced contrast sensitivity (particularly for fine patterns). However, strabismic amblyopes can be distinguished from the anisometropic subtype by an additional loss of accuracy for position judgment tasks—for example, judging the alignment of two lines (called Vernier acuity). Other tasks with stimuli containing multiple targets demonstrate crowding effects in strabismic observers. In other words, a target that would be visible when presented alone can no longer be discerned in a crowded array of targets because of interference from nearby elements. Moreover, strabismic observers sometimes report geometrical distortions in their perceptions. All these additional deficits support the idea that strabismus may cause a different type of amblyopia than does anisometropia, with greater spatial localization impairments. Finally, both types of amblyopia show deficits in tests that require binocular integration such as depth perception, with the strabismic subjects generally performing worse than anisometropic. In particular, the type of depth perception that integrates the small differences in the left and right eye's image (called stereopsis) is severely affected.

Etiology

Debate continues about how the strabismic and anisometropic subtypes differ from each other in disease etiology and visual performance. One approach to this abiding question is to consider the relationship between performance on monocular versus binocular tests. Almost all subjects with amblyopia show impairments on binocular tests, but subjects can be categorized based on the degree of residual function. Most subjects with strabismus, and some more severe subjects with anisometropia, are non-binocular by this definition. It has been recently proposed that the degree of impairment in binocular functions may predict the pattern of monocular deficits, and thereby help explain the mechanisms of amblyopia. Specifically, suppression of the amblyopic eye's inputs by the fellow eye's inputs may be an important etiological factor in the progressive development of amblyopia in non-binocular subjects. This may be an adaptive response to avoid double vision, but it leads to loss of binocular integration, and monocular impairments for spatial localization abilities such as Vernier acuity.

Neural Substrates

General consensus is that the cerebral cortex is the major site of neural changes in amblyopia, historically based on animal models. These models generally induce an amblyopia-like condition through monocular enucleation, lid suture, blurring, or eye deviation during development. In general, impaired vision in one eye leads to abnormalities in the visual system of the brain because the weak eye fails to form normal neural connections that allow it to cooperate with the dominant eye. Specifically, these models show reduced visual acuity and contrast sensitivity in the physiological response of individual neurons in the primary visual cortex (V1) driven by the amblyopic eye. They also show decreased numbers of binocular or disparity-sensitive neurons. Moreover, there is some physiological evidence for active suppression of the strabismic eye by the fellow eye in V1 binocular neurons. Nevertheless, the overall extent of physiological deficits measured to date in V1 is not sufficient to account quantitatively for the visual performance losses observed.

Growing evidence indicates that dysfunction at higher-levels of the visual cortex is important for the neurological account of amblyopia. Currently, this evidence comes from animal studies, from human visual performance, and especially from human brain imaging techniques. Limited information is available about higher-level cortical visual areas in animal models, but deficits have been generally reported. In studies of visual performance, higher-order impairments have been discovered that relate to global form and motion perception, and are not likely to be a simple consequence of neural deficits at the earliest stages of the visual system. During the past 10 years, anatomical brain imaging of children with acute amblyopia as well as functional brain imaging of metabolism levels of adults with long-standing amblyopia has been possible. The results clearly indicate that both the primary visual cortex and higher-level cortex in the parietal and temporal regions are abnormal in subjects with amblyopia.

Treatment

Current strategies for treating amblyopia rely on occluding (patching) the fellow eye, encouraging a type of passive visual training with the amblyopic eye. These therapies can be moderately successful in improving acuity in the weak eye under optimal conditions, when the amblyopic deficit is small and treatment is started early in life. However, patient compliance is often poor, and binocular integration often remains impaired. New approaches are needed to pioneer more effective therapies. Finally, the advent of modern human genetic analysis is relevant to amblyopia because a genetic component to amblyopia is supported by twin studies and other analysis. The potential identification of specific genes would benefit our understanding of the etiology and subtypes of amblyopia in the future.

AMERICAN SIGN LANGUAGE

American Sign Language (ASL), described in this entry, is the visual-motor language used among members of the deaf community in the United States. ASL is one of many different sign languages used by deaf persons around the world. In most countries, deaf persons have their own distinct sign language. Once ASL and other signed languages were recognized as true languages, investigators began examining how the modality difference between spoken and signed languages affected language acquisition, language structure, and brain processing.

For centuries, the sign languages used by deaf persons were not accepted as true languages and often were depicted as consisting primarily of pantomimic gestures. Such pantomimic gestures or "pictures in the air" were not seen as constituting a valid symbol system. Although some ASL signs are pantomimic and clearly resemble the objects, actions, or properties for which they stand, the meanings of most ASL signs are difficult for nonsigners to guess correctly. Rather, the meanings associated with most ASL signs depend on the usage of these signs within the signing American deaf population.

Today, most scholars accord full linguistic status to ASL and other sign languages. The person most responsible for changing people's views about the linguistic basis of sign languages was William Stokoe. Stokoe's pioneering research showed that ASL signs had a distinct linguistic structure and that this structure was different from that of English and other spoken languages. After examining the formational structure of numerous ASL signs, Stokoe proposed that three aspects of sign formation distinguished any one sign from another. These three formational elements were the place or location where a sign was made, the shape or configuration of the hand(s), and the action or movement of the hand(s) and arm(s) while making the sign. Altogether, Stokoe identified 55 different locations, handshapes, and movements from which all ASL signs were composed. These different formational elements operate in a manner largely analogous to phonemes in spoken languages.

Studies of the historical origins of ASL have shown a strong influence of French Sign Language. This influence is related to the establishment of public education programs for deaf students. In 1815, American Thomas H. Gallaudet traveled to Europe to learn about educational programs for deaf students. He returned to the United States with Laurent Clerc, a highly talented teacher from the school for deaf students located in Paris. In 1817, Gallaudet and Clerc helped establish the first public school for deaf students in the United States, now known as the American School for the Deaf. As a prominent teacher there, Clerc relied heavily on his knowledge of French Sign Language. Many of the signs used at the American School were widely disseminated when pupils went home and teachers moved to other newly established schools for deaf students. Some ASL signs, moreover, appear to stem from the indigenous sign-communication systems present among deaf persons in the early United States. Finally, because ASL is a vibrant, living language, new signs frequently are added to its lexicon as the need arises.

ASL and other signed languages may be learned at different ages and in different ways than spoken languages. The hearing status of the parents often affects how children acquire ASL. Most children (hearing or deaf) of deaf parents learn to sign much like hearing children of hearing parents learn to speak. These deaf parents model ASL usage and engage their children in conversation using ASL. Most deaf children, however, are born to hearing parents. Because these parents traditionally do not sign, their children often do not learn ASL until they attend a school for deaf students or join a deaf community organization. This process appears to be changing as more hearing parents and teachers learn to sign.

Because ASL and other sign languages are visual-motor languages, they often transmit information in quite different ways than auditory-vocal languages. ASL makes extensive use of visual and spatial relationships in its transmission of information. Changes in the direction of sign movement, the speed of sign production, the size of signs, and the location of signs in space affect the meaning of sign utterances. Some ASL verbs, for example, vary the direction of their movement to indicate who is performing the action, who the recipient of the action is, and where the action takes place. English, in contrast, relies quite heavily on word order and prepositions to convey such relationships. Given these differences in how information may be effectively transmitted in ASL and in English, it should not be surprising to learn that their grammatical systems are quite different.

The difference in modality between spoken and signed languages has led investigators to ask whether sign languages are processed in the same areas of the brain as spoken languages. Studies of persons who have experienced an aphasia or loss in language abilities (typically after suffering a stroke) provide one source of information on this subject. Damage to particular areas of the left hemisphere is related to certain forms of spoken language impairments; deaf persons with sign language impairments also show evidence of left-hemisphere damage in these same (or closely related) areas.

Although studies of aphasias in deaf and hearing persons have underlined important similarities in left-hemisphere processing for signed and spoken languages, more recent neural imaging studies of fluent ASL users have shown substantial right-hemisphere involvement as well. This right-hemisphere activation in ASL users may reflect the visuospatial processing present in signed languages but not involved in oral languages. Therefore, the answer to the question about whether signed and spoken languages are processed in the same areas of the brain is a complex one: they both show strong similarities in left-hemisphere processing, but the unique characteristics of signed languages such as ASL may activate right-hemisphere areas that are not required for spoken language processing.

Today ASL is seen as a full language capable of effectively conveying a wide range of information. How ASL transmits this information and where ASL is processed in the brain have been rich areas of research in recent years.

AMES DEMONSTRATIONS IN PERCEPTION

The Ames demonstrations consist of about 25 laboratory set-ups that were designed and constructed, from about 1934 to 1950, by a U.S. artist and optical physiologist named Adelbert (Del) Ames, Jr. They became commonly known as the *Ames demonstrations in perception* in the early 1950s, when one of Ames's associates, perceptual psychologist William H. Ittelson, published a users' manual (with instructions on how to rebuild them) with that phrase as its title.

Although there has never been consensus about the validity or significance of these demonstrations, they are most often said to show the ambiguity of retinal images when an object is perceived from a single static point of view. It is also often claimed that they show that the process of seeing is not merely the passive reception of facts, but an interactive (or constructive) process by which we arrive at conjectures, based on retinal data, past experience, expectations, and other factors. This entry describes the Ames demonstrations in perception.

Background

To understand the Ames demonstrations, it is helpful to know the circumstances that contributed to their development. Early in his career, Ames studied law at Harvard University, where one of his influences was philosopher and psychologist William

James, a leading proponent of pragmatism. After practicing law only briefly, Ames turned instead to the study of art, and for several years, collaborated with his sister, Blanche Ames Ames, a painter and illustrator whose husband was a scientist. In the process, Ames's interests shifted toward scientific methods of painting more "realistic" scenes, a quest that eventually led him to the study of optical physiology, and, in time, to join the research faculty at Dartmouth College. There, in 1928, he discovered a visual dysfunction he called *aniseikonia,* a condition in which a person's two retinal images differ enough in size and shape that the brain cannot easily fuse them as one. Some of the Ames demonstrations (which he invented later) may have been prompted by this discovery, partly because those with aniseikonia are susceptible to spatial distortions: Flat surfaces tend to look tilted, rectangles look trapezoidal, and trapezoidal shapes look rectangular.

The Demonstrations

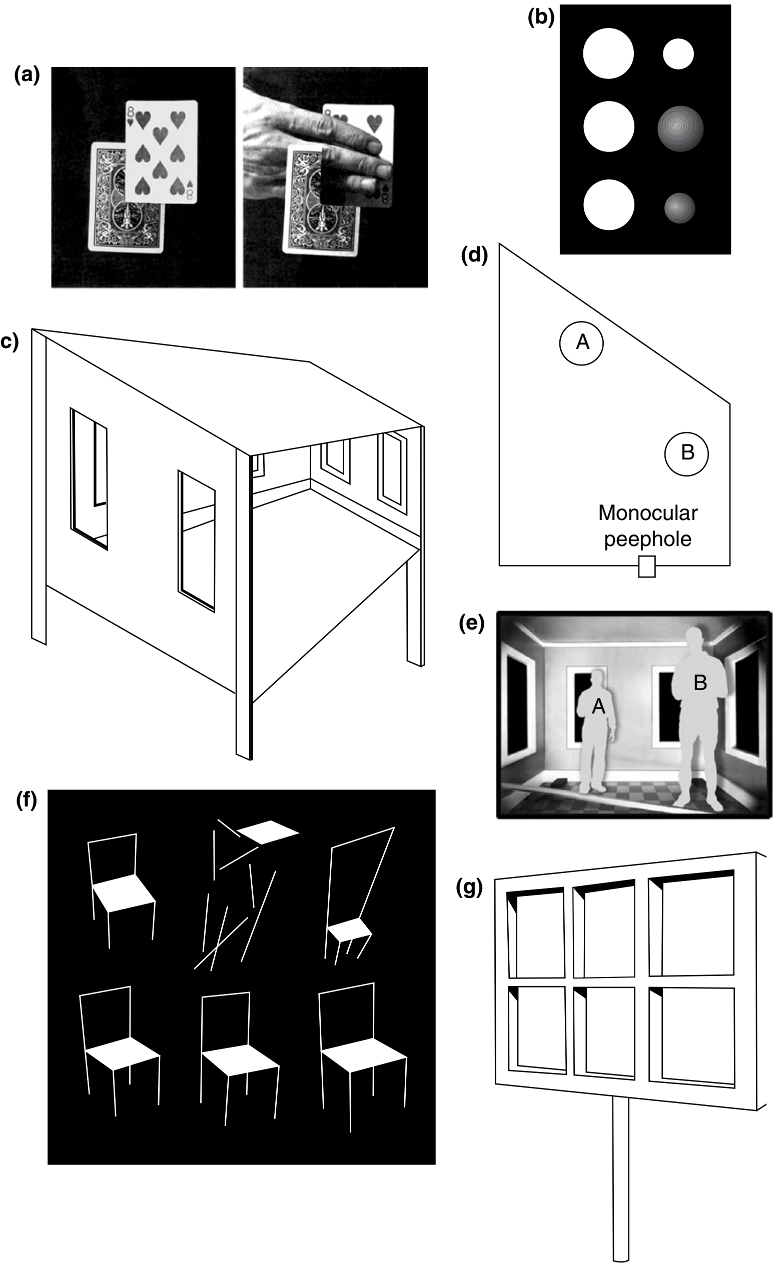
As early as 1934, Ames designed his first "distorted room" in which, from a designated viewing point, trapezoidal walls appear to be slanted rectangles (Figure 1, c–d). His initial room was monocular, requiring that it be viewed through a one-eyed peephole. From that static point of view (and from no others), the space inside appeared to be a conventional room interior, with a checkerboard floor and three visible walls, with a pair of rectangular windows on each.

However, when other components were introduced into the space, the results were astonishing. If two people of the same height stood in opposite corners, one appeared to be tall, the other short; and if they exchanged positions, one appeared to grow, the other to shrink. A ball placed in a wooden trough appeared to roll uphill. Liquid poured from one container to another appeared to be strangely inclined to the side. And if an observer was given a lecturer's pointer and instructed to touch the room's back corners (while looking through the peephole), the result was a baffling sensation in which one's optical reality was at odds with one's kinesthetic reality.

The scientific reason for these "illusions" was the calculated distortion of the room, which is obvious when it is viewed from any point other than the peephole. Supportive of that, the right wall (in all its aspects: the windows, the molding, the checkerboard floor) is only one half the dimension of the left wall, while the rear wall is a trapezoid, inclined at an obvious angle. The floor and ceiling are also inclined and distorted. Nevertheless, from the single position of the peephole, the shape of the room appears normal, so that, with that as the standard, things brought into the room will most likely look oddly misshapen.

People are generally taken aback when they first experience the Ames distorted room, partly because, even when they know in advance that the room is distorted, its effects may be no less convincing. The same is also generally true of Ames' other demonstrations, which he gradually developed in the remaining years of his life. Among the most interesting are the following:

- The *overlay* demonstration (Figure 1a) in which portions of certain playing cards were cut out and arranged to look as if they were in front of (and overlapping) other cards, when in fact they were behind.
- The *size-brightness* demonstration (Figure 1b) in which balloons were made to look nearer or farther away not by changing their actual distance from the viewer, but by precisely modifying their size and illumination.
- The *chair* demonstration (Figure 1f), invented in 1945, was installed in a large wooden box with three peepholes, spaced equally on the front. Looking through each peephole, one sees what seems to be a chair of the same size, in the same position (as shown on the bottom row of the illustration). However, in opening the lid and looking inside the box (as shown on the top row), it is evident that only one of the three is the customary shape of a chair, whereas the other two are constructions of wires, rods, and other shapes.
- The *rotating trapezoid window* (Figure 1g), which Ames invented in 1947, is a flat piece of sheet metal, in the shape of a trapezoid and deceptively painted with shadows, that appears to be a normal dimensional window in perspective. Mounted on a motorized vertical shaft, as the window rotates, it appears instead to oscillate (to sway back and forth). When other components are suspended from it, they behave in unbelievable ways.



Figures 1 Views of Five of the Laboratory Set-Ups (Developed by Adelbert Ames II) That Are Commonly Referred to Now as the Ames Demonstrations in Perception

Notes: (a) The *overlay* demonstration, in which a playing card, from which a portion has been cut out, is positioned in front of a second card, making the furthermost card appear instead to be in front. (b) The *size-brightness* demonstration in which two balloons appear to move closer or further away by changes in size and illumination. (c–e) The *distorted room* in which people and commonplace objects are viewed inside a room that seems (from one point only, through a monocular peephole) to be a simple, normal room. Seen from any other angle, it is apparent that the right wall is one half the size of the left wall, the rear wall is a trapezoid, and both the ceiling and the floor are oddly shaped and slanted. (d) A bird's-eye view indicates the position of the peephole, and (e) the physical locations of two people of comparable height. (f) In the *chair* demonstration, three forms viewed through peepholes appear at first to be chairs (bottom row), but look dramatically different from a higher alternative angle (top row). (g) In the *rotating trapezoid* demonstration, a trapezoidal shape that has been painted to resemble a perspective view of a window, and mounted on a motorized shaft, appears not to rotate but to sway back and forth.

Anamorphosis

The Ames demonstrations were not unprecedented, in the sense that they have much in common with an historic artistic distortion technique called *anamorphosis*, and to other perspective illusions employed in the design of theatrical sets.

In anamorphic constructions, the image looks distorted when viewed frontally (as is customary) but correctly proportioned when seen from the side (often indicated by a peephole). For example, Ames was well acquainted with the work of scientist and philosopher Hermann von Helmholtz, who more than 50 years before had noted that an infinite variety of distorted rooms could be devised that, from a monocular peephole, would nonetheless seem to be normal.

Far in advance of Helmholtz, this same kind of visual distortion was used as early as 1485 by Leonardo da Vinci (and probably even earlier by Chinese artists) as an offshoot of perspective. As early as the 16th century, a group of Dutch artists made anamorphic "peepshows" called *perspectyfkas* or perspective cabinets, a few of which still exist and are now on display in museums. These artistic constructions have much in common with the Ames distorted room, the chair demonstration, and the rotating trapezoid window. In fact, many of the Ames demonstrations make use of trapezoids that appear rectangular, tilted surfaces that appear to be flat, or flat surfaces that appear tilted.

Most of the Ames demonstrations require (or at least work optimally with) a monocular peephole. This is because they rely on the fact that any number of external constructions could produce the same retinal image. Ames explicitly stated that (as Helmholtz had noted) he could have constructed an infinite number of distorted rooms, no two of which would have the same physical shape, yet each would appear to be normal. In the end, he only constructed a few.

Implications

The Ames demonstrations might never have become well known had they not been embraced and promoted by other people who saw them as palpable evidence of their own convictions. They were of particular value to proponents of transactional psychology (not to be confused with transactional analysis), a 1950s spin-off of pragmatism that was partly inspired by the "transactional approach" of philosopher John Dewey (who first saw the demonstrations in 1946, and then corresponded with Ames until 1951). Ames believed, as Dewey did, that we are not passive recipients of a given reality, but instead are active participants in a give-and-take exchange (a "transaction") in which split-second assumptions are made about the nature of reality.

The demonstrations have also had lasting effects on other aspects of culture. Even today, one or more of the demonstrations are invariably mentioned in textbooks on perception, and it is not uncommon for one or more to appear in television documentaries, video clips, cinematic special effects, or advertising commercials.

AMODAL PERCEPTION

Amodal (meaning "without" modality) *perception* is perception of information that is common or redundant across multiple senses (e.g., auditory, visual, tactile). Amodal information includes changes along three basic parameters of stimulation—time, space, and intensity. Properties of objects and events such as temporal synchrony, rhythm, tempo, duration, intensity, and co-location are common across auditory, visual, and proprioceptive stimulation. Properties such as shape, substance, and texture are common across visual and tactile stimulation. For example, the same rhythm and tempo can be detected by seeing or hearing the pianist strike the notes of the keyboard, and the same size, shape, and texture can be detected by seeing or feeling an apple.

Virtually all events occur across time, are distributed across space, and have a characteristic intensity pattern, so virtually all events provide amodal information. For example, speech comprises changes in audiovisual synchrony, tempo, rhythm, and intonation (intensity changes) that are common to the movements of the face and the sounds of the voice. Self-motion produces proprioceptive feedback (information from the muscles, joints, and vestibular system) that is synchronized and shares temporal and intensity changes with the sight of self-motion (e.g., seeing and feeling one's hand move). Perceiving amodal information is critically important for organizing early perceptual and cognitive development and for accurate perception of everyday events in children and adults alike.

The term *amodal* has also been used in a different sense—to refer to perception in the absence of direct information from a specific sense modality. For example, in visual perception, *amodal completion* describes how we perceive a unitary shape (e.g., a ball), even when part of the object or shape is occluded (hidden) behind another object (e.g., a block). Even infants can accurately perceive a partially hidden shape if the occluder is moved back and forth, progressively revealing and then hiding the object's contours. Scientists propose that we perceive unitary shape by detecting visual invariants (patterns that remain constant across change) through object motion, whereas others maintain that we must fill in the missing information by inference or cognitive processes. Whatever the process, the term *amodal* referring to incomplete information is not consistent with the previous definition (which refers to information that is fully available and can be directly perceived through more than one sense) and, thus, will not be discussed further. This entry describes the history, theory, and development of amodal perception.

History and Theory

For centuries, philosophers and scientists have been intrigued by how we perceive unified objects and events even though our senses provide specific information through separate sensory channels. How are these different sources of stimulation bound together? Further, why do our senses provide overlapping and redundant information for many qualities of objects? The concept of amodal perception addresses these important questions and dates back more than 2,000 years to the time of Aristotle. Aristotle proposed a *sensus communis* (an amodal or common sense) that detected qualities that were common to several senses. These common sensibles included number, form, rest, movement, magnitude, and unity—information that today is considered amodal.

Centuries later, philosophers such as John Locke and George Berkeley took a different approach to the question of perceiving object and event unity. They proposed that sensations had to be interpreted and integrated across the senses before a person could perceive meaningful objects and events. Until recently, developmental psychologists, including Jean Piaget, thought this process of integration developed gradually through experience with objects. By coordinating and associating what one sees with what one feels and hears, one could construct a coherent, three-dimensional world of objects and events.

This constructivist view was not seriously questioned until James J. Gibson's ecological view of perception emerged in the 1960s, and a view more consistent with that of Aristotle's reemerged. Gibson proposed that the different forms of stimulation from the senses were not a problem for perception, but rather provided an important basis for perceiving unitary objects and events. Our senses, he proposed, work together as a unified perceptual system to pick up information that is invariant or common across the senses—that is, amodal information. If we attend to amodal information, then there is no need to learn to integrate stimulation across the senses to perceive unified objects. Temporal synchrony (the most basic form of amodal information) has been described as the glue that binds stimulation across the senses. For example, by attending to synchrony, the sounds and sights of a single person speaking would be perceived as united. Sights and sounds that are perfectly synchronized belong together and constitute unitary events. Detecting this information prevents the accidental association of unrelated but concurrent sensory stimulation.

Development

Researchers now know that even very young infants are skilled at detecting amodal information, including temporal synchrony, tempo, rhythm, intensity changes, shape, texture, substance, and prosody in speech. Amodal information is highly salient and directs attentional selectivity, for both humans and animals, especially during early development. When videos of two different events are superimposed, playing a synchronous soundtrack to one of them allows even infants to selectively attend to the synchronous event while effectively ignoring the asynchronous one. This attentional salience may be partly the result of the enhanced neural responsiveness generated by redundantly presented amodal information compared with that observed for each modality alone.

The development of a surprising variety of skills depends on the detection of amodal information. Shortly after birth, infants move their eyes in the direction of a sound, coordinating audible and visible space. This provides a basis for detecting further amodal information common to the sight and sound. By 2 to 5 months, infants detect a variety of amodal aspects of objects and events. For example, they detect temporal synchrony, rhythm, and tempo uniting the sights and sounds of objects banging against a surface, as well as more refined temporal information revealing the substance (rigid and elastic) and composition of objects. Infants detect voice-face synchrony in speech by 2 months and later can use it to separate one speech stream from another concurrent one. Even information for emotion is detected by 5 months and is largely amodal, deriving from differences in the timing and intensity of movement and sound. Learning about the self also depends on detecting amodal information for self-motion. By 3 to 5 months, infants detect the congruence between the proprioceptive feedback from their own motion and the visual experience of that motion (e.g., by feeling and seeing their own legs move), and this provides an important basis for separating the self from other individuals. Even maintaining an upright posture requires detecting amodal information common to the visual flow and proprioceptive feedback from body motions. Young infants also detect the common shape, texture, and substance across tactile and visual exploration, allowing them to visually select an object they have previously explored only tactually. Amodal information can also be used to create the illusion of unity as in the *ventriloquism effect.* The ventriloquist creates amodal information by moving the puppet's mouth in time with his own speech sounds and can therefore fool the audience into perceiving that the puppet is speaking. Thus, amodal information simplifies and organizes incoming stimulation, providing a basis for perceiving unitary, multimodal events rather than a "blooming, buzzing confusion" of unrelated sights, sounds and tactile impressions.

ANIMAL CHEMICAL SENSITIVITY

Humans use their chemical senses in many facets of their lives, yet their abilities pale in comparison with those of most animals. Everyday demonstrations of the chemosensory prowess of animals include dogs tracking invisible chemical trails, mosquitoes homing in on human meals, and game fish lured to baited hooks. The chemicals, sensors that detect them, neural pathways that process them, and roles in the life history of animals are as diverse as are the animals themselves. This entry explores the nature and biological basis of such animal chemical sensitivity.

What Is the Chemical World of Animals?

Jakob von Uexküll, in the early 1900s, emphasized that the "umwelt," or sensory world, of each animal species is unique to it, being shaped through evolution to include those stimuli important to that species. Animals live everywhere, from the bottom of the deepest oceans, to the frozen polar caps, to the bowels of other animals, and each is adapted to detect stimuli that are present in that habitat and are of ecological significance to that species. Chemical information dominates the umwelt of most animals. Chemicals called pheromones reveal the nature of members of their own species, including sex, age, social status, health, and individual identity. Chemicals also inform the identity and location of food, shelter, home, predators, competitors, and more. The molecules that convey chemical information are diverse—they can be protons, such as sour-tasting acids in unripe fruit, or they can be macromolecules, such as sweet-tasting proteins in some ripened fruit.

Many animals are much more sensitive to odorants than are humans. Dogs and cats can detect some odorants at thousands of times lower concentrations than humans can. Although the olfactory systems of dogs, cats, and humans have a similar basic organization, the greater sensitivity of dogs and cats comes from their having many more olfactory receptor neurons in their noses. Moths have different "noses" than humans or dogs do, but their olfactory sensitivity to some odorants such as pheromones is also extremely high compared with that of humans.

However, some animals lack sensitivity to specific chemicals that are a central part of the sensory world of humans. Cats lack a sweet taste, a result of a loss of functional receptors in their mouths that detect sugars. Given cats' carnivorous diet, a lack of sweet taste is not a significant deficit.

High sensitivity of animals to particular chemicals is a proven or promised method of controlling populations of species that are pests to humans. Use of specific blends of pheromones in traps is a standard method of controlling some insect species. A similar application holds promise for an aquatic pest, the lamprey.

How Are Chemicals Detected?

Animal chemosensors are diverse in their structure and organization. This reflects differences in their phylogeny and life history. Sensors include nose and tongue of mammals, antenna of insects and crustaceans, pectin of scorpions, tentacles of sea anemones, osphradium of snails, and olfactory pits of squid. Terrestrial animals have olfaction and taste as their two major chemical senses, and these are distinguishable by the chemicals' carrier medium: olfaction uses volatile molecules delivered in air, and taste uses water-soluble molecules delivered in liquid. Aquatic animals mostly use water-soluble molecules, thus raising the question, can olfaction exist underwater? The answer is yes, as exemplified by frogs, which use their "nose" both underwater and in air. Chemical sensors, with their vast diversity, go beyond the dichotomy of olfaction and taste. Fish such as catfish have an olfactory organ; gustatory organs in the form of taste buds inside their mouth, on their barbels, and on their entire body surface; trigeminal chemosensors; and solitary chemoreceptor cells. Crustaceans have many types of chemosensors based on structural organization and innervation, even on a single antenna, mouthpart, or leg. Even the nose of a rodent has multiple chemosensory pathways that differ in structure and function, including the main olfactory epithelium, vomeronasal organ, trigeminal system, septal organ, and Grueneberg ganglion.

Animals have evolved special means of acquiring chemical stimuli and delivering them to the molecular binding sites to initiate the sensory process. Sniffing in mammals, pumping in the olfactory cavity of fish, flicking of antennules and beating of fan organs in crustaceans, and vibrating of wings and antennae of insects all enhance chemical sampling. Once in the nose, volatile chemicals bind to odorant binding proteins, which solubilize and deliver the chemicals to receptors.

Chemoreceptor cells from different phyla have diverse cellular origins, including neurons and modified epithelial cells. Chemoreceptor cells may be packaged into units, such as taste buds of vertebrates or sensilla of arthropods, the latter being porous extensions of the exoskeleton that allow chemical stimuli to reach the chemoreceptors within them while providing protection. Chemoreceptor cells across the animal phyla transduce chemical information into electrical signals using similar principles and molecular components. For example, many animals use metabotropic signaling pathways that contain receptors coupled to intracellular second messenger pathways for amplification of signals. But the components of these transduction cascades can vary across animals.

A common principle for coding of olfactory information, including in some vertebrates, arthropods, and mollusks, is to have the projections of receptor cells and the brain interneurons receiving those projections organized into units, called glomeruli. The "olfactory brains" are composed of a few dozen to thousands of these glomeruli, the number depending on the species. Each glomerulus is activated by a subset of odorants, some odorants being more effective than others, and each odorant activates more than one glomerulus, some more than others. Thus, each odorant is discriminated based on the distinctive activation pattern generated across the glomeruli because of that odorant's unique molecular structure.

ANIMAL COLOR VISION

Under daylight conditions, most humans experience a richly colorful world in which objects appear to maintain consistent color appearances—such as green grass or blue sky. That familiar association makes it natural to believe that color is an inherent property of objects and lights. Although at first glance this idea seems reasonable, it is wrong. Color is actually a feature of our experience that is constructed from the overall pattern of illumination reaching the eye at any moment as subsequently analyzed and conditioned by the particular details of the organization of the eye and the visual system. Eyes and visual systems show great variation across the animal kingdom, so it is hardly surprising that other animals may experience color in ways that are strikingly different from those familiar to humans. This entry describes how and why color vision varies among the animals.

Critical Definitions and Underlying Biology

Light reaches the eye directly from illuminants, such as a computer monitor, or as reflected from surfaces of objects, such as an apple sitting on the desk. Ignoring changes that may occur across space or over time, light can be physically characterized as varying along just two dimensions—wavelength and intensity. The presence of color vision is formally defined as the capacity of an individual to successfully discriminate between lights or surfaces based on differences in their wavelengths, irrespective of what their relative intensities may be. Note that the definition asks nothing about the quality of what is seen, only whether there is consistent discrimination. If any animal can make such discriminations, it has color vision.

Once the presence of color vision is established, it becomes possible to further characterize the nature of the capacity, for example, by asking what particular wavelengths can and cannot be successfully discriminated. Each of the large range of such tests can provide useful information about the color vision of any given animal. A particularly important description of color vision comes from using a testing procedure called color matching. In such a test, lights of different wavelengths are added together in an attempt to find out which mixtures of lights appear identical to other lights. Although the analysis of such matches can be a bit complex, what results is a description of the dimensionality of color vision. In such an account, if an animal lacks color vision completely, it is characterized as being *monochromatic* (i.e., it experiences a world that is devoid of color variation), an animal with a single dimension of color vision is called *dichromatic,* two dimensions are *trichromatic,* three dimensions *tetrachromatic,* and so on. As the dimensionality of color vision increases, there are corresponding and dramatic increases in the number of separate colors that can be discriminated. For example, it is estimated that a human having dichromatic color vision (a common form of color blindness) can discriminate among some 10,000 surface colors, whereas a human with trichromatic color vision, normal for our species, has the capacity to discriminate something in excess of one million colors.

There is a compelling link between the dimensionality of color vision and the biology of the eye. In the eye, light is absorbed by photopigments that are located in the photoreceptors—in vertebrates, these receptors are called cones. Different types of photopigments vary according to the wavelengths to which they are most sensitive. The number of types of photopigment that are active in daylight viewing is typically directly related to the dimensionality of color vision—monochromats have only a single type of cone pigment, dichromats have two, trichromats have three, and so on. Because of this linkage, it is possible to infer the nature of an animal's color vision from an analysis of the number of types of photopigment contained in eye or, because the photopigment proteins (opsins) are specified by single genes, from direct studies of these opsin genes. Both of these shortcuts allow scientists to learn something about the nature of color vision in a large number of animals for which behavioral tests of color vision may be impractical for one reason or another. This tactic can even be used to infer what color vision must have been like in some ancestral species.

Distribution of Animal Color Vision

What animals have color vision and what is their color vision like? That seemingly simple question cannot as yet be fully answered. A principal problem is that most animal species remain unexamined. That is not surprising because even the total number of animal species remains unknown, with current estimates ranging from perhaps 10 to 100 million species. One useful clue to understanding the extent of animal color vision comes from examinations of the phylogeny of opsin genes. That approach shows that two classes of daylight photopigments (the minimum necessary for color vision) were present early during evolution; certainly at a time well before vertebrates first appeared more than 500 million years ago. It seems likely that color vision has been a persistent feature of animal life over much of the sweep of their history. Beyond that, there have been concrete studies of color vision in enough animal species to permit a number of generalizations.

Invertebrates

This group constitutes the vast majority (about 95%) of all animals. Among the invertebrates that have been studied, there is positive evidence for presence of color vision in many different species—these include familiar animals such as mites, spiders, crustaceans, and a lengthy list of insects (bees, grasshoppers, wasps, butterflies, moths, and various flies). Because of their commercial importance, many good behavioral and biological studies have been done on honeybees. For example, in a behavioral test of color vision, bees might be trained to fly to a small dish of sugar water that is placed on a blue patch of a checkerboard composed of many different colored papers. Over trials, the location of the blue patch is moved about the checkerboard randomly. If the bee consistently finds that blue patch, it must be doing so by using its color vision. Tests like this showed that bees have three types of photopigment and well-developed trichromatic color vision. Early studies led to the surprising discovery that one of three photopigments in the bee has its maximum sensitivity to the ultraviolet (UV) wavelengths, and thus bees can see a part of the spectrum that is invisible to humans. This capacity proves to be highly useful because many flowering plants provide UV signals that bees can exploit in their quests for pollen. Like the bees, many other invertebrates have been found to have UV photopigments, and thus, they too must inhabit a visual world that is quite foreign to humans.

Vertebrates

Although representing only a tiny minority of all animals, there have been good studies of color vision on representative species from each of the large vertebrate groupings. Outside of the mammals, many reptiles, amphibians, fishes, and birds have UV pigments, some having three and others four classes of cone pigments. Many of these species thus have the potential for trichromatic or tetrachromatic color vision and among familiar animals, both goldfish and pigeons have indeed been shown to have tetrachromatic color vision.

Color vision in mammals presents a different picture. Most mammals have only two types of cone pigments, and thus usually have dichromatic color vision. This condition is characteristic of many familiar mammalian species such as dogs, cats, squirrels, and cattle, as well as the close relatives of all these animals. Among the mammals, primates are unique in having added a third type of cone pigment during their evolution and, as a consequence, many primates, for instance humans and their close ape and monkey relatives, have trichromatic color vision. Interestingly, some primate species, among them humans and most of the monkeys found in Central and South America, have striking individual variations in color vision. In humans, such variations include the familiar cases of red-green color blindness, a condition mostly found among men.

ANIMAL DEPTH PERCEPTION

Cats jump onto tables, horses jump over fences, birds land on window ledges, and chameleons can pick insects out of the air with their long tongues. All of these behaviors, and any others that involve moving around in an environment, require the ability to judge depth and distance. Because depth perception is such an important survival skill, evolution has provided almost every species with a repertoire of ways to evaluate how far away a visual object might be. This entry describes cues for depth, assessing animal depth perception, and animals' use of depth cues.

Cues for Depth

Information about depth and distance is available from several external depth cues in the environment and from internal cues that rely on physiological mechanisms to calculate the position of an object. For the most part, the external cues are referred to as monocular, or pictorial, cues because they can be seen using just one eye, and because they provide the impression of depth that one sees when looking at photographs or paintings. These cues include linear perspective, changes in the density of surface texture, shading, and relative size.

A second class of cues relies on the physiological processing of information created by stimuli that are at different distances. In effect, neurons in the visual cortex compute distance based on the location and movement of images across the retina. Of these physiologically based cues, the most important is retinal disparity, which is the slight difference in the position of images on the retinas of the two eyes that is a consequence of the fact that the eyes are separated on the face. The ability to make use of retinal disparity is known as stereopsis and is the basis for the strong sense of depth that we get when watching a three-dimensional movie wearing the appropriate kinds of glasses.

Assessing Animal Depth Perception

A person can say if he or she sees something in depth and how far away it is. It is much more difficult to measure whether an animal has depth perception, and if so, how good it is. Researchers have used a variety of techniques to assess animal depth perception, each one tailored to a specific species. All share some common principles, however: An animal is taught to make discrimination between two visual stimuli and is rewarded for responding to the correct one. If an animal can make this discrimination, the task is made progressively more difficult until performance falls to chance. This gives a measure of the fineness of the animal's discrimination abilities. For example, several years ago, Donald Mitchell and his colleagues developed the *jumping stand* technique in which kittens jumped from a raised platform onto a surface below. For measuring depth perception, they used two patterned surfaces, one of which was closer than the other. By reducing the difference in distance, they were able to measure the kittens' depth thresholds. For larger animals, such as the horse, a wide board with two trapdoors can be used, and the horse is required to press its nose against the trapdoor to indicate its choice. In an experiment to measure stereoscopic depth perception in falcons, Robert Fox trained birds to fly from a perch to the visual stimuli that were a short distance away.

The Use of Depth Cues by Animals

Most of the monocular depth cues are qualitative; that is, they indicate that one object is closer than another, but they do not give a reliable indication about how much closer. Stereopsis and motion parallax, in contrast, can provide fine depth judgments. So it is of interest to determine which cues animals can use to get a sense of how well they can process depth information. Even the animals with simple visual systems are able to use some depth cues. Male hoverflies can keep themselves at a constant distance from a receptive female until she lands on a flower, and then move in to begin mating. It is likely that these flies maintain their distance by keeping the size of the image of the females on their eyes constant until she stops moving. A more sophisticated approach is taken by locusts, which move their heads back and forth to generate motion parallax. There is only limited information about whether mammals are able to recognize pictorial depth cues, but one study has shown that young monkeys will reach to the apparently closer of two objects in a picture when distance information was provided by pictorial depth cues, and horses seem to be susceptible to illusions that are created by pictorial depth cues.

All species with forward facing eyes that have been tested have shown evidence for stereopsis. This includes species as diverse as insects, amphibians, birds, and mammals. In mammals, many studies in cats and monkeys have shown that they possess disparity sensitive neurons in the visual cortex that respond when a target is located at a specific distance from the fixation point.

Among mammals and birds, many species have eyes located on the sides of their heads. Although this gives them a panoramic view of the world, it does limit the extent to which they can use both eyes to see the same region of the visual field in front of them. Potentially, this could restrict their ability to use retinal disparity as a depth cue. However, it appears that if these animals have even limited binocular fields, in which both eyes can see the same region of space, then they have stereopsis. Horses, for example have their eyes located on the sides of their heads, but do have about 60 degrees of binocular overlap. Tests have shown that they have normal stereoscopic vision and that they are able to recognize depth binocularly when there is no other information available. Only a few studies have attempted to assess stereoacuity, or the accuracy of binocular depth judgments, and it appears that with the exception of monkeys, stereoacuity in mammals is not nearly as good as it is in humans.

Research that has been done on a wide range of species indicates that depth perception is ubiquitous in the animal kingdom. The extent to which a particular animal relies on one cue or another varies considerably, but all animals are able to use the available cues to judge depth and distance.

Animal Eye Movements

The brain receives visual information about the environment through photoreceptors in the retina, which convert light into electrochemical signals and ultimately into neural activity. This entry describes various experiments on animal eye movements. The spatial orientation of the retina with respect to objects in the world determines what kind of visual information is perceived. Therefore, in all mobile animals the position of the retina with respect to visual objects of interest must be controlled, to ensure that they are aligned and that the retina is stationary with respect to such objects long enough for visual inspection.

An interesting exception are heteropod mollusks, which have eyes that are shaped as a long narrow stripe only three to six receptors wide and several hundred receptors long. Their visual field of view is only a few degrees high and 80 to 180 degrees long. At any given time, therefore, most of the surroundings are not seen by the animal. To solve this problem, the heteropods systematically scan the environment with smooth rotating eye movements. It seems likely that the function of these movements is to enable the carnivorous mollusks to detect stationary objects in the surrounding water. In contrast, the eye movements of insects, higher crustaceans, cephalopods, and vertebrates have possibly evolved to detect motion, either self-generated as in locomotion, or caused by prey or predators, and that the reason for the maintenance of eye stability is the need to avoid confusion between eye movement and image movement.

The alignment of retina and visual object is controlled by neural mechanisms that either stabilize or shift gaze. Normally, this is achieved by moving the entire eye relative to the body; in some animals, however, only part of the eye is moved. Jumping spiders have excellent vision, with among the highest acuities in invertebrates. Two of their eight eyes, the anterior median eyes (AME), provide high visual acuity but small field of view, and the remaining six eyes provide lower resolution but broad field of view. The AME are long and tubular, which helps their resolution (longer focal length, more magnification) but which means they have a narrow field of view. The AME's have a narrow field of view, so the spider needs to point them in different directions to see objects at different locations. However, the spider cannot move the whole ocular mechanism because the lenses of the eyes are actually built into the carapace. Instead, a special set of muscles moves the retina around, and the lens stays fixed.

Gaze stabilization is also important for animals that cannot move their eyes in their heads at all. For example, insects need to stabilize their gaze during flight. They achieve this by performing very fast (2000 degrees/second) turns of their thorax in mid-flight. These thorax movements start first, and are followed by head movements that are later and more rapid to minimize the time of gaze shift and to maximize the time available for analyzing the surroundings.

Vertebrates use two mechanisms to stabilize the position of the retina with respect to visual objects: the *vestibulo-ocular reflex* and the *optokinetic nystagmus*. The vestibulo-ocular reflex (VOR) compensates for movements of the head and relies on vestibular input from the labyrinthine semicircular canals that respond to acceleration of the head. This information is carried by neurons within the vestibular ganglion and relayed to neurons in the vestibular nucleus. These neurons integrate the vestibular input and generate an appropriate compensatory motor response by innervating oculomotor neurons. The vestibular information is much faster than visual information. Thus, the compensatory eye movements generated by the VOR have a latency of 15 milliseconds (ms), whereas eye movements that rely on visual information typically have latencies of more than 70 ms. However, because the VOR relies on information about acceleration, it becomes increasingly unreliable during sustained head rotations with constant velocity and slow acceleration. In this situation, gaze stabilization relies on visual input, using the optokinetic nystagmus (OKN). The compensatory movements generated by this system are slow, but include the full range of motion of the eyes in the head. Long, sustained head movements can lead to large shifts of the eyes. When the eyes reach the outer corners of the oculomotor range, a corrective rapid eye movement moves the eyes in the same direction as the head rotation, which enables inspection of the oncoming visual scene. These rapid eye movements are generated by the same brainstem neurons that are responsible for saccades, and this system is likely the evolutionary precursor of the saccadic gaze-shifting system.

The evolution of gaze-shifting mechanisms was made necessary by specializations in the structure of the retina. In primates, the retina contains the fovea, a region of maximal photoreceptor density, which allows sampling of visual information with the highest spatial resolution. However, the fovea is limited to 1 to 2 degrees of visual space. Therefore, this zone of higher acuity must be directed to interesting parts of the visual field, which is being achieved by *saccadic eye movements*. The eye movements are rapid, and accurate shifts of the eyes with peak velocities of as much as 500 degrees are generated by a network of neurons in the brainstem.

Lateral-eyed species (such as rodents and ungulates) turn their heads in a series of rapid steps to scan the environment, but frontal-eyed species can turn their head smoothly through an angle of 180 degrees to fixate a target. In addition, they have usually developed the capacity to uncouple saccadic eye and head movements by suppressing the VOR. The higher-order gaze shifting commands that specify where and when the eyes should be shifted are generated in the superior colliculus (SC) and in a number of cortical areas, in particular the frontal eye field (FEF). Once the fovea is aligned with the object of interest, it has to be held on the object long enough that light from this region can be analyzed by the visual system. In the case of a stationary target, this is achieved by active *fixation*. For tracking a smoothly moving object, saccades are of limited use because the image soon slides off after being captured by the saccade and requires another saccade. In between the saccade cycles, there would be a loss of visual acuity. Therefore, the *pursuit* system evolved, which generates smooth tracking movements of the eyes that closely match the pace of the target. However, the visual system responds with a latency of 60 to 100 ms, which introduces a corresponding input lag into the neural feedback mechanism. The pursuit system overcomes this problem by using a feedforward mechanism to anticipate predictable motions of the target. During saccades and smooth pursuit, each eye usually moves in the same direction (these are called version movements), but in animals with binocular vision, for example primates, gaze shifts can also involve *vergence movements,* in which each eye moves in opposite directions. In this way, targets at different depth can be fixated upon.

Although gaze stabilizing mechanisms are automatic reflexes, gaze-shifting mechanisms can be initiated both by automatic and by voluntary, goal-directed processes. This voluntary control depends on a number of areas in the frontal and parietal cortex. These cortical eye fields are connected with the superior colliculus and the brainstem centers for the generation of saccades and pursuit movements both directly and indirectly through the basal ganglia. In recent years, this connection has been used to investigate cognitive processes, such as attention and decision making, by studying higher-order oculomotor areas.

ANIMAL EYES

The structural organization of animal eyes provides the first step toward visual perception. There is substantial diversity among animal eyes, yet they tend to fall into a few distinct categories such as single chamber and compound eyes. Underlying nearly all light perception are visual pigments based on a family of proteins called opsins. These molecules are tightly linked to retinal, a chromophore related to vitamin A, which undergoes a conformational change in response to light exposure. This activates a photoreceptive cell (either by hyperpolarization, as generally is the case for vertebrates, or by depolarization, which is typical for most invertebrates) and, ultimately, after many computational steps, results in the animal's perception of light. Differences in eye design influence factors such as the direction from which a receptor cell absorbs light, or whether light is pooled from many directions. Therefore, the eye structure largely defines how specific animal eyes function, which frequently is near the physical limits of light. This entry describes how the eyes of different animals function.

From a Light-Sensitive Surface to a Camera-Type Eye

Notably, the most important features in eye design are aimed at gaining spatial resolution. Such resolution can be achieved by curving the photosensitive surface. In a flat surface, photoreactive cells absorb photons from different directions in space equally well. This is the case for light-sensitive spots of a limpet. In this animal, only light from beneath is shielded through the presence of screening pigments. If the surface curves inward (concave), as for example is the case for the slit shell mollusk *Pleurotomaria,* individual cells start to become selectively more activated by light from specific directions. This is referred to as spatial resolution, and this property tends to improve with increased curvature and a narrowing of the rim area of the eye pit. In photographic terms, the narrowing of the rim corresponds to reduction of the aperture. The resulting eye type, referred to as a pinhole eye, functions on the same principles as a pinhole camera and is exemplified in the cephalopod mollusk *Nautilus.*

Although pinhole eyes can yield good spatial resolution, their small aperture means that they perform poorly at low light levels. To increase

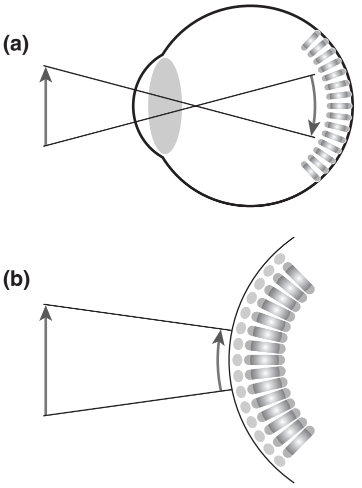

Figure 1 Schematic Organization of a Single-Chamber Eye (a) and a Compound Eye (b)

light capture, the pinhole or aperture has to be widened, which consequently results in a dramatic loss of spatial resolution. The solution in photography and animal eye evolution alike is the introduction of a lens, which allows capture of much more light while using the focusing power of the lens to maintain good resolution. The resulting "camera" or "single chamber" eye (Figure 1a) is found in vertebrates. Although most vertebrate eyes look fairly similar, organizational details do vary with species. For example, although mammals focus images by changing the shape (and hence the refractive power) of the lens, fish and certain amphibians adjust the focus by changing the location of the lens. The organization of the retina also differs in animals, often because of the animal's ecology or environment. For example, for us, the frontal visual space is particularly important, and we humans accordingly have a single fovea (area of increased visual acuity) within our binocular visual fields. Certain birds of prey need to simultaneously keep track of visual stimuli in the front and on the side. Accordingly, they have a second fovea within the monocular visual field of each eye. Another example is that animals living in flat environments, whether fish, mammals, or birds, tend to have horizontally oriented high-acuity areas, which allow them to see particularly well along the horizon.

Figure 2 Eyes of a Male Black Fly

Note: The compound eyes of a male black fly dominate the head and are divided into dorsal and ventral regions that together acquire visual input from nearly all directions in space.

Interestingly, the single chamber eye has also evolved multiple times in invertebrates. The most notable examples are the eyes of squid and octopi, which show remarkable similarities in eye design to those of vertebrate eyes. In addition, single chamber eyes with noteworthy resolving power are found among spiders, in the accessory eyes of certain adult insects, and as the primary eyes of some larval forms of insects that undergo complete metamorphosis (such as beetles and butterflies).

The Compound Eye

Most crustaceans and insects have evolved a different solution toward achieving spatial resolution: rather than curving the photoreceptive epithelium inward, evolution has led to a convex organization (Figure 1b) in these creatures. This outward curvature results in a spatially dependent activation of specific receptor cells that is similar to that of the concave epithelium, except that with the convex surface, the configuration does not allow for the presence of a single lens. Instead, each portion of the insect compound eye (referred to as ommatidium) is usually equipped with its own lens. Although externally the compound eye looks different from a single chamber eye, it essentially represents an inside-out version of our eye, and many organizational principles of the convex eye revolve around the same physical compromises made in the concave eye. For example, both eye types are characterized by trade-offs between how many points in space are resolvable and how much light each point captures. Although they are different in physical design, both eye types have actually converged on the same solution, namely, to devote only a portion of the eye to high-acuity vision.

As might be expected, compound eye design imposes major functional constraints. For example, because each lens tends to be small, these eyes are more likely to operate near the diffraction limit of visible light. For that reason, a compound eye would have to be substantially larger (about one meter in diameter) to achieve levels of spatial resolution that are comparable with those of human eyes. One advantage of compound eyes is that they are well designed to seamlessly monitor many directions in space. In fact, it is quite common to find insects with nearly 360° vision (Figure 2).

ANIMAL FREQUENCY AND PITCH PERCEPTION

Pitch is a perception that is evoked by simple tones and many different types of complex sounds, including speech and music. *Pitch* refers to the subjective experience produced by a sound. The pitch of a sound is closely related to the frequency of a pure tone or to the fundamental frequency of complex sounds, but does not refer to the specific frequency content of the sound. As such, pitch is what results from how the brain analyzes and processes the frequencies present in a sound. This entry describes sensitivity ranges of different animals, the ability to detect frequency differences, and animal perception of naturally occurring sounds.

Animals most likely experience sensations that are similar in many respects to the pitch percepts experienced by human listeners, but scientists cannot directly ask animals about the subjective experience in a way that can be asked of human listeners. To understand animal perceptions, scientists must ask the animal indirectly how it perceives the sound. This is done by training or conditioning the animal to make a behavioral response to a particular feature of a sound that will then be varied. For pitch perception, the frequency content of a sound can be varied. When the animal makes a correct behavioral response, it usually receives some sort of feedback, such as a food reward or avoiding a mild electric shock. Although scientists have no way of knowing exactly what the animal's subjective experience is, from the behavioral responses of the animals, scientists can determine what features of the sounds the animal is analyzing and thus make inferences about what the animal experiences.

It is not surprising that the way in which the brains of animals process the frequency content of sounds is similar, in many respects, to that of the human brain because the general structure of the auditory brain is similar in animals. A major difference among animals is the range of frequencies that animals are able to perceive, and these differences are related to the structures that constitute the outer, middle, and inner ears. The hearing range of frequencies for most fish is fairly low, between 50 and 500 hertz (Hz). However, some fish have accessory auditory structures such as swimbladders and tiny bones that connect the swimbladder to the inner ear. These structures act like the middle ear in land animals and increase the sensitivity to higher frequencies to about 2,000 Hz. Amphibians and reptiles typically have a range of hearing between 100 and 2,000 Hz. Most birds have a relatively narrow hearing range with best sensitivity between 1,000 and 3,000 Hz, but some species of owls have excellent sensitivity as high as 10,000 Hz. Unlike birds, the range of hearing is quite heterogeneous in mammals. For example, the range of hearing for humans is 20 to 20,000 Hz, whereas elephants can hear frequencies below 20 Hz with great sensitivity, and dolphins and bats can hear frequencies above 100,000 Hz with great sensitivity. The range of hearing will determine how the animal perceives the outside world.

Another aspect of frequency processing is the ability of animals to detect differences in the frequency of a simple tone. All animals tested can detect changes in the frequencies of simple tones, but it is well established that human listeners can detect smaller frequency differences in a tone than can all other animals tested. That is, animals are less sensitive to frequency changes than are humans. These findings indicate that animals have a psychological dimension (i.e., a percept) that corresponds to the frequency of a tone. Behavioral data obtained using simple pure tones can be directly related to the map of frequency-to-place that exists along the basilar membrane in the cochleae of birds and mammals. That is, for simple tones, the frequency map along the basilar membrane does correspond to the pitch map.

Most naturally occurring sounds are made of multiple frequencies, and when the frequencies are harmonically related, a single pitch at the fundamental frequency is evoked in human listeners. For example, a sound made of five tones at 1,200, 1,400, 1,600, 1,800, and 2,000 Hz will evoke a pitch that corresponds to 200 Hz. Note that the sound itself contains no energy at the fundamental frequency of 200 Hz, but nevertheless, there is a strong pitch at 200 Hz. The phenomenon of having a perception of a pitch from a sound containing no energy at the fundamental frequency is known as the *pitch of the missing fundamental.* Like humans, birds and mammals respond to these same types of sounds as if they perceive the pitch of the sound to be at the missing fundamental frequency. The auditory areas of the cerebrum appear to be important for the ability of animals and humans to detect changes in the pitch of the missing fundamental. Nevertheless, animals require a larger difference in fundamental frequency than do humans in their ability to detect that the fundamental has changed. Moreover, different types of complex sounds having different frequency contents can evoke the same pitch percept, but the frequency map along the basilar membrane does not correspond to the pitch map for complex sounds.

Changes in the pitch of the fundamental frequency of complex sounds give rise to melody perception, and the pattern of pitch changes between the individual notes of the melody is called the *frequency contour*. Although birds and mammals can discriminate frequency contours, it appears that animals base their discrimination primarily on the absolute frequencies of the tones, whereas humans base their discrimination primarily on the intervals between individual frequencies. Consequently, human listeners can recognize a melody regardless of whether the individual notes change in the same register or whether the individual notes change in octave registers. This phenomenon is called *octave generalization,* and it has been demonstrated to also occur in monkeys. However, in general, octave generalization does not appear to be as salient in birds and mammals as it is in human listeners.

ANIMAL MOTION PERCEPTION

Most animals move around in their environment, and through evolutionary time, this has resulted in specializations in their sensory systems and brains, to detect motion, as described in this entry. These patterns of movement can occur as moving images in vision, as moving sounds in hearing, and as moving tactile patterns in touch. Visual motion can be simply divided into two classes; the first, called *object motion,* is produced when some object moves relative to stationary objects in the world. The second class of motion, called *self-motion,* is produced by the observing animal itself moving its body, head, or eyes and thereby creating movement of the entire image across its visual field.

Although visual object motion can be produced by nonliving things such as rain, snow, leaves, waves, or clouds, most visual object motion is produced by the movement of other animals. It is advantageous for an animal to notice the movement of other animals because other animals may be the viewing animal's prey, a predator, or one of its own species and detecting them will greatly help the animal capture prey, avoid predators, and engage in social interactions, respectively. The other distinctive class of motion patterns is produced by an animal itself moving through a world of stationary objects, and these visual "flow patterns" are used to control its own movements, steer through space, obtain depth information through motion parallax, avoid obstacles, and even help maintain its posture and balance. Not surprisingly, there are separate areas of the visual system to process *moving objects* and *self-produced motion* patterns, which in turn generate distinctive behavioral responses, and they are found in both invertebrates and vertebrates alike.

Visual Neurons

Early research on frogs and insects showed that some visual neurons were specialized to respond only to relatively small moving visual stimuli, and often these preferred a particular direction of motion. These directional specific neurons were sequence detectors. If two adjacent areas in the visual field (say A and B) were stimulated by a moving stimulus that moved over A then B, the neuron would fire to signal this event. However, if the direction were reversed so that B then A was stimulated, the neuron would not fire, but would be inhibited. Early experiments showed that two flashed stimuli one at A and then the next at B after a short delay, also stimulated these movement neurons, but again, they did not fire when B then A were flashed without movement. Thus, these neurons respond to *apparent motion* as well as real motion. These motion-detecting neurons that respond to small moving things are precisely the stimuli that capture an animal's attention and typically produce a turning of the head and eyes ("orienting response") to place the object's image onto the fovea or retinal area of high resolution. In frogs, these were nicknamed "Bug Detectors" because frogs turn and snap at bug-like moving patterns. Typically, larger moving stimuli produce escape or avoidance behavior in animals.

Movement and direction-specific neurons have been found in the visual system of all invertebrate and vertebrate animals where moving stimuli have been used to interrogate the visual system, and so it seems safe to assume these neural specializations are universal. Moreover, wherever motion-detecting neurons occur, it seems that the underlying mechanism in all species is produced by delayed asymmetric lateral inhibition. Object motion sensitive neurons have been found in flies, bees, locusts, crickets, praying mantises, and dragonflies, and also in fish, salamanders, turtles, frogs, toads, chickens, pigeons, owls, mice, rats, cats, ferrets, wallabies, and several species of monkey. Perhaps the most extensive studies have been conducted on the middle temporal cortical area of the macaque monkey cortex.

Camouflage

Many animals freeze when they see something moving, and this behavior ensures that object motion detecting neurons in other observing animals will not be triggered. Together with their protective coloration, which often matches the features of the environment they inhabit, this makes animals difficult to see and for figure ground boundaries that define their shape to be resolved. However, should the background be moving, such as when the wind moves branches or leaves, the animals often move with the background. Walking stick insects rock back and forth as they advance and thus mimic twigs waving in the wind, and Australian horned devil lizards and some species of snake (e.g., oxybelis) use this strategy to foil the object motion detectors of their predators. Moreover, when a predatory animal such as members of the cat family, or jumping spiders stalk their prey, it seems they are attempting to keep their own speed below their prey's threshold for detecting motion, and their crouching posture ensures their legs, which always move with a faster velocity then their bodies, are not visible to their prey targets.

Biological Motion

In courtship displays of many animals, species-specific characteristic motion patterns are produced by the courting pair. In this case, one might assume that there are specific object motion detectors in the brains of these animals to recognize these patterns that play an important role in sexual selection.

When an animal walks, flies, or swims through its environment, the images of stationary objects produce specific patterns of motion across its entire visual field of view. These patterns of *optic flow* can also be produced by an animal's head or eye movements. These self-produced optic flow patterns do not activate object motion detecting neurons, but instead, other visual neurons in specialized parts of the brain of both vertebrates and invertebrates do respond best to large patterns of optic flow. This specialized pathway acts together with the vestibular system to help control an animal's balance and posture and to provide information about how the animal is moving through space. When human observers view an IMAX theater movie, this motion system is activated and produces the compelling illusion the observer is moving through space, which is termed *vection*. Animals placed in a rotating striped drum also must experience this because they make body head and eye movements in an attempt to keep the large moving image stable on their retinae.

Finally, many animals seem to be able to calculate the *time to collision* with an object that is directly approaching or looming toward them and likewise to compute their own time to collision with stationary objects. In the first case, this could be a predator attacking them and would allow them to take evasive action, and in the second case, it provides information so they can land on branches, fold their wings in a streamlined fashion if they are a diving bird, run thorough a thicket, and otherwise skillfully maneuver through their environment. Research has shown that insects landing from flight, hummingbirds, kestrels, and kingfishers hovering in the same spot, and gannets folding their wings while diving for fish are all computing time to collision from the expanding images of the surfaces they are approaching. Again, specialized cells have been found in the visual system of animals that are calculating this time to collision.

APHASIAS

Aphasia is a neurological impairment of the human language system. Language includes several subsystems (speech sounds, grammatical structure, meaning) and is conveyed and understood through various input and output channels (spoken, written, gestured). In aphasia, each of these channels is affected to some degree, with difficulty ranging from minimal to severe. Minimal deficits include being slower to understand reading material, to get a joke in conversation, or to choose a precise word. Severe aphasia impairs even simple language tasks, such as matching a single printed word to the object it represents, or providing one's name and address.

Aphasia results from damage that is nearly always isolated to the left side of the brain. This damage interrupts the blood supply to the brain and starves the affected areas of the oxygen and glucose they need to survive. After several minutes, those brain regions die.

Aphasia is often divided into subtypes. These subtypes are distinguished roughly by relative strengths and weaknesses in language channels and subsystems. Different aphasia types also have been linked with different locations of damage within the left brain. Robert Wertz and colleagues summarize the controversy about the value and validity of these subtype distinctions. Specifically, within each aphasia type, there is a lot of individual variation in the presentation of strengths and weaknesses, and in the location of brain damage. Aphasia also has been described as nonfluent versus fluent, which refers to the average length of uninterrupted stretches of spoken language. Broca's, transcortical motor, and global aphasia are all nonfluent aphasias with relatively short stretches of uninterrupted output, and Wernicke's, conduction, anomic, and transcortical sensory are fluent, with essentially normal phrase length. Some practitioners refer to aphasia as expressive or receptive. It has been argued that these descriptors are neither valid nor informative because people with aphasia have both expressive and receptive components to their disorder, to some degree. Aphasia also is sometimes described as anterior versus posterior. These adjectives are not widely used because they describe a general location in the brain rather than the language characteristics of aphasia.

Aphasia is not a deficit of basic sensory systems—hearing, vision, touch—or of motor function. However, aphasia overwhelmingly affects older adults, so concurrent problems with hearing or vision are common. This entry discusses perception in aphasia, implications of research on perception in aphasia, and mirror neurons and perception of actions in aphasia.

Perception in Aphasia

Speech Perception

Speech perception refers to a set of processes that decode and interpret speech sounds (consonants and vowels) and patterns of speech melody (intonation). The study of speech perception deficits in aphasia can be complicated by co-occurring hearing loss.

Some people with aphasia have trouble perceiving time changes in components of speech sounds and patterns. Aphasia caused by relatively posterior brain damage, such as Wernicke's or conduction aphasia, has been associated with difficulty detecting a brief silent interval in a noise signal, or identifying which tones in a series are closest together in time. Timing parameters like these are important for distinguishing among consonants but not among vowels, and indeed, aspects of consonant perception are more impaired in aphasia than is vowel perception.

Aphasia caused by more anterior brain damage, such as Broca's aphasia, may yield difficulty with aspects of speech frequency (roughly, melodic characteristics). Problems may occur in picking a tone out of a noise signal, or determining if two tones are the same. There may also be difficulty identifying the meaning of certain melodic contours of spoken language. For example, echo questions may be hard to identify. Echo questions are statements with the melodic contour of questions (e.g., "He's going to the store?").

Aspects of frequency perception have also been examined in aphasic speakers of tonal languages. Tonal languages are those, such as Mandarin Chinese or Thai, in which a word's meaning is wholly determined by its melodic pattern. Each tonal language has a fixed number of these melodic patterns, which are also called tones. Tonal language speakers with aphasia have difficulty identifying their language-specific tones, although they do better than people who do not speak tonal languages. There is not enough research on aphasic speakers of tonal languages to determine how this deficit influences the understanding of everyday communication.

For English speakers with aphasia, evidence indicates that problems with speech sound perception do not predict the ability to understand natural language in everyday situations. This may be largely because of the ability of many individuals with aphasia to use top-down perceptual processes to compensate for difficulties in processing speech sounds. Top-down processes help fill in gaps in sensory input. These gaps can occur when an input signal is obscured, incomplete, or otherwise difficult to detect, such as when there is noise in the environment or when unfamiliar words are used. Top-down processes in speech perception rely on sources of information beyond the speech signal itself, such as the perceiver's prior knowledge and expectations, and the remainder of the language utterance or situation.

Music Perception

Music perception in aphasia has rarely been explored. Anirudh Patel reasons that music and language have some common grammatical features. Specifically, both consist of elements (chords, words) that are rapidly combined in sequence into (more and less) acceptable structures. Patel's recent work suggests that in aphasia, grammatical problems in music perception co-occur with grammatical problems in language comprehension. In one experiment, people with aphasia judged whether all chords in a sequence were a good fit musically. The sequences of most interest contained a chord that was out of place, from a harmonically distant musical key. Participants also judged the acceptability of spoken sentences, including some with errors in subject-verb number agreement (e.g., "The *sailors* call for the captain and *demands* a fine bottle of rum"). On both tasks, participants with aphasia were less accurate than were participants without aphasia. Performance of both groups on the music task predicted performance on the language task.

Visual Perception

Visual perception is another rare target of investigation in aphasia. At a global level, visual perception in aphasia is reasonably spared. Even people with relatively severe aphasia can match like objects with each other, and often like pictures. Severely impaired individuals can also copy alphabet letters, simple geometric shapes such as squares and triangles, and often their own names. However, detailed assessment of visual perception in aphasia is nearly nonexistent. One study reports a problem picking an image out of a background when damage was relatively posterior in the brain. Another study indicates that people with aphasia have difficulty determining whether mouth movements are the same or different. This same discrimination difficulty is also evident when only the sounds that correspond with the mouth movements are presented.

Perception of Space

Little is known about spatial perception in aphasia. Some people with aphasia do better on a wide range of language tasks—naming pictures of objects, reading words, generating nouns, determining synonyms, understanding sentences, telling a fairy tale—when their bodies are oriented to the left side of space than when oriented to the right side. People without brain damage perform these language tasks without error. Note here that damage to one side of the brain affects the opposite side of the body, so language performance in aphasia is enhanced when the body is oriented toward its good side. Other evidence suggests a potential spatial influence on sentence production and comprehension in aphasia. A man with grammatical language deficits was shown drawings of two stick figures, one of whom was doing something to the other, such as pushing. This man consistently chose the figure on the left as the one performing the action.

Odor Perception

Odor perception has rarely been explored in aphasia. People with aphasia are reportedly able to discriminate between common aromas, such as coffee, fish, and soap. However, they may have difficulty matching common odors to pictures or objects. Although results are mixed, the largest available study hints that odor may facilitate naming ability in aphasia. Eleven of 30 participants did better naming an object when provided its odor than when presented a picture, and more severely impaired individuals benefited the most from odor cues.

Implications of Research on Perception in Aphasia

Investigation of perception in aphasia has many potential implications. First, if the available evidence can be replicated, there will be new tools to investigate for their effectiveness in language treatment, including musical, aromatic, and spatial orientation cues. As an example, presenting a to-be-named item together with its odor in aphasia treatment is a way to leverage perceptual strengths to improve language performance, in this case naming, for some individuals with severely reduced naming abilities. Similarly, orienting an aphasic individual's body toward the good side of space during treatment may enhance performance on a range of language tasks. Treatment that uses areas of strength to scaffold areas of weakness may contribute to establishing and reinforcing new brain pathways that subsequently help the person with aphasia communicate more effectively in those areas of weakness.

In a related vein are implications for brain plasticity research, or the study of the brain's ability to reorganize after it is damaged. Brain plasticity research aims to identify brain regions that can help support a function, even if they normally do not. Most brain plasticity research in aphasia examines how brain regions are enlisted to spur improvements in the subsystems and channels of language. A few studies have addressed basic timing and frequency parameters of speech perception. In one example, when aphasia damaged a left-brain region that normally supports speech perception, new brain activity was evident in the same region on the right side of the brain.

Investigation of perception in aphasia also has the potential to enrich theories of the relationships among brain function, language ability, and perceptual phenomena and subsystems. For example, research on aphasia and perception could help refine proposals about what parts of the brain are necessary for various perceptual processes. When brain damage disrupts a particular function, such as an aspect of language or perception, one can infer that the brain regions that are damaged are typically necessary to support that function.

Mirror Neurons and Perception of Actions in Aphasia

Mirror neurons are specific brain cells in monkeys that are engaged in two conditions: when the monkey watches an action being performed and when the monkey itself performs the action. Mirror neurons have not been identified in humans, and they were originally described to link basic observational and motor skills. However, research findings in humans, and for higher-level skills such as language, are increasingly being interpreted through the prism of mirror neurons. In aphasia, for example, deficits in interpreting pantomimed actions and in comprehending printed action words have been linked by some to portions of a human analogue of the mirror neuron system. Among others, Luca Turella and his colleagues have recently outlined the as yet highly controversial nature of such interpretations.

AROMATHERAPY

Aromatherapy is the use of essential oils for the treatment of physical and psychological health. An essential oil is the distilled essence of a particular plant typically combined with a vegetable oil base. Contemporary aromatherapy is based on the inhalation of aromas rather than their ingestion or application. Thus, odor sensation and perception are responsible for the reported effects. This entry describes the history of aromatherapy, aromachology, and theories of aromatherapy.

History

The concept of aromatherapy came from ancient cultures that believed in the healing properties of plants. Many plants have therapeutic properties, and the basic derivatives of many modern medicines are plant-based. The term *aromatherapy* (originally *aromatherapie*) was coined in the late 1920s by the French chemist Rene-Maurice Gattefosse, who began the exploration of essential oils for their healing powers after an explosion in his laboratory left his hand badly burned and the accidental soaking of his injury in pure lavender oil produced a miraculously rapid healing.

Popular aromatherapy is primarily rooted in folkloric traditions rather than scientific research and a wide range of therapeutic effects are often attributed to any one aromatic plant. Here are some examples of the purported effects for several commonly "prescribed" essential oils: Sandalwood aroma is sedating, relaxing, and beneficial for treating anxiety, depression, and insomnia. Rosemary clears the mind and stimulates memory. Lavender is uplifting, soothing, and helpful for reducing stress, anxiety, depression, and insomnia. Indeed, authors of aromatherapy textbooks make a number of extraordinary and sometimes contradictory claims. For example, juniper oil is said to have 17 different properties ranging from aphrodisiac to sedative. Aromatherapy today is usually practiced in conjunction with massage, and one of the major claims of aromatherapy is a reduction in anxiety. Considerable evidence shows that massage alone reduces anxiety. If massage is effective, then aromatherapy plus massage is also effective. So "aromatherapy works, even if it doesn't," as several reviews of the literature have noted, at least for the reduction of anxiety. Thus, the wide range of therapeutic effects attributed to a plant's scent alone appear to be unfounded.

Aromachology

The term *aromachology* was coined by the Sense of Smell Institute in 1982, to distinguish between nonscientific claims for odors (aromatherapy) and the scientific analysis of olfactory effects on mood, physiology, and behavior (aromachology). Aromachology research and evidence must meet the following empirical criteria: (a) theory guided goals and clear hypothesis testing, (b) fragrances assessed using appropriate experimental methodology, (c) sufficient and representative subject populations and appropriate contrasting control groups, (d) data analysis with suitable statistical methods, and (e) results vetted by scientific peers and accepted for publication in reputable journals.

A rigorous analysis of the data obtained from aromachology research has shown that various specific odors can significantly alter mood, cognition, physiology, and behavior. However, inconsistencies in the chemical nature of the odors used, the dependent measures assessed, and the findings obtained are observed. For example, in one experiment, subjective emotional changes in the presence of lavender odor were found but no physiological effects were observed, whereas in another test of lavender, physiological changes were shown but there were no concomitant changes in self-reported mood.

Theories

A pharmacological hypothesis and a psychological hypothesis have been proposed to explain how and why odors produce the effects that have been observed on various aspects of mood, physiology, and behavior.

The pharmacological hypothesis proposes that the effects of aromas result from an odor's direct and intrinsic ability to interact and affect the autonomic nervous system/central nervous system or endocrine systems. In support of this proposition, lavender has been shown to act postsynaptically (after synaptic transmission between neurons) where it is suggested to modulate the activity of cyclic adenosine monophosphate (cAMP). A reduction in cAMP activity is associated with sedation. Linalool, a principal component of lavender essential oil, has also been found to inhibit glutamate binding, which may have sedative effects. It is therefore possible that lavender produces sedative effects via these neuropharmacological mechanisms.

The psychological hypothesis proposes that odors exert their effects through emotional-associative-learning, conscious perception, and belief-expectation. Emotional-associative-learning with odors is seen when an odor that has been associated to an emotional state is able to immediately elicit those emotions when later smelled. The reason for the instant emotional response is the uniquely direct and intimate neuroanatomical connection between the olfactory cortex and the amygdala, the region of the limbic system where emotional responses are processed. The physiological responses that then may be observed are simply the physiological sequelae of the emotional state elicited by the odor. Under associative learning, idiosyncratic associations will alter the way an aroma is perceived and what effects it may produce. Illustrating this, one study testing the influence of aromas on the experience of pain found that only odors that participants *self-selected* as pleasant were able to have a positive effect.

Expectation and belief have also been shown to play a major role in aromachology outcomes. In several studies, a water control condition (no scent) was able to produce the expected behavioral and physiological changes in accord with what the participants *believed* about the scent that was present.

Aromatherapy proponents make much of the superior properties of natural versus synthetic chemicals, yet this has not been empirically addressed. The chemical nature of the specific odors tested in aromachology research has varied widely across laboratories, including the use of synthetic, natural or different chemical versions (e.g., isomers) of a particular odor. A number of individual difference factors also mitigate and modulate the responses elicited by an odor, including culture, experience, gender, and personality. For example, in studies examining the effects of odors on sleep, men and women were found to be differently affected by lavender and peppermint, respectively.

At present, there is better empirical support for the psychological hypothesis and that the *perceived* quality of the odor is the most relevant factor for determining how an individual responds to it both emotionally and physiologically. That is, perceptual effects rather than intrinsic chemical properties best explain how specific scents can influence mental and physical states. Nevertheless, pharmacological mechanisms might also be operative with at least some compounds such as (–) linalool, a key aromatic compound in lavender.

ASSISTIVE TECHNOLOGIES FOR THE BLIND

Assistive technologies are devices or software that assist the accomplishment of tasks by a blind or visually impaired person, usually providing feedback via sound, touch, or optimal use of remaining vision. Technology is only one tool in the rehabilitation process, but for some tasks it can be an important one. This entry describes the range of assistive technologies that are available for the blind.

Technology for Reading, Writing, and Note Taking

For straightforward text, reading machines and optical character recognition software (available in both desktop and handheld units) can scan printed material and read it aloud in artificial ("synthetic") speech. Audio recordings from the National Library Service and other sources provide access to many publications. These "talking books" are now available on CDs and other digital media. The National Federation of the Blind provides a service giving access to spoken versions of newspapers and magazines, downloaded via telephone, with sections and articles selected via touch-tone commands.

Braille, a tactile code using raised dots for letters and numbers, is used for reading and writing by blind individuals. A simple stylus is often used to punch raised dots into paper for short notes and labels, but Braille translation software and printers ("embossers") for computer output are now commonplace. Mechanical and electronic Braillers are also available, with a Braille keyboard (six keys corresponding to the dots in a Braille character, and a space bar) coupled to a print head that embosses the Braille characters on paper. Electronic "refreshable" Braille displays mechanically present a line of Braille characters that are replaced by the next line when the reader activates a control switch. These are used for displaying computer output and for compact personal Braille notetakers, which provide much of the functionality that a notebook computer does for the sighted.

For an individual with low vision, some books are available in large print, and individuals can readily produce their own large print text using a computer. The inverse of the Snellen acuity fraction approximates the magnification needed to read small print. For example, someone with 20/60 acuity is likely to need 60/20 = 3 times magnification for normal reading. For this amount of magnification, common optical magnifiers (available with built-in illumination) will suffice. "Reading telescopes" attached to spectacle frames facilitate comfortable posture, farther away from the reading material. A strong positive spectacle lens or "add" focused an inch or two away from the face gives 8 to 16 times magnification compared with a normal reading distance of 16 inches. Even larger magnifications (as much as about 60) can be obtained with closed-circuit television (CCTV) magnifiers that display a magnified video image on a television-type monitor. (At high magnifications, only two or three letters may be visible at a time, slowing reading and making scanning more difficult). Writing materials can also be placed under the unit's camera. The advent of liquid crystal displays (LCDs) has produced handheld versions with a miniature camera underneath an inch-thick screen measuring about 6 by 3 inches, providing as much as 10 to 12 times magnification with a larger field of view than an optical magnifier. Most electronic magnifiers offer a contrast reversal option (i.e., displaying white print on a dark background), which can reduce glare. Some can be mounted on the head, or used for reading text at both near and far (e.g., the blackboard in a classroom).

Appropriate lighting is extremely important in low vision; performance in poor light is often much more affected than standard acuity measurements would indicate. A strong reading light positioned over the shoulder and focused on the reading material to reduce glare can improve the situation radically. Special reading lights are often dispensed by low vision clinics and catalogs.

Access to Computers and the Internet

Nonvisual access to the information on a computer screen is obtained using a screen reader software package. This software allows the user to select text displayed on any part of the screen, and convert it into speech or Braille output. Keyboard commands are used to navigate around the screen. Screen readers allow access to most common office software applications (word processors, spread sheets, etc.) using text and numbers. They cannot interpret pictures, however, so access to pictorial or graphical information is not provided. Screen readers are also used to surf the Web. Because they cannot interpret pictures, a recent Web Access Initiative has issued recommendations for Web site authors to add descriptive text labels (known as "alt text") to each image.

The most common form of output for screen readers is synthetic (computer-generated) speech, which practiced blind users can use at several times the normal speed. Refreshable Braille displays are another output option, but are considerably more expensive.

For those with severely impaired vision, special screen magnification software can provide high magnification and full functionality with different applications. Modern computer operating systems and Web browsers come with some screen magnification options built in. Another often-ignored option for low-vision computer access is simply to buy a larger screen.

Access to Communications and Portable Computing Devices

The complex menus of modern cell phones create difficulties even for a normally sighted person—particularly an elderly one. Most phone networks offer one phone model that has speech output for at least basic functions. Speech-output cell phone "screen readers" have also emerged, similar in concept to computer screen readers. For low-vision users, special phone models with large buttons, numerals, and displays are available.

Most personal digital assistants (PDAs), pocket PCs, MP3 players, and other portable computing devices have small displays that are hard for a visually impaired person to see, and menu functions that are largely inaccessible without vision. Occasionally, an accessible version of a mainstream product appears, but special-purpose talking PDAs with Braille keyboards and screen reading software have been developed by assistive technology manufacturers.

Technology for Independent Travel

The most common technology used by blind travelers is the long cane—usually long enough to reach two steps ahead while striding forward. Tapping the cane tip produces sound echoes from nearby objects, such as walls, parked cars, and entryways. Users listen to these subtle echo patterns to glean additional information about the nearby environment—a technique known as echolocation.

Electronic travel aids (ETAs) developed to assist blind pedestrians include obstacle detection devices that detect echoes from ultrasonic or infrared signals emitted by the device as they reflect off environmental surfaces. This information may be displayed as audio or vibration. More sophisticated FM ultrasonic aids can produce an audible output signal whose pitch is proportional to range, and with a timbre that varies with the nature of the target.

Braille signs can assist orientation, but have to be found before they can be read. This problem led to the development of Remote Infrared Audible Signage (RIAS) to provide the blind user with the ability to locate and read signs remotely. Transmitters at sign or landmark locations transmit infrared signals that are detected and converted to speech by a receiver carried by the user, who can determine the sign direction by aiming the receiver for maximum clarity. Talking navigation aids using the global positioning system (GPS) to establish a blind user's location are also available. These cannot be used indoors or in underground transit, and accuracy is limited near tall buildings, but in more open outdoor areas, accuracy is excellent. Audible pedestrian signals can be installed at intersections to provide information on safe crossing times.

Blind individuals have historically had extremely limited access to street maps. New tactile map automated production (TMAP) technology now makes it possible to request a tactile street map centered on any address via the system Web site. The resulting map can be downloaded and printed on a Braille embosser. Audio map information is also available in conjunction with the various GPS systems mentioned above.

Environmental modifications such as painting the edges of steps and platforms in a contrasting color can greatly aid travel safety for individuals with low vision. Hand-held telescopes can help read street signs or items on a menu behind a counter. Spectacle-mounted manual and autofocus telescopes, and high-powered (up to 40×) hand-held electronic video zoom telescopes are also available. Night travel can be aided by strong flashlights or night vision telescopes or goggles.

Access to Graphical and Pictorial Information

For blind individuals, access to pictorial and graphical information is still extremely difficult. Verbal image description can be used in such tasks as describing electronic circuit diagrams for blind technicians and hobbyists. Tactile drawings often have to be hand made, but are increasingly produced with computer-driven Braille embossers. Touch tablet technology can be used to sense the position of the user's finger on a surface on which a raised tactile image is presented, and provide speech or audio feedback describing the image feature the user is touching. Active tactile displays up to 32 by 48 dots are available with an array of pins set to the "up" or "down" position under computer control to form a desired image. In some cases, graphs and oscilloscope waveforms can be coded auditorily so the pitch of a sound varies with the height of the graph or waveform as it is scanned from left to right.

Access to Appliances, Displays, and Daily Living Activities

On older appliances using control knobs, and on mechanical devices such as insulin syringes, tactile or large print labels can be applied to provide independent verification of settings. Modern appliances and instruments with low contrast LCD displays and complex menus make access by both blind and low vision users problematic. Therefore, assistive technology companies have produced talking versions of certain commonplace devices and appliances such as clocks, calculators, scales, and currency identifiers, blood-pressure monitors and sugar/insulin analyzers. However, there is still a need to impress on mainstream manufacturers the importance of considering the visually impaired when designing products.

Jobsite Adaptation Technology

Numerous special adaptations can be made to facilitate specific job-related tasks. Accessible meters, oscilloscopes, vacuum gauges, machinists' instruments, and all manner of vocational tools with auditory and tactile readouts have been developed. Jigs and fixtures can facilitate positioning, measurement, or the use of cutting tools, and improved lighting and magnification can help workers with low vision. In some cases, jobs can be restructured so task components that are critically dependent on vision are performed by another worker. Through these means, totally blind individuals have been employed in a wide array of jobs and professions.

Recreational Technology

Skiing (primarily cross-country), sailing, and kayaking are popular sports for blind people. Braille and auditory compasses are available, as are kayak and canoe paddles with tactile grips that help orient them correctly. Bowling is aided by a "bowling rail" that gives orientation to the bowling lane. Goal Ball is a game akin to soccer for blind or blindfolded players, in which the ball emits auditory signals to help localize its position. Playing cards and popular board games are available with large print, Braille, or tactile markings. Some blind people pursue electronics, both audio and amateur radio, as a hobby, using accessible audio and audio-tactile electrical meter readouts.

Audio descriptions for the visual action in movies and TV programs are available for certain PBS and cable television series and documentaries and on some home videos. Captioning and audio description of many new release movies are available in some theaters. For low-vision viewers, watching television and live performances can be aided with head-mounted monocular or binocular viewers, including electronic magnifying systems with head-mounted displays.

ATMOSPHERIC PHENOMENA

People hear some remarkable phenomena, such as thunder, and see some remarkable phenomena, such as sun rays, glories, and rainbows, in the atmosphere. These phenomena are studied mainly by physicists and involve the disciplines of *atmospheric acoustics* and *atmospheric* or *meteorological optics.*

Atmospheric phenomena are interesting to perceptionists because perception sometimes disagrees with reality (making these phenomena seem to be illusions) and because they give an opportunity to test the generality of perceptual principles discovered in the laboratory. This entry describes atmospheric acoustics and optics.

Atmospheric Acoustics

Atmospheric acoustics concern how sounds travel through the atmosphere. A notable phenomenon of sounds is the *Doppler effect.* As a sound source moves at constant speed, such as a vehicle with a siren, toward an observer (or as the observer moves toward a stationary sound), the frequency received by the observer when it first becomes audible is higher than the emitted frequency. As the sound source gets closer to the observer, the received frequency decreases until, closest to the observer, it equals the emitted frequency. As the sound source recedes from the observer, the received frequency becomes less than the emitted frequency. Many people, however, describe their experiences as an increase in pitch as the sound source approaches. This illusory initial increase in pitch might be from the increase in intensity of the approaching sound.

Another phenomenon is that distant sounds sometimes fluctuate in intensity markedly. For example, a single-engine plane flying some distance away sometimes sounds as if the pilot has cut the engine. This occurs because distant sounds can take more than one path, via inhomogeneities in the atmosphere, to the ears of an observer. Identical sounds traveling different paths can have their relative phases shifted, leading to cancellation when exactly out-of-phase waves arrive at the ear and to reinforcement when the waves are in-phase.

Atmospheric Optics

The atmosphere has its own optical properties. It can make its own light and it can act like a filter, a prism, and a mirror.

Atmosphere's Own Light

Apart from lightning, the atmosphere can make at least two other sorts of light, seen only at night. *Airglow* is weak light emitted by the upper atmosphere from chemical processes and from interactions between air molecules and cosmic rays. It is dim, about 0.3 ten-thousandths of a candle per square meter, visible only to rod vision as a slight colorless glow. It means, however, that even the darkest sky between the stars is not completely dark.

Aurorae are much stronger lights emitted by molecules of the upper atmosphere when bombarded by energetic particles from the sun. The particles follow the earth's magnetic field lines down the atmosphere, exciting oxygen molecules, giving red and green light, and nitrogen molecules, giving blue-violet light. Aurorae form in a ring between about 20 and 30° latitude from the magnetic poles.

Aurorae can be dim, visible only to rod vision, hence colorless. But other times, they can be bright enough to be seen in color by cone vision above other light sources such as the moon and streetlights. Aurorae can appear as diffuse glows or, startlingly, as vertical rays that look like curtains running approximately east-west. They can be essentially stationary or can form and reform over tens of seconds. The curtains can appear to be blowing about as if in a wind, parts overlapping with other parts. All this light and change occurs completely silently. Aurorae are some of the biggest things one can see in the atmosphere, being 80 kilometers (km) high and thousands of kilometers long. Occasionally the rays can descend directly over an observer, appearing as pattern of diverging rays from linear perspective.

Atmosphere as a Filter

To us, the atmosphere looks transparent. But this is because the wavelengths passed best by the atmosphere for identifying objects are just those to which we are most sensitive. The atmosphere largely protects us by filtering out harmful wavelengths emitted by the sun, such as microwaves and ultraviolet light. But even within the range of visible wavelengths, the sky can look blue or red, and the atmosphere can change the color and contrast of distant objects. These filtering properties arise from *scattering*. Moreover, clouds can be opaque, producing various *shadow* phenomena.

Scattering

About 17% of photons strike particles in the atmosphere, such as air molecules, and have their directions changed anywhere from close to 0°, *forward scattering,* to 180°, *back scattering.* Scattering ensures that the midday sky, away from the sun, is blue. This is because short-wavelength light that appears blue is scattered more than is longer-wavelength light that appears green, yellow, and red.

Scattered light, *skylight,* acts as a cue to the distance of objects. The further an object is from someone's eyes, the more skylight is scattered into his or her line of sight. This extra light reduces the contrast of markings on the object, reduces the contrast of the object with its background, and makes it bluish. If an object is far enough away, so much skylight will be superimposed on it will be indistinguishable from the background sky.

People use these properties of the atmosphere, *aerial perspective,* to judge distances (see color insert, Figure 11a). Aerial perspective does require some calibration: There are many stories of people from smoggy cities coming to some place of clean air and deciding to go for a half-hour walk to a hill that appears nearby, only to discover it is a mountain scores of kilometers away.

Shadows

Clouds consist of numerous particles of water or ice. If they are thick enough, essentially all of the light that falls on them is reflected, casting a shadow on the opposite side from the sun. For a viewer looking at a cloud with the sun behind it, the cloud can look dark. Near the edge, where the cloud is thinner, a viewer can sometimes see a brilliant silver or golden lining from forward-scattered light. Clouds look brightest, whitest, when the sun is behind the viewer. But sometimes in this situation one sees a dark cloud against a more distant white cloud. This is partly from geometry and partly from perception. The dark part is the underside of a near cloud in shadow. The white part is the top of distant clouds in sun (Figure 1). Aerial perspective also superimposes skylight on distant clouds, lightening them. Perception adds *simultaneous brightness contrast,* in which a gray area on the light background of another cloud looks darker than an identical gray area on the dark background of the blue sky.

Cloud shadows also create dark parts of the atmosphere. These are easiest to see when the sun is setting in the west behind clouds and are revealed as a fan-shaped pattern of dark and bright rays that appear to diverge from the sun—*crepuscular rays.* But these rays do not connect with, or diverge from, the sun; they exist only in the atmosphere where there are particles to scatter light into a viewer's eyes. And because the sun's light is parallel, the rays are parallel too. The rays appear to diverge from linear perspective because they are approaching the viewer.

Occasionally crepuscular rays can be seen continuing over the bowl of the sky, following great circles, and then converging to the antisolar point in the east: exactly opposite to the position of the sun in the western sky. These *antisolar crepuscular rays* or *anticrepuscular rays* (see color insert, Figure 11b) are also a simple product of geometry and linear perspective. The rays appear to converge because they are really parallel and receding from the viewer.

Atmosphere as a Prism or as an Interference Filter

A prism *refracts* light, bends it. Because light is bent by an angle related to the wavelength, with short wavelengths being bent more than long wavelengths, prisms also break sunlight into its component wavelengths, called *dispersion.* Refraction occurs in air because air's density varies (giving rise to mirages), and it occurs in ice crystals (giving various halos) and in water drops (giving rainbows).

Some of the beautiful spectral colors in the atmosphere arise via interference between light waves from differences in their phase. These are commonly seen in thin films, such as in soap bubbles, or in interference filters, such as found fortuitously on a compact disk. An interference filter usually consists of a grating of fine slits through which light can pass. The phase differences arise from light from one slit traveling a slightly different distance to the eye than light from another slit. When a particular wavelength is reinforced, it superimposes its associated color onto whatever light is entering the eyes. Interference phenomena occur in the atmosphere from droplets of water or from ice needles, each element acting like a slit in an interference filter (giving *iridescent clouds* and *coronae*).

Atmosphere as a Mirror

The atmosphere can behave like a mirror from backscattering of small particles at angles approximately equal to 180°, giving rise to *glories* and the *Brocken spectre,* and from ordinary reflection from the surfaces of water droplets or ice crystals or from total internal reflection within droplets or crystals, giving rise to *pillars* and to *rainbows.*

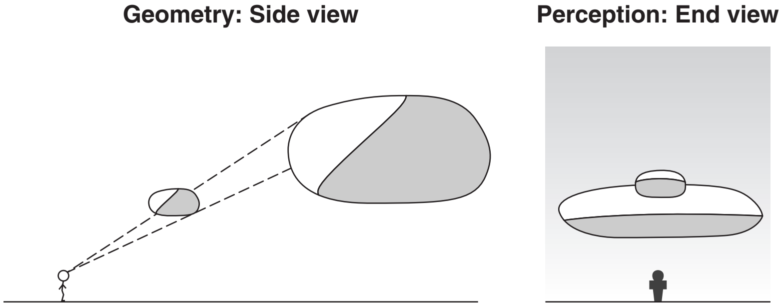

Figure 1 Dark Versus White Clouds

Notes: (Left) Side view of the geometrical arrangement of clouds producing a dark, near cloud visible against a white, distant cloud. The dashed lines show a viewer's lines of sight. (Right) End view of how a dark cloud appears against a white cloud. The shadowed parts of the distant cloud can also be lighter than those of the near cloud because of aerial perspective.

Glories and the Brocken Spectre

Small drops of water, such as in fog or mist, have pronounced backscattering, which is diffuse reflection. When the drops are uniform, they can produce colored rings from interference. These phenomena require strong sunlight to illuminate a viewer and then to pass into the drops; these conditions were originally the preserve of mountain climbers, often seen from the Brocken, an easily accessible peak in Germany's Harz Mountains. Now they are usually seen in clouds by passengers in aircraft. Light blocked by the viewer's head or aircraft creates the *specter,* a shadowed region of fog or cloud; light just missing the obstruction is backscattered to create a bright halo. Surrounding this can be at least one set of colored rings, the *glory.* Often, a viewer's shadow appears magnified, presumably from overestimation of its distance in fog (see color insert, Figure 11b).

Pillars and Rainbows

True reflection can occur when there is an abrupt, large change in the refractive index from one part of the atmosphere to another. This commonly happens on the flat surfaces of ice crystals and in drops of water. When ice crystals float in the air with their axes mainly horizontal, light can be reflected from their surfaces into a viewer's eye, seen as a vertical ray or *pillar* passing through the light source. These reflections have the same color as the light. Drops of water are approximately spherical, so reflection from the surface is weak. But rays of light can enter a drop at one point, then refract to meet an opposite surface at an angle giving *total internal reflection.* The rays also undergo dispersion within the drop, yielding the most spectacular examples of refraction colors: the rainbow (see color insert, Figure 11c).

All these phenomena share some perceptual properties. Each person sees his or her own specter, glories, halo, coronae, and rainbows because only light from the correct angle will pass into a viewer's eyes to create these phenomena. This is most startling in the case of specters and glories because these phenomena can be only 10 to 100 meters from a viewer. A man and a woman, side by side at the top of a mountain, will each see his or her own specter, the woman's being invisible to the man, and the man's being invisible to the woman. It is the same, but less noticeable, with the other phenomena. For example, with rainbows, one person's red region of a bow could be a neighbor's blue region.

All the phenomena have constant visual angles, the angle at the apex of a triangle at the eye and its base at the object. Unlike objects, whose visual angles decline with distance from the eye, these phenomena appear only when rays at the correct angle enter the eye. For example, the visual angle of the width of a rainbow is about 2°; it has this angle whether it is made in the spray from a nearby hose or in distant rain. Consistent with geometry of objects, the rainbow in the hose looks small whereas that in the rain looks enormous. The perceived size is determined by perceived distance.

The perceived distance of these phenomena is mainly determined by the physical distance from a viewer's eyes of the parts of the atmosphere producing them. But it will be influenced by other depth information. For example, a rainbow's end with a visual direction similar to some conspicuous geographical feature (such as a headland jutting into the sea) will tend to have the same depth as that feature. But of course, as soon as one goes to the foot of the rainbow, to find the legendary pot of gold there, it disappears, leaving the searcher only wet.

ATTENTION: COGNITIVE INFLUENCES

In 1880, William James famously defined *attention* as the mind taking possession of one out of several simultaneously possible objects or train of thoughts. The modern study of attention continues to work within this broad definition. It is generally accepted that an individual is only aware of a small fraction of the information provided to the brain by the sensory systems. *Attention* is the name given to the process that governs which material enters awareness and which does not. This entry focuses on how cognitive factors—goals and expectations of an observer—influence visual attention.

Whether a given stimulus is attended depends both on its inherent salience and the state of the observer. The interplay between these two factors is exemplified by the following two situations: (1) Imagine searching for a friend in a crowd. As one searches through the crowd, attention may be captured by elements that are inherently salient, for instance, a person in a red coat among people in black coats, or by dynamic cues such as a person running. However, where one looks in the crowd also depends on one's knowledge. So, if the friend is known to be wearing a black coat and a blue hat, attention may be less likely to be captured by an otherwise salient red coat, but perhaps be misdirected to a blue coat as one searches for anything blue in the crowd. (2) Imagine walking by a golf course and worrying about being hit by a golf ball. Although it is likely that a quickly moving white thing in one's visual field will be noticed under most circumstances, the act of walking by a golf course and worrying about being hit by a golf ball may lower the threshold for detecting quickly moving white things. Directing one's attention to blue things because blue is currently relevant and increasing sensitivity to detecting moving white things are instances of *cognitive influences on attention.* Traditional accounts of attention have placed little emphasis on such influences in comparison with factors that were thought to automatically capture attention (e.g., a red thing among black things). However, it can be argued that the purpose of visual attention is the selection of information most relevant to a present goal. Hence, the effects of goals, expectations, recent history, and even emotions on visual attention have become an area of active research.

Studying Attention: Behavioral Methods

A commonly used paradigm for studying visual attention is the eponymously named Posner cueing task. The basic version of the task requires subjects to press a button anytime they detect a small circle (the target) while looking at the center of a screen without moving their eyes. Before the appearance of the target, a light (the cue) flashes on the left or the right side of the screen. The location of the cue either coincides with the location of the subsequently appearing target (valid trials) or does not (invalid trials). The basic finding is that reaction times are shorter on valid trials than on uncued trials, and are slowest on invalid trials. The interpretation is that attention is automatically "deployed" to the cued region. Targets that appear in the attended region are processed faster than are targets appearing in an unattended region (which require an attentional shift from the previously cued region).

In addition to flashing lights, the cues can be symbolic, such as right or left arrows presented in the center of the screen. Classic studies from the late 1970s showed that flashing lights (also called exogenous or peripheral cues) elicit attentional shifts even when they do not predict the location of the target. In contrast, arrow cues (also called endogenous or central cues) only produce shifts of attention when they are predictive (e.g., the arrow predicts the position of the target 80% of the time). These results have been interpreted to mean that, unlike flashing lights that automatically capture attention, central cues need to be cognitively interpreted and will shift attention only if subjects have a reason to process them. These classic findings led to a dichotomy between automatic (stimulus-driven, bottom-up, exogenous) attentional processes and controlled (cognitive, top-down, endogenous) processes.

Controversies

Recent studies have argued against this dichotomy in favor of a view in which (a) learned associations determine whether nonpredictive endogenous cues elicit attentional shifts, and (b) highly salient cues can fail to capture attention if they conflict with the viewer's goals. For example, studies from Alan Kingstone's laboratory have shown that pictures of eyes elicit attentional shifts in the direction of their gaze even when the direction does not predict the target. Similarly, nonpredictive arrows and even printed words such as *up* and *down* elicit attentional shifts. Conversely, whether a traditional exogenous cue such as a unique color (e.g., a patch of red among greens) captures attention appears to depend on how the viewer is processing the scene. Consider performance on a task developed by Jan Theeuwes to study the degree to which various visual properties automatically capture attention. In this task, participants are presented with shapes arranged on an imaginary circle around a central fixation point. The goal is to report whether a line that appears in a target shape is, for example, vertically oriented. In a basic version of this task, the target is defined by its unique shape (e.g., it is the only diamond among circles). On distractor trials, the display appears with one of the nontarget shapes in a different color from the rest. Because color is irrelevant to the task, greater reaction times on distractor trials indicate that the unique color automatically captured attention. Based on such findings, Theeuwes and colleagues argued that uniquely colored or shaped objects (singletons) automatically capture attention. Howard Egeth and colleagues challenged this conclusion by showing that whether unique objects capture attention depends on the processing mode of the viewer. If the viewer is in a "singleton detection mode," tuned to detect unique objects, attention is broadly focused and is indeed captured by task-irrelevant singletons. However, if the viewer is specifically looking for a certain feature such as a diamond shape (*feature detection mode*) then salient but task-irrelevant distractors do not capture attention. Nevertheless, there do exist properties that capture attention regardless of task relevance or processing mode. One such property is *sudden onset*. A suddenly appearing object generally captures attention. However, when the object is task-irrelevant, attention is disengaged quite quickly (typically in less than 100 milliseconds [ms]).

Although there is now wide agreement that the viewers' goals can affect which objects or features are attended, the locus of these effects remains highly controversial. Does having a goal like "look for the red things" change the priority of redness but not affect visual processing? Or, does the goal actually change how red things are represented throughout the visual system? Traditional accounts have denied the latter claim. For example, Zenon Pylyshyn has argued for the existence of an early vision system—a modular system that is encapsulated from information outside vision such as the observer's knowledge and goals, and is thus "cognitive impenetrable." Support for the claim that attention changes basic visual processes has come from behavioral studies showing that attended objects are actually perceived as more salient (e.g., brighter), from electrophysiological studies on nonhuman animals and neuroimaging studies on humans.

Effects of Goals on Visual Processing and Attention: Evidence From Electrophysiology and Neuroimaging

Electrophysiological studies on behaving animals have allowed researchers to isolate higher-level influences on attention from the processing that reflects the physical properties of the stimuli. For instance, because neurons in the primary visual cortex (V1) fire most to bars with a certain orientation, a researcher can compare the firing of the neuron to a vertical bar when it is task-relevant versus irrelevant. Any difference in neuron's firing rate to a particularly tuned bar between the first and second task reflects the demands of the task because the physical stimulus is identical in both cases. Such studies generally show that V1 neurons fire more vigorously when their preferred orientation is behaviorally relevant.

An immediate implication of such findings is that responses of neurons even in V1—the first part of the cortex to receive visual input—reflect not simply the physical characteristics of a stimulus, but also the cognitive goals of the observer. More recent findings have shown that primary sensory neurons have two types of receptive fields (RFs). The first is the so-called classical RF and corresponds roughly to what is observed in anesthetized animals and is the initial response of a neuron in an awake animal. The classical RF of a V1 neuron is a line segment of a certain orientation projected into a specific part of the visual field. Within a short period (often less than 50 ms, and sometimes as short as 2 ms), the classical RF is modulated by higher-level information including the goals of the observer, the visual context, and the organization of the scene—producing the nonclassical RF. Although the classical RF of a V1 neuron includes only positional and orientation information, the nonclassical RF includes information such as whether the bar is part of a figure, the background, or an object boundary and whether the figure that the segment is a part of is behaviorally relevant.

In similar studies measuring firing rates of Area V4 neurons (sensitive to color properties of a stimulus), attentional capture of task-irrelevant color singletons is reflected in high firing rates that peak at approximately 120 ms after stimulus onset. When the task requires the monkey to ignore the color singleton, one can observe neural responses to a task-relevant color continue to remain at a high level, whereas responses to task-irrelevant color singletons become down-modulated after approximately 75 ms.

Is early visual neural activity immune to cognitive influences? In electrophysiological studies, it has been found that when a task is performed repeatedly, such as attending to a vertical bar for numerous consecutive trials, the classical RF may disappear entirely—the neurons' response being immediately modulated by the current task. Recent neuroimaging work in humans confirms the conclusion that activity in anatomically early visual areas is permeable to cognitive influences. For instance, when human observers are trained to associate cues with either color or attention, presenting the cue alone modulates activity in visual areas (fusiform gyrus for color; lingual gyrus for location) and, crucially, the amount of modulation strongly predicts performance on the upcoming target-detection trials. This suggests that early visual processing can be tuned by goals and expectations.

Recall that attention is thought to be closely linked to awareness (one notable exception is the phenomenon of blindsight). A claim that a red circle among black circles automatically captures attention generally means that one becomes aware of the red circle even if one's goal is to avoid it. Would showing that some early neural activity evoked by the red circle is impermeable to top-down influences be evidence that automatic awareness of the red circle is directly subserved by that early neural activity? Recent work suggests that such a conclusion is unwarranted. Rather, it appears there may be no awareness without top-down modulation of early visual representations. Much of this evidence has come from studies relying on event-related potentials (ERPs) transcranial magnetic stimulation (TMS). Both methods rely on the earlier time-course of bottom-up versus the later time-course of top-down processes to map their respective contributions. In one study, subjects detected visual figures that were briefly presented and then concealed with a pattern mask. By correlating subjects' performance with electrical potential measured by electrodes on the scalp, J. Fahrenfort and colleagues showed that bottom-up activity, which peaked at about 120 ms after stimulus onset, was not correlated with conscious perception, but top-down (recurrent) activity peaking later (160 ms) was. Thus, it appears that top-down modulation in anatomically "early" visual areas (e.g., V1) by higher-level regions (e.g., prefrontal cortex) is necessary for visual awareness. Further evidence for the causal role of recurrent processing comes from TMS studies in which a high-intensity magnetic field is briefly applied to a selected region of a subject's scalp as he or she performs a task. This pulse creates a temporary disruption in neural processing. Several recent studies have shown that disrupting feedback activity in early visual areas disrupts awareness.

Research Conclusions

The study of attention has classically focused on the physical characteristics that determine whether stimuli are attended. Recent studies have shifted the focus to cognitive factors such as expectations and goals of the viewer. These studies show that neural activity causally linked to awareness is deeply permeated by cognitive factors. Although highly controversial, one conclusion is that it may be impossible to fully study visual attention by separating observers from their goals and environments.

ATTENTION: COVERT

Each time we open our eyes, we are confronted with an overwhelming amount of information. Despite this, we have the clear impression of understanding what we see. This requires selecting relevant information out of the irrelevant noise. Attention is what turns looking into seeing, allowing us to select a certain location or aspect of the visual scene and to prioritize its processing. Such selection is necessary because the limits on our capacity to absorb visual information are severe.

They may be imposed by the fact that there is a fixed amount of overall energy consumption available to the brain, and by the high-energy cost of the neuronal activity involved in cortical computation. Attention is crucial in optimizing the use of the system's limited resources, by enhancing the representation of the relevant locations or features while diminishing the representation of the less relevant locations or aspects of our visual environment.

The processing of sensory input is facilitated by knowledge and assumptions about the world, by the behavioral state of the organism, and by the (sudden) appearance of possibly relevant information in the environment. For example, spotting a friend in a crowd is much easier if you are cued to two types of information: where to look and what to look for. Indeed, numerous studies have shown that directing attention to a spatial location or to distinguishing features of a target can enhance its discriminability and the neural response it evokes. Understanding the nature of attention and its neural basis is one of the central goals of cognition, perception, and cognitive neuroscience, as described in this entry.

Spatial Covert Attention

Attention can be allocated by moving one's eyes toward a location, overt attention, or by attending to an area in the periphery without actually directing one's gaze toward it. This peripheral deployment of attention, known as covert attention, aids us in monitoring the environment and can inform subsequent eye movements. Cognitive, psychophysical, electrophysiological, and neuroimaging studies provide evidence for the existence of overt and covert attention in both humans (including infants) and nonhuman primates. Many of these studies have likened attention to increasing visual salience. Whereas covert attention can be deployed to more than one location simultaneously ("in parallel"), eye movements are necessarily sequential ("serial"); they can only be at one location at a given time. Many studies have investigated the interaction of overt and covert attention and the order in which they are deployed. The consensus is that covert attention precedes eye movements and their effects on perception, which in many cases are similar but in others they are not.

Hermann von Helmholtz is considered to be the first scientist to provide an experimental demonstration of covert attention (circa 1860). He experimented with a wooden box whose interior was completely dark. Looking into the box through two pinholes, he reported that he could concentrate on any part of the visual field so that when a spark came, he could focus attention independently of the position and accommodation of his eyes, and get an impression of objects in only the particular attended region. The similarities and differences between eye movements and deployment of spatial attention have been a focus for research ever since.

Many authors state that humans deploy covert attention routinely in many everyday situations, such as searching for objects, driving, crossing the street, playing sports, and dancing. However, other authors think that covert attention is deployed mainly in social situations—for example, when deception about intentions is desired, in competitive situations (such as sports activities), or when moving the eyes would provide a cue to intentions that the individual wishes to conceal.

Endogenous and Exogenous Covert Attention Systems

A growing body of behavioral evidence demonstrates that there are two covert attention systems that deal with facilitation and selection of information: *endogenous* and *exogenous*. The former is a voluntary system that corresponds to our ability to willfully monitor information at a given location; the latter is an involuntary system that corresponds to an automatic orienting response to a location where sudden stimulation has occurred. Endogenous attention is also known as *sustained* attention and exogenous attention is also known as *transient* attention. These terms refer to temporal nature of each type of attention: Whereas observers seem to be able to sustain the voluntary deployment of attention to a given location for as long as needed to perform the task, the involuntary deployment of attention is transient, meaning it rises and decays quickly. The different temporal characteristics and degrees of automaticity of these systems suggest that they may have evolved for different purposes and at different times—the transient, exogenous system may be phylogenetically older.

Behavioral Studies

To investigate covert attention, it is necessary to make sure that observers' fixation is maintained, and to keep both the task and stimuli constant across conditions while manipulating attention. Experimentally, the endogenous and exogenous systems can be differentially engaged by using distinct cues. Michael Posner devised a paradigm that has been widely used to study the endogenous and exogenous orienting of attention. It allows the comparison of performance in conditions where attention is deliberately directed to either a given location (attended condition), away from that location (unattended condition), or distributed across the display (neutral or control condition).

In the Posner cueing paradigm, observers have to respond as quickly as possible to a peripheral target, which is preceded by a central or peripheral cue. In the endogenous condition, a central cue—typically an arrow—points to the most likely location of the subsequent target. In the exogenous condition, a brief peripheral cue is typically presented at one of the target locations but does not predict the subsequent target location. In both endogenous and exogenous conditions, performance in detecting or discriminating a target is typically better (faster, more accurate or both) in trials in which the target appears at the cued location than at uncued locations. Central or symbolic cues take about 300 milliseconds (ms) to direct endogenous attention in a goal-driven or conceptually driven fashion. Central cues are small lines presented at fixation pointing to different locations of the visual field (e.g., upper left quadrant, lower right quadrant); symbolic cues include different numbers or colors that indicate different locations where the observer is to attend (e.g., #1 or a red circle indicates upper left quadrant, #3 or a blue circle indicates lower right quadrant). Peripheral cues, conversely, grab exogenous attention in a stimulus-driven, automatic manner within about 100 ms. Whereas the shifts of attention elicited by central cues appear to be under conscious control, it seems that it is extremely hard for observers to ignore peripheral cues. This involuntary transient shift occurs even when the cues are uninformative or may impair performance.

Neurophysiological Studies

Single-Unit Recording Studies

The development of techniques to record the electrical activity of single neurons in awake-behaving animals (e.g., monkeys) has enabled researchers to probe the biological foundations of endogenous (sustained) attention while monkeys perform attention-demanding tasks. Such studies have provided detailed, quantitative descriptions of how endogenous attention alters the responses of neurons in the extrastriate visual cortex, yielding attentional facilitation and selection. Attentional facilitation results when spatial attention enhances the responses evoked by a single stimulus appearing alone in a neuron's receptive field, so that neurons respond to an attended stimulus much as they would were its luminance increased. Given that stimuli rarely appear in isolation, attentional selection of behaviorally relevant targets from among distracters arguably serves a more ecologically relevant purpose. When multiple stimuli appear within a neuron's receptive field, the firing rate is characteristically determined primarily by the task-relevant stimulus. Numerous studies have compared the response when attention is directed either with one of the two stimuli in the receptive field or outside the receptive field while fixation is maintained. Attending to the preferred stimulus (for which the neuron is tuned) increases the neuron's response evoked by the pair of stimuli whereas attending to the non-preferred stimulus (for which the neuron is not tuned) decreases such response.

Neuroimaging Studies

Neuroimaging has yielded information on the integrated brain activity underlying perception and cognition in humans. Studies documenting the neural correlates of covert attention have used several techniques, among them event-related potentials (ERPs) and functional magnetic resonance imaging (fMRI).

ERPs are electrophysiological responses that arise during sensory, cognitive, and motor processing, which provide precise information about the time course of information processing. ERP recordings can help reveal the timing and organization of stimulus selection processes in the brain's attentional network. ERP studies provide support for a mechanism of early sensory facilitation, at the level of the extrastriate visual cortex, during the spatial cueing of attention.

fMRI measures hemodynamic processes not invasively in the human brain by providing temporally integrated maps of regional cerebral blood flow across the whole brain. It is based on the increase in blood flow to the local vasculature that accompanies neural activity in the brain. There is wide agreement that attention increases fMRI responses in visual cortical areas in a retinotopically specific manner, corresponding to attended spatial locations, both for endogenous and exogenous attention. There is no consensus, however, about whether common neurophysiological substrates underlie endogenous and exogenous attention. Whereas some fMRI studies have found no difference in the brain networks mediating these systems, others have reported differences. For example, endogenous attention is cortical in nature, but exogenous attention also activates subcortical structures. Moreover, partially segregated networks mediate the preparatory control signals of both systems. For example, endogenous attention is mediated by a feedback mechanism involving feedback from frontal and parietal areas, whereas these regions are not necessarily involved in exogenous attention.

Feature-Based Attention

Behavioral Studies

Most studies of overt or covert attention (with or without eye movements, respectively) have examined the effects of spatial attention at different locations in the visual field. Both types of attention, however, can also be allocated to specific visual features, such as orientation or direction of motion or color. Feature-based attention is the ability to enhance the representation of image components throughout the visual field that are related to a particular feature. This type of attention is considered to play a central role when human or nonhuman primates search for a stimulus containing that feature. This ability to detect a target or relevant item among distracters is the basis of a widely used paradigm in visual attention research: visual search.

Many psychophysical studies have shown that feature-based attention improves detection and discrimination performance across the visual field. A visual stimulus always occupies a certain spatial location, so it is important to control spatial selection. Thus, studies of feature-based attention generally use compound stimuli that contain multiple features superimposed over the same spatial location, and observers are required to attend to one of those features. For instance, attending to one motion direction in a compound motion stimulus produces a motion aftereffect consistent with the attended direction, and attending to one orientation in a compound orientation stimulus produces an orientation aftereffect consistent with the attended orientation.

Neurophysiological Studies

Because feature-based attention is independent of location, it is well suited to selectively modify the neural representations of stimulus features within visual scenes that match the currently attended feature. For example, feature-based attention can enhance the neural responses to a given attended feature; e.g., vertical orientation regardless of the locations where vertical orientations appear in the scene.

Single-Unit Recording

Some studies using single-unit recordings to investigate feature-based attention have shown that the responses of individual neurons that are selective for an attended feature (for example, vertical orientation, upward motion direction, or red color) can be selectively enhanced when the monkey attends to that particular feature (for example, upward motion while seeing a stimulus containing both upward and downward motion). Other studies have shown that attending to different feature dimensions (e.g., color or orientation) modulates activity in cortical areas specialized for processing those dimensions.

Neuroimaging

fMRI studies requiring participants to attend to specific features of stimuli have revealed that the neural activity evoked by the attended feature is enhanced both within the retinotopic cortical regions representing the spatially attended location and at other unattended regions that were stimulated by the same feature. Enhanced activation has even been observed at spatial locations where no stimuli were present. These studies suggest that feature-based attention is activated across the visual field. This representation enables the visual system to concentrate its limited processing resources on the most relevant sensory inputs regardless of where in the visual field they are located.

ATTENTION: CROSS-MODAL

Attention refers to those processes that allow for the *selective* processing of incoming sensory stimuli, typically those that are most relevant to one's current goals or to the task at hand, or, alternatively, those that have the greatest intrinsic salience or biological significance. Attended stimuli tend to be processed both more thoroughly and more rapidly than are other potentially distracting ("unattended") stimuli. Although research on attention has traditionally considered selection among the competing sensory inputs within just a single modality at a time (most often vision), the past two decades have seen a burgeoning of interest in the existence and nature of any cross-modal constraints on our ability to selectively attend to a particular object, location, or source of information.

The term *cross-modal* is typically used in situations in which the orienting of a person's spatial attention in one sensory modality (such as vision) results in a concomitant shift of attention in one or more of his or her other sensory modalities (such as audition or touch) to the same location (or object) at the same time. The central question for researchers interested in cross-modal attention concerns how the brain's attentional resources are coordinated or linked between the senses to select just that subset of information that is relevant to a person's current goals from among the abundance of multisensory information impinging on the various sensory receptors at any one time. This entry describes coordination of attentional resources, attentional selection research, mapping of cross-modal links, and future research directions

Coordination of Attentional Resources

One intuitive possibility is that there might be independent modality-specific attentional resources. So, for example, some researchers have argued that there may actually be separate visual, auditory, and tactile attentional systems in the human brain. According to this account (which posits that cross-modal links in spatial attention do not exist), people should, for example, be able to direct their visual attention to one location while directing their auditory or tactile attention to a different location (because the attentional systems are independent). However, other researchers have argued that there is only a single supramodal attentional system, such that people can only attend to a single location at any given time (that is, they cannot split their attention between different locations simultaneously). According to the supramodal account, all stimuli, no matter what their modality, that are presented from a location that is attended should receive preferential processing over stimuli that are presented elsewhere.

A third possibility (that has emerged more recently) is that there might be some intermediate form of organization instead. So, for example, according to Charles Spence and Jon Driver's hybrid separate-but-linked hypothesis, there may be separate visual, auditory, and tactile attentional systems at the earliest levels of human information processing. However, these attentional systems are subsequently linked, such that people's attention typically tends to be (but importantly does not always have to be) focused on the same location in space in the different modalities.

Attentional Selection

Researchers studying spatial attention distinguish between endogenous and exogenous attentional selection. *Endogenous* attention is typically involved in the voluntary orienting of attention to a particular event or spatial location, such as when you choose to attend to a particular person at a noisy cocktail party, or when you concentrate on the feel of the object that you are playing with in your right hand. By contrast, *exogenous* (or involuntary) orienting occurs when attention is reflexively shifted to the location of a sudden and unexpected peripheral event, such as when a person calls your name at the cocktail party, or when a fly suddenly lands on your arm. Orthogonal to this distinction between endogenous and exogenous attention is the distinction between overt and covert attentional orienting: *Overt* orienting refers to shifts of receptors (as in eye, head, or hand movements), whereas *covert* orienting (which is of most interest to cognitive psychologists studying selective attention) refers to internal shifts of attention (e.g., as when we look at someone out of the corner of our eye).

Exogenous Attention

Most studies of cross-modal spatial attention have adapted the spatial cueing paradigm first popularized by Michael Posner back in the 1970s. In a typical study of exogenous attention, a cue stimulus is presented in one sensory modality (e.g., audition, vision, or touch) shortly before a target appears on either the same or opposite side of central fixation. The target stimulus may be presented in either the same or different sensory modality as the cue. Importantly, however, the target is just as likely to be presented on the same, as on the opposite, side as the cue (that is, the cue is spatially nonpredictive with regard to the likely target location). Participants are often instructed to try to ignore the cue as much as possible. However, the results of many studies conducted during the past 20 years have shown that participants typically cannot ignore such cues and respond more rapidly (or accurately) to targets presented at the cued, as opposed to the uncued, location, at least when the target is presented within a few hundred milliseconds of the cue. Depending on the particular task, participants sometimes start to respond more slowly to targets at the cued (compared with the uncued) location as the interval between the onset of the cue and target lengthens, a phenomenon known as *inhibition of return.*

The presentation of either an auditory or a tactile spatially nonpredictive cue has been shown to result in a rapid exogenous shift of spatial attention to the cued location, and this shift of attention facilitates the subsequent processing of auditory, tactile, and visual targets at that location. Meanwhile, visual cues have been shown to elicit a shift of visual, tactile, and, on occasion, auditory attention toward the cued location. Recent studies of exogenous cross-modal spatial attention have shown that perceptual sensitivity is enhanced at the cued location, and what is more, people tend to become aware of stimuli presented at the cued location sooner than when the same stimuli are presented elsewhere, a phenomenon known as *prior entry.* At longer cue-target intervals (typically greater than 200–300 milliseconds), inhibition of return has now been observed in speeded detection tasks between all combinations of auditory, visual, and tactile cue and target stimuli.

Endogenous Attention

Turning to the nature of the cross-modal links that constrain the deployment of endogenous spatial attention, researchers have shown that if people deliberately direct their attention to a particular location in one sensory modality, their endogenous attention in the other modalities will tend to follow to the same location, albeit at a somewhat reduced level (i.e., the attentional benefits are smaller). So, for example, if participants are instructed to attend to their left hand because a tactile target is likely there, visual targets will also be responded to preferentially by the left hand. Evidence in support of the separate-but-linked hypothesis of cross-modal links in endogenous spatial attention comes from the results of studies showing that although they find it difficult, people can nevertheless still direct their attention in different directions in different modalities at the same time. So, for example, under the appropriate experimental conditions it has been shown that people can preferentially process visual stimuli presented by their left hand, while showing an attentional bias toward the processing of tactile stimuli presented to their right hand. Results such as these are inconsistent with both the modality-specific and supramodal accounts of cross-modal spatial attention.

Mapping of Cross-Modal Links

Having demonstrated the existence of cross-modal links in both exogenous and endogenous spatial attention (and in inhibition of return) between all possible combinations of auditory, visual, and tactile stimuli, one of the most important issues currently in cross-modal research is how (and even whether) the brain updates the mapping (or correspondence) between the senses when people change their posture. Each of our senses initially codes information according to a different frame of reference: So, for example, visual stimuli are initially coded retinotopically, auditory stimuli tonotopically, and tactile stimuli somatotopically. The question therefore arises how all of this information is coordinated into a common frame of reference for the control of attention (and subsequently action). To investigate whether cross-modal links in spatial attention are updated following changes in posture, researchers have conducted experiments in which the participants have had to cross their hands over the midline (so that their left hand is in the right side of space and their right hand in the left), or to deviate their gaze (to either the left or right) while keeping their head fixed straight ahead. The results of several such studies now show that cross-modal links in spatial attention are updated following posture change. So, for example, researchers have shown that although people find it easier to attend to tactile stimuli presented to their left hand and to visual stimuli on the *left* side of space when their hands are uncrossed (so that their left hand is on the left side of their body), they find it easier to concentrate on their left hand and *right* visual stimuli when their hands are crossed over the midline (such that their left hand now lies in the right hemispace). Results such as these have led researchers to conclude that the "space" in which attention is directed is itself a multisensory construction.

Many researchers are currently investigating how (and where) such cross-modal links in spatial attention are mediated in the human brain. One popular suggestion has been that multisensory spatial maps, such as those found in the superior colliculus (where spatially aligned maps of visual, auditory, and tactile space are superimposed), might mediate at least some of the behavioral spatial cueing effects that have been observed in the laboratory. However, there is currently much debate about the extent to which exogenous cross-modal spatial attention effects (typically observed by cognitive psychologists in awake human participants) and multisensory integration effects (typically observed at the single cell level in anaesthetized animals by neurophysiologists) actually represent the same underlying phenomenon. There is, then, still much work to be done in bridging the gap between the different methods and the different levels of analysis at which scientists study cross-modal spatial attention. One popular idea that has emerged recently is that multisensory influences on unimodal brain areas might arise because of feedback or back-projection influences on them, from multisensory convergence-zones or attentional control structures.

Future Directions

Our growing understanding of the nature of the cross-modal links that constrain spatial attention will likely increasingly help provide guidelines to aid the effective design of multimodal (or multisensory) user interfaces. For example, research in the field of applied psychology has shown that people find it particularly difficult to hold a conversation on a mobile phone while driving a car. One of the major problems in this multisensory dual-task situation may be that people find it difficult to attend visually out of the windshield to watch the road ahead, while trying to listen to the voice coming from the phone by their ear (due, presumably, to the cross-modal links in spatial attention highlighted earlier). It is possible that performance in this situation could be improved if the speaker's voice were to be presented from directly in front of the driver (i.e., via a "talking windshield"), to take advantage of the underlying cross-modal links that constrain the deployment of endogenous spatial attention. Similarly, a better understanding of the cross-modal links in exogenous orienting may also lead to the design of more effective multisensory warning signals. Indeed, the latest research by Cristy Ho and her colleagues has shown that bimodal cues (i.e., audiovisual or audiotactile) appear to capture the spatial attention of car drivers far more effectively than unisensory warning signals (at least when the various unisensory cues are presented from the same spatial location, or direction).

ATTENTION: DISORDERS

Attention can imply various skills, such as staying on-task (as when driving down a monotonous highway), multitasking (as when talking to a passenger while driving), or focusing on one specific thing (as when reading a road sign). Students of perception are usually concerned with this last meaning of attention as a process of selection. Insights into how selective attention works can be gained from studying people in whom selection has broken down because of brain damage (usually caused by stroke). Attention is normally considered the gateway to conscious awareness, and disorders of attention thus entail losses of awareness for certain parts of the world. This entry discusses three major disorders of attention, and considers what sorts of perception may be possible for things outside of awareness.

Neglect

Neglect is a common and disabling consequence of brain damage. When it is severe, the eyes and head deviate toward the side of the damage, and people may fail to dress or groom the opposite half of their bodies, to eat food from that half of their plates, or to acknowledge anything on that side. Neglect is strongly associated with damage to the right side of the brain, particularly the posterior parietal and superior temporal lobes, so it is usually the left side of space that is neglected. The problem is not one of sensory transmission. The independence of neglect from sensory factors was illustrated elegantly by Eduardo Bisiach and Claudio Luzzatti, who asked two patients to describe a familiar Milanese square from memory. Both described buildings on the right, but not on the left, relative to their imagined viewpoints, showing that even mental images may be neglected.

Neglect is usually understood as a spatial bias of attention, such that items in relatively rightward positions are selected at the expense of those further to the left. Unawareness is not restricted to the visual world. Patients may neglect sounds, touches, and even smells. They may also neglect internal sensations, contributing to a loss of awareness for one side of the body. However, the world is experienced as complete because, by definition, the patient is unaware of the neglected parts. It may thus be difficult for a patient to achieve direct insight into his or her problem, and neglect can be hard to treat. At a theoretical level, the condition offers a unique window on spatial attention. No two patients are exactly alike in their symptoms, and the differences between them can inform us about how attention is organized in the brain. For instance, a patient who neglects visual objects might nonetheless be alert to touches on that side, or vice versa. Such patterns show that attention is not a single function shared across sensory modalities. The mechanisms by which we attend to our different senses must be at least partially separate because they can be disrupted separately by brain damage.

Research into neglect has tended to focus on its visual effects, but even here the symptoms are remarkably varied, suggesting many subdivisions of visual attention. For instance, visual space can be divided conceptually into that which can be accessed directly by reaching and grasping (near space) and that which cannot (far space). This distinction may be of significance for the control of behavior, and neglect research has helped confirm its biological reality. Peter Halligan and John Marshall reported a neglect patient who made large errors in estimating the midpoints of horizontal lines in near space, yet who could accurately bisect lines of equivalent visual extent in far space, by pointing a light-pen or throwing a dart. A further, distinct region of space is personal space, bounded by and immediately surrounding the body. Patients have been reported who can search both sides of external space effectively, yet fail to notice bright markers, such as balls of fluff, attached to one side of their clothing. Visual neglect for personal space may interact with neglect of bodily sensations to destroy awareness for one side of the body.

Visual neglect also highlights the fact that the apparently straightforward concepts of left and right are far from simple because their definitions depend on the spatial reference frame adopted. A primary distinction is drawn between egocentric and allocentric reference frames: the former specify positions relative to the viewer; the latter relative to things within the environment. If you look at a building, then tilt your head to one side, the building seems to stay upright despite your altered viewpoint. Your perception of up and down (and left and right) is not determined by your egocentric viewpoint alone, but also by environmental cues (in this case, the building itself, other objects in the scene, and gravity). Similar manipulations have been applied to patients with neglect, for instance asking them to search for objects in a display while sitting upright or lying on one side. Under such conditions, some objects may be neglected on the left side with respect to the current viewpoint (i.e., the bottom of the display if the patient is lying on his or her left side), and some on the left of the display regardless of posture. These patterns suggest that egocentric and allocentric factors interact to determine the space that is neglected.

One special class of allocentric reference frame is object-centered. If a familiar object (such as a building) has a recognizable top and bottom, we tend to think of it as having left-and-right sides that are independent of its positioning within the visual field. Consistent with this idea, neglect can affect the left side of individual objects, regardless of their position or orientation in space. For instance, a patient who usually neglects letters at the left end of words may continue to neglect the *initial* letters of words shown upside down, even though these are now seen on the right (e.g., reading PEAR as EAR). Patients may even show object-centered neglect at the same time as neglecting whole objects within the left part of space. These remarkable observations imply that selective attention uses spatial representations encoded with respect to multiple frames of reference. These representations are flexibly created, and re-created, as different frames of reference become relevant to the task at hand.

The diversity of symptoms across patients with neglect shows that it is not a single entity, but an umbrella term covering a constellation of related impairments. Moreover, in any given case, the clinical picture may depend on biased spatial attention and on co-occurring consequences of brain damage. These include reduced arousal and vigilance, which aggravate the lack of attention to the neglected side, and spatial memory problems, which impede structured searching of space. Neglect is thus a syndrome of many components, not all of which are necessary for neglect, but each of which can color its expression. At its core, however, is the skewing of attention away from one side. This may sometimes appear as a simple lack of attention for one half of space, but what is more typically seen is a directional bias across the entire space, with things in relatively rightward positions exerting a stronger pull on attention than do those that are relatively leftward.

Extinction

In the most basic assessment of visual extinction, the examiner faces the patient and holds up a finger on either side, while the patient looks straight ahead. The examiner then flexes one or both fingers rapidly, and the patient must report which fingers moved. Extinction is diagnosed if the patient reports single flexions on either side, but only one when both occur together: one event "extinguishes" awareness of the other. Analogous methods are used to diagnose extinction in other modalities (e.g., touch, hearing, smell). Like neglect, extinction reflects the outcome of a spatially biased competition for attention. However, it is elicited only when the stimulation is brief. Extinction may follow damage to either side of the brain, affecting the side of space opposite to the damage. Unlike neglect, extinction shows no preferential association with the right hemisphere. This has led some authors to suggest that it is separate from neglect, though others believe it to be a milder form of the same condition.

Morris Bender, who conducted the pioneering work on extinction, viewed it as a sensory disorder in which subtly impaired sensation on one side is exposed by stimulus competition. His observations of tactile extinction in patients with spinal injuries showed that the symptom can arise from a sensory imbalance. Nonetheless, numerous phenomena have been found that defy sensory accounts and imply an attentional disorder. For instance, tactile extinction can be determined by position in external space rather than by the sensory surface: if a touch to the right hand extinguishes awareness of a touch to the left, then this reverses when the hands are crossed over the midline. Similarly, visual extinction can occur when the competing stimuli are within the same half of visual space, showing that it depends on relative, rather than absolute, location. Visual extinction is also affected by various perceptual properties of the stimuli. For example, if two brackets are presented, extinction may be less likely when they face one another () than when they oppose one another)(. The former pair constitutes a better group according to Gestalt laws of perceptual organization, and are selected together rather than competing for attention.

Simultanagnosia

Simultanagnosia, one of the key features of Bálint's syndrome, typically requires damage to the posterior parietal lobes on both sides of the brain. The condition is reminiscent of extinction, in that the patient perceives only one object when multiple objects are present. However, whereas extinction requires brief stimulation and is determined by spatial location, simultanagnosia persists with prolonged viewing and is insensitive to the layout of a scene, being determined instead by the objects within it. A patient with simultanagnosia will report being aware of only one object at a time. The focus may change intermittently, so that several objects are eventually perceived, but there is no experience of their simultaneous presence. In describing a scene, such a patient may give a halting commentary, naming one object and then another, without grasping their interrelationships. A man posting a letter could be, "a man . . . a letter . . . a postbox."

The existence of simultanagnosia provides reason to believe that visual attention can select specific objects, rather than just regions of space. Simultanagnosia cannot simply reflect spatially restricted attention because the object selected can be of any size, from a single snowflake to Mount Everest. Moreover, if two line drawings are overlapped so that they occupy the same region of space, only one of them will be perceived. Being object-based, simultanagnosia can allow researchers to probe what constitutes an object in vision. The governing principles are again predicted well by the Gestalt laws of perceptual organization. Alexander Luria famously showed that a patient with simultanagnosia saw only one of two overlapping triangles of different colors, but a Star of David (✡) when the triangles shared the same color, thereby cohering as one object. Similarly, only one of two side-by-side circles was seen, but a pair of spectacles was reported when a horizontal line connected the circles.

The Fate of Unattended Things

Neglect, extinction, and simultanagnosia are disorders of attention, not of sensory transmission, so the unattended stimuli are potentially available in the brain for processing. Researchers may thus ask what aspects of perception can proceed without attention, and whether things that escape awareness can shape behavior. As noted, the likelihood of a stimulus being unattended is influenced by Gestalt grouping factors, suggesting that the perceptual organization of a scene into its constituent parts is accomplished before attentional selection. Many other studies have reported that more complex aspects of unattended stimuli, even identity and meaning, can affect behavior. In the most famous such experiment, a neglect patient was presented with two drawings, one of which had flames emerging from its left side. The patient maintained that the houses were identical, but when forced to choose which house she would prefer to live in, reliably tended to choose the one that was not on fire. She avoided the flames unconsciously, despite expressing no awareness of them. Under some circumstances, unattended things may even have as strong an influence as attended things. For instance, a patient with visual extinction was found to avoid an obstacle during reaching, to exactly the same extent, regardless of whether he could report the obstacle's existence. Disorders of attention are thus powerful "natural experiments" that allow us to query the purpose of conscious awareness, by studying what can be achieved without it. Sometimes, this is a surprisingly large amount.

ATTENTION: DIVIDED

For experienced drivers, talking on a cell phone while driving seems relatively easy. From a processing perspective, however, it requires the concurrent perception, analysis, decision making, and response selection of multiple stimuli from different sensory modalities. Research on the efficiency of such concurrent perceptual and cognitive processing of multiple stimuli or tasks comes under the heading of *divided attention.* The degree to which performance deteriorates under such conditions has been studied to characterize limitations on real-world human performance, as well as to inform theoretical models of the functional architecture of the human perceptual-cognitive system. Theories of divided attention have proposed that limitations on multitask performance can be attributed to competition for processing *resources* as well as to competition for processing *mechanisms.*

Laboratory research on divided attention typically involves dual-task methodology, in which performance on a given task performed alone is compared with performance when the same task is performed in combination with another task, whose difficulty is often systematically varied. Deterioration under dual-task conditions is assumed to reflect limitations on divided attention, whereas the lack of any decline in performance is assumed to reflect successful division of limited cognitive resources. For example, despite the apparent ease with which one can talk on a cell phone and drive, laboratory studies reveal significant impairment in driving performance with cell phone use. This is true even with hands-free phones, suggesting that attentional resources cannot be effectively divided between the two tasks.

Not all dual-task decrements necessarily reflect a failure of divided attention. For example, deterioration in certain combinations of tasks or stimuli may reflect structural limitations on sensory processing rather than attentional limits. Thus, the need to look at one's cell phone to dial a number may produce a decrement in concurrent driving performance simply because one's eyes are no longer "on the road." Such a decrement would not be considered an attentional limitation. This entry describes theories of divided attention and effects of practice on the ability to perform multiple tasks simultaneously.

Theories

Everyday experience suggests that the ability to divide attention among stimuli or tasks depends on the nature and difficulty of the constituent stimuli or tasks. For example, reading e-mail messages while listening to a speaker deliver a lecture is intuitively more difficult than is reading e-mail while listening to music. The results of laboratory studies using dual-task methodology confirm these intuitions; the efficiency with which multiple tasks are performed simultaneously depends crucially on the particular combination of tasks and their difficulty. Theoretical attempts to account for and predict the patterns of interactions between tasks fall into two broad classes: *capacity theories* and *structural theories*. These classes of theory are not mutually exclusive, and neither class is able to account for the full range of data, suggesting that a comprehensive theory of divided attention performance may require multiple constructs.

Capacity Theories

Emerging in the 1960s and refined in the 1970s, *capacity theory* is based on the assumption that mental tasks (perception, memory, language, reasoning, problem-solving, etc.) require the graded allocation of cognitive resources (sometimes referred to as mental fuel or effort), and that the available pool of resources to carry out these tasks is finite. Thus, if the resources required by a particular combination of stimuli or tasks exceeds the resources available, performance on one or both tasks will decline, depending on the voluntary allocation policy (i.e., which task is given priority). Note that according to this perspective, the cognitive architecture is such that mental tasks can be carried out at the same time, but the efficiency of task processing varies continuously with resource availability.

General Versus Specific Resources

In its original conception, capacity theory assumed that the resources available for cognitive processing are relatively nonspecific. That is, all mental tasks draw from the same pool of resources, and therefore interference between tasks should be determined only by the amount of resources required by the constituent tasks, rather than by the nature of the tasks or stimuli (e.g., their similarity). However, as noted earlier, and as revealed by subsequent research, the more similar the tasks, the more dual-task interference is generally observed.

One highly influential account of similarity effects in dual-task interference is the notion that there are a number of separate pools of resources that are specialized for particular types of cognitive processes. According to this account, interference will be observed only if the constituent tasks draw from the same specific pool of resources. If the tasks draw from different resource pools, then there should be no interference, even as the difficulty of the tasks is increased.

The most well-developed version of this account, *multiple resource theory,* proposes a set of resource pools defined across three dimensions: (1) stages of processing (perceptual-central vs. response), (2) format of internal representations (verbal vs. spatial), and (3) format of response (manual vs. vocal). Combinations of values across these dimensions are assumed to define a specific resource pool. Evidence consistent with this account comes from a host of dual-task studies that have systematically manipulated constituent tasks with respect to the proposed dimensions.

Despite the usefulness of this model, there are still cases where combining tasks that appear to share little with respect to processing dimensions nonetheless produces significant dual-task interference. For instance, even though cell phone use involves auditory input, verbal representations, and verbal output, it interferes with driving, which involves visual input, spatial representations, and manual output. Such examples would appear to indicate at least some degree of undifferentiated resource sharing.

Structural Theories

Structural models of divided attention performance emerged from the classic dichotic listening studies of the 1950s and 1960s, in which separate messages were presented to each ear. These experiments, which were modeled after early air traffic control environments, revealed severe limitations in people's ability to divide attention between the two messages. In particular, when attending to one message, only crude aspects of the unattended message were noticed (e.g., the gender of the voice delivering the message). In contrast to capacity theories, which attribute such limitations to competition for resources, structural theories implicate competition for processing *mechanisms* or *operations*. The notion is that critical mental operations can only be applied to one stimulus or task at a time, resulting in a processing bottleneck when attempting to simultaneously process multiple stimuli or tasks that all require that operation.

Perceptual Limitations

One proposed locus for a structural processing bottleneck is in the perceptual operations associated with stimulus identification or pattern recognition. According to this view, there is a limit on the number of stimuli that can be identified at one time. The typical experiment designed to evaluate this proposal involves measuring changes in performance as a function of the number of simultaneously presented stimuli. Generally, performance does indeed decline as the number of display items increases. For example, in visual search tasks where observers report the presence or absence of a prespecified target, both response times and error rates tend to increase with the number of distractors in the display, and this is particularly true when the distractors are perceptually similar or share critical properties with the target.

Central Limitations

In addition to limitations on perceptual processing, evidence also shows that central processes may also represent a locus for a structural bottleneck. In particular, research suggests that the process of choosing and selecting an appropriate response can only be applied to one task or stimulus at a time. Thus, when attempting to perform two tasks at the same time, processing on one of the two tasks will have to be suspended temporarily until response selection for the other task is complete, which necessarily produces a decline in task performance.

Evidence for this notion comes from experiments in which subjects must make speeded responses to one stimulus (Task 1) followed, at varying intervals, by a second stimulus (Task 2). For example, subjects might respond to the pitch of a tone (high or low) followed by the identity of a digit (1, 2, or 3). As the time interval between the two stimuli is decreased, performance on Task 2 typically slows down (assuming Task 1 is given priority). This phenomenon, known as the *psychological refractory period,* is consistent with a processing bottleneck, in that as the interval between the two stimuli decreases, and processing of the two tasks overlaps to a greater and greater extent, some aspect of Task 2 processing has to wait until response selection for Task 1 is complete.

Evidence that the bottleneck in these experiments consists of response selection comes from systematic manipulations of the difficulty of Task 2. Difficulty effects that influence processing before response selection (e.g., the difficulty of perceptual processing) are actually reduced as the amount of dual-task slowing increases. This makes sense if perceptual processing of difficult stimuli can continue during the time Task 2 is waiting for response selection of Task 1 to finish. In contrast, difficulty effects that influence response selection itself (e.g., the intuitiveness of the mapping between stimuli and responses) simply add on to dual-task slowing, indicating that response selection cannot occur during the wait time. In other words, response selection itself constitutes the processing bottleneck. However, there are exceptions to this pattern. In particular, studies have shown that with practice on the constituent tasks, or with particular combinations of stimulus and response modalities, response selection for the two tasks can proceed concurrently.

Effects of Practice

As discussed earlier, the difficulty of tasks has a strong influence on the ability to perform multiple tasks simultaneously. The difficulty of a given task is influenced by the type or amount of processing required, as well as by the amount of experience or practice one has had with the task. For example, although novice drivers may be unwilling to carry on a conversation with a passenger while driving, the situation changes dramatically with only moderate amounts of driving experience. With practice, tasks become subjectively easier. In the context of capacity theories, improvement in performance with practice is assumed to reflect a reduction in the amount of resources needed to accomplish the task. At the extreme, a highly practiced task may become "automatic" in the sense that few, if any, limited cognitive resources are required to accomplish the task. For example, studies of visual search have shown that when observers search for the same target letters for thousands of trials, the number of distractor letters present in the display has no effect on response times, suggesting that the identification of the targets no longer requires the controlled allocation of limited processing resources. It follows that as the resource demands of a particular task decline, the ability to perform that task in combination with other tasks should improve, and this prediction is indeed supported by laboratory research. In the context of structural theories, practice is assumed to reflect an enhanced ability to coordinate critical processing operations. For example, practice may improve the ability to rapidly switch the response selector back and forth between tasks.

ATTENTION: EFFECT OF BREAKDOWN

Many encyclopedia entries and introductory chapters written about attentional selection start by noting that our environment is rather rich in sensory stimulation that cannot possibly be processed simultaneously and there has to be a mechanism (attentional selection) that deals with this bombardment of sensory stimulation by processing only the relevant information. This statement is valid, but what is the evidence for this implied limited capacity (i.e., the breakdown of attention)? Perhaps you have had the experience of walking into a crowded café trying to find an empty table while holding a tray with hot soup and a sandwich. After quite a bit of searching around, you finally find a table and sit down to enjoy your food. But just as you are about to bite into your sandwich, a friend of yours comes by your table asking why you've ignored her waving at you. This example illustrates a simple yet startling fact—even though we may feel as if we perceive everything around us, the perceptual reality is that we are only aware of a small subset of sensory events at any single moment in time. The failure of attention, illustrated with this example, reflects the fact that most of the sensory information available in the physical world is actually not processed, and therefore is not available for conscious perception. This lack of conscious access to the sensory information present in the physical world is termed *breakdown of attention.* Such apparent breakdown, or limited capacity, arises because there is too much distraction from all the possible sensory input that competes for conscious perception. This entry focuses on instances that demonstrate the need for attentional selection, give examples of breakdowns of attentional selection, and briefly considers the fate of the information that failed to reach conscious perception.

Behavioral Phenomena

One of the most striking examples of the breakdown in the attentional system, caused by sensory overload, was demonstrated by Daniel Simmons and his colleagues. The authors conducted a series of experiments that revolved around a simple scenario—a young man (one of the experimenters) approaches a passerby (unsuspecting participant in this experiment) asking for directions on how to get to one of the buildings on campus. In the middle of the conversation, however, two people carrying a door (experimental accomplices) walk in between the experimenter and the participant briefly obstructing the participant's view of the experimenter. During the time that the experimenter was invisible to the subject, another person trades places with the experimenter, so that once the door has passed, the participant is left talking to a new person! This experiment found that only 50% of the participants noticed that, after the interruption, the identity of the person they were conversing with was switched, even though the two experimenters were dissimilar in build, had different haircuts, had different pitched voices, and wore dissimilar clothing. This example is particularly potent because the experiment was conducted not in the contrived laboratory environment, but rather in our natural environment (i.e., outside) with innocent bystanders serving as participants. In addition, this experiment was not conducted in the middle of a hustle and bustle of, say, Times Square (an environment that we often think of as being conducive to sensory overload). This experiment demonstrates a striking breakdown of attention in our day-to-day environment, even under conditions when part of the stimulus was attended (few would argue that two people who are carrying a conversation with one another do not, at least on some level, pay attention to each other's identity). The breakdown of attention in this experiment could be attributed to competition from a multitude of sensory and mental events related and unrelated to the actual task at hand of giving directions—for example, remembering the campus layout, remembering landmarks on the way, hearing birds chirping in the background, or feeling faint pain from a blister on the left foot. All these cognitive tasks place enormous constraints on attentional selection, ultimately resulting in a failure of perception.

Such failures of perception are the rule rather than an exception. As such, we live in a limited world of what our attentional selection mechanisms have reconstructed for us. An insight into just how limited our perceptual world is without attentional selection is gained from examining perceptual experiences of patients with hemispatial neglect. This disorder is termed *hemispatial neglect* ("neglect") to reflect the failure to attend to information appearing on the contralesional left side.

Recipe for Breakdown—Competition and Attentional Load

What are the circumstances that lead to breakdown of attention? Robert Desimone and John Duncan proposed a biased competition model for selective attention suggesting that items presented in a multielement scene are not processed independently, but rather interact in a mutually suppressive way (i.e., each items competes for processing, increasing the odds of attentional failure). In other words, processing a single item within the scene will not be enough to tax capacity limitations, whereas multiple items within the scene will compete for sensory processing and will compete for attentional resources. Such suppressive interactions have been observed not only behaviorally but also with neurophysiological and neuroimaging techniques. For example, Sabine Kastner and her colleagues examined the consequence of suppressive interactions (i.e., when multiple sensory stimuli compete for processing) using functional magnetic resonance imaging (fMRI). The authors presented participants with a set of four colorful pictures that were either presented simultaneously (i.e., simultaneous condition) or one at a time (i.e., sequential condition) and participants were simply asked to passively view the presented items. fMRI blood-oxygenated-level-dependent response (BOLD) was recorded during presentation of sequential condition (summed over presentation of four items) and during the simultaneous condition. The overall fMRI response was much reduced in the simultaneous condition compared with the sequential condition. This finding demonstrates that stimuli presented in close spatial proximity do compete for attentional resources, thus inhibiting and interfering with one another. Such competition is eliminated, however, when items are presented one at a time.

In a recent investigation, Sarah Shomstein and Steven Yantis demonstrated that competitive interactions are not limited to a single modality. Rather, competition is observed when multiple stimuli, of any kind, vie for attentional resources. In this study, participants were presented with visual and auditory information simultaneously and were asked to pay attention to one or the other depending on instructions, and to occasionally shift their attentional focus from visual stimulation to auditory stimulation (and vice versa). Using fMRI, the authors demonstrated that overall activity in the corresponding sensory regions (i.e., auditory cortex and visual cortex) was decreased in presence of competing sensory information, similar to the simultaneous condition in the Kastner study described earlier. Moreover, even though the subject was not attending to the competing information, it was observed that when participants were paying attention to the visual stimuli, activity in the visual cortex increased and activity in the auditory cortex decreased. The opposite pattern was observed when auditory information was attended. These findings support several conclusions. First, early sensory cortical responses, as measured by the fMRI signal in auditory and visual cortices, are modulated by attention. Second, the "push–pull" effect of switching attention between vision and audition suggests a neural basis for behavioral evidence that focusing attention on auditory input (e.g., a cellular telephone conversation) can impair the detection of important visual events (e.g., what's happening on the road while driving an automobile). When attention must be directed to audition, the strength of early cortical representations in the visual system are compromised (and vice versa), leading to potentially significant behavioral impairments.

Another contributing factor to breakdown of attentional selection, bearing directly onto biased competition, is attentional load. According to the load hypothesis, originally proposed by Nilli Lavie, the extent to which distracting elements compete for resources is a function of how attentionally demanding the task is. In other words, under high perceptual load (e.g., reduced size or contrast of stimuli or number of stimuli), attentional capacity will be maximally taxed, thus resulting in increased competition, but under conditions of low perceptual load, there would be enough capacity to enable processing of all the available sensory input, reducing the need for competitive interactions.

The Fate of the Unattended

Although much recent research has been devoted to understanding the psychological and neural processes underlying attentional selection, researchers know little about the fate of the sensory information that is not selected. In other words, the question is what happens to all the information that is not processed, that is not available for conscious perception? Did the breakdown of attention result in total and utter failure of perception, or is the unattended sensory information available for perception and for behavior in some capacity? For example, when an observer selectively attends to some subset of the visual input, the degree to which the remaining, unattended input is represented remains largely unknown. That our current knowledge of such scenarios is so underspecified may be surprising given that understanding the nature and extent of processing of unattended information is one of the long-standing and seminal issues in perception. It is not particularly contentious that after the light hits the retina, or the air moved by a sound excites hair cells in the cochlea, some amount of processing is accomplished, regardless of whether the specific information is attended or not. What remains more uncertain, however, is the extent to which the unattended information influences behavior.

A strong claim made by some researchers is that little, if any, visual processing can occur in the absence of attention and that perception cannot proceed without attentional selection. Evidence supporting this account comes from inattentional blindness paradigms, pioneered by Arien Mack and Irvin Rock, in which task-irrelevant grouped items went unnoticed and did not influence the behavioral performance of the observers. In one well-known version of this paradigm, observers judge whether the horizontal or vertical arm of a briefly flashed cross was longer. On the fourth trial, an unexpected item—a word, a face, a shape, a texture—was presented simultaneously with the cross but at a different position on the screen (within the arms of the cross, but not at the cross section of the arms). When the cross was presented at fixation and the unexpected item was presented parafoveally (peripherally), about one quarter of the observers failed to perceive the presence of the unexpected object. Even more startling, when the cross was presented parafoveally and the unexpected item was presented at fixation (i.e., precise location of where the participant was gazing directly), nearly three quarters of observers failed to detect the unexpected item. These findings suggest that, in the absence of attention, information is not processed and therefore perception fails.

An equally strong but opposing account suggests that fundamental visual processes such as perceptual grouping and figure-ground segmentation can take place in the absence of attention. In one illustrative study, Cathleen Moore and Howard Egeth asked participants to judge which of two parallel lines, superimposed on a background matrix of black-and-white dots, was longer. The background dots, whose presence was orthogonal to the line-judgment task, were either randomly colored or were grouped to form the Müller-Lyer illusion (optical illusion that consists of two sets of arrow-like figures, one with both ends pointing in, and the other with both ends pointing out; when asked to judge which of the two lines is longer, viewers typically chose the inward pointing arrow—see Cultural Effects on Visual Perception, Figure 1). Because the length judgment was clearly influenced by whether the background dots gave rise to the illusion, the authors concluded that background dots, though not attended, were in fact perceptually processed and as such affected behavior. Further support for the view that unattended information influences behavior comes from a recent study by Ruth Kimchi and Irene Razpurker-Apfeld, in which subjects performed a change detection task on a small, centrally located black-and-white matrix, presented for a brief duration. The matrix-like target stimulus was embedded in the center of a background pattern, consisting of colored dots that grouped by similarity into either rows, columns, or simple shapes. On each trial, two successive displays were presented, and subjects judged whether the central target matrix remained the same or changed. In addition, within a trial, the organization of the background elements stayed the same or changed, independent of the status of the target matrix. Of greatest relevance was the finding that the grouping of the background, unattended stimuli influenced the detection of changes in the target matrix, leading to the conclusion that unattended background elements were perceived to an extent that was enough to influence task-relevant perceptual judgments.

ATTENTION: EFFECT ON PERCEPTION

Attention is the mechanism that allows us to select relevant information for processing from the vast amount of stimuli we are confronted with, prioritizing some while ignoring others. Attention can affect perception by altering performance—how well we perform on a given task—or by altering appearance—our subjective experience of a stimulus or object. Visual attention is commonly divided into three types: (1) spatial attention, which can be overt, when an observer moves his or her eyes to a relevant location and the focus of attention coincides with the movement of the eyes, or covert, when attention is deployed to relevant locations without accompanying eye movements; (2) feature-based attention, which is deployed to specific features (e.g., color, orientation or motion direction) of objects in the environment, regardless of their location; (3) object-based attention (which will not be discussed further here). By focusing on different kinds of information, these types of attention optimize our visual system's performance: whereas spatial attention guides an observer to a particular location, feature-based attention guides an observer to a particular feature of the object or stimulus. For instance, when waiting to meet a friend at a café, we may deploy spatial attention to the door (where he or she is likely to appear) and feature-based attention to orange objects (because he or she often wears an orange jacket).

This entry deals with the effects of covert attention on performance and appearance. Note that overt attention also plays a pivotal role in selectively processing information. The eyes can be moved quickly and efficiently, enabling overt attention to compensate for the rapid decline of visual capacities away from the fovea. Thus, the perceptual consequences of overt attention at the attended location correspond to the immediate benefit of high-resolution foveal vision.

Spatial Attention

To investigate covert attention, it is necessary to make sure that observers maintain fixation, and to keep both the task and stimuli constant across conditions while manipulating attention. It is well established that covert attention improves perceptual performance—accuracy and speed—on many detection, discrimination, and localization tasks. Moreover, attention affects the appearance of objects in several tasks mediated by dimensions of early vision, such as contrast and spatial frequency.

There are two systems of covert attention: endogenous and exogenous. *Endogenous attention* refers to the voluntary, sustained directing of attention to a location in the visual field. Experimentally, a central cue—typically an arrow or a bar at fixation—points to the most likely location of the subsequent target. Within about 300 milliseconds (ms), attention can be deployed to that location and can be sustained there. *Exogenous attention* refers to the automatic, transient orienting of attention to a location in the visual field, brought about by a peripheral cue or a sudden abrupt onset of a stimulus at that location. Exogenous attention has a transient effect; its effectiveness peaks at about 80 to 120 ms and decays shortly thereafter.

Spatial Attention and Performance

Endogenous (voluntary) and exogenous (involuntary) attention have some common perceptual effects. Detection or discrimination of a target are typically better (faster, more accurate or both) in trials in which the target appears at the cued location than at uncued locations. For instance, both exogenous and endogenous attention improve contrast sensitivity and spatial resolution. Many studies have shown that spatial attention lowers the contrast threshold at which observers attain a given performance level when they perform tasks mediated by contrast sensitivity. Enhanced contrast sensitivity enables people to better detect the presence or absence of a stimulus, discriminate its characteristics (e.g., was the stimulus tilted left or right? moving upward or downward?), and localize it (e.g., was the stimulus in the right or left visual field?). Interestingly, whereas contrast sensitivity is enhanced at the cued location, it is decreased for the stimuli appearing at uncued locations. This is the case even when few clearly visible stimuli appear in the display, and observers know with certainty the stimuli locations and which stimulus to respond to.

Likewise, when spatial attention is directed to a given location, performance improves in texture segmentation tasks and acuity tasks that are limited by spatial resolution. For instance, when attending to a location observers can resolve information that is unresolvable without attending to that location and can discriminate finer details than they can without directing attention to the cued location. As is the case with contrast sensitivity, the improved performance at the cued location is accompanied by impaired performance at the uncued locations. The same pattern of results has been reported for human and nonhuman primates in acuity tasks.

Despite their similarities, endogenous and exogenous attention can yield different perceptual effects: Whereas endogenous attention improves perception, exogenous attention can in some conditions actually impair perception. For instance, in a texture segmentation task in which performance is influenced by spatial resolution, cueing attention improves texture segmentation in the periphery, where spatial resolution is too low for the task, but impairs performance at central locations of the visual field, where spatial resolution is already too high for the task. In contrast, endogenous attention improves performance across the visual field. Exogenous attention also impairs temporal order judgment, whereas endogenous attention improves it. These findings illustrate that both endogenous and exogenous attention affect performance in spatial (texture segmentation) and temporal (temporal order judgment) tasks, but that the mechanisms underlying these attention systems differ, with endogenous attention being more flexible.

Spatial Attention and Appearance

It is well established that attention improves performance on many tasks. However, for more than 100 years, psychologists, philosophers, and physiologists (e.g., Ernst Mach, Gustav Fechner, Hermann von Helmholtz, Wilhelm Wundt, and William James) have debated whether attention changes one's subjective experience of the visual world. Although the effects of attention on performance may suggest that attention affects the stimulus representation and subjective appearance, many authors have attributed these effects to a decision-making process or selective read-out. The question of whether attention alters appearance has rarely been investigated, though. Which aspects of our visual experience does attention affect? Can attention make a visual pattern seem more detailed, or a color more vivid? Much of the early work on this topic, which is relevant to the topic of subjective experience and awareness, was introspective and conflicting conclusions were often drawn from such subjective methods of investigation. Whether and how attention affects appearance has been systematically investigated only recently. This may be because of the difficulty in objectively testing and quantifying the subjective experience of perceived stimuli and changes in such experience with attention. It is important to distinguish a change in appearance from any bias that may arise because of experimental design and task demands.

A psychophysical paradigm developed by Marisa Carrasco and colleagues enables the assessment of the phenomenological correlate of exogenous (involuntary) attention, and makes it possible to study subjective experience and visual awareness more objectively and rigorously. This paradigm allows for simultaneous measurement of the effect of attention on appearance and performance. It manipulates exogenous attention via an uninformative peripheral cue and quantifies the observer's subjective perception using a task contingent on a comparative judgment between two stimuli with regard to a particular feature. For instance, to investigate the effects of attention on perceived contrast, observers are presented with two stimuli (Gabor patches, commonly used to investigate spatial vision; Figure 1a), one to the left and one to the right of fixation. Observers are asked to report the orientation of the higher contrast stimulus. These instructions emphasize the orientation judgment, when the main interest is in contrast judgments. Observers are not asked to directly rate their subjective experience on contrast, but to make a decision about a stimulus property, its orientation.

On each trial of this paradigm, the "Standard" stimulus is of a fixed contrast, whereas the contrast of the "Test" stimulus is randomly chosen from a range of contrasts near the standard contrast. The orientation of each stimulus is also chosen randomly. By flashing a dot (peripheral cue) briefly, exogenous (involuntary) covert attention is automatically directed to the cued location (at which either the Standard or the Test stimulus will appear).

Carrasco and colleagues have shown that by assessing observers' responses, it was possible to determine the contrast of the test stimulus that the observer judged to have the same contrast as the standard stimulus. This contrast was measured under three conditions: when the dot preceded (1) the location of the test stimulus, (2) the location of

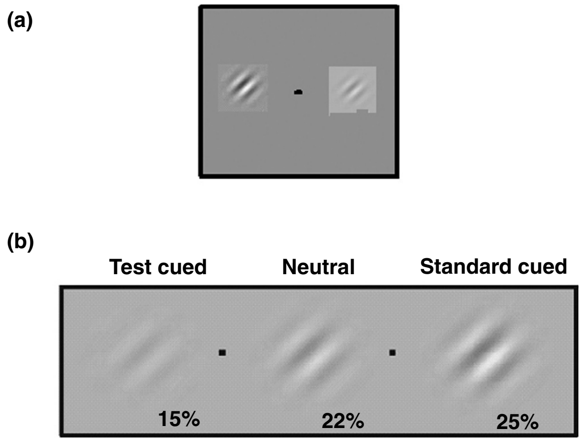

Figure 1 Effect of Attention on Contrast

Source: Carrasco, Ling, & Read, 2004.

Notes: (a) Display screen of the type of stimuli observers were shown by Marisa Carrasco and colleagues. Observers saw two stimuli, preceded by a brief neutral (at fixation) or peripheral (attentional) cue (appearing above one of the upcoming stimulus locations). The peripheral cue had equal probability of appearing on the left or right side, and was not predictive of the stimulus contrast or orientation. Observers were asked to indicate the orientation (left versus right) of the higher contrast stimulus. (b) Effect of covert attention on apparent contrast. If you were to look at 1 of the 2 fixation points (black dot), and the stimulus to the left of that fixation point was peripherally cued, the stimuli at both sides of that fixation point would appear to have the same contrast. With attention, when a 16% contrast stimulus is cued, it appears as if it had 22% contrast, and a cued 22% contrast stimulus appears as if it had 28%. (Note that this effect cannot be appreciated by inspecting the figure because a comparison between both patterns would lead to distributed allocation of attention to both patterns.)

the standard stimulus, or (3) the central location (fixation), so that covert focal attention was automatically directed toward the test stimulus, the standard stimulus, or neither stimulus. Exogenous attention was shown to significantly increase perceived contrast (Figure 1b). When observers' attention was drawn to a stimulus location, observers reported that stimulus as being higher in contrast than it actually was, thus indicating that attention changes appearance.

By coupling this paradigm with control experiments, cue bias or response bias have been ruled out as responsible for the observed effects. For instance, because of the ephemeral nature of transient attention (approximately 120 ms), lengthening the interval between the cue and target should eliminate any effect that it may have on perception, and any residual effect would be attributed to a cue bias. When the cue preceded the stimuli by 500 ms, neutral and peripheral conditions did not differ.

Most studies using this paradigm show that exogenous attention alters appearance of basic spatial (contrast, spatial resolution, color saturation, object size) and temporal (flicker rate, motion coherence, motion speed) visual dimensions. A modification of this experimental paradigm has revealed that endogenous (voluntary) attention also enhances perceived contrast. Although for many visual dimensions the attention effect on appearance is accompanied by an effect on performance (e.g., a higher proportion of correct responses in orientation discrimination), the performance effect is not necessarily mediated by the subjective change in appearance; for example, attention improves orientation discrimination of stimuli defined by hue, but it does not alter hue appearance.

By showing that the spatial deployment of attention leads to a change in phenomenological experience, these studies confirm that covert attention can intensify the perceptual impression of a stimulus. Attention affects how well we perform a visual task and it affects what we see and experience.

Feature-Based Attention

Feature-based attention is the ability to enhance the representation of image components throughout the visual field that possess a particular feature. Directing feature-based attention to specific features—such as color, orientation, and motion direction—increases performance for detecting, discriminating, or localizing those features across the visual field. This type of attention is critical when human or nonhuman primates search a display to detect a target among distracters.

Studies of feature-based attention generally control for spatial selection by using compound stimuli containing multiple features superimposed over the same spatial location, and requiring that observers attend to one of those features. For instance, in a compound motion stimulus (consisting of dots moving right and dots moving left), attending to one motion direction (e.g., dots moving right) produces a motion aftereffect consistent with the attended direction, and in a compound orientation stimulus (consisting of right-tilted and left-tilted lines), attending to one orientation (right-tilted lines) produces an orientation aftereffect consistent with the attended orientation. Psychophysical and neuroimaging studies have shown that the effects of feature-based attention occur at the spatially attended location as well as at non-attended locations across the visual field.

ATTENTION: OBJECT-BASED

Efficiently representing visual information requires that the observer select only a fraction of the multitude of information that is available to the visual system at any one instant in time. Attentional selection is the mechanism by which a subset of incoming information is extracted from the complex sensory environment. The selection can be achieved in a top-down, goal-directed fashion (e.g., when one sets out to find one's keys on the kitchen counter), or in a bottom-up fashion in response to highly salient or novel stimuli in the input (e.g., a red strawberry among greener strawberries on a bush captures the viewer's attention). Early models of attentional selection suggested that attention is directed to particular regions or locations in space (the region of the keys or the region of the red strawberry), enhancing perceptual processing of information appearing in the attended location, whereas more recent models have also included object-based representations as possible candidates of attentional selection (i.e., the keys or the red strawberry as objects of attention themselves). This entry considers this latter, object-based form of attentional selection in which attention is guided or influenced by object structure.

Behavioral Phenomena

The primary signature associated with object-based attention is the enhanced processing of information belonging to or appearing within the confines of one object that is selectively attended. Numerous behavioral studies have confirmed this *single object advantage*. For example, in a now-classic study demonstrating the advantage in processing features from a single object conducted by John Duncan in 1984 (see Figure 1a), subjects were shown displays consisting of an outline box upon which a diagonal line was superimposed, thereby occupying roughly the same spatial region as the box (so that spatial attention could not enhance just one of the two "objects"). Subjects were required to make judgments about two features that appeared on the same object (e.g., line orientation and texture from the line, or box size and gap side from the box) or, in a second condition, when one feature appeared on each of the two different objects (e.g., line orientation and box size). The critical result was that subjects were less accurate in reporting two features when they came from the two different objects (one feature from each) than when they came from a single object. Indeed, under simple conditions, subjects identified two properties of a single object just as accurately as they identified one feature. These results were taken as favoring a view that the visual field can be segmented or parsed into separate objects and that attention can then be directed selectively to a single object, thereby facilitating the processing of all of its features.

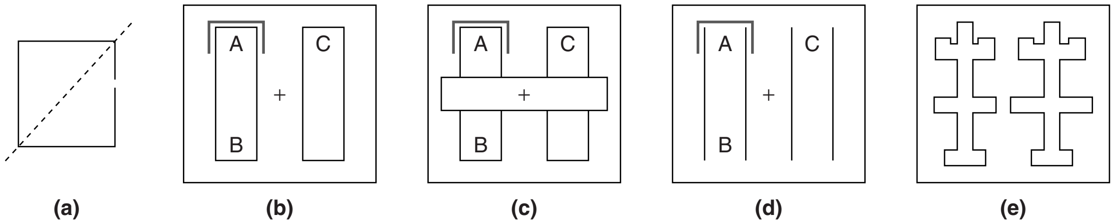

Figure 1 Examples of Object-Based Attention Displays

The single object advantage was also demonstrated in a further seminal study by Robert Egly and colleagues in 1994. In this study, subjects were presented with a display of two horizontally or vertically oriented rectangles. A cue appeared at one of the four ends indicating the most likely location in which the target would appear (see Figure 1b). Participants were required to detect the presence of the subsequently presented target (small white square). Unsurprisingly, detection times for the target in the cued location (valid trials; in Figure 1b with the cue in the upper left, this is the A position) were faster than for targets in the uncued locations (positions B or C). Most relevant for the current purpose is that reaction times were faster for targets that appeared at the uncued end of the cued rectangle (invalid; within object; position B) than for targets that appeared in the uncued rectangle (invalid; between object; position C), notwithstanding the fact that the spatial distance between the cue and both uncued locations was equivalent. The advantage for the uncued, within object location (position B) over the uncued, between object location (position C) is taken as evidence that all locations within an attended object are enhanced, the benchmark indicator of object-based attention, independent of spatial distance from the cue.

Several other behavioral paradigms have also successfully uncovered object-based attention. One such paradigm requires participants to compare two targets both of which lie on the same or on different objects—better performance is observed in the former than in the latter case. A further example is a variant of the Eriksen “flanker” task in which participants judge the identity of a target in the presence of flanking distractors that lie on the same or different objects: greater interference is observed when the flankers were in the same object, a consequence of enhancement of information within a single object. Taken together, such studies provide robust evidence that humans can select one object and, subsequently, all its information is preferentially facilitated.

Underlying Mechanisms

Having established the existence of object-based attention, much recent research has become increasingly concerned with the type(s) of visual representation and underlying mechanisms that constrain attentional processes. Indeed, growing consensus is that object-based attention may not be influenced only by object representations per se but also by the perceptual organization processes that the visual system uses to derive structure from the input. Consistent with this, many studies have uncovered object-based attention in displays in which the input can be organized into structured elements that adhere to the gestalt principles of grouping: thus, a single-object advantage can be observed for two spatially disparate parts of a single object that are occluded by a central bar (Figure 1c), for parts of an object that are discontinuous but benefit from shared symmetry, and for parts of an object that are separated but share common motion or color. Similarly, a cueing advantage has been reported for distant stimuli situated within arrays of evenly spaced parallel lines even when these lines do not form closed, coherent objects (see Figure 1d), as revealed by Alex Marino and Brian Scholl. Subparts of these holistically structured but disparate elements, which are perceptually organized, can also be selected, presumably by the same object-based attention process, but perhaps operating at a smaller scale, at the level of parts of an object. For example, this part-based attention was demonstrated in a study by Shaun Vecera and colleagues that borrowed the procedure from Duncan in which participants reported two attributes that appeared on the same part or on different parts of a single multipart object (see Figure 1e). Subjects reported two attributes in the display (e.g., gap side and arm length), and these could be from the same part or from two different parts of the same object. The report was more accurate when the attributes belonged to the same part than to different parts of the same object. Moreover, this part-based effect was not influenced by the spatial distance between the parts, ruling out a simple spatial attention interpretation of the results.

Several hypotheses have been put forward to account for the single-object attention advantage. One hypothesis maintains that object-based attention arises from the spread of attention (object-guided spatial selection)—when spatial attention is directed to one part of an object, there is a facilitation of early sensory processing that spreads to encompass other regions within the object's boundaries, hence the enhancement of all features and parts of the single object. This can be contrasted with the hypothesis that locations within the attended object are given higher priority for target search. If a target is not found at the cued location, other locations within the object's boundaries are searched before locations on uncued objects are searched. This attentional prioritization mechanism, which invokes a more top-down strategy, is proposed to control the order of locations to be searched, and on this account, the enhancement is not by virtue of early sensory processing. Ongoing investigations compare and contrast these views (as well as others) and much remains to be done to adjudicate between the alternative competing hypotheses.

Neural Basis of Object-Based Attention

Several recent investigations have begun to explore the neural mechanisms that underlie object-based attention and a series of functional magnetic resonance imaging (fMRI) and event-related potential (ERP) studies have been undertaken. One study, done by Notger Müller and Andreas Kleinschmidt using the Egly and colleagues paradigm described earlier, showed that the same object advantage is observable even in the early visual cortex (V1–V2). In an ERP study using a paradigm similar to that of Egly and colleagues in which a peripheral cue directed attention to the probable target location, an enhanced N1 component was documented at 130 to 150 milliseconds (ms) in response to targets in the cued or valid case, reflecting spatial attention, as shown by Antigona Martinez and colleagues. In addition, there was increased amplitude of the posterior, sensory-evoked N1 component over the interval 150 to 190 ms in response to uncued stimuli included within the common object, presumably reflecting the object-based selection. This site also serves as the source of these two signals, but one is earlier than the other, indicating that some of the same mechanisms likely support spatial and object-based forms of attention but that they may operate over different time scales.

Several studies (e.g., Liu et al.; Serences et al.; Shomstein & Yantis; Yantis et al.) have also explored the neural mechanism associated with the signal to switch attention between objects (i.e., the control system that triggers the switch between objects). Using fMRI, these studies have shown that the blood-oxygenation-level-dependent (BOLD) activity in the posterior parietal cortex is enhanced following instructions to shift versus to hold spatial attention, suggesting that a signal triggers the system to shift attention from one object to another. Shifting from one spatial position to another may engage different cortical regions than does shifting from one object to another; specifically, enhanced activity for the former engages the parietal cortex bilaterally, whereas shifting or redirecting attention between objects revealed activation in the left posterior parietal cortex. Interestingly, in this same study, object-sensitive shifts of attention were accompanied by modulations within the extrastriate regions of the occipital cortex (as in the study by Martinez et al. using ERP). These neuroimaging results elucidate the neural mechanism underlying object-based attentional selection described in many behavioral studies and reveal a network in which the consequences of attentional shifts triggered in the parietal cortex are manifest in earlier, sensory regions of the visual system. This dynamic circuit between the parietal and earlier visual regions presumably enables observers to focus preferentially on objects of interest that appear in complex visual scenes.

A final ongoing question concerns the relationship between the mechanisms mediating spatial and object-based attention and the extent to which these mechanisms are shared or separate. Specifically, some researchers have suggested that similar mechanisms might be at play; for example, some studies indicate that attention is spatially spread and then constrained by the object boundaries and groupings, and that this is true over a certain spatial extent. Moreover, as stated earlier, evidence from some fMRI and ERP studies (e.g., Müller & Kleinschmidt; Shomstein & Behrmann) report that similar brain areas are activated by spatial and object-based attention and that attention-based modulation of "within" object structure is evident even in early retinotopic areas of the cortex. This provides physiological evidence that directing spatial attention to one part of an object facilitates processing of the entire object, and thus, both spatial and object-based attention contribute to the single object advantage.

ATTENTION: PHYSIOLOGICAL

Often, when we're interested in an object, we move our eyes toward it, allowing us to see it more clearly. However, it has long been known that even in the absence of overt movements, perception of an object in the periphery can be improved by covertly shifting attention to it. *Covert attention* refers to our ability to internally modulate sensory processing of a selected stimulus. Attention can improve perception of the attended object, even though the input to the system (the physical stimulus reaching the retina, for example) is unchanged.

When we shift attention to an object, it may appear clearer, more distinct, or more intense, whereas ignored objects may seem less distracting or even fade from awareness. These perceptual effects are caused by changes in the responses of sensory neurons. Thus, one important issue in the physiology of attention is to understand the *effects of attention on sensory processing*. A second major issue is to understand how the brain controls which particular objects are attended. This is referred to as the *neural control of attention.*

Effects of attention on sensory neurons have been observed in all the major sensory systems. Most studies have found that attention increases the gain of sensory neurons encoding the attended object or feature, effectively amplifying signals from the attended stimulus. The effects of attention on sensory neurons become progressively stronger in higher-level brain areas compared with areas closer to the sensory input. Attention has been studied most extensively in the visual system, and effects of attention on visual neurons can be observed as early as the lateral geniculate nucleus (LGN), an area that receives input directly from the retina.

The control of attention has been studied more extensively for spatial attention than for feature attention. *Spatial attention* refers to the allocation of attention to specific objects or locations in the environment, whereas *feature attention* refers to the allocation of attention to particular sensory features (for example, the color red) regardless of location. Behavioral studies have shown that spatial attention can be attracted to objects or locations, either by virtue of their physical salience (for example, a bright flash of lightning tends to draw attention) or their behavioral relevance (for example, when driving, one can intentionally ignore a distracting billboard along the side of the road to attend to the cars ahead).

Physiological research suggests that spatial attention is controlled by a network of brain areas that includes the frontal and parietal cortex, as well as subcortical areas. Neurons in most of these areas are organized into maps that represent locations in the environment. The level of neural activity at a given location in the map is thought to represent the physical salience and behavioral relevance of stimuli at the corresponding location in the environment. The cells on the map having the greatest activity correspond to the most important location in the environment, and the greatest amount of attention is directed to this location. The assumption is that these maps influence sensory processing by modulating the activity of sensory neurons. Indeed, feedback connections linking attention control areas to sensory areas are known to exist and could serve as a conduit for these control signals to modulate sensory neurons. This entry describes the effects of attention on sensory neuron responses and neural control of attention.

Effects of Attention on Sensory Neuron Responses

Although the effects of attention on sensory neurons have been investigated most extensively for the visual system, it has been found across all the sensory modalities that higher-level brain areas show larger effects of attention than do areas located earlier in the processing stream. However, even within a given brain area, there is typically a great deal of variability in the extent to which attention influences the responses of individual sensory neurons.

Amplification of Signals Generated by Attended Stimuli

When attention is focused on a stimulus, sensory neurons encoding that stimulus tend to increase their firing rates, resulting in an amplification of the neural response to the attended stimulus. This amplification is similar in some ways to the increase in neural activity that would occur if the stimulus were more intense (e.g., higher contrast or louder). An amplification of neural responses is seen for feature attention as well as for spatial attention. For example, if attention is directed to downward motion, the gain of sensory neurons coding downward motion increases, and the gain of neurons coding upward motion tends to decrease.

Attention to a location or feature can cause sensory neurons to increase their activity even in the absence of an immediate stimulus. For example, if subjects are expecting an important object to appear at a certain location in the visual field, neurons that respond to that location may increase their baseline level of activity in anticipation of the appearance of the stimulus. Similar effects on baseline activity have been observed in the auditory system.

Effects of Attention on Encoding of Multiple Stimuli

The amplification of neural responses to an attended stimulus can have important implications when multiple stimuli are present in the environment. For example, in the visual system, each sensory neuron responds to visual stimulation within a restricted region of the visual field, called its *receptive field.* In complex visual scenes, two (or more) objects may lie within a single neuron's receptive field. A study of the visual system of monkeys by Jeffrey Moran and Robert Desimone found that when two stimuli are in the receptive field of a neuron, the neuron will predominantly respond to the stimulus to which the monkey is attending, rather than to an unattended stimulus. Thus, amplification of signals from the attended stimulus appears to reduce the influence of unattended stimuli on the responses of sensory neurons. Indeed, it is as though the receptive fields of sensory neurons effectively constrict around the attended item.

Effects of Attention on the Tuning of Individual Neurons

In addition to amplifying attended stimuli, one could imagine that attention might also sharpen the extent to which sensory neurons discriminate small differences in the features of an attended stimulus. For example, a visual neuron sensitive to the movement of objects in the visual field might be expected to discriminate smaller differences in the motion of an attended stimulus. However, with the exception of the sharpening of location tuning described previously, a sharpening of tuning for features has rarely been observed for individual sensory neurons. Thus, the primary mechanism of attention at the level of single neurons appears to be amplification of neural responses to the attended stimulus.

Synchronized Firing as a Mechanism of Attention

Focusing attention on an object changes the overall firing rate of neurons and can cause groups of sensory neurons encoding the attended object to fire in synchrony, such that the timing of their spikes is more closely matched in time. When neurons fire in synchrony, their activity tends to have a stronger effect on the downstream cells that receive their signals. An analogy would be to consider how well a message would be heard if a group of people all spoke it together in unison rather than speaking at different times. Thus, increased synchrony of sensory neurons could contribute to the improvements in perception that are afforded by attention.

Neural Control of Attention

The brain areas controlling attention have been studied primarily for the visual system. The posterior parietal cortex, prefrontal cortex, superior colliculus (located in the midbrain), and pulvinar nucleus of the thalamus are all believed to contribute to the control of visual attention. For example, neurologists have found that patients with damage to the right parietal lobe often have deficits in attending to objects on the left side of space. Even though these patients are not blind to stimuli in their left visual field, they tend to ignore people, objects, and events on that side, especially when a distracting stimulus is present in the opposite visual field. Damage to the frontal cortex in the vicinity of the frontal eye field can result in similar, although less severe deficits.

Physiological studies in monkeys have further delineated and refined our knowledge of the role of these areas in controlling attention. For example, it has been shown that if neurons in the parietal cortex, the frontal eye field, or the superior colliculus are activated, this activity can cause a shift of attention into the region of space encoded by the activated neurons. Other experiments have used microinjection of drugs to cause a temporary decrease in activity in the frontal eye field or parietal cortex. This decrease in activity causes temporary deficits in visual attention at locations in the visual field corresponding to the injected brain regions. These experiments provide direct evidence that neural activity in these structures controls the allocation of spatial attention.

Posner's Disengage-Shift-Engage Model

An early model for the control of attention was introduced by Michael Posner, who proposed that attention shifts could be decomposed into three elementary operations: first, attention must be disengaged from wherever it is currently focused; second, attention must be shifted to a new location; and, finally, attention must be engaged at this new location. On the basis of data from neurological patients, Posner proposed that the posterior parietal cortex was responsible for the disengage operation, that the superior colliculus was responsible for the move operation, and that the pulvinar was responsible for the engage operation.

A Salience Map for Shifting Attention

More recent models of attention shifting have focused on the concept of a salience map rather than on discrete disengage-shift-engage operations. A salience map is a topographical representation of external space that is laid out across the surface of a neural structure, such as the frontal eye field, posterior parietal areas, or superior colliculus. The activity of the neurons composing this map is affected by both the physical salience and the behavioral relevance of stimuli in the environment. Under this view, bottom-up signals related to physical salience (such as brightness or color) are sent from sensory areas to neurons in the salience map. The activity of neurons in the salience map is also strongly modulated by top-down signals related to the behavioral relevance of stimuli, which depends on the internal goals of the animal. Attention is allocated to the location in space corresponding to the peak of activity across this map. Specifically, signals from the salience map are believed to modulate the activity of neurons in sensory areas, such that sensory responses to stimuli at locations with strong activity in the map are boosted, as described in the previous section. In this way, perception of the most important stimuli is improved.

ATTENTION: SELECTIVE

We experience the world around us, in all its sensory detail and complexity, directly—or at least so we believe. Yet a simple test reveals that our sense of direct experience may be misleading. If you are asked to reflect, with your eyes closed, on the details of the picture on the wall, or the number of cars on the road, or the shape of a stranger's eyes, the limits in processing information become evident. At times, we may not even notice when a significant part of a visual scene has been removed or altered, seemingly in front of our eyes. Attention is the portal through which sensory information is selected for more detailed examination, classification, and registration. *Selective attention* refers to selection of certain sensory inputs for privileged perceptual processing, further analysis, and improved transfer to memory. Attention selects some regions or objects in the visual display, or some voices or environmental sound sources in the auditory display, as the focus of active processing, reducing, or eliminating the competition.

The scientific interest in selective attention and its benefits for perception date to the late 1800s, when William James observed that an object that captured attention among many simultaneously possible objects seemed perceptually vivid and important. An introspective analysis of Wilhelm Wundt at about the same time asked the reader to fixate the eye on the center of an array of letters, while placing the subjective-fixation of attention on a letter some distance away. He noted that the attended letter and its immediate surround were more clearly perceived and letters away from the focus of attention seemed unclear and outside of immediate consciousness. These authors identified attention as an important, indeed core, aspect of perception. Their introspective observations presaged the concepts of *covert attention,* the dissociation of the focus of attention and the fixation of the eye, of *spatial attention,* a focus of attention on a region of space, and of *object attention,* the selection of focus based on objects. Yet almost a century went by between the introspective identification of these aspects of human perception and an objective, scientific understanding of the causes and consequences of selective attention in human information processing and the brain.

How does selective attention operate? Under what conditions is it important? How does attention affect the efficiency of information processing? Answering these questions about attention depends on a combination of clever selection of test conditions and an analysis of behavioral measures using formal or computational models of attention. Just as a physicist may arrange conditions to reveal a physical process, experimenters arrange test conditions to reveal mental processes. And just as mathematical theories assist in understanding many physical systems, so too are formal and computational models necessary for interpreting the behavior of human systems. Objective behavioral measures, such as the time taken to find a target, or the probability of finding a target in a very brief display presented for a fraction of a second, have replaced introspection and intuition in the study of attention.

This entry describes sensory processes and cued selective attention; selective attention in visual search; selective attention and control; selection, flanker effects, and crowding; and the significance of selective attention.

Sensory Processes and Cued Selective Attention

Sensory inputs arrive by stimulating sensory systems in the eye (or ear, or skin) that respond to specific patterns of light (or sound, or touch). Different cells in brain areas that process the sensory inputs respond to different patterns, and specific locations or objects often stimulate neurons in different locations in the brain. When you look at the visual world, sensory responses to the many stimuli across the visual field occur simultaneously, or nearly simultaneously, in parallel. They constitute a "blooming, buzzing" collection of sensory inputs or representations. Selective attention picks out the relevant from the irrelevant, the focus from the background. Many theorists have argued that attention selects one thing (or perhaps a few things) at a time for processing. So, they felt, this implied the processing of visual inputs serially—one after the next in time in a series. Selective attention may, however, function differently in distinct circumstances and is often best understood by modeling the ways in which attention operates.

Perhaps the strongest effect of selective attention occurs when a precue actively directs attention to a particular location or feature in advance. Researchers distinguish between two types of precues. Exogenous cues are flashes or other direct indicators at the location to be attended, and endogenous cues are cues that are not at the attended location. An example of an endogenous cue might be an arrow located at the center of a display asking the subject to attend to a separate, corner region. It takes between a tenth and a quarter of a second to process a precue and focus selective attention to a particular location in space.

Laboratory tests have shown that selective attention may speed a response to the stimulus but, more importantly, may improve the accuracy of identifying or classifying a briefly presented target pattern. When attention increases the accuracy of pattern identification, we can say it has improved the quality of processing. Knowing when and where to focus selective attention can be especially important when the target is obscured by noise, camouflage, or dense arrays of distracting elements. Models and tests of selective attention have shown two distinct ways in which attention may improve perception. One is to enhance responses to weak or low-contrast stimuli, rather like increasing the contrast on a television set to improve visibility. The other is to filter out other irrelevant items in noisy or cluttered displays and so improve the focus on the target. In both cases, the quality of processing is noticeably improved by directing the mind's eye of covert selective attention.

Selective Attention in Visual Search

Precueing of a spatial region focuses selective attention in advance. Researchers have also been fascinated with understanding the role of selective attention in searching visual displays in which the target location is unknown and may appear anywhere. The act of finding visual targets in complex visual scenes is a capacity that represents a common real world activity. Efficient visual search for environmental dangers likely had evolutionary significance. The processes—by which the natural targets of a lost child, the ripe fruit, or the proverbial tiger in the foliage are found—can also be tested in the laboratory. Visual search displays in scientific studies are designed to vary from simple to complex and generally consider sets of spatially separated objects.

For visual search, the primary theoretical question has been whether deployment of attention is serial, moving the focus of attention to one location or object after another, or can be done in parallel. In the laboratory, this involves looking for a single red target among distractors. Some cases, such as looking for the red target among all green items, can be direct and simple regardless of the number of items in the display. In these cases, the likelihood of finding the target in a brief display, or the time to find it in a longer display, is almost independent of the number of items. Searches where the target is immediately obvious regardless of the number of irrelevant distractors have been called *pre-attentive* (i.e., identified without attention) by some. In such cases, all the locations could be scanned in parallel, or at the same time, for the presence of the target feature, redness.

In more difficult searches, the target is not unique. An example is looking for a red horizontal line among distractor items that vary in color (red and green) and in orientation (horizontal and vertical). But this time, there are many red items and many vertical items, so the trick is to find the conjunction of the two properties together. One major question has been whether such difficult attentive searches require serial processing. If searching for a target among more distractor items takes longer or is less accurate, does this imply a serial process of attending to a sequence of items in turn? Not necessarily. If the job is to state whether a target was present in a display, even simultaneous parallel searches could show more errors or longer search times with, say, 10 distractors than with 2. Distractor items may be mistaken for a target or a target may be missed. Increasing the number of distractors leads inevitably to more missed targets or more false alarms. If there are too many false alarms, it makes sense to tighten the criterion for deciding that something is a target—thus increasing the likelihood of missing it. Furthermore, even parallel searches that begin simultaneously finish at different times. If no target is present, finishing the last of all of 10 items will be slower than finishing the evaluation of 2, even if all items are processed in parallel. So, parallel searches can show somewhat lower accuracy and longer search times with more distractors, but serial search models of attention predict more dramatic slowing as displays become larger. Other ideas about search include a combination of parallel and serial processes. Search may be serial, but may be guided by pre-attentive parallel evaluations that point to the more likely or salient items first, or eliminate some classes of distractors. For example, now the red horizontal target is hidden among a small number of red vertical items and a large number of green horizontal items. Often, people can use the comparative salience of the fewer red items to guide their analysis. These models have made it possible to more accurately understand how attention operates in different conditions.

The evidence indicates that parallel processing is more pervasive, and the role of covert attention selection more restricted, than was originally believed. The ability to accurately find a target in brief displays is quite often consistent with parallel processing of multiple objects, with added distractors causing exactly the predicted increases in errors. Parallel processing seems to account for the results of many tests, including many difficult visual search conditions that on the surface seemed to be limited by serial selective attention. However, serial processes may have a role to play in some difficult situations—those where targets cannot be seen well in the periphery, or where direct scrutiny is required to tell targets and distractors apart. Often, such difficult visual searches engage explicit movements of the eye to new positions in the field in addition to any deployment of covert selective attention. Such movements of the eye and associated episodes of attention are intrinsically serial. However, moving the eye is quite different from moving the internal focus of covert attention.

Selective Attention and Control

Selective attention is influenced both by goal-directed top-down control and by bottom-up processing of the visual or auditory inputs. Goal-directed control of attention occurs when a particular spatial region or feature is cued as more likely to include a target or when we know the goal of a search, or its features. A bird watcher may look for a bluebird by looking for blue features of a particular size in the trees. The focus of attention reflects needs and priorities, here the goals of the bird watcher. Conversely, selective attention may be triggered by salient elements in the visual (or auditory) field. A salient item may be one that suddenly appears, or a sole moving object, or an item that is unique in color or some other feature. Selective attention may be drawn without our volition to such unique elements within the field. Even when focused on blue features of the bluebird, attention may be automatically refocused by the sight of a red cardinal. These two mechanisms for directing the action of selective attention work together. Goal-directed selective attention can alter the sensory processing of the selected inputs, and unique features in the field may draw or redistribute selective attention.

Selection, Flanker Effects, and Crowding

Selecting desired target(s) and filtering out other inputs are the central role of attention. Selection by location, or by source, is a fundamental aspect of attention in both audition and vision. However, the ability to focus solely on a specific location is often imperfect. Nearby objects may influence behavior, especially those that are similar in content to the target objects. For example, if you are asked to classify the middle of three shapes, similar flanking shapes may become confused with the target. This is especially true when the focus of attention is away from the fixation of the eye. This phenomenon can easily be seen if you look at a page and try to identify the middle of three letters some distance from the fixation in the periphery. The spacing between letters matters, as does the similarity of the flanking items. For example, identifying a middle letter as an E or F will be more difficult if the surrounding letters are also Es or Fs than if they are Os. Again, peripheral targets are hard to see precisely when covert selective attention is insufficient for accurate identification and where eye movements must be used to move the potential targets closer to fixation during visual search.

Significance of Selective Attention

Selective attention is an important aspect of how we process incoming sensory information from the world. Deficits in attention, often measured as deficits in selective attention, are disrupted or altered in a range of mental conditions, including attention deficit disorder, schizophrenia, and stress and anxiety disorders, and is an aspect of aging. Further research in selective attention may have implications for understanding the changes in perceptual and cognitive processing in these conditions.

ATTENTION: SPATIAL

One of the fundamental properties of our environment is that it is composed of a multitude of sensory information. Given such richness of input, humans are faced with the problem of having limited capacity for processing information, on the one hand, and the need to analyze as much of the sensory input as possible, on the other hand. Attention is the cognitive mechanism that allows effective selection of relevant information (e.g., the letters that you are reading right now) and an inhibition of "at the moment" irrelevant information (e.g., the humming sound of your computer).

Effective selection of information from the surrounding environment depends on the ability to select information in the most efficient manner and to distribute attentional resources in a systematic fashion based on the properties of the input. One fundamental property that describes our environment is its spatial nature—everything in our environment can be described by a set of unique three-dimensional coordinates (i.e., no two objects ever occupy the same location in space). Given that space is a unique descriptor, it is reasonable that the human attentional selection has evolved to use space as its fundamental unit of selection. Spatial orienting is not the only mode of attentional selection, however. Other units of attentional orienting are considered as possible candidates for attentional selection (e.g., object-based, feature-based, and modality-based orienting) on the grounds that spatial selection alone cannot account for the efficiency of attentional selection. This entry describes behavioral characteristics of spatial orienting, biased competition, attentional modulation, and sources of spatial attention.

Behavioral Characteristics of Spatial Orienting

Early models of attentional selection suggest that attention is directed to spatial locations in a manner analogous to a graded spotlight (or a zoom lens), selectively enhancing the perception of items that happen to occupy those spatial locations. An intuitive way to imagine how such a spotlight of attention might operate is to envision an image that has been blurred. An attentional spotlight is then moved around this blurred image bringing into focus spatial locations falling within its circumference. Consequently, items within the spatial spotlight are processed faster and more accurately than are those that fall outside of it.

One source of support for the existence of space-based attentional selection are the findings demonstrating that when a specific spatial location is attended, target detection at that spatial location is faster compared with targets that appear elsewhere on the screen. In such studies, subjects are typically seated in front of the screen and are asked to fixate their eyes on the small plus sign positioned at the center of the screen. Targets, flashes of light, or alphanumeric characters are then presented in various positions to the left and to the right of the fixation point. Participants are asked to respond with a button press once the presence of the target stimulus is detected. Of main importance is that the target flashes are preceded by a spatial cue—usually a flash of light—that is somewhat predictive (probability of 0.6 or higher) of the target location. Such design yields two types of cues: (a) valid—those that appear in the same location as the target, and (b) invalid—those that appear in locations other than the location of the target. The main finding from such behavioral cueing paradigms is that subjects respond faster to targets appearing in the same location as the cue (valid trials) compared with reaction times to invalidly cued targets. These results are interpreted in terms of a spotlight theory of attentional selection, such that spatial locations are selected in a manner analogous to a spotlight (i.e., only stimuli illuminated by the spotlight are selected), and that there are both costs and benefits to sharing attentional resources between spatial locations.

Space-based attentional orienting is not unique to the visual system (although it has been studied most extensively within the visual modality). Actually, early studies on spatial attentional orienting were conducted within the auditory domain. In a typical auditory spatial attention experiment, subjects are presented with two auditory streams (one in each ear, or dichotic presentation) simultaneously and are asked to shadow (i.e., repeat what is being spoken) one of the streams thereby focusing spatial attention on the sensory input within the left or the right ear. The first interesting observation emerging from such studies is that participants are able to perform this task at all! In addition, it is observed that subjects know surprisingly little (or almost nothing) about the ignored stream except that the sound is present. Subjects fail to notice such striking changes as language switches (e.g., from English to German), speech streams playing backward, or changing the gender of the speaker. Interestingly, not everything in the ignored stream is missed, and some stimuli can capture auditory spatial attention. In 1959, Neville Moray presented his subjects with a similar dichotic shadowing task, but in some cases, the experimenters inserted subject's own name in the ignored auditory stream. It was observed that the presence of one's own name could be detected within the ignored stream. As a result of such auditory spatial capture, however, subjects could no longer shadow the stream that was supposed to be attended. The results from these experiments suggest that in audition, just as in vision, stimuli that fall outside spatial attention are suppressed and fail to enter consciousness.

Biased Competition

The term *spotlight of attention* is merely a metaphor for changes in neural processing that follow spatial attentional orienting. The spotlight of attention is said to enhance an early sensory representation of the selected stimulus. Such enhancement can be viewed as a result of biased competition among neural representations. The biased competition model of selective attention proposes that items presented in a multielement scene are not processed independently, but rather interact in a mutually suppressive way. Such suppressive interactions have been observed behaviorally (e.g., harder to see an item when it is embedded among other items) as well as with neurophysiological and neuroimaging techniques. This neural competition, however, can be resolved via a biasing signal that is either bottom-up (e.g., red item among blue items) or top-down (e.g., looking for an apple in a supermarket's fruit aisle). To the extent that the biasing signal is spatially imprecise, its benefits spread within a local region, falling off with distance from the epicenter of the attended region. This could account for the distance effects as measured by both speed and accuracy in attentional paradigms in which items that appear closer to the cued location tend to be processed more efficiently (though not as efficiently as the valid location) than do those positioned further away.

The framework of biased competition consists of two general components: the source that generates the spatial bias and the effects of that attentional modulation bias on early sensory representations. The following two sections describe the neural mechanisms of each of these components in turn.

Attentional Modulation

When an item is attentionally selected (via the source signal), its representation is biased (i.e., enhanced) compared with the representation of this same item when it is not attended and/or is presented among other items (thus resulting in an attentional effect).

Studies of the effects of visual attentional selection demonstrated behavioral facilitation and enhanced cortical responses to attended locations. Neurophysiological studies investigating the effects of spatial attentional bias demonstrated that when a stimulus is presented in a neuron's receptive field (RF) the response to that stimulus is increased when spatial attention is directed to it compared with when attention is either unfocused or diverted elsewhere. For example, in their seminal study, Jeffrey Moran and Robert Desimone first identified the classic receptive field of a V4 neuron and its corresponding preferred and ineffective (not response eliciting) stimuli for that neuron. Monkeys were then trained to attend to stimuli in a specific location within the visual field while ignoring stimuli in other locations. Both effective and ineffective stimuli were then presented within the classic RF of a V4 neuron to elicit competitive interactions in a multielement display. The authors found that the responses of the V4 neurons were strongly modulated by the locus of the monkey's attention. The firing rate to the preferred stimulus was only one third as great when the monkey did not attend to it (i.e., attending to the ineffective stimulus) compared with when the preferred stimulus was attended. What is particularity interesting about this study is that when attention was directed to one of two stimuli in the RF of a V4 cell, the effect of the unattended stimulus was attenuated, as if the RF had contracted to only include the attended stimulus. Effects of attentional orienting are observed even when only one stimulus is present in the display.

Several neuroimaging studies, mainly event-related potentials (ERP) and functional magnetic resonance imaging (fMRI), also observed early sensory enhancement following spatial attentional selection. Studies employing neuroimaging techniques take advantage of the fact that visual stimuli presented to the left of the center are processed within the right primary visual cortex, whereas stimuli presented to the right of the center are processed within the left primary visual cortex. When one presents stimuli to the left and to the right of the fixation point, similar to the cueing paradigm discussed earlier, it is observed that directing spatial attention to the left hemifield results in the increased stimulus evoked neural activity of the early visual areas in the right hemisphere (and the converse is true for attention directed to the right hemifield).

Sources

Complementing studies that demonstrate the effects of attentional modulation is research that aims to determine the source of the attentional signal itself. Evidence from multiple methodologies has been accumulating that implicates a network in the posterior parietal and frontal cortices as likely candidates for the control of spatial attention.

Some of the first studies that investigated the role of the parietal cortex in the control of spatial attention have come from the neuropsychological literature. Certain forms of brain damage produce perceptual deficits in attending to regions of space. The most common of such deficits are extinction and unilateral visual neglect, both of which result from unilateral brain damage primarily in and around the parietal cortex. In extinction, the patient is able to respond to and recognize events and objects when they are presented in isolation anywhere in the visual field. When two items are presented simultaneously, however, one in the contralesional field (opposite to the location of the lesion) and one in the ipsilesional field, the contralesional object often is not reported or responded to. In unilateral neglect, the deficit is more severe in that even a single object in the contralesional field tends to be ignored in the absence of competition from other objects. Unilateral neglect tends to be a more debilitating condition in everyday life than does extinction, and some have argued that extinction amounts to a mild form of neglect. As such, the deficit in spatial orienting that is exhibited by unilateral neglect patients has been taken as evidence that the parietal cortex is involved in control of spatial attention.

Recent neuroimaging findings propose that control of spatial attention is likely subserved by the frontoparietal network of regions in the human cortex. Voluntary deployments of spatial attention are associated with neural activity in regions of the dorsal parietal cortex (intraparietal sulcus [IPS]), superior parietal lobule (SPL), and frontal eye fields (FEF). Conversely, the temporoparietal junction (TPJ) and ventral frontal cortex (VFC) are recruited when spatial attention is captured by a stimulus presented in an unexpected location (e.g., one's own name inserted within the unattended auditory stream).

ATTENTION: THEORIES OF

Every moment of our lives, the world bombards us with a multiplicity of sights and sounds and other information taken in through the senses. These stimuli may be relevant or not to your current cognitive goal, or of such potential importance that, unexpected as the input may be, you must break out of your current goal-directed activities to understand the new input. A mother might be looking for her child in the playground, but may still respond to the sound of her cell phone. An air traffic controller may be busy tracking a large number of display inputs while actively interacting with only one or two. These and myriad other examples reveal that we are exquisitely tuned to the ebb and flow of new information. Attention is the mind's solution to the problem of sensory and processing overload. Whether this involves the selection of a particular piece of sensory information for additional processing or carrying out two tasks at once, attention systems select inputs and coordinate processing resources of the human brain. Scientists have furthered their understanding of attention through both empirical and physiological observations and the development of theoretical models for mechanisms of attention, as described in this entry.

Early and Late Selection

Inspired by analogies between humans and computers, the first of the modern theories of attention tried to explain how humans selected some sensory inputs for further processing while ignoring others. These theories also emphasized the extent to which sensory inputs could be processed without attention. *Early selection* theories claimed that the attention system acted like a filter that could select some inputs for additional processing based on visual physical characteristics such as location, color, or texture or based on auditory characteristics such as location, pitch, or the speaker's unique voice. Processing for identification or memory was claimed to occur only for attended-to inputs—unselected inputs were filtered out completely. At the other end of the continuum, *late selection* theories argued that considerable processing could be carried out on many inputs without limitations, and that the bottleneck in processing occurred just before the choice and execution of a response.

Initial tests of these theories were similar in essence to the "cocktail party" phenomenon, where a listener must pick out a single speaker in a room full of competing conversations. Experiments present different messages, sometimes by different speakers, in each ear ("dichotic" listening) using headphones. Listeners might be asked to immediately repeat ("shadow") a target speaker, as the message is heard in one ear, while ignoring messages in the other ear. However, attention filtering was ultimately shown to be by no means complete or absolute. Unattended messages, such as those presented in the other ear, were at least partially processed, especially salient or high-valence messages, as in hearing one's name in the unattended message. People notice if a word in an unattended message is the same or related to the attended message, so long as they occur close together in time. Consistent with this, physiological measures have shown that the effects of attention seem to begin at the first stages of sensory processing. Event-related potentials (ERPs), or electric activity of the brain in response to visual inputs, show stereotypical differences in the responses for attended compared with unattended stimuli. Attention can modify the brain's responses to stimuli, amplifying relevant inputs or attenuating irrelevant ones, even the first and fastest responses. For example, the response over the visual cortex to an attended visual stimulus ("pay attention to targets in the upper right quadrant") causes a larger response within the first 100 milliseconds (ms) in the P100 wave of the ERP, and this extends through early visual responses in cases where attention focuses on one location over longer blocks of many trials. Ignoring inputs does not, however, eradicate the sensory responses. In short, a modified form of the early selection model provides a good account: selection affects the earliest forms of sensory processing, but ignored inputs are attenuated rather than filtered out completely. The magnitude of the difference in response between attended and unattended inputs depends on exactly how attention is controlled. Attention has smaller effects on the earliest brain responses in cases where the focus of attention is changed to a new location by a cue on each trial. So, the impact of attention on perceptual processing can be more profound with a sustained period of attending to one location or feature than if selective attention is shifted moment to moment by changing cues.

Filtering and Amplification Mechanisms of Attention

Early selection theories claimed that attention filters some stimuli out and enhances others, but they failed to do more than sketch the mechanisms of filtering or the consequences for information processing accuracy. However, two related mechanisms of attention have been proposed and tested within computational models of a human observer's performance. In these models, stimuli are processed through perceptual templates tuned to respond to targets. For example, a template might be tuned for the letter A, or a particular shape or sound. The response of the template is noisy, and this and other noisy processes limit the accuracy of identification. Separate mechanisms exist for the enhancement or amplification of an attended stimulus and the filtering out of external noise or distractors. The *template model of attention* specifies how filtering and enhancement separately affect the accuracy of detecting a target or discriminating between targets within a framework of signal detection theory. For visual tasks such as identifying a letter or the orientation of a patch of pattern, tests have been developed that measure identification accuracies in the presence of different amounts of noise in the stimulus, something like looking at a poor television image that has a lot of visual "snow." Here, cueing attention to a location has one widely observed mechanism that filters out the noise—it improves performance most precisely when noise or distractors would otherwise damage performance. A second less frequently seen mechanism, enhancement, improves performance in an attended location even in the absence of competing inputs and is especially important for weak targets. Attention enhancement and attention filtering can occur separately or together. These mechanisms can also be directly related to models of neural processing in the visual cortex.

Signal Detection Theory Framework

Signal detection theory (SDT) explains how performance accuracy depends on the strength of the target ("signal") stimulus compared with nontargets in the context of the variability, or noise, in the signal strength over test trials. SDT assumes a noisy response to each stimulus, and determines how criteria or decision rules classify the stimuli to make a response; it separates the true discriminability of target and distractor stimuli from possible changes in criterion. The SDT framework was the basis of the template model (discussed earlier) and has been important to understanding attention limitations in searching for a target among other items. SDT models make predictions about the accuracy of performance when people look for a target among different numbers of distracting stimuli or locations under conditions where people cannot achieve perfect accuracy.

One interpretation of poor performance with more distractors was that people have a limited capacity for processing many items at once. For example, early behavioral tests of these ideas involved briefly presenting a dim light in one of several locations, and noted that the accuracy of reporting the correct location decreased as the numbers of locations increase. Early researchers took these results at face value to say that it was not possible to process more locations without reductions in performance because of capacity limitations in attention. Today, researchers know that such conclusions require first an analysis of the role of chance guessing (or criteria) and require signal detection computations. Even if each item is processed as well in the presence of distractors as alone, the natural variability in the sensory registration of each item causes more errors with more distractors.

In the signal detection framework for visual search, each location (or item) yields an estimate of sensory strength, or match to a target template (the "signal"). Each estimate, whether from a target or a distractor, is noisy because of processing inefficiencies or variation in the presented stimulus. Each added input to the decision increases the potential for false alarms, or classifying a nontarget as a target in error. Even for an ideal machine in which all evidence is processed perfectly and recalled without capacity limits, added inputs reduce accuracy. Only when the losses in accuracy exceed those predicted for an ideal observer are capacity limits implicated. For almost all displays where a target is defined by a single feature or a simple combination of features, the detection or discrimination accuracy is consistent with the predictions of the unlimited-capacity ideal observer model. This includes simple detection ("did something appear?"), but also discrimination of features such as length, orientation, color, or simple shape ("was there a longer one?"). It also includes many difficult cases of visual search where the target stimulus is defined by conjoining two simple features, such as a given orientation and color, where the distracting nontarget stimuli may share either orientation or color with the target. In all these cases, the increases in errors with the number of display elements have been almost exactly those expected from signal detection computations of increasing false alarms (or reduced hits caused by increasing criteria to avoid those false alarms). Limited capacity seems to be limited to special cases where discriminating a target involves spatial relationships, such as two touching bars in which white is on the left and black on the right, or vice versa. Related models of the speed of decision also support unlimited capacity parallel processes, at least for the accuracy-limited brief displays.

Salience and Guided Search

Guided search or salience models of attention predict visual search time when it is possible to scrutinize displays with eye movements. Models of salience, which mark certain items for priority processing, have illuminated how attention may be guided bottom up from stimulus characteristics and top down through goals. Strong or unique sensory stimuli such as the only vertical item among all horizontal items, or one that appears suddenly, have high salience that makes a search easy if the salient item is the target, or make it more difficult if it is not. Stimulus attributes also can interact with behavioral goals to increase the relevance of some items over others, so if one is searching for a red vertical line, items sharing these features may inherit higher salience. In these models, salience of each item is computed in terms of bottom-up factors such as how different it is from other items, especially items that are close in the visual field. The salience is also determined by top-down factors such as the similarity of each item to attributes of a goal or target. For example, in searching for that red vertical line among red horizontal and green vertical items, the ease of search often depends, all else equal, on whether there is a small subset of red items (or vertical items) to which search can be guided.

Several models of salience-guided search have been developed and tested that provide algorithms for the computation of salience and predictions about how these salience computations interact with distinct behavioral goals and tasks. These salience models, and other forms of guided search model, have modified and improved a set of previous models that were based on the notion that the role of limited-capacity, serial attention processes was to bind back together, or integrate, the features of objects that were analyzed and taken apart by separate feature maps in early visual analysis. The original feature integration models of visual search made a contrast between visual searches without needing attention ("pre-attentive") and those that are sufficiently demanding that they need serial scrutiny. Pre-attentive searches occur when any single feature such as any red item independent of orientation, size, and other features is sufficient to define a target as distinct from all other cases where a conjunction or combination of several features (i.e., red and vertical) is needed to define the target. The search must locate an object that contains both features. However, more refined guided search models account for all the early results of visual search used to support the feature integration theory, but also account for findings that reject the feature integration model, such as the ability to restrict search to the subset of red stimuli. Predicting the time to find a target in a visual search task has been the primary goal of guided search and salience models. The salience computations may also make predictions about the likely focus of eye fixations during visual search. Salience-based attention and search models have also been developed in computer science or machine-vision applications, where image-analysis algorithms or programs that do salience calculations are developed to mimic human-like capabilities (and limitations) in visual search tasks.

Capacity and Scheduling

What happens when people try to carry out multiple tasks at the same time? Successful multitasking could magnify human efficiency. However, as failures such as the dangerous use of cell phones while driving or the inability to benefit from listening to different lectures in each ear show us, there are often important limitations to how much can be simultaneously processed. Models of attention capacity and bottlenecks have been used to explain these limitations in simultaneously carrying out two tasks, each with a decision and response. One approach measures *attention operating characteristics,* graphing performance measures from two tasks against one another while varying the instructed division of effort, from focusing entirely on one or the other and different sharing ratios (e.g., 70 to 30%), to show the extent to which two tasks interfere with one another. For example, accuracy of Task A (e.g., visual contrast increment detection) is graphed against the accuracy of Task B (e.g., an auditory contrast increment detection). Observing no sharing losses, that is, where the two tasks can be performed as well together as separately, corresponds to the absence of mutual capacity limitations, or the "ideal point," where the accuracies of Tasks A and B performed together with equal emphasis ("attend equally" or 50 to 50%) are as high as when each is performed alone. The "switching-line" connects single-task performances (from single Task A performance and chance Task B performance to chance Task A performance and single Task B performance), where performance improvements in one task trade directly with performance losses in the other, reflects choosing one or the other task, but not both, to do on any given trial. Often, performance is worse than the ideal point but better than the switching line, corresponding with some degree of successful sharing. The attention-operating characteristic provides a powerful measure of dual-task compatibility.

In other kinds of tasks, people are asked to carry out one task first, followed as quickly as possible by the other. Presentation of the two stimuli is offset by different amounts of time to measure the *psychological refractory period.* If asked to classify a briefly flashed letter by speaking the name and to classify a tone as high or low by pressing a key, the response to the second-arriving stimulus may be delayed. To be refractory is to be resistant, or unresponsive to a stimulus. If two stimuli occur close together in time, then the response to the second is often delayed as though it were necessary to process the first before there is capacity available to process the second one, often by as much as a second or more. In general, it has been concluded that initial perceptual analysis often is carried out on multiple inputs simultaneously, and the need for limited-capacity attention occurs later, perhaps at the level of decision or response selection. The extent of capacity limitation or interference depends on the demands of the tasks. There are two distinct interpretations. One is that bottlenecks of limited attention are intrinsic to certain stages, such as decision, and the other is that introduction of delays is a strategic choice designed to eliminate conflict at the level of the peripheral systems, such as the eye or the hand, which cannot be in two different places at once, and not a central capacity limit at all. This second theoretical framework has been tested using computer programs that simulate specific tasks and predict the pattern of response times. Whether obligatory or strategic, the existence of temporal delays in responding to two input stimuli close together in time is a general finding demonstrating people's limitations in responding to two tasks.

Control of Attention and Attention Switching

Shifting attention from one location to another is an essential part of how we view the world. Covert attention, movement of the mind's eye, leads and targets the movements of the eye. Covert attention shifts are also used to take up information in different spatial regions without movement of the eye. Instructing people to make shifts of covert attention is one strategy for measuring how attention is shifted from one location to another. In one classic example, an arrow points at and leads attention to a possible target location. The costs of misdirection, called invalid cueing, can be measured in lower accuracy and longer response time compared with valid cueing. In another example, individuals may be asked to search for a target in a stream of letters appearing in one location, one after the next, and then to switch immediately to a second stream to detect the next item. The theoretical metaphor of covert attention operating like a spotlight led some researchers to suppose that moving the mental attention spotlight would entail activating spatial regions between the current location and the new location. Clever theories and experiments, however, have shown instead that items in intermediate locations do not benefit from the shift of attention. Instead, if attention is redirected from one location to another, it is as if one spotlight is dimmed while another spotlight focused at a second location is lighted. Excellent quantitative models account for attention switches as such episodes of information acquisition through attentive deployment that operate separately in space and time.

As in the case of visual search, many of these tasks combine a goal-directed, or top-down, specification of a location or a target with a stimulus-based, or bottom-up, analysis of the items in the field and their salience. Indeed, it seems that many visual searches involve naturally evolving cycles of attention deployment that lead to eye movements, and then to a new reassessment of the search field, and another eye movement. In visual search, in planned sequences of shifts of covert attention, or in unplanned or evolving sequences of movements of the eye, the control and shifting of covert attention plays an important role in how information is acquired from the inputs of the outside world.

Physiological Substrates of Attention

With the explosion of new knowledge about brain structure and function, new physiological theories can describe the impact of attention on individual cells in the sensory analysis systems and in networks of centers that act to engage attention or to disengage and move attention, and to maintain vigilance. Spatial attention changes the strength, or rate, of response for individual neurons in the early visual cortex, especially in the presence of distracting stimuli. Individual neurons may respond as though distracting stimuli have been excluded from influence on the response, a property similar to signal-detection-based template models of attention as a filter. Individual neurons can increase the level of response to an attended stimulus as though the contrast or strength of the stimulus was increased. This property, sometimes called contrast-gain, is directly related to the concept of enhancement or amplification of the attended stimuli in quantitative signal-detection models of attention. Computational model frameworks that integrate these parallel models from the cellular level in one or another individual region of the sensory cortex up through full analysis and behavior remain to be developed. Still, it is clear that the behavioral and the neural responses share close functional analogies.

Distinct networks of brain centers have been implicated in goal-directed preparation for expected inputs or targets and in the reorienting of attention in response to salient or unexpected sensory stimuli. Frontal and parietal regions of the cortex, including frontal eye field and lateral intraparietal areas, are activated during goal-directed preparation or deployment of attention in response to a cue to a relevant location or feature. These systems are activated during the period when the expectations from a cue are maintained and may be recruited during goal-directed tasks such as visual search. A different network, one that is lateralized in the right ventral frontoparietal area, appears to be involved in the resetting and reorientation of attention when an unexpected or salient input overrides goal-directed orienting. In goal-directed situations, recent evidence suggests that frontal activity precedes activity in the relevant sensory areas. If attention is attracted by the stimulus, however, then activity in the sensory representations seems to lead to the frontal activity. These networks have been identified through new imaging technologies that sense the activated regions of the brain during attention tasks in humans, through behavioral anomalies in humans with lesions, and by measuring neural responses in tasks in monkeys that parallel those in humans.

Future of Attention Theories

Attention is a critical function in the mental arsenal, one that has fundamental implications for how we interact with the world. As we learn more about how the brain works, computational models could help link cognitive function to physiological responding, and psychophysical models of function and behavior to the workings of physiological components of the relevant brain networks or systems underlying control of attention. These new theories and models, in turn, would help us better clarify the role of attention. A better understanding of attention's "exquisite control" in determining which inputs are processed and when would further our understanding of intelligent information-seeking behavior and how we choose to manage multiple task demands. In turn, the understanding of the distinct mechanisms and brain circuitry of attention may also increasingly serve as a basis for understanding how the attention systems fail to function or function differently across the life span or in different mental health conditions such as attention deficit disorder or schizophrenia.

ATTENTION AND CONSCIOUSNESS

Have you ever arrived at work or a store and realized that you have no memory of seeing, hearing, or otherwise experiencing anything along the way? This is a sufficiently common experience (or lack of experience) that it has received a nickname in the perception literature. It is referred to as having been in the *zombie state.* The idea is that in this state, people behave as functioning beings with the capacity to take in and respond appropriately to sights, sounds, and other stimulation but do so while being unconscious of them. Unlike horror-movie images of walking corpses, this zombie state is not necessarily bad. In athletics, it is referred to as being *in the zone,* and it is often a goal state. For athletes and non-athletes alike, this apparently unconscious yet functioning state is most likely to occur when executing a skilled behavior such as driving a highly familiar route.

The idea of attention is often invoked in thinking about what controls whether one enters the zombie state. For example, if nothing unusual happens on your drive to work and you are thinking intently about something, such as a project at work or a problem at home, you are likely to be unaware of your surroundings. If, however, something draws your attention, such as a pedestrian darting across the road, you are likely to become quickly aware of your surroundings. Reputedly, one can knock an athlete out of "the zone" by getting him or her to attend to details of an action—"Do you grip more tightly with your left or right hand when making a long putt?" Both intuitively and empirically, there seems to be a strong link between attention and consciousness.

The link between attention and consciousness remains a controversial issue. Some theorists assert that attention is both necessary and sufficient for consciousness. The idea is that you must attend to something to become conscious of it, and if you do attend to it, then you will become conscious of it. This is tantamount to arguing that attention is the same thing as consciousness, in which case, for simplicity, it might be best to jettison one or the other construct. Other theorists assert that attention is necessary but not sufficient for consciousness. The idea here is that you must attend to something to become conscious of it but that attending to it will not always make you conscious of it. This position assumes that attention serves as a gatekeeper by which the cognitive system is protected from being overwhelmed by the vast amount of information that impinges on the sensory systems. Finally, still other theorists assert that attention is neither necessary nor sufficient for consciousness. Under this view, attention and consciousness serve distinct functions, but they interact with each other. What evidence is there for these different views? This entry will discuss some of this evidence.

Link Between Attention and Consciousness

Some of the earliest evidence for a link between attention and consciousness came from attentional cueing experiments pioneered by Michael Posner and colleagues. In these experiments, attention is directed to some location and awareness of information at that location is compared with awareness of information at other locations. A cue such as a brief flash of light might be used to direct attention to a location. Stimuli are then presented at that cued location or at uncued locations. Observers are relatively poor at identifying or otherwise indicating that they were aware of stimuli at uncued locations compared with cued locations, suggesting that awareness depended on attention.

Other evidence of a strong link between attention and consciousness comes from "selective looking" experiments. Here, two scenes are superimposed and observers are asked to attend to one while ignoring the other. For example, Ulric Neisser and Robert Becklen superimposed two movies—one of a pair of people engaged in a hand-clapping game such as "See My Playmate" and another of a group of people tossing a ball from one person to the other. When observers were asked to report on some aspect of one of the movies, such as how many times hands made contact or how many times the ball was passed from person to person, they were strikingly unaware of events in the other movie. In one case, for example, a woman holding an open umbrella walks through the group of people playing ball. Many observers who were monitoring the hand game failed to notice this odd event.

Exploring the link between attention and conscious perception further, Arian Mack and Irvin Rock designed experiments to ask whether stimuli are perceived at all when they are "truly" unattended, that is when attention has not been directed to them and when observers have no reason to suspect that they will be relevant to the task at hand. These experiments involved a difficult attention-demanding task. For example, observers would be shown a large plus sign in which either the horizontal or vertical bar was slightly longer, and the task was to report which was longer. Unbeknownst to the observer, after completing several trials of this difficult task, an additional stimulus was presented along with the plus sign, such as a colored shape. When asked after the trial whezther they noticed any stimuli other than the plus sign, observers often reported seeing nothing. This happened even when the additional stimulus was presented directly at the location where their eyes were fixated. Apparently, the plus-sign task prevented observers from attending to anything else and, as a consequence, concluded Mack and Rock, nothing else was perceived, a phenomenon they labeled *inattentional blindness*.

A related phenomenon, known as *change blindness,* seems to reinforce the link between attention and conscious perception. In these studies, which were pioneered by Ronald Rensink, Daniel Simons, and others, observers failed to notice large changes in a scene that they were viewing unless attention was somehow directed to the change. These experiments are similar to "find the differences" puzzles in children's magazines, except that the scenes are presented at different times instead of in different locations. For example, two versions of a city scene—one in which a (large!) steeple on a building is present and one in which the steeple is missing—are presented one at a time with a brief blank screen in between. Observers must find and report the difference across the two versions. This is a remarkably difficult task. In some cases, the scenes often cycle for more than one hundred times before observers reliably detect the change. Moreover, when monitoring eye movements during this task, it has been found that observers sometimes fixate the change without noticing it. Apparently, until attention is paid directly to the change itself, the experience is of an unchanging scene across the two views.

Finally, individuals who have suffered certain types of brain damage have also provided insight into the link between attention and consciousness. Patients who have suffered damage to parietal regions of their cerebral cortex, for example, which have been implicated in the control of attention, seem to show something like inattentional blindness, referred to as *neglect.* When attention is drawn to the areas of their visual field that correspond to the damaged brain areas, they are able to perceive stimuli normally. When attention is not drawn to these areas, however, the patients behave as though those stimuli are not there at all. A related phenomenon known as *extinction,* which also occurs with parietal damage, similarly highlights the link between conscious perception and attention. When a single stimulus is presented in a location that corresponds to the area of cortical damage, these patients do notice and can report on this stimulus. However, when two stimuli are presented—one in a location that corresponds to undamaged brain areas and one that corresponds to damaged areas—these patients will often report seeing only the stimulus in the "good" area, as if perceiving that stimulus "extinguished" conscious awareness of the other stimulus.

An important aspect of all these phenomena—attentional cueing, inattentional blindness, change blindness, neglect, and extinction—is that when attention is directed to the stimuli in question, observers are able to see them easily. Thus, it is not the quality of the stimuli that determines awareness, but rather whether or not they are attended. The question remains, however, is attention *both* necessary and sufficient for consciousness?

The Issue of Sufficiency

Several theorists have noted that although attention may be necessary for consciousness, sufficiency is yet a further step. Daniel Levin and Daniel Simons, for example, noted that observers are often unaware of changes that occur to aspects of a scene to which they are attending. Observers were asked to watch films in which various changes occurred, in anticipation of answering questions about the film afterward. Strikingly, about 50% of the observers failed to notice that the actor playing the main character in the film changed across a scene cut. In an even more dramatic example, observers came into the lab and met an experimenter behind a counter. After engaging the observer in a brief conversation, the experimenter ducked below the counter as if to get some materials on a shelf. Unbeknownst to the observer, a second experimenter who had been waiting below the counter, came up and resumed the conversation with the observer. Fewer than 40% of the observers in this experiment noticed this change.

Theorists who espouse the view that attention is necessary but not sufficient for consciousness tend to attribute a gatekeeping role to attention. The idea is that much more sensory information is available at any given time than can be fully processed. Attention controls the flow of information to later processes that are especially limited in their capacity. Consciousness is thought to arrive through access to some subset of these later processes. Thus, attention is necessary to achieve access to those processes, but it does not follow that all information that is let through will gain access to them. Stanislas Dehaene and Lionel Naccache, for example, codified this view into what they refer to as a *global workspace* framework following theorist Bernard Baars. The idea is that attention activates within a central representation—the workspace—information that is most relevant to the current contextual demands. Observers become conscious of some of this information when it engages some of the processes within this workspace, such as the establishment of a durable and explicit representation, or the initiation of intentional spontaneous behavior, but do not necessarily become aware of all of activated information. In this way, attention controls what one can be conscious of, but it does not directly determine conscious awareness of any information.

Perhaps Attention Is Neither Necessary Nor Sufficient for Consciousness

Although there is a strong link between attention and consciousness, some theorists have pointed out that this link may be neither necessary nor sufficient; attention and consciousness may simply interact with each other. Formally, for attention to be neither necessary nor sufficient for consciousness, one must occur without the other and vice versa. In two separate analyses of the literature, Christof Koch and Victor Lamme argued that exactly this situation holds. Examples were cited of every condition—attended and conscious, unattended and unconscious, attended and unconscious, and unattended and conscious. The first three categories constitute those reviewed in the preceding two sections of this entry. The fourth condition—unattended yet conscious—has been the most controversial and the most difficult on which to reach agreement: Can one be conscious of unattended information? The difficulty in answering this question is that assessing whether someone is conscious of something would seem to require asking about it, but in asking about it, attention is drawn to it, thereby destroying the necessary conditions for assessing whether consciousness is possible without attention.

Two strategies have been taken to circumvent the challenge of assessing consciousness without directing attention. One has been to seek indirect evidence that something has been perceived. Cathleen Moore, for example, presented the inducing portions of simple visual illusions in the backgrounds of displays using Mack and Rock's inattention method, which was described earlier. Despite being unable to report the patterns in the background, many observers nonetheless experienced the illusions that they were designed to induce. This suggests that those patterns were perceived at least sufficiently well to alter other aspects of the perception. Jeremy Wolfe coined the term *inattentional amnesia* to characterize this sort of experience and to contrast it with the term *inattentional blindness*. The idea is that observers may be immediately aware of sensory stimuli at the time they are present, but if attention is not drawn to it, it is not committed to memory, and the observer cannot report on it after the fact. The term *visual stuff* has been used by Wolfe, philosopher Wayne Wright, and others to characterize the type of perceptual experience that one has of unattended sensory information.

The second strategy for assessing perception without directing attention has been to use dual tasks. The idea is to engage observers' attention with a difficult task, and then ask them, secondarily, to report on other stimuli that might occur. Leila Reddy and colleagues used this strategy to ask whether people can identify faces without attention. Observers were asked to focus on performing a difficult letter-discrimination and search task in the center of the screen, while face stimuli were presented in peripheral locations. Reddy and colleagues found that observers were able to reliably detect the gender of the face with essentially no decrement in performance on the letter task and could identify individual faces with relatively little effect on the central task.

Conclusions from dual-task experiments always face the challenge that because observers were aware of the relevance of the other stimuli, they may have—however briefly—redirected attention to those secondary stimuli. Therefore, any awareness they may have of those stimuli could be attributable to residual attention. Because of this limitation, conclusions from dual-task experiments are usually limited to being of the form, for example, "gender identification in the near absence of attention," rather than "in the absence of attention."

Return of the Zombie

The difficulty of explicitly characterizing what is meant by "visual stuff" and the difficulty of ascertaining that no attention is paid to secondary stimuli in divided attention tasks constitute serious challenges to resolving the final critical question—Can people be conscious of things that they do not attend to? The view of theorists such as Koch and others, however, is that the zombie state reflects exactly this. It seems implausible that we drive to work, for example, with no perceptual awareness. Consciousness and attention are clearly closely linked. The final answer about the nature of that link will hinge on confirmation of the existence of the zombie state and an understanding of information processing while in that state.

ATTENTION AND EMOTION

Daily life presents such a bombardment of information that people would be overloaded without some means of prioritizing what they process. Attention and emotion systems both contribute to such prioritization. Emotions, for example, provide rapid, efficient means for identifying high-priority aspects of the environment, and attention mechanisms allow people to select manageable subsets from an otherwise overwhelming influx of information. Although these two systems influence each other, studies of attention within the traditional perception literature have often overlooked the role of emotion, examining instead how attention operates on various perceptual features. But the world is not characterized solely by assemblages of colors, angles, and motions; the objects, people, and events around us resonate with emotional meaning, so it is crucial to understand how attention and emotion interact. This entry describes emotional stimuli and varieties of attention, preattentive biases, rapid orienting versus delayed disengagement, emotional stimuli and mechanisms supporting awareness, asymmetry of attention-emotion interactions, and reciprocal influences.

Emotional Stimuli and Varieties of Attention

Attention refers to a family of mechanisms that—although they converge in the service of stimulus selection—differ from each other in important ways; orienting of attention to spatial locations is not the same as selectively attending to some features of a stimulus while ignoring other features, and neither of these processes is necessarily identical with the attention mechanisms involved in bringing information to awareness. Although evidence does suggest dissociations between these types of attention, each of them appears to be strongly influenced by emotion; emotional information seems to "capture" and hold various aspects of attention more robustly than does nonemotional information. For example, when it comes to attending to some features of a stimulus over others, *emotional Stroop* experiments have shown how difficult it is for people to ignore emotional aspects of a stimulus even when such aspects are task-irrelevant. In a typical version of this task, participants try to name as quickly as they can the colors in which words or monochrome pictures appear (or are printed). Frequently, they are slower to do so when the words and pictures happen to have strong emotional significance, suggesting that people had difficulty tuning out the task-irrelevant emotional information to focus only on the relevant color information.

A large portion of research on attention-emotion interactions has focused on the orienting of spatial attention. One procedure commonly used to tap into spatial orienting is the *dot-probe* task, where pairs of words or faces are typically presented on a computer screen and are followed quickly by a dot at one of the word/face locations;

participants are required to respond as soon as they detect the dot, and they tend to be faster when it appears at the former location of an emotional word or face than of a neutral one, suggesting that attention had already oriented to the emotional stimulus at that location (similar effects have been found even when people were not aware of the emotional stimulus). Similarly, in a *cueing* task—another measure of spatial orienting of attention—participants make speeded responses to targets, which could appear at one of at least two locations. On some trials, a cue appears before the target at one of the potential target locations, but the location of the cue does not predict the actual location of the subsequent target. In standard, non-emotional versions of this task, people tend to be slower to respond to the target when it appears away from the cue (an "invalid" cue) than when it appears at the same location as the cue (a "valid" cue), indicating that they had reflexively oriented to the cue despite knowing that doing so would not aid their performance. In emotional versions of this task, the cues themselves can be emotional or neutral stimuli (e.g., words or faces), and when they are emotional, their effects on spatial orienting are amplified. Notably, the emotional Stroop, the dot-probe, and various cueing experiments have revealed general biases to attend to emotional stimuli and have shown that such biases tend to be stronger among clinical and highly anxious individuals.

Pre-Attentive Biases

A number of models straddling the divide between cognitive and clinical branches of psychology have suggested that biases to prioritize emotional stimuli originate *pre-attentively,* meaning that they occur before attentional selection and are not necessarily bound by capacity-limited constraints. According to such models, pre-attentive evaluation of a stimulus's emotional significance helps direct the subsequent allocation of attention. Indeed, theorists such as J. Mark Williams, Fraser Watts, Colin MacLeod, and Andrew Mathews have suggested that high trait anxiety might be linked with a tendency to orient toward stimuli that were pre-attentively evaluated as threatening, whereas low trait anxiety might be linked with a tendency to orient away from such stimuli.

Some neurobiological evidence suggests how such a pre-attentive evaluation system might be instantiated, although such claims have also been challenged. For example, work on the amygdala—a subcortical structure strongly linked with the processing of emotional significance—has revealed direct connections with the visual system, suggesting neurobiological pathways through which emotional information could conceivably bypass many attentional circuits. Converging neuroimaging evidence has found heightened amygdala activity in response to emotional stimuli even when the stimuli were rendered unreportable through backward masking (i.e., when noisy visual patterns appearing immediately after emotional stimuli disrupted subjective awareness of such stimuli) and when attention was directed away from them to perform a secondary task. However, although such findings are provocative and have been widely influential, other work has found scant evidence of such heightened amygdala activity when the effectiveness of masking was rigorously ensured and when attention was strongly occupied by a secondary task. Additional studies have found that personality variables such as trait anxiety are linked with the degree to which attention manipulations modulate amygdala response to emotional stimuli. Such relationships may have been observed either because anxiety is linked with hyper-responsiveness to emotional stimuli or because anxiety is linked with a reduced ability to direct the focus of attention. Evidence exists to support both accounts.

Recent behavioral evidence also has led some to question whether emotional or otherwise high-priority stimuli are indeed processed independently of attention. In a study by Christine Harris and Harold Pashler, participants made speeded judgments about the relationship of two digits to each other and either an emotional word, the participant's own name, or a neutral word could appear in between the two digits. When the emotional word or one's own name was the only text alongside the digits, response times were slowed relative to when a neutral word appeared; this effect was especially large for one's own name. However, when one's name was only one of several words appearing alongside the digits, response times were no different from when no name was present. This finding suggests that rather than reflecting pre-attentive mechanisms, high-priority stimuli may receive preferential processing only when attentional resources are readily available. Of course, as the authors noted, it is possible that different results would have emerged had stimuli been even more emotionally evocative or had participants represented a more highly anxious population.

Rapid Orienting Versus Delayed Disengagement

Related to the question of whether emotional information can be extracted pre-attentively is the question of whether biases to attend to emotional stimuli reflect faster attentional orienting to emotional stimuli in the first place (which would be consistent with pre-attentive evaluation mechanisms) or delayed disengagement from emotional stimuli already at the focus of attention. Some evidence suggests the former. For example, one study used a *visual search* task in which participants searched for a fear-relevant stimulus (a spider or snake) among non-fear-relevant stimuli (mushrooms and flowers). Typically, in a visual search task, the time it takes to detect a target within an array of items increases as the number of array items increases. However, when the target was fear-relevant, response time seemed relatively unaffected by the number of array items (an effect known as visual "pop out"), suggesting that it had been among the first of the array items to draw attention. On the other hand, attentional cueing research in which cues could be neutral or threatening stimuli has suggested that rather than preferentially drawing an initial orienting response, emotional stimuli simply "hold" processing resources once they are attended. In one cueing experiment, when cues appeared at the location of the subsequent target, participants' response times were not affected by the emotionality of the cue, suggesting that the emotional cues did not elicit faster orienting. In contrast, when cues were invalid, appearing away from the target location, emotional cues led to slower response times, suggesting that participants indeed had difficulty disengaging from them to reorient attention to the target. This evidence suggests that when it comes to spatial orienting of attention, biases to attend to emotional stimuli may be driven by tendencies to linger on—rather than initially orient to—such stimuli.

Emotional Stimuli and Mechanisms Affecting Awareness

Recent studies have begun to examine the impact of emotional stimuli on attention mechanisms that help drive visual awareness itself. These experiments have suggested that emotional stimuli both gain more ready access to such mechanisms and, perhaps in doing so, prevent spatially or temporally neighboring, non-emotional information from doing the same. In large part, such experiments have used what is known as the *attentional blink* task, where participants search for targets within rapid streams of stimuli (e.g., streams of alphanumeric characters in which each item appears for about 80 to 100 milliseconds [ms] before being replaced by the next). In a typical non-emotional version of this task, people often detect the first target but fail to detect the second if it follows too soon afterward. One widely influential explanation for this effect is that the attentional processes that select information for consolidation into visual awareness are relatively slow, and that failures to detect the second target stem from such processes already being engaged by the first target. Notably, when the second target happens to be an emotional word, it is less susceptible to the attentional blink, suggesting that it captures the processes necessary to support awareness (although this does not occur among patients with bilateral amygdala damage). In a similar rapid presentation task, participants searched for only a single non-emotional target, and the target could be preceded in the stream by a task-irrelevant emotional or neutral picture. When the task-irrelevant picture was emotional, participants had difficulty perceiving the subsequent target; thus, in drawing attention to themselves, emotional stimuli appear to distract or disrupt attention processes that would otherwise usher other information into awareness. Consistent with this notion, evidence suggests that emotional stimuli associated with disrupted target detection are, in themselves, better remembered than are those not associated with such disruption.

Asymmetry of Attention–Emotion Interactions

The literature on attention–emotion interactions seems to contain an asymmetry wherein emotionally negative stimuli influence attention more than emotionally positive stimuli do. Such findings have led to suggestions of evolved mechanisms for attending specifically to threat; arguably, such mechanisms could aid one's chances of survival. However, some have argued that the observed asymmetry stems not from evolved threat-detection mechanisms, but from the fact that emotionally negative stimuli tend to be more emotionally "arousing" or intense than are emotionally positive stimuli. A few studies have attempted to control for the general emotional arousal elicited by stimuli and, in doing so, have reported that the positive–negative asymmetry largely disappears. In other words, it may be that the degree of arousal elicited by a stimulus drives attention effects more than does the evaluation of a stimulus as being positive or negative. The degree to which arousal and positive–negative evaluations respectively contribute to attention–emotion interactions is still a topic of considerable inquiry.

Reciprocal Influences

In addition to evidence suggesting that emotion influences attention, recent evidence has highlighted the bidirectional nature of this relationship, exploring ways in which attentional withdrawal from stimuli affects emotional responses to them. Jane Raymond and colleagues, for example, have found that when a visual search task requires that people ignore otherwise attractive visual distractors, participants later rate the ignored distractors as being less pleasing than visually similar items that had not been ignored. Notably, the harder a person had to try to ignore a distractor (e.g., the closer a distractor had appeared to a target), the more they affectively "devalued" it. Such findings reveal reciprocal influences between attention and emotion and carry implications for how patterns of attention allocation may foster affective preferences in daily life.

ATTENTION AND MEDICAL DIAGNOSIS

When a radiologist is presented with a medical image, be it a radiograph or the many hundreds of images generated from a computerized tomography (CT) or magnetic resonance imaging (MRI) scanner, he or she needs to make sense of the images, which are representations of the human body, and perceive pathology among the different ambiguous shapes, shades, and contours. Abnormalities are generally perceived quickly, as eye tracking has demonstrated, with pathology usually looked at within the first two or three fixations. It takes many cases and years of training to become proficient in interpreting medical images as perceptual discrimination is learned and acquired knowledge is converted into a variety of cognitive strategies and cognitive skills. This process is still not fully understood, but it seems practice with feedback is the only way to achieve clinically acceptable performance. Medical imaging has seen many developments in equipment, including the recent move away from film to digital technologies. Research has, however, demonstrated that error rates during the past 50 years remain resistant to these improvements and changes in technology. This demonstrates the importance of perceptual and cognitive factors in the performance of radiologists when interpreting medical images. This entry discusses eye movements, models of medical image perception, searching medical images, and decision processes.

Eye Movements

Eye tracking as a research methodology has provided some insight into the strategies and types of errors that are made by radiologists. Eye movements are not involuntary in visual search but can be described in terms of target selection, which in turn is related to the motivational state of the radiologist and to higher cognitive processes.

Errors can be search errors because of incomplete scanning, detection errors caused by failure to recognize visual features, and decision errors where the wrong decision is made. Most errors, however, are not caused by a failure to perceive but by a failure to recognize and make the correct decision. In mammography, about 30% of cancers are missed, and 70% of those missed cancers are actually looked at, although not identified as cancer.

Eye tracking has demonstrated different search patterns between novices and experts. For example, when looking at a chest radiograph, the expert will exclude large parts of the image during a search for lung nodules and concentrate on regions where lung cancer is more likely to occur. Compared with the novice, the expert will also make fewer fixations and have a greater distance between fixation clusters.

Reflecting the fact that there is currently no formal theory of optimal eye movement strategy in conducting visual search, there is no optimal strategy for radiologists, but eye tracking is useful for attempting to understand the way radiologists assimilate information from a medical image.

Models of Medical Image Perception

The global focal model of medical image interpretation, developed by Harold Kundel and Calvin Nodine, can actually be applied to any situation where domain-specific knowledge is important. According to this model, two forms of image analysis are performed sequentially. The first stage is the global or holistic impression (see color insert, Figure 12). This occurs instantaneously, in the same way as recognition of a familiar face happens. Any perturbations in the image are identified based on learned templates, and are flagged for subsequent searching before the first fixation. This is why abnormalities are usually looked at within the first few fixations. The second stage is when focal scanning takes place, which is essential for subtle lesions that are less conspicuous.

With experienced radiologists, the concept of normal is so highly developed that normal features are not consciously processed, but the abnormal ones are identified for focal scrutiny, so visual attention is perceptually attuned to the detection and decision making requirements of the task. For example, in mammography, where the appearances of some cancers can be subtle, the emphasis is on the cognitive aspect of visual search, which depends on training and expertise.

Searching Medical Images

There is a great deal of variability between radiologists in the way medical images are searched, but despite the variability, search patterns are rarely random. The relative importance of the image properties or cognitive structures in driving search depends on the task. Medical image interpretation is essentially task driven, where knowledge structures are more important than visual saliency. This is perhaps best illustrated by the way that clinical history or knowledge of the clinical indications for the imaging test can change the allocation of attention to different parts of the image, so perception can be changed in response to information about the implied meaning of the image. For example, knowing the patient's symptoms and the mechanism of injury can facilitate the detection of subtle fractures, such as some injuries to the pelvis commonly suffered by long jumpers, hurdlers, and gymnasts. Medical images are also representations of reality so perceptual organization depends on the observer's ability to retrieve stored mental representations of targets they may encounter.

One phenomenon that affects performance is the satisfaction of search effect (SOS) in which an abnormality is missed because another abnormality has been detected. Search is terminated once an expected pathology is found. This has been extensively researched by Kevin Berbaum in a recent study in which fractures were added to the images of 70 simulated multi-trauma patients leading to a substantial reduction in the detection of subtle fractures by radiologists.

Decision Processes

Once an abnormality is perceived, the decision about whether to report it is not always clear-cut. Radiologists will have different thresholds of abnormality depending on factors such as the task or even personality traits such as the cautiousness of the radiologist. For example, in screening examinations such as mammography where the occurrence of disease is rare (approx. 0.5%) and the consequences of missing a cancer are serious, then the radiologist when deciding on any abnormalities perceived in the image is likely to err on the side of caution and suggest a biopsy.

Computer-aided diagnosis (CAD) has been used to support the radiologist in his or her decision making by indicating any potentially abnormal locations that the radiologist might not have perceived and so reduce the number of missed cancers. Studies generally indicate that there is an improvement in detection with CAD, but not always, because not all observers use the CAD information in the same way, particularly if the CAD information conflicts with the physician's perceptual processes. For example, CAD can be used in mammography as a prompting system by highlighting suspicious areas for the observer to assess; however, cancers are rare in mammography so most prompts would need to be ignored, which, apart from being distracting, will also reduce the threshold a film reader will put on any prompt that it is a true positive.

ATTENTION AND MEMORY

Behavior in a variety of visually guided tasks—from remembering a few objects to executing complex activities—is strongly influenced by the interplay between attention and memory. This entry highlights these interactions as we process our visual surroundings. Reflecting the corpus of scientific literature, the primary focus of this entry will be on short-term memory, although some interactions with long-term memory will also be described. Specifically, the focus is on the role of attention in determining the contents of visual memory, and, reciprocally, the role of visual memory in controlling attention during perceptually guided tasks.

As the following sections show, the likelihood that an object is represented in visual short-term memory (VSTM) is related to the amount of attention it receives during initial perceptual processing. Once in VSTM, attention-based rehearsal mechanisms affect the likelihood information is retained there or transferred into a more durable long-term memory (LTM) store. Retained short- and long-term memory representations of object location and identity can then reciprocally influence the subsequent guidance of attention through the visual world.

Encoding of Information Into Visual Short-Term Memory

As its name implies, visual short-term memory enables the temporary retention of newly acquired visual information over short periods (seconds). For example, VSTM allows one to keep track of car positions and movement trajectories between glances to the rear-view mirror while driving. In contrast to the seemingly limitless capacity of long-term memory, however, VSTM is a limited capacity resource restricted to, at best, four items—only a tiny percentage of the world around us (long-term memory enables an observer to accumulate information beyond this limit). With such a limited ability to store shortly relevant visual information in the short term, some set of mechanisms must govern access to VSTM. Although the importance of attention in determining the contents of VSTM has been known for some time, it is highlighted by two phenomena that have received recent consideration: change blindness and just-in-time search strategies.

Change blindness is the tendency for an observer to fail to notice changes introduced to a scene such as color alterations, object additions or deletions, and object substitutions from one view to the next. To induce this effect, one only needs to temporarily block an observer's view of the world when the change takes place. A lab-based example might be a momentary flicker on a computer screen and a real-world example might be a bus moving across a pedestrian's line of sight. These failures in visual memory and visual awareness result from a limited ability to efficiently encode the myriad objects and features contained in a scene into VSTM. Change blindness is reduced, however, when changes are made to objects that are likely to be attended. For example, changes to objects that are of central interest in a scene are detected faster than are those of more marginal interest. Indeed, once a change is found, it becomes so obvious to observers that they are surprised the task was so difficult.

Performance on perceptually guided action tasks such as making a sandwich, preparing tea, or sorting blocks, also suggests that attention is in some sense a gatekeeper for VSTM. When executing these various natural actions, observers adopt a *just-in-time strategy* in that they only obtain and represent information in VSTM when it is needed. For example, when asked to arrange a random assortment of colored blocks to match a model, observers typically fixate (attend to) a block in the model before picking up a block of the same color only to then look back at the model before placing the selected block in their copy. Observers apparently only acquire color in the first fixation and have to re-attend to the model to obtain location information in the second fixation. Hence, in perception-for-action situations, specific momentarily relevant features of an object or scene are selectively attended and retained in memory at the expense of task-irrelevant features. In conjunction with studies on change blindness, results of this kind suggest that focused attention may be necessary before an object (or a subset of its specific component features) is encoded into VSTM.

Maintenance of Information in Visual Short-Term Memory

Given its limited duration and capacity, the contents of VSTM must be constantly updated or "refreshed." Attention also plays a role (although not a solitary one) in determining the degree to which information is maintained in VSTM. Consider a situation where an observer is asked to remember a set of objects across a short retention interval. If at the same time, observers are also engaged in a difficult attention-demanding task such as counting backward from a random three-digit number in multiples of three, they experience a decrease in the amount of information that they can retain about the objects. Similarly, if a sudden visual distraction occurs during the retention interval, such as a localized flash of light, memory for objects previously presented near the distracting event are remembered better than are those that were further away as though a "spotlight beam" of attention shifted and narrowed from all objects to just a few. Finally, the number of objects that a particular individual can remember is directly related to his or her ability to vigilantly attend to task-relevant information and to ignore task-irrelevant information. Collectively, these results have led researchers to postulate attention-based rehearsal mechanisms that maintain information in VSTM.

Guidance of Attention

To interact with the visual environment, whether to find a misplaced book, to make lunch, or to safely maneuver an automobile, observers shift their attention from place to place. Although the guidance of attention through a visual display is likely influenced by perceptual factors such as local luminance, contrast, color, and motion, cognitive factors including memory are also important. For example, the contents of VSTM can bias the deployment of attention toward some objects and away from others and thereby influence the ease with which objects can be located and identified. To illustrate this, the following discussion focuses on the role VSTM plays in visual search tasks by considering how VSTM for spatial location and object identity affect attention guidance.

Memory for Object Location

Visual search is more efficient if an observer can remember the locations he or she previously searched and avoid revisiting them in the future. One method that has been used to explore the role that memory for object location plays in selecting items to interrogate has been to engage observers in a search task in which items are revealed a few at a time. For example, in the preview or *gap paradigm,* a search array is revealed in two stages. First, a set of distractor objects is presented, all of which the observer knows are not targets. After a delay of about 1 second, another set of items, one of which is the target, is added to the display. When objects are presented in this manner, the target is found faster than in situations where all search items are presented simultaneously. In order for this preview effect to be observed, some memory for the locations of the old and new items must be involved because once the second array appears, it is impossible to perceptually distinguish the two groups of items.

In addition to showing that attention is biased away from previously attended locations, researchers have also shown that visual search is slowed when observers are asked to remember a series of spatial locations during a visual search task. This occurs because VSTM is limited in capacity and the additional task interferes with the observers' ability to remember the locations of the searched and the to-be-searched items in the display. Additionally, these spatial memory loads increase the likelihood that attention will return to previously examined objects, thereby decreasing the efficiency of visual search.

Memory for Object Identity

When engaging in a visual search task, observers have to remember what they have looked at, as well as what they are looking for. Many models of visual search suppose that this is accomplished by generating a *target template,* or a representation of what one is looking for, in VSTM. Several lines of experimental evidence suggest that once this is done, attention is biased toward objects that are similar to this stored template, especially when the identity of the target changes from trial to trial (although this biasing is not automatic or mandatory, indicating that the contents of VSTM can be used flexibly across various task demands to guide the allocation of attention). In addition, after memorizing a given object, one's ability to locate and identify a search target in a visual array is facilitated if the target appears near an item that matches the to-be-remembered object compared with situations where the target appears near a visually distinct distractor. This memory-guided allocation of attention by object identity improves overall discrimination times and can attenuate set size effects (the tendency for search time to be directly related to the number of objects in the display) during serial visual search.

The bias of attention toward objects that match the contents of VSTM is not confined to serial search where observers must attend to each object in a display one-at-a-time. Even in a pop-out search task where observers are to report the shape of a color singleton target (e.g., the red target among green distractors or vice versa), search is faster if the target on trial N and N–1 are the same color compared with cases where their colors mismatch. By varying the lag between matching target trials, this priming of pop-out effect has been shown to persist for approximately 30 seconds.

Although explicit knowledge of the target identity facilitates search, recent evidence suggests that VSTM can help guide attention even when the identity of the target is unknown. For example, if one asks an observer to search for a suddenly appearing object in a real-world scene—and assuming that these objects are onset so that low-level motion signals that would otherwise capture attention are eliminated—the speed with which the targets are overtly attended increases with additional viewing time before the onset of the target. This result suggests that as more information is added to VSTM as viewing progresses, the resulting representation becomes more functional in the sense that it can be used to help orient attention within scenes even when precise search templates cannot be formed in memory.

Visual Long-Term Memory

In contrast to short-term memory, visual long-term memory has no clear limit on its capacity or storage duration. In one striking demonstration of this, after being shown hundreds of photographs for just a few seconds each, observers are able to recognize the pictures they saw even after a retention period of an entire year. Access to this LTM store relies on attention in much the same way as VSTM because the objects that are attended during the perception of the environment and that are rehearsed in VSTM may be retained long-term. However, the long-term maintenance of information in memory is accomplished without the need for sustained attention. As the previous example shows, even with long delays between study and test where attention has been removed from an object, its representation in LTM perseveres.

In addition to enabling the accumulation of information in memory beyond the limits of VSTM, long-term memory can also modify the allocation of attention to a visual display. For example, if an observer is repeatedly exposed to a constant arrangement of target and distractor items in a visual search task, search becomes progressively more efficient, an effect known as *contextual cueing*. This increase in efficiency occurs because repeated experience with a display leads to long-term memory for the configuration of objects that in turn can help guide visual attention to behaviorally relevant targets. That is, when the spatial relationships among objects in a scene are relatively constant, such as the arrangement of furniture in your living room, by virtue of knowing the locations of any set of objects, one also knows (or at least can predict) the location of any other item, thereby reducing the need to execute a detailed serial search for some desired target.

Long-term memory for object or scene identity is also used to guide attention during visual search. For example, target detection is facilitated if a target object is consistently presented with the same distractor objects, compared with situations where the distractor and target objects are uncorrelated. Additionally, the visual knowledge stored in LTM regarding semantic associations between objects influences search. When searching for a target object (e.g., nails) that is—unknown to the observer—absent from a display (hence the target cannot attract attention itself), the presence of a semantically consistent object (e.g., hammer) draws attention because, in our experience, these objects tend to be co-located. Thus, the visual information accumulated over one's lifetime can be brought to bear on search tasks in an effort to increase efficiency. Finally, returning to contextual cueing, if a learned configuration of objects is unexpectedly mirror-reversed so that they are spatially translated across the display, observers first shift their gaze (attention) toward the position in the display in which the target had previously appeared. However, when this initial search fails, attention is quickly directed to the target's new position, suggesting that LTM for scene and object layout are also used to guide attention.

ATTRACTIVENESS

The term *attraction* can refer to numerous interpersonal factors from liking to love, but it is most commonly used to indicate evaluative judgments of physical attractiveness. Although now prominently featured in journals of many disciplines, the scientific study of attraction is a relative newcomer to psychology. Since its beginnings, however, numerous perceptual cues have been identified that reliably affect perceptions of attractiveness. This entry reviews theoretical approaches to the study of attractiveness and then describes the visual, auditory, and olfactory cues that affect perceived attractiveness.

Theoretical Perspectives

Social Beginnings

The original and long-standing approach to the study of attractiveness was purely social. Classic studies examined the effects of physical proximity and interpersonal similarity to determine which factors affected interpersonal attractiveness and the consequences thereof. Two effects have emerged as important components of interpersonal attraction. First, the effects of propinquity, or closeness in physical proximity, on attraction are clear. People are more attracted to those with whom they have the least functional distance, and this is true for both friendships and romantic attractions. This occurs because of multiple factors including availability and mere exposure. Second, the effects of similarity are also clear, and they emerge along several dimensions. Overall, people tend to be attracted to others who share similar interests and personalities. Additionally, people tend to pair-bond with others who are similar in the degree of physical attractiveness (called *assortative mating*). Empirically speaking, attraction is more likely to follow the adage "birds of a feather flock together" instead of "opposites attract."

Other classic studies examined the consequences of perceived attractiveness. Attractive individuals, for example, enjoy what is called a *halo effect.* When someone is perceived to be attractive, observers are also likely to perceive the person to be likeable, successful, and socially skilled. Moreover, attractive individuals elicit more positive behaviors from others. These effects begin early in life. Infants prefer to look at more attractive others—including men, women, and even other infants! Despite the numerous benefits that beauty affords, it would be incorrect to assume that the effects of perceived attractiveness are entirely positive. Attractive individuals are also likely to be perceived as bourgeois, vain, and more likely to divorce, among other things.

All told, the early work investigating perceptions of attractiveness, though interesting, presumed that cues to attractiveness were socially constructed. Recently, however, this perspective has been largely supplanted by research that focuses on the biological, rather than social, determinants of perceived attractiveness.

Evolutionary Perspective

The interest in biological determinants of perceived attractiveness is typically described as evolutionary psychology. Researchers who adopt this perspective propose that human preferences reveal the distal determinants of mate selection. What is perceived to be attractive, it is argued, may also be adaptive. Thus, perceptions of attractiveness reveal mechanisms governing mate choice, and specific preferences increase the likelihood of getting one's genes into future generations. This perspective recently regained the imagination of researchers across disciplines, and research examining such questions proliferated.

Although the theoretical perspectives that generated the extant research base may vary, each finding in the literature rests on social perception in some respect. Indeed, numerous cues—including visual, acoustical, and olfactory—have been implicated for physical attraction. This entry now turns to these three distinct modalities of perception and highlights the relevant findings within each.

Physical Determinants of Attractiveness

Visual Cues

Most perceptual research focused on attractiveness has examined the visual cues that observers find attractive. Such cues are plentiful, and they appear from head to toe. In many cases, similar principles apply to the perception of bodies and faces.

Symmetry

One factor that is strongly linked to perceptions of attractiveness is bilateral symmetry in the face and body. Symmetry is argued to be an honest indicator of health. Because exposure to pathogens during development disrupts physical development, only those who experienced low pathogen exposure embody physical symmetry. Indeed, studies have linked bilateral symmetry to both health and fertility outcomes, suggesting that preferences for symmetric others may serve adaptive goals.

At times, symmetry can be perceived directly. Yet, bilateral symmetry need not be noticeably apparent to affect perceived attractiveness. Most research that has examined the effect of symmetry on social perception has measured more inconspicuous regions of the body (e.g., the length of earlobes or the circumference of wrists). Even when symmetry is less visually prominent as in these cases, it nevertheless affects attractiveness ratings reliably. Moreover, symmetry—and the health that it is theorized to signal—is also revealed in the perception and evaluation of other cues such as dancing ability (more symmetric men are better dancers) and body scent (symmetric people smell better). In such cases, it is unlikely that symmetry, per se, affects dancing ability or body aroma, but rather that healthy individuals tend to exhibit a set of cues including symmetry, physical abilities, and body odors, that co-occur and are perceived to be attractive by observers.

Neoteny (“Baby Face” Appearance)

Cues to youth are perceived to be attractive, and this is especially true of women. Many of these factors include infantile features and are apparent in the face. For example, faces with a youthful appearance include wide-set and large eyes, small noses, and smooth texture. These cues change dramatically with age, and they are perceived by observers to be attractive. Similarly, hair coloring darkens with age (before possibly going gray, which is a distinct cue to advancing age), and lighter hair is also judged to be attractive. Because perceived attractiveness of such features is more potent for judgments of women, scholars have argued that such preferences promote the selection of fecund mates.

Averageness

It at first seems odd to say that averageness is attractive. Yet a considerable amount of research has found just that, though perhaps not in the way that comes to mind immediately. “Average” images are not images of the most average members of society, but rather composites of several faces that have been *averaged* together. When such composites, or averaged faces are presented to observers, they are typically perceived as more attractive than are the individual faces that went into the composite. Figure 1(a) shows an averaged female face created by combining a number of individual faces.

Why is this the case? Some argue that facial composites represent the population average—which is likely to be processed by observers with great ease. Others argue that facial composites are deemed attractive because they enhance visual cues that are theoretically related to health and fertility: symmetry and some aspects of neoteny such as smoothness of skin. Regardless of the underpinnings, “average” faces are indeed attractive.

Cues to Gender Typicality/Sexual Dimorphism

Gender typicality emerges as an important factor for both faces and bodies, and extremity of

Figure 1 Two "Averaged" Faces Created by Computer Averaging of a Large Number of Individual Faces

Source: Courtesy of Ben Jones and Lisa DeBruine, Face Research Lab, University of Aberdeen.

gendered cues can, under some circumstances, be an important cue to attractiveness. In face perception research, results differ for male and female faces. Feminine female faces (or gender typical faces) are consistently perceived to be attractive by men and women alike. Perceptions of attractiveness for male face, in contrast, show a different pattern. Specifically, the extent to which masculine facial morphology is perceived to be attractive varies across women's menstrual cycle. At the peak of the fertile window of their cycle, women tend to find more masculine male faces to be attractive; at other periods, women find more feminine male faces to be attractive. Because facial masculinity has been linked to health, it is argued that women's cyclical change in preferences reveals women's desire to find mates with good genes.

In body perception research, early reports indicated that men preferred women with hourglass figures and argued that such preferences were adaptive because body shape relates to health and fecundity. Subsequent research challenged this interpretation, however. Men's preferences for specific body shapes were found to vary dramatically across cultures, and the health outcomes indicated tend to occur late in life (i.e., after childbearing years). Moreover, other research demonstrated that the perception of gender typicality, rather than perceptions of health or fertility, was a stronger predictor of perceived attractiveness. Bodies that combined female typical shape with feminine motion or male typical shape with masculine motion, for example, were perceived to be attractive. Other combinations were not. Thus, bodies are perceived to be attractive when they are gender typical. In some cases, the most attractive cues are quite extreme.

Elected Cues

Much of the prior research that specified cues related to perceived attractiveness has focused on those that are difficult to change (i.e., biologically determined). Without surgical intervention, for example, it is difficult to alter one's facial symmetry or the body's structure. Other cues, however, are more easily modified. Manner of dress, application of cosmetics, and physical adornment (e.g., tattoos and piercings) are *elected* or chosen by individuals. Although the specific manifestation of such cues may vary, the overall tendency reveals universal themes. The nature and location of adornment tends to accentuate the factors discussed. Cosmetic application, for example, is more common in women and tends to accentuate neotenous features by changing the apparent size of the eyes. Clothing styles and body adornment such as tattoos tend to accentuate sexually dimorphic regions of the body (shoulder breadth for men, and breasts and a small waist for women). Research has even demonstrated that at peak fertility, women tend to expose more skin and dress in a slightly more attractive manner.

Auditory Cues to Attractiveness

Like visual cues in the face and the body, voice cues also carry important information that affects perceptions of attractiveness. Many such cues convey sexual dimorphism, health, and fertility. Testosterone exposure during puberty alters young men's vocal folds thus changing voice's fundamental frequency (the acoustic correlate of perceptual pitch). Voice pitch is one sexually dimorphic cue that affects the perceived attractiveness of both men and women. More masculine voices (that have a lower pitch) are generally perceived to be more attractive for men. This tendency is more pronounced when female raters are at or near peak fertility. Similarly, more feminine voices (that have a higher pitch) are generally perceived to be more attractive for women. Moreover, women's voices are evaluated to be most attractive when they are at the most fertile point in their cycles. Finally, some evidence indicates that the perception of attractiveness in voices covaries with bilateral symmetry of the body, an indicator of genetic fitness.

Olfactory Cues to Attractiveness

Scent proves to be a multimillion-dollar industry annually, so it is not surprising that scent is a potent cue to attractiveness. Research in the attractiveness of scent, however, has focused not on people's preferences for perfume, but on their evaluations of body odors. When it comes to scent, beauty really is in the eye (or the nose) of the beholder.

Research suggests that the body odor that one finds attractive is highly systematic, though at times idiosyncratic. Several distinct effects support this claim. First, both men and women appear to prefer the body odors of members of the opposite sex who have *dissimilar* immunities (produced by major histocompatibility complex genes). According to this research, such preferences make sense insofar as they increase the likelihood that offspring will benefit from the diversity of genes from mom and dad, receiving "the best of both worlds," or in this case, the best from both parents. Second, scent preferences fluctuate with fertility (for both men and women). Men, for example, appear to prefer the body odors of women who are at or near peak fertility. This tendency, it is argued, promotes sexual attraction and interaction during the narrow window in which a woman can conceive. Women reliably prefer the aroma of symmetrical men (linked to genetic fitness), but only near ovulation when the risk of conception is high. Thus, olfactory cues to attractiveness appear to solve adaptive problems, and the particular scent that is deemed attractive is likely to vary across time and individual.

Perceptions of attractiveness are multifaceted, supported by numerous visual, auditory, and olfactory cues. Many such findings have been described as evolved preferences that serve adaptive ends. Regardless of their origins, cues to attractiveness show remarkable stability across age and culture.

AUDIOLOGY

The number of hearing-impaired people worldwide is estimated to be around 300 million and rising because of the growing global population and longer life expectancy. Hearing impairment is now the third leading chronic disability after arthritis and hypertension in the Western world. Therefore, most individuals, or members of their family, will attend an audiology service to have their hearing assessed at some point in their lives. *Audiology* is the science of hearing, but the term is used in a healthcare setting to generally mean the study and assessment of hearing and balance problems and the treatment and prevention of disorders of these functions. This entry describes various audiological assessment procedures.

Hearing Sensitivity

The human ear has an extremely wide perceptual dynamic range. The lower limit of hearing where sound is just detectable is referred to as the *threshold of hearing* (also known as absolute threshold or absolute sensitivity). The upper limit of hearing where sound begins to become uncomfortably loud is referred to as the *threshold of discomfort* (or uncomfortable loudness level). In quantitative terms, the difference in level between these two extremes is of the order of 10 million times. The human ear can hear single frequencies of vibration from around 20 to 20,000 hertz (Hz), although the upper limit, in particular, reduces during the natural ageing process.

The general relationship between the dynamic range of hearing and frequency has been well understood for many years. Studies measuring the minimum audible level of hearing have been made with stimuli presented to each ear separately or both ears together (usually via an earphone and loudspeaker, respectively). The results from the two methods are similar, but not identical, and show human hearing to be generally most sensitive between 500 and 10,000 Hz. The typical values obtained in a group of young healthy individuals, at individual frequencies, are used as the baseline reference level to which listeners with a suspected hearing impairment can be compared.

The Pure Tone Audiogram

The most widely used assessment procedure in clinical audiology is known as pure tone audiometry. The listener's hearing threshold level, in decibels (dB), is plotted on a chart, known as a pure tone audiogram, with hearing threshold level plotted on the ordinate as a function of signal frequency on the abscissa. The conventional clinical audiogram plots hearing level with low values (normal hearing) at the top of the chart and raised levels closer to the abscissa. Therefore, raised hearing levels are plotted lower on the pure tone audiogram chart (see Figure 1, next page).

The reference baseline is called audiometric zero and represents the zero decibels hearing level line on the audiogram chart. If, for example, a listener's hearing threshold level for a particular signal is 60 dB, this means that the listener's hearing threshold is 60 dB higher than the median value obtained from a group of normal healthy young persons. Not every healthy young adult has a hearing threshold level that falls on the zero decibels line, however, and the range of normality is generally taken to be ±20 dB of the zero line.

For clinical purposes, the hearing threshold is usually measured for single frequency tones at discrete frequencies from 500 Hz to 8,000 Hz, in octave or half-octave intervals, and reported in step sizes of 5 dB. The signals are selected and presented to the listener using a classical measurement method known as the methods of limits. A series of signals are presented in an ascending or descending run (from loud to quiet, or vice versa), and the task for the listener is to respond every time he or she detects a signal. As with any psychophysical measurement, there will be a level above which the pure tone is always heard and a lower level where the tone is never heard. The threshold of hearing is taken as the lowest level at which the signal is detected at least 50% of the time. A whole host of extrinsic and intrinsic factors can influence the measurements (e.g., ambient noise level and duration of the test signal, respectively), so there are clearly defined procedures for clinical testing.

Although the measurement of hearing thresholds from each ear separately appears a relatively straightforward procedure, sound may cross from one side of the head to the other. For example, if a listener has poor hearing in the ear under test, the signal may be sufficiently intense that it may cross the skull and be detected by the opposite ear that has better hearing. In these circumstances, a masking noise is presented to the non-test ear to prevent *cross hearing* of the

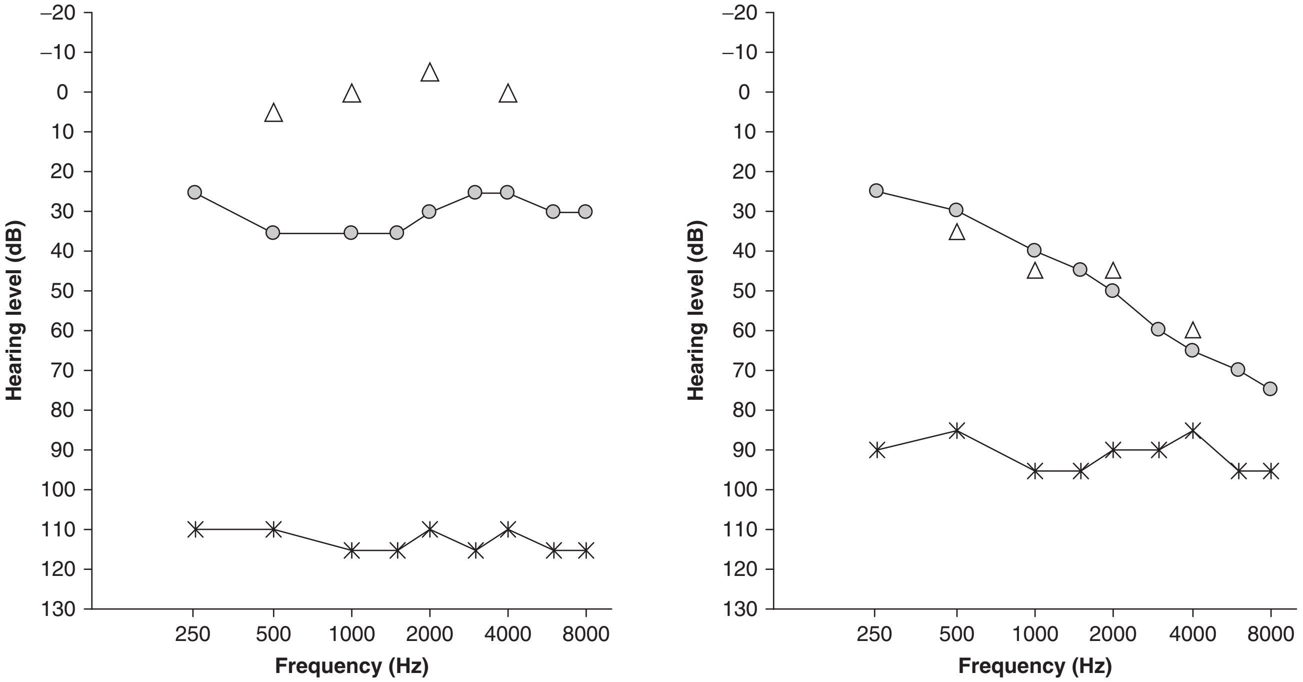

Figure 1 Pure Tone Audiometry Data for a Listener With a Mild Hearing Impairment (left panel) and a Listener With a Moderate High-Frequency Sloping Hearing Impairment (right panel)

Notes: Only data from one ear of each listener is shown: right air conduction, circles; right bone conduction, triangles; loudness discomfort level, asterisks. The presence of an air-bone gap in the left panel means the listener has a conductive hearing impairment. The lack of an air-bone gap on the right panel means that this listener has a sensorineural hearing impairment. The ear with the conductive impairment has a normal dynamic range, that is, air conduction thresholds and loudness discomfort levels are both elevated (lower on the chart) by approximately 30 decibels compared with that of a normal listener. The loudness discomfort levels in the right panel are present at normal levels, despite the raised hearing thresholds: this listener has a greatly reduced dynamic range of hearing. The findings in the left panel are typical of an individual who has fluid in the middle ear space. The findings in the right panel are typical of a listener with a natural age-related hearing impairment.

test signal. Standard procedures have been developed for when and how to use masking. If masking is insufficient, the test signal may continue to be detected by the non-test ear: if too much masking is used, this may result in *cross masking* and artificially raise the hearing threshold in the test ear.

The degree of hearing impairment can, and usually does, vary with frequency although it is usually summarized as mild, moderate, severe, or profound, based on an average of the hearing threshold levels. The ability to hear speech is related to the degree of impairment. Slight hearing impairment (26–40 dB hearing level) can cause some difficulty following speech, especially in noisy situations. Moderate hearing impairment (41–60 dB hearing level) can cause difficulty following speech without a hearing aid. Conversational speech will not be audible in cases of severe (61–80 dB hearing level) or profound (81 dB hearing level or greater) hearing impairment, and some of these listeners may need a special type of hearing aid known as a cochlear implant if they are to perceive speech. The proportion of speech that is audible and useable for a listener, with or without a hearing aid, can be quantified using a procedure known as the Speech Intelligibility Index. At relatively high presentation levels, the test signal can sometimes be perceived as a vibration, especially for low frequency stimuli. Therefore, sometimes it can be difficult to determine if a threshold measurement is an auditory or a vibro-tactile perception.

Conductive and Sensorineural Hearing Impairment

Hearing impairment is generally categorized into two groups: conductive and sensorineural. Conductive hearing impairment occurs when there is a problem in the outer or middle ear that prevents sounds being conducted to the cochlea in the inner ear. Sensorineural hearing impairment involves a problem with either the *sensory* transducer cells in the cochlea or, less commonly, the *neural* pathway to the brain. Conductive hearing-impairment can often be corrected via surgery and is relatively common in childhood, but sensorineural hearing impairment is usually permanent. Therefore, it is important to distinguish between the two categories. One method of doing this is to compare air conduction and bone conduction hearing threshold levels. This involves measuring hearing sensitivity using two different types of earphone. When a pure tone is presented via an earphone (or a loudspeaker), the signal travels through the air in the outer ear to the middle ear and then to the cochlea in the inner ear. This is known as *air conduction testing*. Alternatively, the outer and middle ear can be largely bypassed by stimulating the cochlea via mechanical vibration of the skull. This is known as bone conduction testing. Instead of using an earphone, an electromechanical earphone is placed on the skull.

Normal hearing individuals will have a hearing threshold level close to zero decibels for both air and bone conduction. Disorders of any part of the auditory pathway will affect the air conduction threshold, but disorders of the conducting mechanism will have much less effect on bone conduction measurements because these generally bypass the outer and middle ear. When a hearing impairment is present but the air-bone gap (air conduction minus bone conduction) is close to zero, it is assumed that there is no impairment of the outer or middle ear and the listener has a sensorineural hearing impairment. The presence of an air-bone gap signifies a conductive hearing impairment.

The dynamic range between the threshold of hearing and loudness discomfort level is around 80 to 100 dB in normal hearing listeners. Listeners having a sensory hearing-impairment will have raised hearing thresholds, but their loudness discomfort levels are essentially similar to those of normal hearing listeners. Listeners with a sensory hearing impairment have a reduced dynamic range and an abnormal rate of loudness growth: This is known as loudness recruitment, that is, an abnormally disproportionate increase in loudness for a small increase in intensity. This has implications for the design of hearing instruments because soft sounds will require greater amplification than will loud sounds—that is, nonlinear amplification is required. Although a nonlinear hearing instrument can compensate by providing more amplification for soft sounds, it cannot compensate for the loss of supra-threshold abilities such as impaired frequency resolution. This means that hearing in background noise remains a problem for many listeners.

Pediatric Assessment Procedures

Between a developmental age of 6 months and 3 years, the measurement technique of choice is visual reinforcement audiometry. This involves pairing a head turn response to a sound with an interesting visual reward such as a flashing light or an animated toy animal. Once this classical conditioning has been established, operant conditioning then takes place where a visual reward is presented after an appropriate sound-elicited head turn. This technique is used to determine the minimum response level that will elicit a head turn. Although it is usual to attempt ear-specific measurements in children, in some cases, earphones will not be tolerated and the signal is presented from a loudspeaker: this is known as sound field audiometry. Hearing sensitivity in infants is slightly raised compared with that of young adults although there is debate about whether this is purely a physiological maturation or if it is related to nonsensory factors such as attention and motivation.

Before a developmental age of 6 months, behavioral testing is of limited use in determining hearing threshold levels. However, a small amount of sound is generated in the healthy cochlea, and this otoacoustic emission can be measured with a small sensitive microphone in the ear canal. This normal response from a healthy ear forms the basis of a clinical procedure that can be used, for example, to screen the hearing of a newborn baby. If no otoacoustic emission can be recorded, event-related potentials can then be used to estimate hearing sensitivity. This involves the measurement of electrical potentials via recording leads attached to the scalp. The method of choice in infants is the auditory brainstem response because this can be obtained during sleep. A typical procedure is to commence at a high level and reduce this until the evoked response can no longer be detected. The presence of a response is based on the tester's subjective interpretation of the waveform. An alternative technique that is gaining popularity is the auditory steady state response, and the presence of this response is based on statistical data. Event-related potentials can also be used to estimate hearing sensitivity in adults who are unable or unwilling to provide reliable information via pure tone audiometry. Historically, event-related potentials have had a valuable diagnostic role, especially when identifying tumors associated with the hearing nerve, but these have largely been replaced by advanced diagnostic imaging techniques.

A commonly used procedure that provides information about the condition of the eardrum and the middle ear is known as tympanometry. Although this can also be used in adults, it is particularly useful in children who are prone to fluid gathering in the normally air-filled middle ear space. The procedure works on the principle that some sound entering the ear canal is reflected back from the eardrum and this can be measured with a sensitive microphone. Stiffening the eardrum by changing the pressure of the air trapped in the ear canal should result in more sound being reflected by the eardrum. However, if there is fluid in the middle ear, then the stiffness of the ear drum will be unaffected by changing the air pressure in the ear canal.

Vestibular Assessment and Management

Sudden changes in the function of the vestibular organ in the inner ear can result in rotatory vertigo, which gives the illusion that the environment is spinning around. Useful information about vestibular function can be obtained by observing eye movements during certain visual and vestibular stimulation. The audiologist is particularly interested in the presence of a slow-quick oscillatory movement of the eyes known as nystagmus. This eye movement will be present spontaneously after a change in vestibular function and may continue for days or weeks until the brain has time to compensate. Nystagmus may also be provoked by changes in body position such as getting out of bed in the morning. The sensitivity of the right and left vestibular organs can be compared by irrigating the external ear canal with hot or cold water to induce a response: This is known as the caloric test. Increasingly, audiologists are using a force platform to measure body sway because this can provide information about the use of the visual, vestibular, and proprioceptive systems for balance function and postural control. Rehabilitative procedures generally involve head and eye exercises that aid the central compensation mechanism.

AUDITION

It seems likely that *audition,* commonly known as hearing, initially evolved to alert organisms to significant events in the environment. Unlike visual stimuli, sounds can be detected whatever their direction of incidence. Hearing can indicate the presence of a predator or prey, and it can indicate the appropriate location to direct visual attention. Hearing can also convey information about the properties of sound-emitting objects, such as their size and whether they are approaching or receding, which may determine whether they are threatening or not. In many species, and especially in humans, hearing has evolved further as a means of communication, speech communication being the prime example. Indeed, the ability to convey information using sounds as symbols for objects and actions is one of the characteristics that distinguishes humans from other animals, as this entry describes.

How Information Is Carried in the Auditory System

Sounds are transmitted through the outer ear and middle ear into the inner ear or cochlea, where they are subjected to a frequency analysis on the basilar membrane; each place is tuned to respond best to a limited range of frequencies. Low frequencies produce their biggest response toward the apex of the cochlea, and high frequencies produce their biggest response toward the base. Each neuron in the auditory nerve derives its response from the vibration at a specific place on the basilar membrane.

Information about the characteristics of sounds is carried in the auditory nerve in three basic ways:

1. By the rate of firing of individual neurons, which will be referred to as the "amount" of neural activity. The more vibration there is at a given place, the greater is the amount of activity in neurons connected to that place. It is commonly believed that the subjective loudness of a sound is related to the amount of neural activity evoked by that sound, although this idea has been disputed.

2. By the distribution of activity across neurons. Each neuron is tuned so that it responds most strongly to a specific frequency, called the characteristic frequency (CF); the tuning reflects the tuning of the place on the basilar membrane that the neuron is driven by. The distribution of amount of neural activity as a function of CF is called the *excitation pattern.* The concept of the excitation pattern, developed by pioneers such as Harvey Fletcher and Eberhard Zwicker, plays an important role in many theories of auditory perception—for example, theories of the perception of pitch, loudness, and timbre. The excitation pattern can be considered as conveying "place" information because the CF at the peak of the excitation pattern is related to the place on the basilar membrane that is excited most.

3. By the detailed time-pattern of the neural impulses, and especially the time intervals between successive nerve impulses. This form of information is known as "temporal" information. Neural impulses tend to be evoked at times corresponding to a specific phase of the waveform on the basilar membrane, an effect called *phase locking.* As a result, for a periodic sound, the time intervals between successive nerve impulses are approximately integer multiples of the period of the sound. Phase locking breaks down at high frequencies (above about 3–6 kilohertz [kHz] in most mammals), but the upper limit in humans is not definitely known. Studies of pitch perception suggest that the limit in humans is about 5 kHz.

In addition, information about sounds is conveyed by the differences between the two ears in all of those methods previously mentioned. In particular, differences in intensity at the two ears (which are primarily conveyed by differences in neural firing rate) and differences in the time of arrival of sounds at the two ears (conveyed mainly by subtle differences in the exact timing of nerve spikes at the two ears) play a strong role in determining the perceived location of sounds.

Knowledge about the way that the properties of sounds are represented in the auditory nerve has played an important role in the design of cochlear implants, which are used to restore hearing to people with severe to total hearing loss; these implants restore hearing by electrical stimulation of the auditory nerve via an electrode array implanted into the cochlea. The "coding schemes" used in cochlear implants attempt to mimic, albeit in a crude way, the neural patterns that would be evoked by sound in the auditory nerve of a person with normal hearing.

Place Versus Temporal Information

A classic debate in hearing theory is concerned with the relative importance of place and temporal information. Originally, this debate revolved mainly around the relative role of place and temporal information in the perception of the pitch of pure and complex tones. The debate about pitch continues, but most researchers now believe that pitch perception involves the use of both place and temporal information; indeed, there might have to be a correspondence between the two types of information before a clear pitch can be perceived. More recently, researchers have proposed that both place and temporal information play a role in several other aspects of auditory perception, including masking (the process whereby one sound is rendered inaudible by the presence of another sound) and speech perception.

Temporal information may be especially important in situations where a background sound is fluctuating in level from moment to moment. The normal auditory system can make use of information present during brief dips in a background sound to enhance perception of a target sound. This is often called "listening in the dips." For example, a target talker can be understood much better in a fluctuating background sound than in a steady background sound with the same average level. This ability seems to depend at least partly on the use of temporal information; changes in the temporal information during the dips can be used to determine that a signal of interest is present, and what its characteristics are. Interestingly, recent data suggest that even relatively mild hearing loss can adversely affect the ability to use temporal information, and this may help explain why hearing-impaired people usually get little benefit from dip listening.

Peripheral Versus Central Processes

Peripheral processes in hearing are those occurring in the outer and middle ear, in the cochlea, and in the auditory nerve. Central processes are those occurring at stages of the auditory system following the auditory nerve. Many theories and models of auditory perception are based on relatively peripheral processes. For example, models of loudness perception, such as developed by Harvey Fletcher, Eberhard Zwicker, Brian Moore, and their coworkers, consider the effect of the outer and middle ear on the sound transmitted to the cochlea, and also consider the processing of sound within the cochlea. In particular, the influence of the "active mechanism" in the cochlea, which introduces strong nonlinear effects, has been studied intensively. However, processing occurring in the central auditory system has been largely ignored. Early theories of pitch perception were also largely based on the information that was present in the auditory nerve. Only in the case of sound localization, which requires comparison of the neural signals from the two ears, were central processes considered. The trend during the last 20 years has been to consider the role of central processes in much more detail, both at the physiological and the psychological level. The trend has partly come from an increasing realization of the limits of explanations based on peripheral processes. It makes sense to consider the role of peripheral processes and the extent to which they can explain the perceptual phenomenon in question, but once such explanations have been exhausted, more central processes have to be considered.

Energetic and Informational Masking

An example of the increasing consideration of central processes comes from studies of auditory masking, which is the process by which one sound (the masker) makes it difficult or impossible to hear another sound (the signal or target). Many of the cases of masking studied in the laboratory, for example, the detection of sinusoidal tones in white noise, can be explained largely in terms of processes occurring in the cochlea and auditory nerve. Some models of masking can predict the detection thresholds of typical human listeners for such cases with high accuracy. Indeed, these models are incorporated in digital systems for storing and transmitting sounds, such as MP3 and the systems used in transmitting cell (mobile) telephone signals; such systems are referred to as perceptual coders because they exploit the (predictable) properties of masking in the human auditory system to reduce the number of "bits" needed to transmit or store the audio signal. Masking of this type is sometimes called (inappropriately) energetic masking, and it occurs when the response of the auditory nerve to the masker-plus-signal is similar to the response to the masker alone. In other words, the signal is masked because the information conveyed by the auditory nerve is inadequate for its detection.

When a masking sound is highly similar in some way to the signal, or when the properties of the masker vary in an unpredictable way from one stimulus to the next, there may be much more masking than would be expected from energetic masking alone. This "extra" masking is called informational masking. It is assumed that informational masking occurs because the signal is confused with the masker, or because attention is directed to an inappropriate aspect of the sound.

When the task of a listener is to identify the speech of one talker (the target) in the presence of another talker (the background) with similar characteristics, informational masking may play a strong role. Under these conditions, the amount of informational masking is greatly influenced by whether or not the target and background are perceived to come from the same location in space. Richard Freyman and his coworkers illustrated this in an experiment. Listeners were asked to identify nonsense syllables spoken by a female talker in the presence of a background of either noise (with the same average spectrum as the speech) or a second female talker. In the case where the background was a talker, it was difficult to determine which parts of the sound came from the target talker and which came from the background because the two voices were similar in quality. In one pair of conditions, the target and background were both presented from two loudspeakers, one located directly in front of the listener and one located 60° to the right. The target speech from the loudspeaker at 0° was presented slightly earlier in time than the target speech from the loudspeaker at 60°, which made the target speech appear to come from in front. This happens because of an effect called the precedence effect. In one condition (called the coincident condition), the background sound was presented in the same way, so that it too was heard as coming from in front. In a second condition (called the separated condition), the background sound was presented slightly earlier in time from the loudspeaker at 60° than from the loudspeaker at 0°, which made the background appear to come from the right. For the noise background, the percentage of key words identified was only 5 to 10% better for the separated than for the coincident condition. However, for the female-talker background, the corresponding difference was 15 to 30%. The greater effect for the speech background was probably caused by a release from informational masking caused by the perceived spatial separation of the target speech and the background. When the target was perceived as spatially separated from the background, it was easier to determine which parts of the sound came from the target talker.

Informational masking, and the conditions under which it occurs, has been an area of increasing research activity during the last 20 years. One finding of this research is large individual differences; some people appear to be much more susceptible to informational masking than are others. There can also be considerable learning effects, with informational masking decreasing as training proceeds over many weeks of daily training. The existence of such large learning effects confirms that the masking is not determined by peripheral processes, but depends on limitations in central mechanisms, which can partly be overcome by training.

Veridical Perception and Auditory Illusions

Following pioneers such as Hermann von Helmholtz, many researchers in the field of perception take the view that our sensory systems are designed to help us determine the true nature of the outside world. When such veridical perception fails, the percept is often described as an illusion. This view is more difficult to assess experimentally for hearing than for vision. For vision, it is usually relatively obvious what the "correct" perception ought to be; for example, a straight line ought to be perceived as straight. For hearing, it is often much less obvious how a sound ought to be perceived, and it is often not clear whether an auditory percept should be described as an illusion.

In the early days of research on the perception of the pitch of complex sounds, the phenomenon of the missing fundamental—the perception of a pitch corresponding to the fundamental frequency, even when the sound contains no component at the fundamental frequency—was sometimes described as an illusion. Nowadays, the phenomenon is simply assumed to reflect the way that pitch perception normally works. The pitch of a complex tone is usually determined by components (higher harmonics) other than the fundamental frequency. It became inappropriate to refer to the phenomenon as an illusion once better theories of pitch had been developed.

As another example, consider the so-called continuity illusion. When a sound A is alternated with a sound B, and B is more intense than A, then A may be heard as continuous, even though it is interrupted. Quite complex aspects of the percept may be heard as continuing through the interruption. For example, if B is noise and A is a tone that is gliding upward in frequency, the glide is heard as smooth and continuous even though certain parts of the glide are missing. If A is a tone that is amplitude or frequency modulated, so that it sounds like it is fluctuating in loudness or pitch, the fluctuation is heard to continue during the time that the tone is replaced by noise. Notice that, for the perceived continuity to occur, the gaps in the tone must be filled with noise and the noise must be a potential masker of the tone (if they were presented simultaneously). In the absence of noise, gaps in the tone are clearly heard.

Although the continuity effect is described as an illusion, the auditory system's interpretation of the tone A as being continuous is reasonable. If the tone were continuous, the pattern of neural activity evoked by the tone plus the noise bursts would not be detectably different from the pattern evoked by the alternating tone and noise. Generally, the auditory system seems to create a percept that corresponds to the most likely or most plausible interpretation of the sensory information. It is thus not clear whether it is appropriate to describe the continuity effect as an illusion.

Auditory Scene Analysis and the Concept of Auditory Events and Objects

The sound reaching our ears rarely comes from a single source. Rather, several sources are often active simultaneously. The auditory system is faced with the task of analyzing the complex mixture and deriving a perceptual representation of each individual sound source. This task has been described as being analogous to monitoring the pattern of waves at two closely spaced points on the surface of the sea (corresponding to the acoustic waves at the two eardrums) and using this information to work out the nature and position of all of the ships, boats, and swimmers in the vicinity. The task is immensely difficult and complex, and most computational methods that have been developed to perform the task—often described using the term *computational auditory scene analysis*—perform much more poorly than do human listeners.

Albert Bregman has emphasized the distinction between two concepts: source and stream. A sound source is some physical entity that gives rise to acoustic waves, for example, a person talking. A stream is the percept of a group of successive or simultaneous sound elements as a coherent whole, appearing to come from a single source. For example, it is the percept of hearing a person talking. Some researchers have argued that the auditory system has evolved primarily to allow it to accomplish the task of deriving streams when multiple sources are active. Millions of years of evolution have led to the superiority of human listeners over machines in performing this task.

In recent years, the phrase *auditory object* has often been used as an alternative to *stream*. Also, sometimes the term *auditory event* is used. However, there is no universal agreement about what is meant by an auditory object or event, apart from a general consensus that both are perceptual entities. The difficulty can be illustrated by considering the situation of listening to a violin being played, or a person talking. In each case, the source produces a sequence of sounds (complex tones or words), which are usually not separated by silences. The perceptual experience is that of hearing a sequence of sounds. The auditory system somehow derives discrete perceptual representations of the individual notes or words despite the continuous nature of the sound wave. Each of the perceived sounds (each note or word) may appear different from the preceding and following sounds, but, at the same time, the sounds from a given source appear coherent; they all have the characteristic quality of that specific violin (as played by that specific player) or that specific talker.

The questions thus arise: Does each of the perceived sounds correspond to an auditory object, or is the object more appropriately defined in terms of the perception of the sequence of sounds? If the former, can a single note played on a violin, or a single word uttered by a talker, be perceived as an auditory object? Does the "object" correspond to the individual note or word, or to the source of the note or word? The following classification scheme may be useful in answering these questions.

Any sound source can evoke perceptual attributes, such as loudness, pitch, timbre, roughness (which is linked to rapid fluctuations in amplitude), and apparent location. When these attributes are perceptually linked, as if they all belong together, then the joint percept may be described as an auditory event. When that auditory event is associated with a particular sound source, that is, the event is perceived as being produced by the source, the perceived sound source may be described as an auditory object. According to this classification scheme, a sound such as a single note or word can (and usually does) lead to both an auditory event and an auditory object. The auditory event corresponds to the perceived note (with its specific pitch, timbre and loudness) or the perceived word (with its specific pitch, timbre, loudness, and identity), whereas the auditory object corresponds to the perceived sound source, the violin or the talker.

Perceptual Constancy

Perceptual constancy refers to the fact that the perceived properties of objects remain relatively constant despite changes in the conditions of viewing or listening. For example, the shape of a coin does not appear to change when it is viewed from an oblique angle. Perceptual constancy has been studied intensively for the visual system, but has received relatively little attention for the auditory system. Consider the case of loudness perception. The physical intensity of the sound reaching a listener's ears depends partly on the sound intensity emitted by the source and partly on the distance of the listener from the source. It remains somewhat unclear whether loudness is related more to the intensity at the ears or to the intensity of the sound emitted by the source. However, at least when the sound source is visible, a form of constancy sometimes holds; the intensity at the source plays a stronger role than does the intensity at the ears. In other words, the auditory system appears to base loudness mainly on the properties of the source, the distal stimuli, rather than on the properties of the sound reaching the ears (the proximal stimulus). For example, when the sound intensity at the ears is held constant, judgments of loudness are influenced by the perceived distance of the source, as determined visually.

Perceptual constancy may also play a role in the perception of the timbre of sounds, which refers to their characteristic quality. If two tones have the same loudness and pitch but are perceived as different, then the difference is described as a difference in timbre. Timbre depends partly on the shape of the spectrum of sounds. In many everyday situations, the sound reaching the ears is composed partly of sound coming directly from the source and partly of sound that has been reflected from nearby surfaces and reaches the ears after a delay. The interference of the direct and reflected sound changes the spectrum of the sound at the ears, relative to the sound emitted by the source. The influence of the reflected sound has been studied extensively for its effects on sound localization, which are surprisingly small. However, the effect on timbre perception has received little attention. One might expect the reflected sound to have a strong influence on perceived timbre, but everyday experience suggests that this is not the case. Rather, perceptual constancy seems to operate. For example, the sound quality of a familiar person's voice does not seem to differ markedly when listening to that person outdoors and or a reverberant room. Studies conducted by Tony Watkins and colleagues suggest that listeners are able to compensate for the effects of room acoustics (reflections from the walls, floor, and ceiling of a room), at least for identifying speech sounds. However, further work in this area is needed.

AUDITION: COGNITIVE INFLUENCES

Audition is the ability to sense and perceive sound. Audition relies on bottom-up sensory mechanisms, which govern how the sound is changed from physical energy in the environment to electrical impulses used by the brain, and top-down cognitive perceptual mechanisms, which govern how we identify and interpret sounds. The ability to transduce sound is only one small part of audition because the cognitive abilities we bring to bear when listening are also important for auditory perception. For example, imagine that you are walking down a dark street at night and you hear the sound of a dog barking. A wealth of auditory information is available in the signal that will tell you about the dog and determine how you will react to it. Bottom-up processes will allow you to identify where the dog is located (in front or behind you; on your left or right), tell you about its proximity (near or far away), and whether the dog is outside in a yard (if the sound is clear and unobstructed) or inside a building (if the sound is muffled and filtered by the walls). However, top-down mechanisms will influence your perception of the auditory information and determine how you will react to the sound. Such mechanisms allow you to accurately identify the sound as being produced by a dog rather than some other source (a cat, or a person imitating a dog) and allow you to determine its size (small or large) or possibly its breed (such as a Bassett hound, Chihuahua, or Rottweiler). You may also be able to determine the mood of the dog (does it sound friendly or unfriendly? does it sound excited, sad, fearful, or aggressive?). If you have had bad experiences with dogs, you may interpret the sounds as being aggressive, eliciting a fear response. If you have had good experiences with dogs, the sound may elicit a more neutral or positive response. Even in the seemingly simple case of hearing a barking dog, a variety of cognitive processes are brought to bear when you interpret the auditory information and will ultimately determine your response. This entry describes adaptation, attention, and context of cognitive influences on audition, as well as perceptual learning and expertise.

Adaptation, Attention, and Context

From the previous example, we can see that top-down information can alter our perception of sound. The knowledge that a listener has about sound and how the listener uses that information is an important part of audition. The amount of attention that is required during listening and the context of the environment play central roles in altering our perception of sound. For example, you quickly adapt to the din of the conversations around you when in a noisy restaurant: Instead of hearing individual voices, you hear a rumbling babble in the background. Yet, occasionally a sound will emerge and become perceptually salient (such as when someone coughs loudly, or we hear our name being called). Adaptation to an environmental context will allow us to move our focus of attention from things that do not concern us (such as the conversation at the next table) to things that are more important (such as the other people at our table or hearing our own name). The ability to separate sound sources and focus attention on a particular source (in this case a specific talker) is central to our success in listening in noise and is determined by our cognitive abilities. Listening to speech in noise becomes much more difficult when we perform multiple tasks: when our attention becomes divided, we may not be able to devote enough conscious attention to a particular speaker and will not be able to understand the speaker as well. This is an especially challenging problem for people who are hearing impaired.

Hearing impairment (the loss of auditory sensitivity) is a significant problem for many people. Yet hearing loss can be difficult to diagnose because of conscious and unconscious adaptive strategies that people develop to understand spoken language. Individuals with mild hearing loss may not notice the loss of sensitivity because they devote more attention to auditory perception (next time you are at a party, notice how you are directing your attention when talking with someone). Many people with hearing loss even fill in missing parts of a conversation with highly predictable information based on the context of the discourse. Thus, attention (top-down) can make up for lack of auditory sensitivity (bottom-up). These adaptive strategies are remarkably successful, but will ultimately break down when the hearing loss becomes more severe. When the loss of auditory sensitivity becomes so advanced that a large amount of auditory information is unavailable, context and attention no longer provide a benefit. In such cases, a person may seek consultation with a hearing specialist and receive a diagnosis of hearing loss.

Another way in which top-down cognitive mechanisms and prior experience influence auditory perception comes from our familiarity with particular talkers. Although we may speak a common language, all talkers produce speech differently and the listener must rapidly and efficiently adapt to talkers on an individual basis. Talker familiarity can provide significant benefits when listening to speech in noise. Research has shown that individuals find talkers that they know more intelligible than unfamiliar talkers. In this case, the information that we have learned about a specific talker's voice (the talker's accent, dialect, idiosyncrasies in pronunciation, and speaking style) influences our auditory perception. In these examples, our perception is altered by what we know about a talker's voice and allows us to devote attention to those aspects that will be most useful under difficult listening conditions. Additionally, listeners have better memory for speech produced by familiar talkers compared with that of unfamiliar talkers, suggesting that familiar talkers may be afforded different status than are unfamiliar talkers. The power of such an exposure effect may be why many radio and TV commercials use voices of well-known celebrities without explicitly identifying them to promote a certain product: if the listeners are familiar with the voice of the speaker, they may pay more attention to and remember the message that the advertisers want to convey. Such indexical features (the acoustic properties of a speaker's voice that reflect his or her identity and condition, such as age, gender, size, health, dialect, etc.) can thus significantly alter our interpretation of speech.

The context under which we are listening is also particularly important for auditory perception because it will determine where we direct our attention and what "pops out" from the background. In certain environments, we would not expect to hear a certain sound and may differentially direct attention when an unexpected sound occurs. The sound of a police siren may indicate different things if you are sitting in your living room versus when it is behind you in traffic. The sound of a growling bear may mean one thing if you are at a zoo, but something completely different if you are on a hike in the woods. In both examples, the sounds are the same, but the way we perceive and interpret them and, hence, how we react to them will differ significantly because of context. A sound that may be perfectly mundane in one environment will become particularly salient when heard in a different context. Expectation can alter auditory perception in profound ways. Sine wave speech is a form of artificial speech that consists of three tones that vary in frequency, intensity, and rhythm as does the original speech signal. Yet, the perception of such stimuli depends on the instructions that the listener is given. If told that they are listening to birdsong, listeners will identify the stimulus as birdsong. However, if told that they are listening to computer-generated speech, listeners will perceive the signal as speech. In this case, the same identical stimulus can be heard in two different ways depending on the context in which we are listening. Similar top-down effects may be responsible for detecting subliminal messages in records when played backwards: If we expect to hear a secret message in “Stairway to Heaven,” then that is exactly what we perceive.

Perceptual Learning and Expertise

Perceptual learning plays a central role in auditory cognition and is especially important when learning about sound. Auditory perceptual learning is caused by exposure to and familiarity with sound and will alter our perception of sound in the future. From a young age, children are encouraged to identify sources of sound in their environment. Whether playing with toys that match a sound with a picture of the source that produced it (e.g., the sound of a cow with the picture of a cow), children are constantly refining their cognitive abilities through interactions with their environment. Understanding the sources of sounds is especially important for survival because the sounds that surround us contain information that will help to determine what actions are most appropriate. Alerting signals in the environment can indicate situations that require our attention. The sound of a smoke detector or car horn may alert us to impending danger, prompting us to react. Yet, the perception of environmental sounds is not limited to simple alerting functions. Returning to our example of the barking dog, a person who has extensive experience with dogs may interpret the sound differently than does someone who does not have much experience with dogs. Experience with sounds alters the number of dimensions that we can use to classify the sounds. A person who has grown up having dogs as pets may be able to hear many different things in the sound of a barking dog compared with a person who is unfamiliar with dogs. Through their past experience with a sound, its perceptual dimensionality (the number of different dimensions on which a sound can be classified) has increased. This is especially salient for auditory experts.

Auditory expertise comes from practice and experience. Many auditory experts perceive sound differently than do nonexperts. For example, a skilled auto mechanic may be able to listen to the sound of an idling engine and diagnose what is wrong with a vehicle. Similarly, cardiologists may be able to listen to our breathing or the beating of our hearts and determine our relative health. Parents may be able to listen to the cries of a baby and determine whether the baby is hungry, lonely, needs to be changed, or is in distress. In all of these examples, auditory expertise and experience increases the number of perceptual dimensions on which the sound can be classified. Practice listening to specific sounds will influence how we perceive them in the future, and the processes of perceptual learning are the heart of these interactions.

Another salient example of perceptual learning leading to auditory expertise comes from music. Whether listening to the radio, at a concert, or in an environment that has background music, the auditory perception of music is a part of our daily lives. Yet, nonmusicians encode and perceive music differently than do people who have had extensive musical experience. This goes beyond mere music appreciation (some people may prefer heavy metal, but others may feel that it just sounds like noise) and focuses more on the perceptual abilities of musicians (or music aficionados) and nonmusicians. A musician may be able to listen to a piece and pick out individual instruments from among a symphony. Musicians may be able to determine whether an instrument is slightly out of tune or whether the music is being played out of time. They may even be able to identify an individual musician based on the particular musical style. Some gifted musicians may even be able to listen to a piece of music once and replicate it on a particular instrument. Although many novice listeners can appreciate and enjoy music, they perceive music differently based on their previous auditory experience. Recent work in cognitive neuroscience has shown that musicians even use different brain regions when listening to music than do nonmusicians. In all of these cases, perceptual learning increases the number of dimensions on which a sound can be classified and recruits different neural systems.

AUDITION: DISORDERS

The World Health Organisation (WHO), in its factsheet on deafness and hearing impairment, refers to hearing impairment as "the complete or partial loss of the ability to hear from one or both ears. The level of impairment can be mild, moderate, severe or profound."

The classifications are based on hearing thresholds (see Table 1, next page), most commonly measured using a standard procedure known as pure tone audiometry. In this approach, a measure of the quietest sound an individual can perceive is recorded at a number of different frequencies of sound. Plotting these values creates the audiogram.

WHO estimates from 2001 suggest that if an audiogram were to be recorded for every individual on the planet, approximately 600 million people worldwide would have a hearing loss affecting both ears, and 250 million of these would be of moderate-to-profound severity.

The actual level of disability resulting from a hearing loss is influenced by many factors beyond hearing thresholds. These factors include the amount of distortion in audible sounds, difficulties in processing and filtering auditory information, and the complexity of listening environment exposed to in a hearing impaired person's daily life. In general, a hearing loss of moderate or worse severity in both ears is deemed of particular clinical significance because, to be audible, a significant proportion of speech sounds must be raised beyond normal conversational levels. This has important consequences for the development of speech and language in children, which may be limited unless measures are taken to overcome the loss.

Additional to the level of hearing loss, the affected site or sites along the auditory pathway are used when labeling hearing impairments. Divisions are usually made into conductive (affecting the outer or middle ear), cochlear, retrocochlear (affecting the nerve of hearing), and central (affecting the cognitive processing of sound information).

This entry describes different types of hearing loss as well as some information on the relevant management options available.

Conductive Disorders

A conductive hearing loss occurs when the passage of sound between the outer ear and the cochlea is disrupted.

Obstruction of the Outer Ear Canal

Perhaps the most obvious cause of a conductive hearing loss is the inability of airborne sound waves to reach the tympanic membrane, as a result of occlusion of the ear canal. This may be caused by swelling or discharge resulting from infection (otitis externa), foreign bodies, or cerumen (earwax). Abnormalities during fetal development can result in a complete absence or a progressive narrowing of the ear canal, known as atresia or stenosis, respectively. The latter may occur later in life as a result of exostoses, bony growths commonly associated with extended exposure to cold water, such as repeated sea swimming.

Perforations

A hole, or perforation, in the tympanic membrane reduces the amount of sound energy passed from the ear canal into the middle ear bones. A

Table 1 WHO Classifications of Hearing Impairment Severity

Level of Impairment	*Hearing Loss in Decibels (dBHL)*	*Description*
Grade 0 None	25 dBHL or less	Hears whispers
Grade 1 Mild	26–40 dBHL	Able to repeat words spoken in normal voice at 1 meter distance
Grade 2 Moderate	Child 31–60 dBHL Adult 41–60dBHL	Able to repeat words spoken in raised voice at 1 meter distance
Grade 3 Severe	61–80 dBHL	Hears words shouted into better ear
Grade 4 Profound	81 dBHL or more	Cannot hear shouted voice

Note: The values are averages of hearing thresholds at the most significant frequencies in speech: 500 Hz, 1 kHz, 2 kHz, 4 kHz.

perforation can be caused by a shock wave traveling down the ear canal from an explosion or an impact across the surface of the ear. Alternatively, the tympanic membrane may rupture during acute middle ear infections, alleviating the intense pain associated with a "bulging" eardrum. On rare occasions, middle ear infections may progress to the air-filled spaces situated in the mastoid area behind the ear, the surgical treatment of which may result in a cavity that links the mastoid to the ear canal, often with an accompanying conductive hearing loss.

Glue Ear

The swelling of tissues within the sinuses, adenoids, and throat associated with head colds often compromises the function of the pharyngotympanic (Eustachian) tube, which is responsible for equalizing the pressure in the middle ear cavity with the atmosphere (the sensation of ears popping during a yawn or swallow). If this tube remains closed for extended periods, the cells of the middle ear will absorb gases from the cavity, reducing the air pressure in the middle ear relative to the external ear. The most common consequence is for fluid to be drawn from the cells of the middle ear cavity, filling the space with viscous mucus. This condition is known as glue ear and is extremely common in young children.

Middle Ear Growths

In rare cases, growths in the middle ear may lead to conductive hearing losses. A cholesteotoma is a growing ball of infected tissue and debris arising from the tympanic membrane and progressing into the middle ear cavity. A glomus jugulare will lead to a one-sided hearing loss and often results in a pulse being clearly heard in the affected ear because of the high number of blood vessels in the growth. Both of these require surgical removal.

Otosclerosis

Surgical management may also be considered for otosclerosis, a condition associated with reabsorption and remodeling of bone material within the structures of the ear. Commonly, the changes lead to the stapes becoming fixed in place, preventing the piston-like motion required to drive sound waves into the cochlear fluids. The resulting impairment may progress to a moderate severity.

Additional to otosclerosis are a wide variety of other possible abnormalities of the ossicles (malleus, incus, and stapes) that can result in a conductive hearing loss.

Management of Conductive Hearing Impairment

Management depends on the nature of the loss: glue ear will often resolve spontaneously, but in persistent cases, a ventilation tube (grommet) is put into the tympanic membrane. Eventually the tube will work itself free and the membrane will heal. In the case of any perforation, its size and location on the tympanic membrane will determine if it will close spontaneously or need surgical intervention using a skin-grafting procedure known as tympanoplasty.

A discontinuity along the chain of middle ear bones can be surgically reconstructed, and worn middle ear bones can be replaced by prostheses. In the case of otosclerosis, the stapes can be replaced or freed from fixation. Middle ear surgery can also be performed to insert a *middle ear implant,* a small vibrating device that can drive sound waves into the ossicles.

Hearing aids may be chosen to overcome a conductive hearing loss. However, in the presence of a chronic infection, occluding the ear canal with a hearing aid will further exacerbate the problem. In these cases, the use of a bone-anchored hearing aid (BAHA) may be considered. As the name suggests, this device is connected to the skull bones (usually by means of a titanium plate partially integrated with the bone material) and passes sound waves through the temporal bone to the cochlea, bypassing the compromised conductive pathway.

Cochlear Hearing Losses

The cochlea is responsible for transducing sound energy in the form of vibrations into neural impulses. Damage or abnormalities in the sensitive structures of the cochlea is almost always permanent, with the most common causes described here.

Congenital

Cochlear hearing loss at birth may be associated with infection (specifically cytomegalovirus and rubella), ototoxic drugs, and preeclampsia or toxemia. Genetic abnormalities can lead to hearing impairment, often as part of a syndrome.

Several countries now operate a newborn hearing screen to identify permanent hearing losses as early as possible, although in some cases deafness can be delayed in onset.

Acquired

Noise

Most cochlear hearing impairment is acquired: An example is the mild temporary hearing loss, usually accompanied by a characteristic “ringing” in the ears, after an evening of loud music. Depending on the level of exposure, the hearing should gradually recover but repeated noise exposure will lead to a permanent reduction in hearing sensitivity, affecting the mid-to-high pitch range.

Age

Presbycusis is the name given to a gradual reduction in hearing sensitivity with age. It primarily influences the same pitch range as noise-induced hearing loss and is almost universal across populations.

The permanent nature of this loss results because, unlike other cell types in the human body, inner and outer hair cells in the cochlea cannot regenerate. Researchers continue to investigate the mechanisms that result in inner and outer hair cell degeneration, with the aim of determining how these delicate structures can be replaced and the damage to them prevented, slowed, or repaired.

Sudden Onset

In cases of sudden-onset hearing losses, emergency attention from an ear, nose, and throat (ENT) specialist is required within 48 hours of occurrence. If there is no obvious cause such as traumatic injury or severe infection (e.g., bacterial meningitis), then investigations will be undertaken to identify possible causes, which may be viral, vascular, or autoimmune (the latter referring to an erroneous immune-mediated attack of the structures of the inner ear). Steroids or antivirals may be prescribed to limit permanent damage to the inner ear, and in many cases, the hearing may fully or partially recover, even in cases where the exact cause remains unknown (idiopathic).

Perilymph Fistula

A small hole may develop in the membranes of the inner ear as a result of trauma from middle ear surgery, a sudden change in pressure (such as during scuba diving), or intense physical strain. If this leads to the escape of cochlear fluid, it is known as a perilymph fistula. The most common sites for this to occur are the oval and round windows, leading to compromised hearing and often accompanied by tinnitus and dizziness. The symptoms may be exacerbated by coughing, sneezing, changes in middle ear pressure, and possibly loud noises (Tullio phenomenon).

Ménière's Disease

Another disorder thought to be associated with abnormal pressure of the internal fluids of the cochlea is Ménière's disease. For reasons yet to be fully determined, researchers believe that there are spontaneous periods of abnormally high pressure within the cochlea that distort the delicate internal membranes. This results in the simultaneous occurrence of three or more of the following symptoms: hearing loss, tinnitus, an intense feeling of spinning, and a pressure or fullness in the ear.

Ototoxicity

A number of drugs have a toxic effect on structures in the auditory system, especially the cochlea. These include some antibiotic and chemotherapeutic treatments, and as a result hearing loss may be an unavoidable consequence of the treatment of life-threatening diseases. The extent and nature of ototoxic hearing loss is influenced by a wide variety of factors, specific to both the individual and the treatment regime, and research continues to further understand the biochemical and physiological processes involved in drug ototoxicity, an in-depth discussion of which is beyond the scope of this entry.

Management

Dead Regions and Profound Hearing Loss

Loss of inner hair cells in a particular region of the basilar membrane will result in an inability to encode sound at that particular pitch, known as a cochlear dead region. If inner hair cell damage is widespread, there may be no significant benefit from a standard acoustic hearing aid. If this is the situation in both ears, nonverbal methods of communication such as sign language and lip-reading may be adopted, or a cochlear implant may be considered. Alternatively, a similar device can be implanted into the auditory brainstem if the nerve connections to the cochlea are compromised.

Mild-Moderate Hearing Losses

Mild-moderate cochlear hearing loss is associated with damage to outer hair cells, which are responsible for preferentially amplifying low-level sounds. This leads to the inaudibility of quieter components of speech, although often sounds of greater intensities remain about as loud as they would be heard in the absence of a hearing loss, and in some cases are actually perceived as being louder. This effect is known as recruitment.

A number of features on digital hearing aids aim to overcome the complexities of cochlear hearing loss. Even so, some hearing aid users with cochlear hearing loss remain unable to hear speech clearly, and most will still have difficulty understanding speech in noisy environments. This is partly because of a compromise of other auditory abilities including the ability to discriminate between different pitches of sound, and the ability to follow changes in sound level over short time intervals.

Retrocochlear

The retrocochlear portion of the auditory pathway refers to the nerve that carries auditory information (the VIIIth cranial nerve and the point at which it connects to the brain). Retrocochlear lesions have several possible causes, including the following:

- Immaturity caused by premature birth
- Degeneration caused by multiple sclerosis
- Vestibular schwannoma

The last example is a benign tumor that develops from the cells that insulate the vestibular portion of the VIIIth cranial nerve. To avoid life-threatening consequences, the growth may be surgically removed, which (depending on the technique used) may result in a complete loss of hearing on the affected side.

Central

Abnormalities in the cognitive processing of auditory information may result in difficulties with speech comprehension or sound localization, even though hearing thresholds are "normal." The origin of the problem may be damage to the auditory cortex caused by trauma or a stroke.

In cases where there is no obvious cause for abnormally poor auditory performance, the test batteries that exist to quantify these difficulties are described by the collective term *auditory processing disorders* (APD). Those suffering from APD often find speech comprehension to be improved when the impact of background noise is limited and visual information, such as lip-reading, is used to supplement auditory information.

When a hearing loss is present without intervention for an extended time, the resulting deprivation of stimulus leads to a reorganization in the central auditory system (this ability to organize and reorganize in response to long-term changes in sensory input is known as plasticity). This might limit the performance of a hearing aid or implant tried later. Additionally, auditory plasticity in the early years of life facilitates the ability to perceive and process spoken language, and this is one of the reasons why newborn hearing screening programs aim to identify hearing impairments as early as possible, at a stage where intervention can make use of this critical period to maximize the resulting auditory ability.

AUDITION: LOUDNESS

Loudness is a subjective attribute of sounds that allows us to experience the dynamics of music, speech, and our environment. Sounds can range from soft and calming to so loud that they startle us. The louder the sound, the faster we respond to it. Loud sounds draw our attention, alert us to danger, and pump us up when we are working out at the gym.

Exposure to very loud sounds can also cause hearing loss. When most sounds reach potentially damaging levels, they become unpleasant and we refrain from exposing ourselves to them. The exception to this rule is music. The normal controls that protect us from sound exposure that can result in hearing loss seem to be absent for music, but only if we find the type of music pleasant. Loud music can be mood altering and is often sought after. This appears to be true across a number of different cultures and may be universal.

Problems arise not only when a sound is too loud, but also when a sound is too soft. We may not be aware of a soft sound that we want or need to hear because it blends in with background sounds. Attending to a soft sound requires effort, and we strain to hear. Listening to a sound at a comfortable loudness is preferred.

Achieving a comfortable loudness requires an understanding of the many factors that influence the perception of loudness. Loudness changes with the physical properties of sound and the physical and psychological states of the perceiver. The influences of these properties are described in this entry following a definition of loudness and a short description of the methods used to measure loudness. This entry also includes a description of our ability to detect and discriminate small changes in level and concludes with an overview of models of loudness.

Language of Loudness: Definitions and Terminology

Although we know what loudness is, we may not be aware of the exact definition and terminology used for loudness. Loudness is the perceptual strength of a sound that ranges from very soft (or quiet) to very loud. Loudness is the *primary* perceptual correlate of the level of a sound. The study of loudness is a subarea of psychoacoustics. *Psychoacoustics* is the study of the relationship between physical properties of sound (e.g., frequency, level, and physical duration) and our perceptual response to them (e.g., pitch, loudness, and subjective duration).

Loudness is often erroneously described as the "volume" or "intensity" of a sound. The term *volume* is used to describe a percept different from loudness and should not be confused with loudness. Volume refers to the subjective size of a sound. The term *intensity* refers to a physical property of a sound, which is related to its level. A common unit of measure is sound pressure level in decibels, or dB SPL, which is the logarithmic ratio of intensity. Therefore, the terms *volume* and *intensity* should not be used interchangeably with *loudness.*

Since the late 18th century, it has been common for composers to use written notation to indicate the level at which a piece of music should be played to produce a corresponding loudness. These are called dynamic markings and are usually in Italian. Examples of dynamic markings are *pianissimo* (very soft), *mezzo piano* (medium soft), *forte* (loud), and *fortissimo* (very loud). These dynamic markings refer to relative levels, rather than to specific levels, so that a passage of music may be a little louder or softer than another. Music notation also includes words to indicate a general increase (*crescendo*) or decrease (*decrescendo* or *diminuendo*) in loudness. In addition, a composer can indicate that one note should be louder than the other notes by using accents. Such notations help to give music the proper loudness dynamics and indicate the beat of the music.

Measuring Loudness and Units of Loudness

Because loudness is a subjective attribute, it cannot be measured directly. Two common methods used to indirectly measure loudness are equal-loudness matching and scaling. In equal-loudness matching, a physical property of one sound is adjusted so that the sound is judged equal in loudness to a fixed reference sound; usually the two sounds are presented alternately. Equal-loudness matches were used to derive the phon scale. The phon is a unit of loudness level that indicates the level of a tone required for it to sound equal in loudness to a 1,000-hertz (Hz) reference tone. For example, the loudness of a 70-phon tone at any frequency is equal to the loudness of a 1,000-Hz tone at 70 dB SPL.

In scaling methods, a sound is presented to a person many times at different levels that encompass a wide range of levels. After the presentation of each sound, the person's task is to provide information about the loudness elicited by the sound. One common task is to ask a person to assign a number to the loudness of a sound. This number is called a *loudness estimate* and the method is called *magnitude estimation.* The sone scale was determined by magnitude estimation. One sone is the loudness corresponding to a 1,000-Hz tone at 40 dB SPL, which is the same as a loudness level of 40 phons. In another task used to obtain information on loudness, a person is asked to adjust a physical property of a sound to produce a certain subjective magnitude of a sound. This is called *magnitude production.* The final estimate is an average of data obtained with both methods. In another type of scaling method, cross-modality matching, a person is asked to match the loudness of a sound to a perceived property in another modality, such as brightness or perceived line length. For example, a person may be asked to cut the length of a string as long as a sound is loud. In still another method, five to seven fixed category labels are used (such as "very soft," "soft," "comfortably loud," "loud," "very loud," and "too loud") and a person is asked to assign the loudness of a sound to a preselected category. This method is called *category scaling.*

Loudness and the Physical Properties of Sound

Loudness changes as a function of level, frequency, bandwidth, duration, spectral complexity of a sound, and the presence of other sounds. There is no simple one-to-one correspondence between loudness and any physical property of a sound, including level. Audible sound levels that do not immediately damage hearing range from roughly 0 to 120 dB SPL. In general, loudness will double for every 6 to 10 dB increase in SPL, but does not increase indefinitely. As the level is increased beyond being "too loud," sensation transitions from a "tickle" feeling to pain. Research on loudness at such high levels is no longer performed because of ethical concerns.

The way in which loudness increases with level has been measured using magnitude estimation. A plot of loudness estimates on a logarithmic scale as a function of audible sound levels in dB SPL is known as a *loudness function.* The loudness function has been described as $L = kI^e$, where L = Loudness, k = a constant, I = Intensity, and ^{e} = the exponent, which is proportional to the slope of the function. Although simple, it is not the most accurate description. There are two important deviations. The first is that loudness increases rapidly with increasing level near threshold. The second is that loudness changes more slowly with increasing level at moderate levels than at high and low levels. These two deviations result in an entirely different psychophysical law that relates level to loudness (i.e., a nonstationary point of inflection law or an inflected exponential [INEX] law).

Loudness changes throughout the audible frequency range from about 20 to 20,000 Hz. A plot that shows the levels required to keep loudness constant as frequency changes is called an equal-loudness level contour (or equal-loudness contour). Most textbooks and the recommended readings at the end of this entry present a family of these contours that range from near threshold (about 10 phons) to high levels (about 100 phons), in steps of 10 or 20 dB. Near threshold, the equal-loudness level contours follow absolute threshold. This means that the levels of tones at very low and very high frequencies need to be set to higher levels than the 1,000-Hz reference tone to sound equal in loudness to it. For example, a 125-Hz tone at 34 dB SPL is equal in loudness to a 1,000-Hz tone at 10 dB SPL, and both have a loudness of 10 phons. Therefore, a 24-dB difference in level is required for the two tones to be perceived as equally loud. At high levels, the equal-loudness level contours flatten, which means that the difference required to set the two tones to equal loudness is much less. For both tones to have a loudness of 100 phons, the 125-Hz tone needs to be about 104 dB SPL and the 1,000-Hz tone needs to be only 4-dB lower for the two tones to be perceived as equally loud.

Loudness increases with bandwidth (frequency range) and duration of sounds, but only within certain physical parameters. If the overall level of two tones is kept constant and the frequency separation between them is increased, loudness of the two tones heard together will remain relatively unchanged until the frequency difference between the tones exceeds about 20% of the geometric average of the frequency of the two tones, after which loudness increases. This is called spectral loudness summation. It occurs for sounds as the bandwidth is increased. The magnitude of increase changes with level and is greatest at moderate levels, so that a 1,000-Hz tone would need to be as much as 18 dB SPL higher than a sound encompassing a broad range of frequencies for the two sounds to be perceived as equally loud. Loudness also increases as the duration of a constant-level sound increases up to about half a second, after which loudness remains relatively constant. This is called temporal integration (or temporal summation) of loudness. The magnitude of this effect can be as much as 15 to 20 phons.

Loudness changes with the spectral complexity of a sound and the presence of other sounds. The details of the influence of spectral complexity is beyond the scope of this entry, but sounds that come before and after a sound can affect its loudness. Finally, loudness changes depending on the background against which a sound is heard, or the background "soundscape." For example, a friend's voice will sound softer on the street near a noisy construction site than in a quieter area. This phenomenon is referred to as partial masking of loudness because the loudness of a sound that you are listening to (i.e., a friend's voice) is partially masked, or blocked, by the background sounds.

Physiological and Psychological States of the Perceiver

Loudness changes as the physical and psychological states of the perceiver change. For example, loudness can change depending on whether a person listens with one or two ears, whether the ears have been exposed to loud sounds, whether a hearing loss is present, and whether a person is paying attention to the sound. A person with normal hearing in one ear and a hearing loss in the other ear will perceive sounds as less loud than when listening with two normal ears. This occurs because loudness summates across the two ears. This phenomenon is called *binaural loudness summation.* Although sounds heard by two ears are louder than sounds heard by only one ear, the amount that loudness increases is still a matter of debate and appears to change with the type of sound and listening environment.

Loudness, as well as threshold, may also change after a person is exposed to high-level sounds. This change in loudness can be temporary, taking anywhere from a few minutes to several days to return to normal. For example, sounds may be perceived softer than normal after attending a rock concert without hearing protection, but loudness returns to normal by the next day. This temporary condition is called *fatigue,* or *temporary loudness shift.* However, with exposure to very loud sounds over a prolonged time, or even a short time with sufficient intensity, changes in loudness can be permanent.

Loud sounds draw our attention and we instinctively turn our attention toward them. Attention plays a role in our perception of loudness. For example, evidence indicates that sounds that are not attended to may be perceived as less loud than sounds that have our full attention. Furthermore, a sound that is continuously presented at a low level for a long period will fade into inaudibility. This is called *loudness adaptation.*

Detection and Discrimination of Level Differences

This section describes the impressive ability of the auditory system to detect changes in level (level detection) and discriminate small level differences (level discrimination or intensity discrimination). The topics of level detection and level discrimination are usually raised in conjunction with discussions of loudness. This is a debatable practice because the subjective attributes of changes in small level differences may not be perceived as differences in loudness, they may be perceived as changes in pitch or other subjective attributes of sound. Level detection and discrimination are included in this entry because of the implications of these types of experiments for understanding the physiological encoding of level information in the auditory system.

The smallest audible difference in level between two sounds has been called the just noticeable difference (JND) or the difference limen (DL). The JND has been measured by increasing and decreasing the level difference until it is just audible using three types of tasks: (1) discrimination of two sounds separated in time that differ only in level, (2) detection of amplitude modulation (i.e., variations in strength) of a sound, and (3) detection of an increment in the level of a continuous sound. Although the exact values of the JND differ somewhat among the different tasks, the general trends in the data are the same.

The JND for level changes as a function of level, frequency, and duration of the sound. One of the oldest scientific observations in hearing describes how the JND for intensity changes with increasing intensity of a noise. It is called *Weber's law* (also known as Weber's fraction) and refers to the fact that the JND is proportional to the physical magnitude of the sound. In other words, the just-noticeable change in intensity divided by the intensity of the stimulus remains constant with increasing level. This means that the JND is about 0.5 to 1 dB for all levels, except the lowest levels. Weber's law does not work at low levels for noises, or as well for tones as it does for noises. For tones, there is a deviation from this proportional relationship, called the *near miss to Weber's law.* This deviation is a decrease in the Weber fraction with level, which results in a smaller JND in decibels at high levels.

An excitation pattern model provides a good theoretical framework for describing our ability to discriminate small level differences. According to this model, any audible sound creates a pattern of activity in the auditory system. These activity patterns are called excitation patterns. As the level of a tone is increased, its excitation pattern increases and spreads to adjacent frequencies. When a critical difference is reached between the excitation patterns of two tones that differ in level, the auditory system has sufficient information to discriminate the sounds. For example, a low-level tone has a small excitation pattern and requires a 2-dB level difference between two tones to create a difference between the two excitation patterns large enough to reach the threshold of discrimination. A high-level tone has a large excitation pattern that spreads to adjacent frequencies and requires only a 0.5-dB level difference between the two tones to create a difference between the two excitation patterns large enough to reach the threshold of discrimination.

The theoretical framework of excitation patterns can also explain the effect of frequency on level discrimination. The JND for level is larger for frequencies close to the high-frequency limit of audible sounds. According to the model, this occurs because the excitation patterns are effectively cut off because of the frequency limits of audibility. In the absence of the spread of excitation at the high frequencies, the JND must be increased to create a difference between the two excitation patterns large enough to reach the threshold of discrimination.

If you recall temporal integration (or temporal summation) of loudness described earlier, it is not surprising that the auditory system sums up information over time. This summation also occurs for level discrimination. As the duration of a tone increases up to about one-half to one second, the level difference required for discriminating two tones decreases.

Although the basis for coding of level in the auditory system is not completely understood, any model of coding must consider the impressive ability of the auditory system to detect and discriminate relatively small level differences. Much of what is known about the physiology of level perception comes from correlating psychoacoustic measurements with the physiological responses to level differences. For example, information from a single neuron in the auditory nerve is enough to account for our ability to discriminate two sounds that differ in level. However, just because information is available does not mean that it is used by the auditory system. Exactly how information is carried from the auditory nerve to the brain is not well understood, but the models described in the next section may give us some insight.

Models of Loudness

Although no model of loudness can account for all the phenomena associated with the perception of loudness at the time of this entry, models exist that can explain certain aspects of the perception of loudness. These models can be divided into two types: models that describe and predict the relationship between the stimulus and the perception of loudness (i.e., psychoacoustic models) and models that attempt to make correlations between changes in the level of a stimulus and the physiological response to these changes (i.e., physiological models). These two types of models are described here.

As described earlier, an inflected exponential function is the most accurate descriptive psychoacoustic model of how the loudness of a tone increases with increasing level. However, most sounds are much more complex than a tone. Complex models have been developed to predict the loudness of sounds from the physical spectrum. Basically, these models include three stages: the physical spectrum is divided into frequency bands, a weight is assigned to each frequency band, and the weighted outputs of the individual bands are summed. The most recent models also consider filtering of the signal by the ear and listening condition. Loudness models were initially developed for steady-state sounds and people with normal hearing, but variations of these models exist to account for the loudness of time-varying sounds and the presence of hearing loss. These models are still under development and do not presently account for all conditions.

Physiological models of loudness are less developed than psychoacoustic models are. Only some aspects of the physiology of loudness appear to be explained. For example, the increase in loudness with increasing level is consistent with the basilar-membrane response function. There is a good correlation between the inflected exponential function and physiological data. However, how the loudness of a sound increases with level is less well understood at the auditory nerve. As the level of a tone increases, the firing rate of neurons in the auditory nerve also increases, but most neurons tend to saturate within a dynamic range of only 30 to 60 dB so that increases in level cause no further increase in the firing rate. Although some benefit is obtained from a small number of neurons with higher thresholds, this does not appear to be enough to account for the fact that loudness increases over a level range of about 120 dB SPL. This is known as the dynamic range problem.

Although our understanding of the physiology of loudness is far from complete, two compelling lines of thought that are not mutually exclusive explain the dynamic range problem. The first is that loudness is related to the total amount of neural activity. The second is that loudness is related to the temporal properties of the neural activity. As a tone increases in level, it excites neurons with primary sensitivity (characteristic frequency or the frequency to which it responds best) near the tone frequency, and it excites an increasing number of neurons with adjacent characteristic frequencies. This is known as the *spread of excitation.* Temporal theories are based on the fact that neurons that respond to a certain frequency tend to phase lock to it. In other words, they produce neural firings at precise times correlated with temporal properties of the sound wave. When the level of a tone increases, more neurons phase lock to it and the overall synchrony across the population of auditory nerve fibers increases. However, the timing theories have difficulty at high frequencies because the ability of the auditory nerve fibers to phase lock decreases at high frequencies, which is known as the roll-off in phase locking. It is possible that the amount and range of neural activity, as well as the timing and phase locking of neural activity, play roles in the perception of loudness. Despite how much data have been obtained, surprisingly little has been proven regarding the connection between physiological responses and our perception of loudness.

There is a need for models that can predict the average perception of loudness for large groups of listeners, such as those in concert halls and other public spaces. A sound-level meter provides information about the level of a sound, but does not provide information about loudness. Attempts have been made to design "loudness meters" that provide a number corresponding to the subjective experience of loudness for an average group of people with normal hearing. Because loudness can vary among individual listeners, measures from these meters do not apply to any one individual person. Whereas meters may provide a good estimate of the group average for steady-state sounds, scientists are still in the process of designing meters for time-varying sounds that constitute most environmental sounds.

At the time of this entry, there is no comprehensive theory that can explain all phenomena related to our ability to perceive loudness—this amazing ability that allows us to experience the dynamics of music, speech, and sounds in our environment.

AUDITION: PITCH PERCEPTION

Pitch is a subjective attribute of sound that allows one to enjoy a musical melody, differentiate between talkers, and identify many different sound sources. Sound itself does not have a pitch. However, without an ability to perceive pitch, speech would be Morse code (only changes in the loudness or duration of a sound could be used to convey language), music would be only drum beats, and the sound from most sources would go unrecognized. This entry examines the physical dimensions of sound, discusses how pitch is measured, and describes some of the relationships between the physical dimensions of sound and perceived pitch.

Sound

Sound has the physical dimensions of frequency, level, and time. Sound is caused by objects that vibrate and send out sound waves. *Frequency* refers to the rate at which an object vibrates, and *level* refers to the magnitude of that vibration. Hertz (Hz) is the physical measure of frequency. A sound with a 100-Hz frequency is a sound whose vibratory pattern repeats 100 times per second; if the vibration occurs at rate of 1,000 times per second, the sound's frequency is 1,000 Hz, and so on. The perception of pitch is the auditory system's means of processing information about the physical properties of sound: frequency, level, and time. When the physical frequency of the sound from a source varies, it is almost always perceived as a pitch change. A short string on a violin vibrates faster than a longer string does and produces a high-frequency sound that is perceived as a high pitch. But many other aspects of frequency, level, and time can lead to the perception of pitch. The study of pitch perception involves understanding the relationship between the physical properties of sound and the subjective perception of pitch. As of yet, there is not a complete understanding of these relationships and, as a consequence, the study of pitch perception is an active area of research in the auditory sciences.

Measuring Pitch

The standard definition of pitch is that pitch is that subjective attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from low to high. Pitch is measured subjectively in three ways: using musical scales, using a frequency scale, and occasionally using the mel scale. The musical scale contains notes (in Western music, 12 notes: A, B, C, D, E, F, G, and in the sharps, #, and flats, b: Ab, Bb, F#, A#, Eb). The musical scale may be divided into octaves. An octave is a doubling of frequency (880 Hz is the octave above 440 Hz, and 220 Hz is the octave below 440 Hz; 440 Hz is the approximate vibratory frequency of the musical note A played in the middle octave of the piano keyboard). Each octave can be divided into 12 equal logarithmic divisions called semitones. Thus, all the A notes on a piano keyboard are separated from each other by an octave, and each of the 12 notes (e.g., black and white keys on the piano keyboard) within an octave are spaced in frequency by about a semitone. Each semitone has 100 cents (hence an octave has 1,200 cents). Musical notes, semitones, and cents are used as scales to measure pitch.

In many experiments, the pitch of a sound with a known pitch (the comparison sound) is matched to that of a sound with an unknown or to-be-measured pitch (the target sound). In such pitch-matching procedures, listeners are asked to adjust a physical property of the comparison sound (e.g., frequency) so that the comparison and target sound have the same perceived pitch. Usually a pure tone (a periodic sound) or a periodic series of clicks (click train) are used as comparison sounds. The frequency of the pure tone or the repetition frequency of the click train, both expressed in Hz, are used as the scale or measure of pitch. That is, Hz is a measure of pitch, just as it is a measure of frequency. However, physical frequency and subjective pitch are not the same thing, as several examples will indicate.

In some cases, the mel scale is used to measure pitch. The mel scale is derived from a subjective scaling procedure such that the pitch of a tone presented with a frequency of 1,000 Hz is defined as having a pitch of 1,000 mels, and the 1,000-mel sound is the standard pitch sound. If a sound is perceived to have a pitch that is half that of the pitch of the standard, then the pitch is 500 mels. A sound with twice the pitch of the standard would have a 2,000-mel pitch.

Different Meanings of Musical Pitch

Musical pitch can take on two different meanings. If one starts at the left most piano key on the keyboard and one strikes each key in succession moving from left to right, each key will produce a higher pitch than the preceding note. In addition, the pitch of each piano key in one octave has the same pitch as the corresponding key in another octave (e.g., each A key across the key board has the pitch of A), in the sense that a recognizable melody can be played in any octave (the basis of musical transposition). Thus, the A key to the left of the piano keyboard has both the same pitch and a lower pitch than that of the corresponding A key to the right on the keyboard. *Pitch height* is used to refer to perceived musical pitch that occurs independent of the octave (e.g., each key on the piano keyboard produces a different pitch height), and *pitch chroma* refers to the perceived musical pitch of corresponding notes across octaves (e.g., all of the A keys on the piano keyboard have the same pitch chroma).

Humans, especially those with musical training, and several animals appear to perceive octave relationships among pitches as unique from non-octave arrangements. The pitch of a sound can support melody recognition; such pitches are referred to as *musical pitches* and are considered the strongest form of pitch perception. Other sounds produce pitches that are poor for melody recognition but listeners can accurately judge musical intervals (semitones), and other stimuli do not support either melody or musical interval recognition, but the pitch of a pure tone can be matched to the stimulus. In some cases, the pitch of a sound is weak leading mainly to a change in the perceived quality (timbre) of the sound.

Listeners who can reliably label (or produce by singing) the correct musical note of a sound without a referent sound are said to have an *absolute pitch* ability. Some listeners who do not have absolute pitch possess a relative pitch ability in that they can reliably judge the musical interval (semitone) between two sounds. And many listeners have neither an absolute nor a relative pitch judging ability. Whether the causes of these different pitch abilities are genetic factors or experience and training is not clearly understood.

Perceived Pitch

The pitch of a simple sound is directly related to the sound's physical frequency. For instance, the pitch of a pure tone is equal to the tone's frequency. The pitch of most periodically repeating sounds is equal to the reciprocal of the period of the repetition, expressed as hertz. For instance, a series of brief sounds (transients) that are periodically repeated produce a pitch related to the reciprocal of the period of the sound. If this click train of transients has a periodic repetition of 100 Hz, then the period between each transient in the click train is .01 seconds (i.e., 1/100 Hz = .01 seconds or 1/.01 seconds = 100 Hz). Because the period of most audible sounds is short (fractions of a second), period is often expressed as milliseconds (msec), where 1 millisecond is 1/1,000 of a second. Thus, in the previous example, a period of .01 seconds is also 10 msec (1,000 × .01 = 10 msec).

The pitch of sound can also change as a function of sound level. In the physical description of sound, a sound wave's frequency is independent of its level. Level is often correlated with the subjective attribute of loudness. The subjective attributes of pitch and loudness can change with changes in either a sound's frequency or level. So although frequency and level are physically independent, either can lead to a change in perceived pitch. Composers have been known to write music with an increase in the level (loudness) of a note to also produce a slight increase in the perceived pitch of that note. Thus, even though physical level is independent of physical frequency, subjective pitch can be altered by changes in either physical frequency or level. This makes the relationship between the physical dimensions of sound (frequency, level, and time) and perceived pitch complicated.

Any complex sound can be expressed as a sum of simple or tonal sounds, where each tonal component (spectral component) has a physical frequency.

A click train is a complex sound that can be described as the sum of many different spectral components. A click train will have a fundamental vibratory frequency that is equal to the reciprocal of the period between the transients in the click trains. And, the click train is made up of the fundamental spectral component and all of its higher harmonics. A harmonic is an integer multiple of the fundamental frequency. Thus, a click train with transients that repeat once every 10 msec (once every .01 seconds) has a fundamental frequency of 100 Hz (1/.01 seconds = 100 Hz) and all of the higher harmonics of 100 Hz (200 Hz, 300 Hz, 400 Hz, 500 Hz, etc.). All musical instruments, including the human voice, produce such harmonic complexes, and the pitch of a note played by any instrument is equal to the frequency of the fundamental. Thus, the A note in the middle octave of the piano keyboard produces a harmonic complex with a 440-Hz fundamental frequency and many of the higher harmonics of 440 Hz (e.g., 880 Hz, 1,320 Hz, 1,760 Hz). The perceived pitch of this A note is 440 Hz. Many other sound sources (e.g., a rotating motor) also produce harmonic complexes and if the sound source produces a perceived pitch it is usually associated with the fundamental frequency of the harmonic complex. For example, a motor may rotate 120 times per second, which produces a fundamental frequency of 120 Hz and many of the higher harmonics of 120 Hz. In many cases, the whine of the motor would be perceived as having a 120-Hz pitch.

Thus, the pitch of such harmonic complexes could be explained by several properties of the sound. The frequency of the fundamental of the harmonic complex could be used to account for pitch. Or, the repetition rate of the sound's overall vibratory pattern could be used to account for pitch. Or, that the spacing between each successive harmonic of the sound is equal to the fundamental frequency might be a basis for the pitch of a harmonic complex (e.g., a harmonic sound with 100-Hz fundamental will have harmonics at 200 Hz, 300 Hz, 400 Hz, 500 Hz, etc., each spaced 100-Hz apart).

An interesting experiment conducted in the 19th century indicates that the pitch of harmonic complexes probably does not result from the fundamental frequency itself. A particular type of sound source (an optical siren) produces a sound with the harmonics of a fundamental, but the fundamental is not physically present in the sound's spectrum. For example, the optical siren could produce a sound with spectral components of 200 Hz, 300 Hz, 400 Hz, 500 Hz, but not 100 Hz (the fundamental frequency). The fundamental frequency (100 Hz) is missing from this sound's spectrum. The perceived pitch of the siren is 100 Hz, even though there is no physical spectral component at the fundamental. This is an example of the missing fundamental pitch. Many musical instruments (including the human voice) produce a missing fundamental pitch in that the spectral component at the fundamental is either not present or weak compared with the higher harmonics in the sound's spectrum produced by the instrument.

Accounts and Theories of Pitch Perception

Thus, the frequency of the fundamental cannot be used to account for perceived pitch, because stimuli with no fundamental in the sound's spectrum still produce a pitch equal to the missing fundamental. Harmonic complexes without the fundamental still vibrate with a period that is equal to the reciprocal of the missing fundamental (e.g., a sound containing spectral components of 200 Hz, 300 Hz, 400 Hz, 500 Hz, etc., will vibrate with a period of 10 msec or .01 seconds, the reciprocal of 100 Hz, which is the frequency of the missing fundamental). And the spacing between the spectral components of this 100-Hz missing fundamental harmonic complex is still 100 Hz. Thus, either the repetition period or the spectral spacing of the harmonics could be used as a basis to account for the pitch of the missing fundamental.

Using aspects of the temporal repetition of the vibrating sound to account for pitch perception is a temporal explanation of pitch, and using aspects of the spectral spacing of the harmonics is a spectral or frequency explanation of pitch processing. The history of attempts to develop theories and models of pitch perception can be described as a competition between spectral and temporal explanations. Some hearing scientists have also suggested that some combination of spectral and temporal approaches might provide a coherent theory of pitch perception. Currently, no one theory has been universally accepted as accounting for pitch perception.

The auditory nervous system preserves information about both the temporal repetition of sounds and the spectral content of sounds. That is, auditory nerve fibers produce neural discharges that repeat at a rate that matches the vibratory repetition of the incoming sound's waveform (to repetition rates as high as 5,000 times per second). And the auditory nervous system preserves information about the harmonics of a complex sound (at least for low-frequency harmonics). Thus, current models and theories of pitch processing attempt to account for the perceived pitch of sound based on what aspects of the physical properties of the sound (e.g., repetition period or spectral harmonics) are preserved and processed by the auditory nervous system. Several competing models of pitch perception are based on such neural processing assumptions. Thus, at present no single theory of pitch perception can account for all of the data that have been collected regarding what is arguably the most important perceptual aspect of sound, pitch.

AUDITION: TEMPORAL FACTORS

Most sounds are temporally complex, marked by variations over time in acoustic characteristics or events. Both speech and music represent common examples of sounds that vary over time with change of characteristic and of content. Extraction of the information contained in temporally complex sounds requires response by the auditory system to these changes. Resolution, the ability to temporally resolve or follow stimulus variations, is a central aspect of the study of auditory temporal factors. Often, however, auditory perception is governed by a summation or accumulation of information over time. Thus, a second temporal factor is integration. Finally, a third aspect that incorporates both resolution and integration is the study of the perception of a sequence of resolved acoustic events in terms of pattern processing. This entry describes temporal factors of audition such as time, frequency, and modulation; resolution; integration; and auditory segregation and pattern processing.

Time, Frequency, and Modulation

Sound is a pressure waveform that is generated by a vibrating object. With sound a waveform that varies over time, temporal processing by the auditory system is a central basis for determining the information conveyed by sound. The vibrations that generate most sounds repeat in some manner or another. These periodicities are described in terms of repetition frequency. Repetitions per second are defined in units of hertz (Hz). For example, a simple or sinusoidal vibration that repeats one thousand times a second has a frequency of 1,000 Hz.

Representation of the periodicities in the time waveform in terms of frequency illustrates the relationship between the temporal and frequency-based descriptions of sound. The implication of this relationship, formalized by the Fourier theorem, is that change in one domain affects the other. The auditory system codes both the temporal and frequency characteristics of sound. Time is coded by the temporal pattern of the response of auditory neurons, and frequency by both response pattern and by which neurons respond among the many thousands in the auditory nervous system. A consequence of the interrelationship between time and frequency, and the direct coding of each aspect by the auditory system, is that studies of auditory temporal factors must ensure that the basis of measured effects is indeed temporal. Thus, studies of temporal factors often use stimuli with wideband frequency content or include maskers to restrict the influence of unintended frequency variations.

A further effect that ties together time and frequency is their inverse relationship in resolution. That is, enhancement of frequency selectivity results in a sluggish temporal response, and a rapid temporal response results in broad or poorly tuned frequency selectivity. The complexity of the auditory system no doubt arose partly to meet the conflicting demands of temporal and frequency resolution.

Variations in the time waveform of sound can generally be described in terms of modulation. *Modulation* simply refers to some pattern of change conveyed by a carrier. For auditory processing, the relevant variations are amplitude modulation (AM) and frequency modulation (FM). At slow rates of variation, listeners can follow the modulation, with AM perceived as fluctuation in loudness and FM as fluctuation in pitch. At faster rates, both types of modulation change the stimulus quality, timbre, or pitch, often adding a richness or roughness to the sound. Modulated stimuli play an important role in assessing temporal resolution and discrimination abilities, and also temporal-pattern processing.

Temporal Resolution

In a general sense, temporal resolution refers to how quickly a system is able to respond to stimulus changes. For auditory stimuli, these are most often changes in loudness, pitch, timbre, or source location. If the changes are not well resolved, the response of the auditory system represents some sort of averaging across the stimulus changes. Consequently, temporal resolution is often viewed as a measure of the minimum integration time of the auditory system.

A variety of procedures have been used to assess auditory temporal resolution. One simple procedure, termed *gap detection,* involves determination of the shortest silent interval that can just be detected when inserted in a sound burst or continuous sound. Gap detection thresholds can be as low as a few one thousandths of a second (i.e., several milliseconds [ms]). Roughly similar acuity estimates are obtained from other procedures that measure sensitivity to rapid changes in sound other than the introduction of a brief silent gap. A notable exception, however, is seen in measures of binaural temporal acuity. The just-detectable timing difference between the sounds arriving at the two ears can be as low as a few millionths of a second.

Related to gap detection are effects observed in temporal masking. Temporal masking refers to situations in which a target signal is either preceded or followed by a masking sound. Interference from the interaction between sequential sounds is a common aspect of many everyday listening situations. With temporal separation between the signal and masker in temporal masking paradigms, interference represents a failure of temporal resolution; that is, the system could not fully resolve the signal from the masker. In the case of forward masking in which the masker precedes the signal, two separate factors have been suggested as the source of the interference. The first is a persistence of the sensory effect evoked by the masker so that despite the acoustic temporal separation, the responses to the signal and masker are overlapping at some level of the auditory system. The second factor is neural adaptation in which the response to the masker adapts the system so that it is less responsive to presentation of the subsequent signal. Across various possible stimulus configurations, both factors can show some involvement in temporal masking.

The envelope of an acoustic signal describes how amplitude or level changes over time. As such, AM is modulation of the signal envelope. Gap detection measures sensitivity for a single envelope modulation, that is, the detection of the single brief silent interval or gap. In AM detection paradigms, the modulation occurs over the entire stimulus duration with the procedure determining the size of the just-detectable variation or fluctuation in the stimulus envelope. AM changes the perceived quality of a sound. At low AM rates that lead to slow level changes, listeners perceive the changes as fluctuations in loudness. At higher modulation rates at which the loudness variations are not resolved, AM results in a change in sound timbre often described as “motor-boating” or roughness.

AM detection procedures measure temporal resolution by showing the change in the ability to respond to envelope fluctuation as a function of the rate at which the fluctuation occurs. In psychoacoustics, this function is termed the *temporal modulation transfer function* (TMTF). With appropriate assumptions, a measure of temporal resolution can be derived from the TMTF. Consistent with other measures of temporal acuity, TMTFs estimate minimum-integration times of several milliseconds.

Temporal Integration

Temporal integration refers to the ability to summate response or information to affect perception. Results from detection experiments indicate that for durations of up to several hundred milliseconds, lower signal levels are needed for detection as signal duration is increased. These integration times in the tens or hundreds of milliseconds are several orders of magnitude greater than are those derived from measures of temporal resolution. Along with affecting signal detection, other effects of stimulus duration are commonly observed both in task performance, which can improve with stimulus duration (e.g., frequency discrimination ability), and increase in the strength of percept (e.g., loudness). In some cases, the change in task performance or percept with stimulus duration is not a result of actual temporal integration. Changing duration affects the frequency content of a sound with variation in frequency content the basis of some duration effects.

Several approaches have been used to reconcile the time constants of resolution and integration experiments. Based on the complex structure of the auditory system, one approach assumes that differing estimates reflect task-dependent processing at different levels of the system. Alternative models attempt to account for both temporal resolution and integration with a single processing structure. For example, the "multiple look" model proposes multiple sampling of the short time-constant process of temporal acuity. By combining information across multiple looks, the model is able to account for results from integration experiments.

Another type of information integration is observed with modulated stimuli. In these cases, the integration is across frequency regions. An example of a typical stimulus configuration would combine a low- and high-pitched tone, both having the same pattern of AM. This common modulation across frequency regions can aid detection of a signal added to the mixture. The improvement in detection resulting from common or coherent modulation is called comodulation masking release (CMR). If the task requires AM detection, modulation added to a different frequency region can hinder performance, with this effect termed modulation detection interference (MDI). For both CMR and MDI, information concerning temporal modulation is combined across frequency regions to influence performance.

Auditory Segregation and Pattern Processing

In some measures of temporal acuity, the onset of specific frequency components is delayed with the task to detect the presence of the asynchrony. Delaying the onset of a single component of a complex is referred to as asynchronous gating. With asynchronous gating at roughly 10 times the detection threshold (i.e., roughly 20 ms), listeners detect the delay and can report the temporal order at which frequency components are turned on. This judgment requires ability to perceptually segregate, or "hear out," individual frequency components from a complex sound. The effect of asynchronous gating can be quite robust, among the strongest of any of the stimulus factors that influence perceptual segregation. Auditory processing of asynchrony and temporal order are crucial in many everyday listening situations. Asynchrony is a common marker that distinguishes one sound source from another, and prescribed temporal order is one of the major acoustic characteristics of speech.

A gating asynchrony among stimulus components can also lead to the perception of sequential auditory events. The perception of multiple auditory events as a coherent sequence, in essence the output of a single sound source, is referred to as streaming. Common examples of auditory streaming are the ability to follow a single melody from a mixture of musical sounds, or attributing consecutive speech sounds to a single talker. A general characteristic of streaming is that pattern recognition is superior for elements that have arisen from a common source in contrast to multiple real or implied sources. This characteristic is often observed in experiments that evaluate whether a repeating series of sounds forms a single or multiple stream sequences. When using tonal stimuli, the perception can be one of hearing one or several concurrent melodies. In the simplest case, the stimulus is a repeating series of two pure tones with the frequency separation of the tones and the repetition rate being the primary experimental variables. Increasing the value of either of these variables increases the segregation of the two tones into separate streams. Long before experimental validation, awareness of these effects was used in contrapuntal music to effect segregation of melodic lines. In experimental work, the absolute values of the frequency separation and repetition rate at the threshold for stream segregation can vary with the metric used to determine threshold and the requirements of the task. Dependent on stimulus parameters, listeners may report an ambiguous percept that switches between stream segregation and sequence integration. In many studies, results also indicate a buildup of the percept of stream segregation over time. Collectively, results obtained from both temporal-order and streaming experiments highlight that time is the dimension that defines auditory patterns, making temporal processing a fundamental property of auditory perception.

AUDITORY FREQUENCY ANALYSIS, NEURAL

Speech, music, and every other sound one hears can be described by the pattern of amplitude at different frequencies. This pattern, which is called the sound's spectrum, distinguishes one sound from others. In human speech, for example, the vowel in the word *heat* sounds different from the vowel in *hat* because amplitude peaks occur at different frequencies in the spectrum of the first vowel. Frequency analysis, described in this entry, refers to the ability to process different regions of the spectrum separately. This ability allows a person to discriminate two tones of different frequencies, but more importantly, it allows the locations of the amplitude peaks in the spectrum of any sound to be encoded and represented in the brain. Frequency analysis begins in the cochlea, where the spectrum of the acoustic signal is converted to a representation called a *place code* for frequency. The place code for frequency that is created in the cochlea is preserved as the signal is represented in the responses of neurons and processed in the brain. Throughout the auditory system, the representation of frequency by a neural place code is the predominant organizational principle.

Sound arriving at the eardrum is transmitted through the middle ear into the cochlea, where it causes a long, narrow structure called the basilar membrane to vibrate. Because of the way the stiffness of the basilar membrane varies along its length, it responds to a sine wave stimulus with a traveling wave whose maximum displacement occurs at a location that varies systematically with the frequency of the tone. Each location along the basilar membrane responds best to a restricted range of frequencies; that is, each location is "frequency-selective." The frequency selectivity of any single location can be described by its tuning curve, which shows the pattern of thresholds as a function of stimulus frequency. Each threshold is defined as the level of a sine-wave stimulus that displaces the basilar membrane by a fixed amount. Tuning curves are V-shaped, and the frequency for which the threshold is lowest is called the *characteristic frequency* (CF). Thresholds increase rapidly for frequencies above CF, and increase more slowly for frequencies below CF. This pattern of thresholds means that each location responds to some frequencies but not others.

The mechanical frequency analysis accomplished by the basilar membrane is enhanced by the action of outer hair cells (OHCs). When stimulated by low-amplitude vibration of the basilar membrane, OHCs generate a mechanical response of their own. The effect of this "electromotile" response is called the cochlear amplifier. The feedback provided by the cochlear amplifier increases sensitivity to low-amplitude sounds near the CF and improves frequency selectivity.

The next step in frequency analysis occurs when the vibration of the basilar membrane is converted into neural activity. Motion of the basilar membrane stimulates inner hair cells (IHCs). IHCs in turn stimulate auditory nerve fibers (ANFs), the neurons that carry information about sound from the cochlea to the brain. Because each ANF receives input from a single IHC, it is also frequency-selective, with a tuning curve that is essentially the same as the tuning curve of the basilar membrane location that it innervates. A sine-wave stimulus will activate a subset of ANFs that has CFs that are close to the frequency of the tone. When the frequency of the tone changes, it activates a different subset of ANFs. This change in the place of activation provides the neural basis for frequency discrimination. Of course, most sounds are more complex than sine-wave tones. For a sound like one of the vowels mentioned previously, ANFs whose CFs are close to the frequencies of peaks in the vowel's spectrum will be activated most strongly. When the sound's spectrum changes, so that spectral peaks occur at different frequencies, the locations of peaks of neural activation will also change. This description leaves out many details, especially the contributions of cochlear nonlinearities, but in general, the pattern of activation as a function of place provides the basis for neural frequency analysis.

ANFs also convey information about frequency in their temporal discharge patterns. For frequencies below about 4 kilohertz (kHz), ANFs respond with a temporal pattern that is related to the waveform of the stimulus. For example, consider an ANF responding to a sine-wave tone whose frequency is 333 hertz (Hz). The waveform repeats every 0.003 seconds (3 msec). The fiber will respond at precisely timed intervals determined by that period: 3 msec, and integer multiples of 3 msec (6 msec, 9 msec, 12 msec, etc.). Now suppose that the frequency of the stimulus changes to 250 Hz. The period changes to 4 msec, and the interval between responses also changes, to 4 msec and integer multiples of 4 msec. Sounds that are more complex than sine waves are also represented with a precise temporal pattern. This response property, called phase-locking or discharge synchrony, contributes to frequency analysis, especially in the presence of noise.

The place code for frequency created in the cochlea is preserved in the central auditory system. The tuning curves and CFs of central auditory neurons are determined by their direct and indirect connections to auditory nerve fibers. In every structure in the main ascending auditory pathway, neurons are arranged so that CF changes systematically as a function of location. In the brain, this is referred to as tonotopic organization. Tonotopic organization allows the neural frequency analysis that starts in the cochlea to be completed.

AUDITORY FREQUENCY SELECTIVITY

Our world is filled with acoustic energy. Sound waves radiate from different sources, bouncing off walls, floors, and other objects, and intermingling before finally reaching our ears. What the ear receives is a complex mixture of sources and reflections, all combining to form a single pressure wave that causes the eardrum to vibrate. How do we segregate such a mixture, and how do we identify and recognize the sources? This question, which forms part of the well-known cocktail party problem, is still not completely solved. However, one contributing factor is our ability to hear and segregate different frequencies within the sound mixture. This *frequency selectivity,* described in this entry, is established at an early stage of auditory processing and is maintained throughout the auditory pathways, right up to the primary auditory cortex.

Frequency Selectivity in the Cochlea

When sound vibrations reach the cochlea via the eardrum and the middle ear bones (ossicles), the vibrations disperse as "traveling waves" along one of the partitions within the cochlea, known as the basilar membrane. How far along the basilar membrane a wave travels depends mainly on its frequency, with high-frequency waves reaching their peak early and low-frequency waves peaking further down along the basilar membrane. In this way, a complex waveform is broken down into its constituent simple frequencies so that the energy at each frequency produces its own peak of vibration along the basilar membrane. The pattern of vibration along the basilar membrane in response to a sound is called an *excitation pattern.*

The frequency selectivity of the cochlea is limited: As two tones become closer in frequency, their peaks of vibration along the basilar membrane will also become closer, and at some point the two peaks will merge to form an excitation pattern with just a single peak. The limits of cochlear frequency selectivity are determined by the mechanical properties of the basilar membrane, as well as by the functioning of the outer hair cells, which sit on top of the basilar membrane, within the organ of Corti, and amplify quiet sounds and sharpen the tuning of the cochlea. Damage to the outer hairs results in a reduction in cochlear tuning, and a loss of frequency selectivity. In other words, when the outer hair cells are not functioning properly, the excitation patterns in the cochlea become broader, making it more difficult to separate the responses to different frequencies.

Perceptual Measures and Consequences of Frequency Selectivity

Masking has been a popular way to probe perceptual frequency selectivity in the laboratory, but it is also an everyday occurrence—think of holding a conversation in a noisy bar, or of not hearing someone because you have the vacuum cleaner on. Masking can occur when the excitation pattern produced by the masker overlaps with, and swamps, the excitation produced by the target. If auditory frequency selectivity were infinitely sharp, then no masking would occur, as long as the frequencies of the masker did not overlap completely with those of the target. Thus, the extent to which masking does occur can tell us about the limits of frequency selectivity. Some rules of thumb have emerged from research into frequency selectivity. In general, two frequencies have to be separated by at least 10 to 20% to be perceptually segregated, at least in the range of frequencies between about 500 and 6,000 Hz, which are arguably the most important for speech perception. The ability of one sound to mask another diminishes as the frequency separation between them increases and, at high sound levels, low-frequency sounds mask high-frequency sounds more readily than the reverse, in what is known as the upward spread of masking.

Frequency selectivity can be determined physiologically in the auditory nerve, or along the basilar membrane, by measuring the range of frequencies that elicit a given response. The measurement of these physiological "tuning curves" requires for the most part invasive procedures and so cannot be performed in humans. However, the few studies that have investigated both perceptual and physiological frequency selectivity in the same species have found good correspondence, meaning that perceptual frequency selectivity is likely determined in the cochlea. Hearing loss often results from a functional loss of the outer hair cells, leading to poorer frequency selectivity in the cochlea. Perceptual studies of hearing-impaired people have found that their frequency selectivity is poorer than normal. This decrease in frequency selectivity may underlie many common complaints of people with hearing loss, such as an impaired ability to understand speech in noisy backgrounds.

The limits of frequency selectivity can also be put to positive use in certain practical applications. For instance, the popular audio coding scheme known as MP3 relies on humans' limited frequency selectivity to "hide" coding noise in frequency regions where it is masked by the audio signal. In MP3 coding, the original audio signal is split up into frequency "sub-bands" and the resolution of the signal within each sub-band is degraded, which is the equivalent of adding noise. Because the added noise is limited to the same frequency region as the signal, engineers can be sure that the signal will perceptually mask the added noise, so long as its level remains well below that of the signal. By making clever use of frequency selectivity and masking, the designers of the MP3 and related systems have been able to reduce the data rate by a factor of nearly 10 without any noticeable loss in audio quality.

AUDITORY ILLUSIONS

The sounds we perceive do not always correspond to those that are presented. When such a mismatch occurs, we are experiencing an *auditory illusion.* These illusions show that the auditory system does not faithfully transmit the sound information as it arrives at our ears, but alters and reorganizes this information in various ways, as described in this entry.

The Precedence Effect

Our hearing mechanism has evolved an ingenious mechanism for minimizing problems caused by echoes in the environment. Instead of correctly perceiving a set of overlapping sounds, each coming from a different location in space, we obtain the illusion of a single sound that appears to be coming from its original source. This phenomenon was first discovered by the 19th-century physicist Joseph Henry. To demonstrate this effect, the listener is seated in front of two loudspeakers, with one to his left and the other to his right. A single stream of speech is presented through both loudspeakers; however, the signal at the right loudspeaker is delayed relative to the left one. When the sounds coming from the speakers differ in onset by less than about 30 milliseconds (ms), the listener perceives the sound as coming only from the left loudspeaker. The right loudspeaker contributes to the loudness and liveliness of the sound, but appears to be completely silent. When the offset exceeds the critical time limit, two distinct streams of sound are correctly heard as coming from separate loudspeakers.

The Octave Illusion

The octave illusion was discovered by Diana Deutsch in 1973 and is experienced with tones that are presented via stereo headphones. Two tones an octave apart are alternated repeatedly at a rate of four tones per second. The identical sequence is presented to both ears simultaneously; however, the tones are offset in time such that when the right ear receives the high tone the left ear receives the low tone; and vice versa (see Figure 1, left panel).

Despite its simplicity, this pattern is almost never heard correctly, and instead produces a number of illusions. Many people hear a single tone that alternates from ear to ear, while its pitch simultaneously switches back and forth between high and low. So it appears that one ear is receiving the sequence "high tone—silence—high tone—silence" while the other ear is receiving the sequence "silence—low tone—silence—low tone." Even more curiously, when the earphone positions are reversed most people hear exactly the same thing: The tone that had appeared in the right ear still appears in the right ear, and the tone that had appeared in the left ear still appears in the left ear. As a further surprise, right-handers tend to hear the high tone as on the right and the low tone as on the left, regardless of how the earphones are positioned; yet left-handers vary considerably in where the high and low tones appear to be coming from. The illusion is hypothesized to result from the use of incompatible cues to determine *what* sounds are being presented, and *where* each sound is coming from. The strong association with handedness indicates that the ways in which the octave illusion is perceived reflect differing patterns of brain organization.

The Scale Illusion

The scale illusion was discovered by Deutsch in 1973 and is best experienced through stereo headphones. The pattern that produces this illusion consists of a musical scale, played simultaneously in ascending and descending form. The successive tones of the scale alternate from ear to ear such that when a tone from the ascending scale is in the right ear a tone from the descending scale is in the left ear; and vice versa. This sequence of tones is played continuously without pause (see Figure 1, center panel).

As with the octave illusion, the scale pattern gives rise to a number of illusions that vary with the handedness of the listener. Most commonly, a melody corresponding to the higher tones is heard as coming from one earphone, with a melody corresponding to the lower tones from the other one. Right-handers tend to hear the higher tones as on their right and the lower tones as on their left. And as with the octave illusion, when the earphone positions are reversed the right ear continues to hear the higher tones, and the left ear the lower ones. However, left-handers as a group are less likely to localize the tones in this way. As with the octave illusion, the handedness correlates with the way the scale illusion is perceived, indicating that this illusion reflects differing patterns of brain organization.

Variants on the scale illusion can be produced with other melodic patterns, and by natural instruments in concert halls, so that on listening to complex orchestral music, individual members of an audience may well be hearing certain musical passages in different ways.

(b) The pattern that produces the scale illusion, and the percept most frequently obtained. (c) The tritone paradox as perceived by two different listeners.

The Glissando Illusion

The glissando illusion was created by Deutsch in 1995. It is best heard when the listener is seated in front of two stereophonically separated loudspeakers, with one to his left and the other to his right. The pattern producing the illusion has two components: a synthesized oboe tone of constant pitch, and a sine wave whose pitch glides up and down. These two components are presented simultaneously, and switch repeatedly between the loudspeakers at four cycles per second such that when the oboe tone is coming from the speaker on the left, the glissando is coming from the speaker on the right, and vice versa.

On listening to this illusion, the oboe tone is heard correctly as switching between the loudspeakers. However, the segments of the glissando appear to be joined together quite seamlessly, so that a single, continuous tone is heard that appears to be moving around in space in accordance with its pitch motion. Handedness correlates again emerge where the higher and lower portions of the glissando appear to be located: Right-handers tend strongly to perceive the glissando as moving slowly in space between a position to the left when its pitch is low, and to the right when its pitch is high. Yet left-handers vary considerably in where the higher and lower portions of the glissando appear to be located.

The scale and glissando illusions can be partly explained by assuming that the listener adopts the most plausible interpretation relative to the environment. For the scale illusion, it is extremely unlikely that two jerky but overlapping pitch patterns should be coming from different positions in space. We therefore reorganize the tones perceptually, so that the higher tones appear to be coming from one location and the lower tones from another. For the glissando illusion, it is extremely unlikely that a sound that changes smoothly in frequency should be switching abruptly between two different spatial locations. It is far more probable that such a sound is coming from a single source that is either stationary or that is moving slowly through space. So we perceptually reorganize the gliding tone accordingly.

Pitch Circularities

Tones whose frequencies are in a ratio of 2:1 are said to be in octave relation, and they are in a sense perceptually equivalent. This is acknowledged in the system of notation of the Western musical scale. The core of this scale consists of 12 tones, which correspond to the division of the octave into equal steps, called semitones, and each tone is given a name (C, C#, D, D#, E, F, F#, G, G#, A, A#, and B). The entire scale, as it ascends in height, consists of the repeating presentation of this sequence of note names across successive octaves. Pitch can therefore be described as varying along two separable dimensions: The dimension of *pitch height* corresponds to the position of the tone from high to low, and the circular dimension of *pitch class* (corresponding to note name) corresponds to the position of the tone within the octave.

In the early 1960s, Roger Shepard showed that the two dimensions of pitch can be separated by employing computer-produced tones whose pitch classes are clearly defined, but whose heights are ambiguous. This can be achieved, for example, with a bank of 12 tones whose names correspond to those of the musical scale, but each of which consists only of components that are related by octaves. For example, one such tone would consist only of components C_2, C_3, C_4, . . . ; such a tone would clearly be heard as a C, but its octave placement would be ambiguous.

Shepard found that when two such octave-ambiguous tones were played in succession, people heard either an ascending pattern or a descending one, depending on which was the shorter distance between the tones along the pitch class circle. This enabled Shepard to create an illusion of pitch circularity: When a bank of such tones is played that traverses the pitch class circle clockwise in semitone steps (C, C#, D, and so on), it is heard as eternally ascending in pitch. When it traverses the circle counterclockwise (C, B, A#, and so on), it is heard as eternally descending instead. Soon after this, Jean-Claude Risset generated analogous pitch circularities using a similar algorithm but with gliding tones.

Pitch circularities are not confined to tones consisting only of components that are related by octaves. In 2008, Diana Deutsch, Kevin Dooley, and Trevor Henthorn produced circular banks of tones each of which constituted a full harmonic series. This was achieved by manipulating the relative amplitudes of the odd and even harmonics of the tones.

The Tritone Paradox

Demonstrations of pitch circularity raise the question of what happens when pairs of octave-ambiguous tones are presented that stand in opposite positions along the pitch class circle, so that the same distance between them can be traversed in either direction. Such tones form an interval called a tritone. Deutsch discovered in 1983 that when such tone pairs are presented, paradoxical differences in perception emerge (see Figure 1, right panel). For example, when presented with C followed by F#, one listener will clearly hear an ascending pattern; however, another listener may clearly hear a descending pattern instead. And when the pattern G# followed by D is presented, the first listener now hears a descending pattern and the second listener an ascending one. Furthermore, for any one listener, the pitch class circle is oriented with respect to height in a systematic way, so that tones in one region of the circle are heard as higher and tones in the opposite region as lower.

Such differences in perception correlate with the pitch range of the listener's speaking voice, and with the language or dialect to which listeners have been exposed. Strong differences were found, on a statistical basis, between listeners who had grown up in California and those who had grown up in the south of England. Such differences in perception of this musical pattern again indicate that individual members of an audience may hear certain musical passages in different ways.

Illusions of Auditory Continuity

Another class of illusions involves perceptually replacing missing portions of sounds that would otherwise be drowned out by noise. When we are conversing with someone in the street, for example, the noise of traffic masks out many portions of the speech we are listening to, and our perceptual system generates these missing portions, so that the speech sounds continuous. Richard Warren found that when listeners heard a recorded sentence in which a speech sound was deleted and replaced by noise, they were unable to tell which sound was missing, and could not locate the position of the noise in the sentence. The sound that listeners "reconstructed" changed depending on the context. When presented with the sentence "It was found that the *eel was on the ___," listeners tended to "hear" the missing sound depending on the last word. So, for example, when the last word was "table," listeners tended to hear the word "meal," and when the last word was "shoe," they tended to hear the word "heel." Similar effects have been found on listening to music. When a note in a repeating scale is deleted and replaced by a noise burst, listeners reconstruct it perceptually. Also, as discovered by Albert Bregman, when a gliding tone is sounded, and a portion of the glide is removed and replaced by a loud noise burst, the listeners reconstruct the missing portion of the glide.

AUDITORY IMAGERY

Auditory imagery refers to the common experience in which people report that they "hear" a voice, melody, or other sound, in their "mind's ear," all in the absence of an actual acoustic stimulus. In some cases, this experience is deliberate (and so someone can, if he or she chooses, try to imagine what his or her mother's voice sounds like, or what a particular musical performance sounds like). In other cases, the image arises spontaneously, and, indeed, people sometimes complain that they cannot avoid hearing a melody (or a snippet of a melody) over and over—a maddening experience sometimes given the striking label of "having an ear-worm."

Auditory images are not hallucinations—people experiencing the images can tell that the images are "in their head," and not a real sound. Nonetheless, the experience of "hearing" the imagined sound does resemble the experience of hearing an actual sound. Subjectively, the imagined sound seems to have a clear pitch, duration, and timbre, just as an actual sound would. Functionally, the image seems to provide direct information about these attributes, suggesting that the image truly does depict the sound, rather than merely describing or referring to the sound. This entry describes imagined pitch, duration, and timbre; differences between sounds and auditory images; enacted auditory images; the neural substrate of auditory imagery; and memory for enormously familiar sounds.

Imagined Pitch and Imagined Duration

Research on auditory imagery has taken several different paths. One line of research has sought to confirm the subjective sense that auditory images do directly represent a sound's pitch. One series of experiments, for example, asked participants to imagine a specific pitch, and then to detect a faint tone either of the same pitch or different. Participants' performance was better when the tone they were trying to detect was the same pitch as the one they were imagining—suggesting both that the image had accurately represented the pitch and that this imagined pitch primed the processes of actual hearing. A different series of experiments asked participants to imagine a particular melody and then to hum the starting pitch of the melody they were thinking about. Two days later, participants returned to the lab and did the same task. Across this two-day interval, the data show remarkable consistency in the pitch that each participant hummed for each song—indicating both that participants imagined the song at a specific pitch and that they were consistent in the pitch they chose for each melody.

A different line of research confirms the subjective sense that images are stretched out in time in just the way actual sounds are. In one study, participants were given specific words from a song's lyrics (for example, *can* and *by* from "The Star-Spangled Banner"), and had to judge whether the pitch of the note accompanying the second word (*by,* the seventh beat of the phrase) was higher or lower than the pitch of the note accompanying the first word (in this case, the third beat). The data showed that the time needed to make this judgment increased in a regular fashion if the first note was further from the song's start, and also if the second note was further from the first. It would seem, then, that participants perform this task by "playing" the melody "in their heads," starting with the melody's actual start—and the more notes they have to "play" to make their judgment, the more time needed.

Imagined Timbre

Still other research confirms that auditory images accurately depict a sound's timbre (i.e., the quality of sound, with other properties, such as pitch or loudness, held constant, that distinguishes one sound source from another; for example, the quality that distinguishes a flute and a clarinet each playing the same pitch). For example, in one study, some participants had to rate the similarities of a series of actually presented sounds that differed in timbre. (In one version of the procedure, the sounds were those of orchestral instruments; in another version, the sounds were environmental sounds.) Other participants had to *imagine* these sounds, and also rated the similarities between the sounds. The statistical summary of these data relied on a procedure termed *multidimensional scaling*. In this procedure, the individual sounds are represented by distinct points in space, and the similarity ratings are interpreted as "distances" among these points; the analysis asks how the sounds must be positioned to create the complex pattern of "distances," from one sound to the next, revealed in participants' pair-wise ratings.

The multidimensional space produced by this analysis, based on the similarity ratings for the imagined sounds, closely resembled the space based on the ratings for the actual sounds, indicating that all the pair-wise relationships between sounds are well preserved in imagery, which implies in turn that the timbres were represented in a fashion that is at least consistent and, more strongly, true to the actual sounds.

Differences Between Sounds and Auditory Images

Other results, however, suggest some complications in the comparison between imagined sounds and actual sounds. For example, actual sounds necessarily have some specific loudness; findings suggest, however, that auditory images may be indeterminate in their loudness. In addition, auditory images may not be purely "auditory," because some data suggest that imagination may often represent complex, multimodal events, containing both auditory and visual aspects. As a result, some judgments about auditory images may be guided by information about other aspects of the represented events. Thus, for example, participants imagining familiar *voices* may create an image that also depicts the familiar *face* of the person speaking, and judgments about the voice—such as whether it is similar to some other voice—may be shaped by information about the visual qualities of the face.

Auditory images are also distinct from sounds in another way: Sounds exist in a fashion that is independent of any perceiver's interpretation—how the perceiver parses the sound-stream (i.e., determines where one sound stops and the next begins, and decides which sounds are parts of a larger acoustic event), or interprets its meaning. Auditory images, in contrast, seem to exist only in the context of the perceiver's interpretation; according to some authors, the image is accompanied by a *perceptual reference frame* that specifies how the sound is organized and understood. As a result of this reference frame, the meaning of the imaged sound, for the person holding the image, may be quite specific and relatively rigid. In one study, for example, some participants heard the word *stress* being uttered again and again and again; within a few seconds, their perception shifted, so they heard the sequence first as repetitions of *stress,* then of *rest,* then of *tress*—reflecting apparently spontaneous shifts in how the sound stream was parsed. If these repetitions of *stress* were imagined, however, the parsing of the stream was apparently specified within the perceptual reference frame that accompanied the image, and so these shifts in interpretation did not occur, and the (imagined) sequence was understood as a rigidly unchanging repetition of the initial word, *stress.*

Enacted Auditory Images

In some settings, however, participants seem able to escape the limits set by the perceptual reference frame. Specifically, in some tasks, participants seem spontaneously to supplement an imagined stimulus with silent subvocalization (and so, in addition to imagining the sounds of "stress, stress, stress," they might silently mime the speaking of this sequence). This combination of imagery plus subvocalization produces what some authors call enacted imagery, and enacted images (unlike "pure" images) seem readily re-interpreted (and so enacted images of "stress-stress-stress" are easily re-parsed).

The role of enactment is evident in a variety of other tasks that rely on auditory imagery. In one study, participants were given letter and number strings, and had to decide what these strings would sound like if pronounced aloud. (X-T-C, for example, would be *ecstasy;* N-L-S-S would be *analysis.*) Participants could easily do this task if given no other constraints. If, however, participants were blocked from subvocalizing (e.g., by asking them, silently and repeatedly, to mouth "ta-ta-ta" while doing the task), their performance dropped markedly. If participants were in a noisy environment (so that they couldn't "hear" what they were saying to themselves), performance was also quite low. It appears, then, that participants perform this task, in essence, by talking to themselves, and then "listening" to what they have (silently) pronounced. Put differently, this task, apparently relying on auditory imagery, seems instead to rely on a mix of auditory imagery and motor activity (the enactment), and if either the audition or the motor action is prevented, performance drops.

Neural Substrate of Auditory Imagery

Still another line of research has examined the brain mechanisms that support (and shape) auditory imagery. Both positron emission tomography and functional magnetic resonance imaging studies indicate that auditory imagery for familiar melodies depends on activation in the right auditory association cortex and activation in the frontal cortex. Tasks requiring judgments about musical timbres seem to activate both primary and secondary auditory areas, especially in the right hemisphere. These studies indicate considerable neural overlap between the brain areas needed for auditory imagery and those needed for the actual hearing of overt sounds (a pattern that parallels the findings for visual imagery and vision), underscoring the strong resemblance between imagery and perception. More specifically, we can see that imagery and perception resemble each other subjectively (images "feel like" hearing), functionally (e.g., in the information they make prominent), and biologically. In addition, activation of the supplementary motor area (SMA) also appears to be involved in the generation of auditory imagery, again suggesting a role for motor codes in auditory imagery.

Memory for Enormously Familiar Sounds

Finally, yet another line of research has examined imagery for materials that are enormously familiar—such as a favorite song that someone has heard countless times. Evidence suggests that when someone imagines this sort of familiar song, the person's imagination is remarkably faithful to the original: The song is imagined in the same key as the original, and probably in the right octave, and at essentially the right tempo. Apparently, then, the person's memory for this familiar auditory event is quite accurate, and the reproduction of the melody, in imagery, preserves the acoustic qualities of the original.

Even with these diverse lines of research, however, many questions about auditory imagery remain; indeed, far less is known about auditory imagery than about visual imagery. For example, subjective reports suggest that people differ in how rich or detailed their auditory images are, and in how often they experience spontaneous images. Little is known about these points, however, including the fundamental issue of whether these differences can be taken at face value, or whether, instead, people are quite uniform in their auditory imagery and differ only in how they describe their images. Or, as a different example, little is known about how (or when, or whether) people use their auditory images. There are many indications that visual images are often useful (as aids to memory, or to problem solving); the history of scientific discovery or of artistic innovation suggests many steps forward inspired by (or created through) visual images. Whether a similarly rich set of functions can be documented for auditory imagery remains among the many points in need of further research.

AUDITORY LOCALIZATION: PHYSIOLOGY

The ability to locate the source of a sound is a fundamental property of normal hearing. Compared with the visual system, however, for which a relatively complete understanding of spatial processing has been achieved, at least with respect to the two-dimensional representation of visual space projected on the back of the retina, the study of neural coding of auditory space constitutes an altogether more complex problem. This is partly because the hearing organ of the inner ear—the cochlea—is arranged to represent the frequency of a sound, rather than the location of its source. This frequency tuning is known as *tonotopy,* with the highest frequency (pitch) sounds represented at the base of the coiled cochlea and the lowest at the apical end. Brain centers dedicated to processing hearing in the central nervous system are organized according to this tonotopic map, such that the preferred sound frequency to which neurons are found to respond changes systematically from low to high moving from one end of a sheet of brain tissue to the other. Neural sensitivity to auditory spatial cues only emerges several stages above the cochlea. This entry describes cues for location, neural sensitivity to binaural cues, maps of auditory space, the neural code for interaural time difference, and cortical codes for auditory space.

Cues for Localization

Sound localization is provided for by sensitivity to a combination of acoustic cues that arise from the interaction of sounds with the head. These include binaural (or "two-eared") cues of interaural time and level differences (ITDs and ILDs, respectively). ITDs arise because the ears are separated in space by the distance of the head. Sound sources directly in front (or behind) generate zero ITD because the sound sources are equidistant from the two ears; for sound-sources located to one side or the other, however, the sound arrives later at the further ear than at the nearer ear, generating an ITD. In humans, these ITDs are maximally in the order of several hundred microseconds (*millionths* of a second) for sources located directly to one side or the other. ITDs are useful for localizing low-frequency sounds (< 1,500 Hz; approximately the note G two octaves above middle C on the piano).

For frequencies higher than 1,500 hertz (Hz), the head creates an "acoustic shadow" such that the sound arriving at the ear further from the source is less intense than the sound arriving at the nearer ear, creating an ILD. As well as depending on the location of the source, the magnitude of the ILD depends on the frequency of the sound and the size of the head (ILDs are bigger at higher frequencies and bigger for bigger head sizes). This dichotomy of ITDs for low-frequency localization and ILDs for high-frequency localization is referred to as the *duplex theory* of sound localization.

A final cue for sound localization arises because of the convoluted shape of the outer ear, or pinna. The various nooks and crannies of the pinna lead to sound waves interacting with each other, with the result that sound energy is reduced at some frequencies and increased at others. This effect is different for different frequencies, depends on the location of the sound source, and leads to a different pattern of sound energy reaching the eardrum compared with that arriving at the outer ear. As well as contributing to the perception of source location above and below the horizon, these "spectral cues" are necessary for disambiguating sound sources located behind from those in front.

Neural Sensitivity to Binaural Cues

In mammals, the dichotomy suggested by the duplex theory is reflected in the brain structures that generate sensitivity to ITDs and ILDs. It is now well established that the medial superior olive (MSO) and lateral superior olive (LSO)—two aggregates of neurons in a region of the brainstem known as the superior olivary complex (SOC)—constitute the initial sites at which information from the two ears is brought together to create sensitivity to binaural hearing. Neurons in the MSO are sensitive to ITDs, and neurons in the LSO to ILDs.

Until recently, the most influential model for generating ITD sensitivity suggested that MSO neurons act as binaural coincidence detectors, neurons that respond maximally when nerve action potentials arrive simultaneously from the two ears. In this model, first developed by Lloyd Jeffress in 1948, each coincidence detector (MSO neuron) is innervated by axons from each ear, and these axons can vary in length. The purpose of these axonal "delay lines" is to compensate for ITDs generated by the spatial location of sound sources. This is illustrated in Figure 1 (see also color insert, Figure 1), where each neuron in the array is contacted by axons of varying length from each ear. So, for example, for a sound with zero ITD—generated by a source directly in front—signals from each ear enter the circuit simultaneously, and reach the middle coincidence detector (Number 3) simultaneously because the path length from each ear is identical. The firing of this detector, therefore, indicates that ITD was zero. Now consider what happens if the sound is located nearer the left ear, so that it is delayed in reaching the right ear. In that case, the signal from the left ear enters the circuit first, then the signal from the right ear, with a delay, such that the signals reach a neuron such as 4 or 5, which is closer to where the right-ear signal enters. The firing of this coincidence detector indicates that particular ITD and, by extension, the location of the source. Experimental recordings from a range of mammalian and avian species have demonstrated the existence of neurons that respond as coincidence detectors, being maximally activated by certain ITDs and minimally by others. This ability to compare the time of arrival of sounds at the two ears relies on the fact that the first neurons in the auditory pathway—the auditory nerve fibers (ANFs) that synapse with the sensory inner hair cells of the cochlea—generate action potentials only at specific times during each stimulus cycle, a process called *phase-locking*. Thus, by comparing the timing of action potentials arriving from each ear, it is possible to know the timing of the sound arriving at each ear and, hence, construct the location of the sound source. Phase locking of action potentials occurs for frequencies of sound up to a few kilohertz (kHz), and this upper limit is reduced between the ANFs and the MSO neurons. Hence, ITD processing is restricted to sounds with frequencies below about 1.5 kHz in mammals.

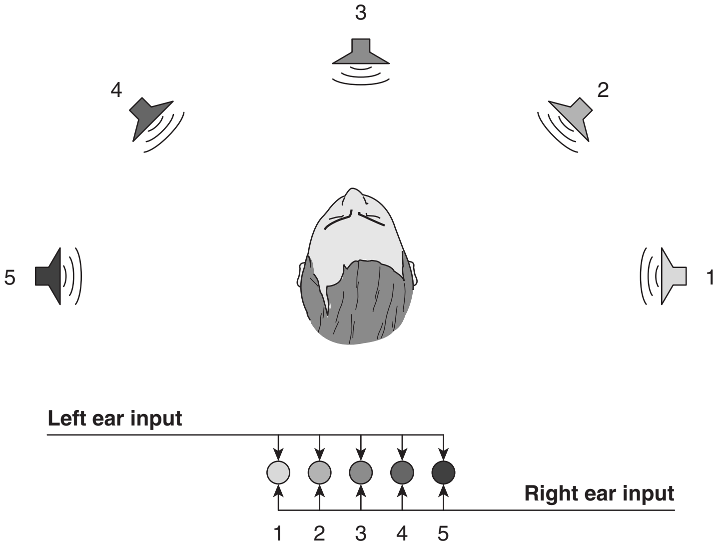

Figure 1 Axonal Delay Lines

Note: Each neuron in the array is contacted by axons of varying length from each ear.

Further, anatomical studies by Matsuka Konishi in barn owls, the "textbook" species for spatial hearing, suggests that ITD is mapped in an orderly manner across the neural tissue, with axonal delay lines favoring short ITDs at one end of the barn owl's equivalent brain-structure to the MSO, and delays lines favoring long ITDs at the other. This is mapped in the direction orthogonal (90°) to the tonotopic map, meaning that each sound frequency will contain a complete representation of ITDs. Evidence for such an arrangement of delay lines in the mammalian brain is equivocal, however, and mechanisms other than the Jeffress circuit for generating a neuron's preferred ITD have been suggested. One potential mechanism relates to the recent finding that MSO neurons are innervated by a significant, and temporally precise, source of inhibition. Studies in the laboratory of Benedikt Grothe in particular suggest that when the action of neural inhibition in the MSO is blocked by the drug strychnine, the difference in axonal conduction delay from each ear to the MSO is essentially zero. In other words, although neurons act as coincidence detectors, their preferred ITD is determined by neural inhibition, without which their preferred tuning would be for zero ITD (i.e., sounds straight ahead or behind).

The mechanism by which neural inhibition influences ITD tuning remains unclear. However, it is thought that because inhibitory inputs originate from the opposite side of the brain to the MSO and arrive directly on the soma (cell body) of a coincidence detector neuron, whereas excitatory inputs arrive from both ears distant from the soma—on the neuron's dendrites (processes)—the relative timing of the sound at each ear determines whether excitatory or inhibitory influences dominate the response. For one particular ITD, the inhibitory influence on the coincidence detection of the excitatory inputs is minimal, and the neuron responds maximally to this ITD. Regardless of the mechanism, the experimental demonstration that blocking inhibition shifts neurons' preferred ITD to zero indicates that the Jeffress model is only one means of generating a system of internal delays.

Generating neural sensitivity to ILDs is an altogether less complex affair than is the case for ITDs. It is generally accepted that ILD sensitivity arises first in the LSO, where neurons are innervated by excitatory synapses derived from the ear on the same side and the inhibitory synapse from the other. The generation of a significant head-shadow at higher sound frequencies for sound sources located to one side or the other results in either the excitatory or inhibitory influence dominating responses in each LSO. When the source is located closer to the excitatory ear, the LSO responds more vigorously, and less so as the source is moved relatively closer to the excitatory ear. Thus, the neural code for ILD, at least at the level of the LSO, is one in which the relative balance of activity in each brain hemisphere could provide the means by which a sound is judged to originate from one side or the other. Unlike with ITDs, there is no requirement for exquisite temporal sensitivity in the excitatory or inhibitory inputs to the LSO. Consequently, a number of studies have demonstrated *de novo* generation of ILD sensitivity at neural stages beyond this.

Maps of Auditory Space

The extent to which any brain region provides for an integrated representation of all of the auditory spatial cues remains to be determined. The superior colliculus (SC) of the midbrain appears to contain a map of auditory space aligned with that of the visual world. Neurons in the middle layers of the SC respond to light and sound arriving from the same direction in two-dimensional space, and project onto motor neurons in the deep layers of the SC to facilitate head- and body-orienting responses. Although such a map is clear evidence for integrating visual and auditory spatial cues, it is unclear the extent to which all of the spatial cues contribute to the space map in the SC; evidence exists to suggest that ITD, the main cue used by many mammals for localization in the horizontal plane, does not contribute to this map.

The clearest evidence for such a map in the SC again comes from studies in the barn owl—a hearing specialist that can use sound alone to catch its prey. However, these animals are sensitive to ITDs for frequencies up to 10 kHz, well beyond the upper limit observed in other species. Further, barn owls, because of the relative geometry of their ears, uniquely employ ILDs for localization in the vertical, rather than horizontal, plane. The presence of two cues, one for azimuth (the horizontal plane) and one for elevation, over the same frequency range, renders such a two-dimensional mapping of binaural cues possible. For most other species, however, the restriction of ITD sensitivity to low frequencies, and ILDs to high frequencies, means that the two binaural cues operate independently over different spectral regions. Aside from the visually controlled SC map, there is little evidence in mammals for any organization in the ascending auditory pathways that provides for orderly maps of auditory spatial cues such as ITD. Evidence for such a map in the MSO is weak at best, and the anatomical projection pattern of the MSO to the major auditory structure in the midbrain, the inferior colliculus (IC), does not appear to be organized in any fashion that would suggest a map of auditory space. This could be taken to suggest that an *orderly* map of space is not required in the auditory system to determine the source location. Maps of space in other modalities of vision and touch arise because the peripheral sensors at the back of the eye and on the surface of the skin are spatially arranged maps of visual and somatosensory space, respectively, in the same way that the peripheral sensors in the inner ear are a spatially arranged map of sound frequency.

The Neural Code for Interaural Time Difference

The form of the neural code for ITD is the subject of ongoing debate. According to Jeffress' model, ITD-sensitive neurons indicate the location of a sound source by virtue of their maximum firing rate—they are tuned to a preferred ITD. However, recent studies have called into question the basic tenets of this model. Apart from questioning the means by which individual neurons are tuned to their preferred ITD (axonal conduction delays vs. neural inhibition), experimental recordings from a range of small mammals suggest that neurons are best able to discriminate between different values of ITD where their response changes most rapidly as the ITD is shifted. This generally occurs on the slopes rather than the peaks of the firing rate functions, and possibly accounts for why so many ITD functions have their most sensitive slope around zero ITD, where auditory spatial acuity is known to be greatest, rather than at their peaks. Indeed, in a manner similar to that of the paired LSOs, the activity in each MSO may act in a "push-pull" manner, one MSO more active when the source is located to one side, and the other MSO more active when the source is located to the other. The relative activity in each MSO would therefore indicate the location of the sound source.

Cortical Codes for Auditory Space

Although the representation of auditory space in higher brain centers, such as the neocortex, remains to be determined, evidence is emerging that it takes the form of a panoramic representation; that is, neurons respond to sounds in almost all locations on the opposite side of space. The relative contributions of binaural and spectral cues to this tuning remain to be determined. Regardless of the precise nature of the underlying mechanisms, the form of the neural code has been a matter of great interest. Although source location could be encoded by spike rate, a code for auditory space based on spike timing has also been suggested, and several models have suggested that spike-timing information alone is sufficient to replicate localization performance. By whatever means the various spatial cues are combined into a single representation of auditory space, however, it is clear that by some level of cortical process an integrated representation of auditory space is accomplished, and human cortical imaging studies have started to elucidate specific brain regions potentially contributing to the various aspects of spatial sound, including source location and motion, and the spatial extent of such sources.

AUDITORY LOCALIZATION: PSYCHOPHYSICS

Humans and most other animals can locate the source of sound in all three spatial dimensions: left-right (horizontal or azimuth) dimension, up-down (vertical) dimension, and near-far (distance or range) dimension. The sound produced by a sound source has no spatial properties, only the physical properties of frequency, intensity, and time. Thus, the ability to locate the position of a sound source is based on cues that result from the interaction of sound and objects (e.g., the head and the body of the listener or reflective surfaces) in the path of the sound as it travels from the source to the ear canals and ear drums on each side of the head. A different set of cues is used to determine the location of a sound source in each of the three spatial dimensions. This entry describes the psychophysics of locating auditory signals for each spatial dimension and also considers lateralization (when signal is presented through headphones) and localization in reflective spaces.

Horizontal Dimension

A sound from a source that lies to one side of a listener in the azimuth dimension such as a source off to the right will arrive at the ear closer to the sound before it reaches the ear on the other side of the head. This small interaural (between ears) time difference in the arrival of the sound at the two ears produces an interaural time difference (ITD) cue for locating sound sources in the azimuth dimension. The sound will also be more intense (have a higher sound level) at the ear closer to the sound source relative to that at the opposite ear. Thus, there is also an interaural level difference (ILD) cue for sources that lie in the horizontal dimension (see Figure 1). When the sound source is directly in front of a listener, the ITD and ILD cues are both zero because the sound source is midway between the two ears. As the location of the sound source is moved to one side or the other, the ILD and ITD cues increase. Thus, large ITD or ILD values indicate sound sources that are located well to one side of the listener.

The ILD cue is based largely on the fact that the head and body shield the sound on the ear opposite the sound source relative to that on the side of the sound source. That is, the head provides a sound shadow for the sound that arrives at the ear opposite the location of the sound source. This sound shadow produces a lower level sound at the far ear. The amount of attenuation of the level of the sound at the far ear depends on the sound's frequency. Higher frequencies receive more attenuation than do lower frequencies (the short wavelengths of high-frequency sounds allow high-frequency sounds to be reflected from the head), resulting in large ILDs for high frequencies compared with low frequencies. Thus, ILDs provide a better cue for sound source location in the azimuth dimension for high frequencies relative to low frequencies. For several reasons, the ITD cue provides most accurate information about the location of a sound source in the azimuth dimension when the sound has low frequencies (below about 1,200 hertz [Hz]). Above about 1,200 Hz, sounds such as sinusoidal and other narrow-band sounds cannot be located on the basis of an ITD. Thus, ITDs provide the best cue for sound source location in the azimuth dimension for low frequencies.

Humans are good at localizing the azimuth position of a sound source at low and high frequencies but are less accurate for mid frequencies (between 1,200 and 2,000 Hz). This and other results support the duplex theory of sound localization, which contends that in locating sounds in the azimuth dimension, ITD cues are used for low-frequency sounds and ILD cues are used for high-frequency sounds. For mid-frequency sounds, neither cue is as useful and localization acuity suffers.

Humans can detect a difference in ITD as small as 10 one-millionth of a second (10 microseconds) and a difference in ILD as small as 0.5 decibels (dB). If the location of a sound source directly in front of a listener is changed by about one degree of visual angle, the listener is likely to perceive the change in location, but about seven degrees is required to detect that the location of a sound source has changed when the source was originally located to the side opposite an ear.

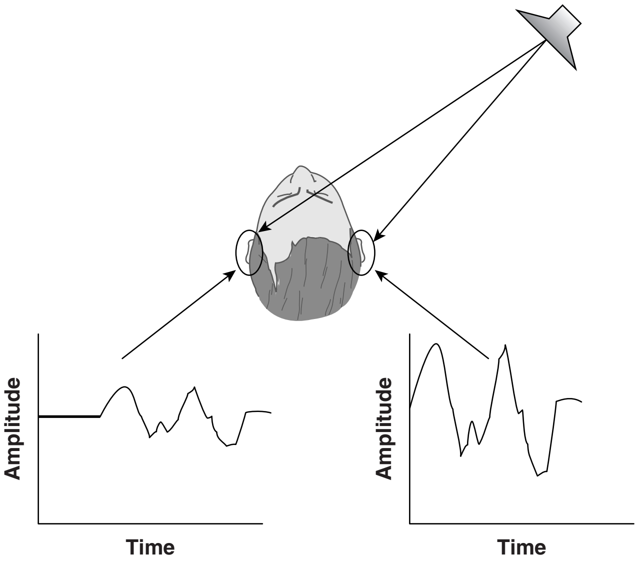

Figure 1 Interaural Differences in Arrival Time and Sound Level

Source: From Yost (2007).

Notes: A sound off to one side of a listener produces an interaural difference in arrival time (interaural time difference, ITD) and an interaural difference in sound level (interaural level difference, ILD).

Vertical Dimension

A sound source located directly in front of a listener and one located directly over head and one located directly behind a listener all are midway between the ears, resulting in all of these locations producing zero ILDs and ITDs. These sound sources are located on the mid-sagittal plane that describes the location of all positions around a listener such that the sources are midway between the ears. The mid-sagittal plane is a cone of confusion because the ILD and ITD cues are all the same value. A cone of confusion is any situation in which the ILDs and ITDs are the same for the spatial location of several different sound sources. This means that ILDs and ITDs cannot be used to determine the location of the sound source positioned on a cone of confusion. Yet, listeners can locate the position of sound sources located on cones of confusion.

The ability to locate the sources of sounds on cones of confusion means that a different set of cues than ITDs and ILDs must be used for localizing the position of sound sources in the vertical dimension and to avoid front–back confusions (confusing a sound source in front for one in back when both sources produce the same ITD and ILD). That is, some other interaction between sound and objects (e.g., the body, head, and ears) in the path of the sound must be used to provide vertical localization cues besides those producing ITDs and ILDs.

As the sound from a source travels across the body, head, and ears (especially the pinna, which are the external parts of the ears), the sound encounters many small obstacles (e.g., ridges in the pinna) that impede and delay its transmission to the ear canals. Thus, the sound arriving at the ear canal is different from that at the source because of the many parts of the body the sound encounters. The sound's spectrum, especially in the high frequencies, is altered as the sound is transferred from its source to the ear canals. A head-related transfer function (HRTF) describes these spectral changes. The levels of high-frequency sounds are especially changed by these various body parts. Exactly how the sound changes depends on the angle of the sound source relative to the ears. Thus, the characteristics of the HRTF, especially in the high frequencies (above 6,000 Hz), depend on the location of the sound source in the vertical direction, and the HRTF is different for a sound source located in front from that located in back of a listener (e.g., the pinna stick out from the side of the head blocking sound coming from a source behind a listener). Thus, features of the HRTF at high frequencies provide potential cues for locating sounds in the vertical dimensions and on cones of confusions. Figure 2 depicts the left-ear and right-ear HRTF amplitude spectra for sound sources occurring at four locations in the mid-sagittal plane. Most of the changes in these spectra as the vertical position of the sound source changes are at high frequencies. Note, for instance, that the frequency of the first noticeable valley in the spectrum (at approximately 7 kilohertz [kHz] for the lowest HRTF spectrum for the left ear) shifts upward in frequency in both ears as the position of the sound source moves up in the vertical direction.

Human listeners are not as good at localizing sounds in the vertical direction as they are at locating sounds in the horizontal direction. Sounds that contain only low frequencies are poorly localized in the vertical dimensions or along cones of confusion because, as Figure 2 indicates, there is little change in the HRTF spectra at low frequencies. Listeners have an especially difficult time separating sound sources located in front from those located behind them (front-back and back-front confusions occur frequently) when the sources are located on cones of confusion. Moving one's head can overcome such confusions, most likely because the auditory system receives several different estimates of ITD, ILD, and HRTF cues as the head moves, and it can interpret these several cues to aid in sound source localization.

Distance Dimension

The ability to locate how far a sound is from a listener is especially poor. Two cues can probably be used to determine the distance of a sound. The loudness of sound varies with distance—the greater the distance between the location of a sound source and a listener, the softer the sound. However, the actual level of a distant sound could be increased, which would increase its loudness even if the sound source's position was not changed. Thus, loudness is only a reliable cue for sound source location if the listener knows something about the expected loudness of the sound—for

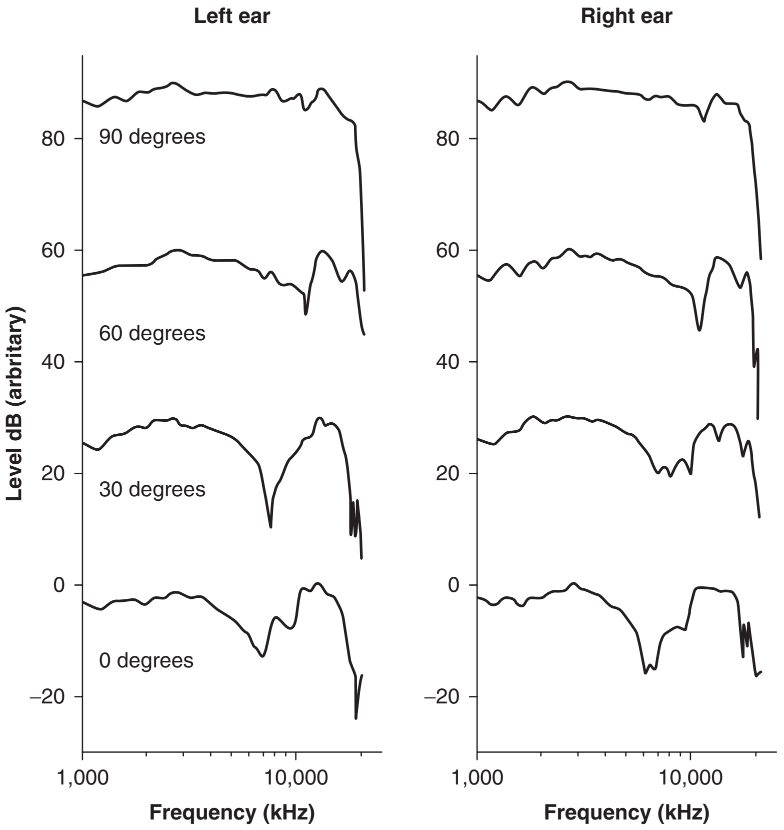

Figure 2 Left Ear and Right Ear HRTF Amplitude Spectra Measured at Four Different Elevations Relative to the Listener's Head

Source: From Yost (2007).

Notes: Note the spectral valley that is around 7 kHz for the 0 degree measurements increases in frequency as the elevation of the sound source rises. This increase in the frequency of the spectral valley may be a cue this listener can use to localize the vertical location of sound sources.

example, for a sound source that is moving away, or a familiar sound, such as a person speaking.

The other potential cue for distance results from the interaction of sound with reflective surfaces the sound may encounter. In a room, a sound source that is close to a listener will arrive at the ears of the listener with a far greater level than sounds arriving from any reflective surface (e.g., a wall) because the sound must travel some distance to the reflective surface and then from the surface back to the ears of the listener (the greater the distance a sound travels, the lower its sound level will be). But, if the sound source in this room is moved further away from the listener, the difference in the level at the listener between the sound from the source and that from the reflective surface is likely to be smaller. Therefore, the direct-to-reflective ratio of sound level is a potential cue for locating the distance of a sound source. Large direct-to-reflective ratios of sound level would be associated with close sound sources. Indeed, locating the distance of sound is better in reflective spaces than in spaces without reflective surfaces (e.g., outdoors). Thus, there are three classes of cues for locating the position of a sound source: interaural differences of time and level (ITDs and ILDs) for localization in the azimuth direction, high-frequency characteristics of the HRTF for vertical localization and that involving cones of confusions, and direct-to-reverberate sound level and, on occasion, loudness for distance.

Lateralization and Localization

The study of sound localization can involve actual sound sources (e.g., loudspeakers and headphones) and variables such as ITDs can be manipulated to determine how the auditory system process a particular cue (e.g., ITDs). Lateralization refers to the perception of sound images when the sounds are presented over headphones and localization is used to describe the perception of sounds from actual sound sources or loudspeakers. Presenting sounds over headphones provides a great deal of experimental control of the variables used in sound localization. In many situations, sounds presented over headphones appear to lie inside the listener's head and to move (e.g., left or right) based on the variable that is manipulated (e.g., an ITD = 0 places an image in the middle of the head, and an ITD = 300 microseconds places the image toward the ear that receives the sound first). Sounds presented via loudspeakers are usually perceived as real sources outside the head out in the real world. That is, sounds presented over headphones are not perceived as actually being out in the real world where actual sound sources exist. Using technology based on HRTFs, sounds presented over headphones can be perceived as if a sound source was at an actual location in three-dimensional space. Such a virtual perception of sound source location requires careful control of the stimuli delivered by headphones to each ear before a veridical perception of a real sound source in the real world can occur.

Localization in Reflective Spaces

In a reflective environment (e.g., a room), sound arrives at the listener from the source but also from the many reflective surfaces. Each reflective surface is like a different sound source. Thus, the auditory system receives sounds from many different locations when the sound source is in a reflective environment. Yet, except in extremely reflective places, listeners are able to accurately judge the location of the actual sound source and are not confused by the sound arriving from reflective surfaces. This fact is referred to as the *precedence effect,* indicating that the sound from the source takes precedence in sound source localization over that from reflective surfaces. This is partially because the sound from the source reaches the listener before any sound from reflective surfaces because the sound from a reflective surface must travel a longer path (from the source to the surface and then to the listener). Thus, the auditory system appears to suppress information about a possible sound source location from later arriving copies (the reflected sound) of the earlier arriving sound from the originating sound source.

Thus, the auditory system uses a variety of cues to localize the source of sounds in many contexts including reflective spaces.

AUDITORY MASKING

Noise is everywhere nowadays. Often, one cannot carry on a simple conversation because it is impossible to hear or to be heard over the din of competing background sounds. What hinders communication in these cases is auditory masking. By definition, *auditory masking* is the ability of one sound to make another sound hard to hear. This entry briefly describes the laboratory techniques for measuring auditory masking, the effects of major factors and their interactions, and the possible causes of auditory masking.

Measurement

In the research literature on auditory masking, the sound to be detected is referred to as the *signal,* and the interfering sound is the *masker.* Audibility of the signal in the presence of the masker is measured through many experimental trials. A typical procedure involves presenting on each trial an instance of the signal-plus-masker and masker alone in random order and having the listener judge which of the two sounds contained the signal. This procedure ensures that any bias the listener might have to overreport or underreport the presence of a signal will not influence the results. After the listener has received a period of practice in the task, the level of the signal is found that produces a criterion level of percent correct detection performance. This level is taken as the *masked threshold* for the signal. The difference in decibel (dB) between the masked threshold and the threshold for the signal in quiet is then taken as a measure of the *amount of masking*.

Effects of Factors

The types of signals and maskers that have been studied most extensively in research on auditory masking are speech, pure-tones, and bands of noise. The amount of masking produced by any one of these sounds depends on a complex interplay of factors involving the sound's intensity and its spectral, temporal, and spatial properties in relation to the signal. Years of research in audition have mapped out in great detail the major effects of these factors and their interactions.

As might be expected, increasing the intensity of the masker generally increases the amount of masking regardless of the type of signal or masker one might choose. The rate of increase, however, is generally greatest when the masker spectrum falls just below the frequency of the signal: an effect referred to as the *upward spread of masking*. If the level of the masker is fixed, the amount of masking will also decrease rapidly as the masker is moved away from the signal in frequency. The rate at which masking decreases provides a measure of the *frequency selectivity* of the auditory system, the degree to which the ear is capable of resolving individual details in the spectrum of sounds.

Sounds also have masking effects that extend over time. *Forward masking* occurs when the masker precedes the signal in time; *backward masking* occurs when the masker follows the signal in time. Little backward masking is obtained for practiced listeners unless the signal is quite brief and the masker follows the signal closely in time. Forward masking, on the other hand, is obtained for much longer duration signals and extends over a much longer period following the offset of the masker. The time course of forward masking provides one measure of auditory *temporal resolution*, the ability of the ear to follow rapid fluctuations in the amplitude of sound over time. Forward masking is also commonly used as a means to study complex processes occurring in the cochlea that are known to affect auditory frequency selectivity.

No less important to masking is the spatial dimension of sound. Everyday experience tells us that the interference among sounds is less when they originate from different locations than when they originate from the same location. This is certainly borne out by research. However, most of the research has actually been conducted with sounds played over headphones to permit precise control over the relevant spatial cues. One important spatial cue is the difference in the time of arrival of the sound at the two ears, referred to as the *interaural time difference* (ITD). Masking is generally less when the ITD of the signal is made to differ from that of the masker. The reduction in masking is referred to as the *binaural masking level difference* and can amount to as much as 15 dB. Such sizable reductions in masking attest to the importance of spatial cues for normal listening in everyday noisy environments.

Other factors affecting masking become evident when sounds are constructed in the laboratory to more closely approximate those encountered in the real world. Trial-by-trial variation in the spectra of maskers, intended to imitate the type of variation found in natural sounds, can significantly elevate masked threshold for a pure-tone signal over the course of trials, even when masker frequencies are prevented from falling anywhere near the signal. Qualitative similarities between signal and masker can have an equally profound effect, as when amplitude fluctuations of the masker covary with the signal over time or when a speech signal is masked by speech versus noise. *Informational masking* is the term often used to describe such masking effects that cannot be accounted for by known factors involving the spectral, temporal, or spatial overlap of signal and masker.

Causes

Auditory masking occurs for different reasons at different levels of the auditory system. If the signal and masker are close in frequency, they will produce overlapping patterns of vibration along the length of the basilar membrane and so compete for the response of the same auditory nerve fibers—a type of *line busy effect*. The masker may also *suppress* the response to the signal at this level because of active processes that are known to occur in the cochlea. Further along in the chain of processing, auditory nerve fibers undergo *adaptation* in response to the masker. Masking may therefore result if the signal occurs before nerve fibers have had time to recover, as in the case of forward masking. Finally, maskers may have effects on *attentional* or *perceptual processes* occurring at a more central level of the auditory system. Such effects are believed to play a role in informational masking though they are not well understood. This continues to be an active area of research.

AUDITORY PROCESSING: CENTRAL

The two main functions of hearing are localization and identification of sounds. *Central auditory processing* deals with the coding of sounds into neural representations in the central auditory pathways, but mostly at the level of the cerebral cortex. In other words, research on central auditory processing is interested in the perception, storage, and (re) cognition for purposes of behavior of different types of sounds, including communication sounds and music. How are the neural codes found and tested? Neural activity patterns in the brain in response to acoustic stimuli can be measured noninvasively (via blood flow and blood oxygenation changes) with functional imaging techniques in humans or, at much greater precision using microelectrodes, with electrophysiological techniques in animals. In addition, this entry addresses what auditory representations may have in common with other sensory systems, such as the visual system, and what may be special about them.

Tonotopic Organization

Since the days of Hermann von Helmholtz, the auditory system has been considered to function primarily as a frequency analyzer. According to work by Georg von Békésy, who was awarded the Nobel Prize in 1961, sound reaching the eardrum generates a traveling wave in the cochlea of the inner ear. Depending on the frequency of the sound, the traveling wave achieves maximum amplitude in different locations along the *basilar membrane* of the cochlea. Thus, sound frequency (from low to high) is translated into a place code, along a tonotopic axis, which is preserved from the cochlea through the processing stations of the brainstem (e.g., inferior colliculus, IC) and thalamus (medial geniculate nucleus, MGN), all the way to the auditory cortex.

Topographic organization in the auditory pathways (*tonotopy* or *cochleotopy*) can be demonstrated with electrophysiological mapping studies using tones of a single frequency (pure tones) and testing the responses of single neurons to such stimuli. Usually, a best frequency can be found that evokes the highest firing rate (or number of action potentials fired) in response to such a tone. At early stages of the central auditory pathways, best frequencies are arranged in an orderly fashion—a tonotopic map. In the primary auditory cortex of humans or monkeys, for example, neurons at its anterior end respond best to low frequencies (a few hundred hertz [Hz]), whereas neurons at the posterior end fire most to high frequencies (10 kilohertz [kHz] or above). Tonotopic organization is analogous to retinotopy in the visual system and somatotopy in the somatosensory system, in the sense that stimuli close to each other along a physical domain are mapped into positions next to each other in the brain. Topographic maps provide for efficiency of coding and shorter wiring of local neural circuits, and they facilitate the orderly development of sensory systems.

Processing of Complex Sounds

One problem that the frequency analyzer theory has not solved is how information from different frequency channels gets integrated, or how an organism analyzes complex sounds, that is, sounds that vary in both frequency and time. Most natural sounds are complex sounds, so solving this problem is of the essence in the analysis of higher auditory pathways. The problem has been tackled successfully in a number of specialized systems, such as frogs, songbirds, barn owls, and echolocating bats. For all these species, a neuroethological approach has been adopted based on functional-behavioral data and use of complex natural sounds for stimulation. The same approach has been used more sparingly in higher mammals, including primates.

The neurophysiological basis in humans for processing complex sounds, such as speech or music, can rarely be studied directly with invasive methods at high resolution, except sometimes before epilepsy surgery. Therefore, animal models, such as cats or nonhuman primates, have to be used. The question then arises to what extent it is valid to apply human speech sounds as stimuli for the study of neurons in animals, when we know that their brains did not evolve to process human speech but communication sounds from their own species. From a biological-evolutionary vantage point, it seems more meaningful, therefore, to employ species-specific vocalizations. In this case, we can be confident that the central auditory system of the studied species must be capable of processing these calls.

When comparing human speech sounds with communication sounds in other species we can see, however, that most systems have certain components in common, that are used as carriers of semantic (meaning-related) information. Among them are brief segments of frequency changing over time (e.g., formant transitions in human speech) or noise bursts with specific center frequencies and bandwidths. Such universal elements, alone or in combination, make up phonemes, that is, the basic units of human speech, but are also common in animal communication sounds. Thus, it is meaningful to use them as stimuli for probing central auditory structures that are intermediate between the primary auditory cortex (where neurons respond best to tones) and what would be considered the language cortex in humans (where more higher-level processing of complex stimuli is carried out). Similarly, to study how the brain processes music, we can start with the use of complex harmonic tones or chords. In the case of both speech and music processing, we would also need to consider how the short constituent elements (syllables, words, and chords) are tied together, at the neural level, to form longer sequences of sounds, such as sentences and melodies. Auditory sequence processing may require the use of the same or similar structures as the programming of motor sequences, including the premotor cortex, basal ganglia, and cerebellum.

Hierarchical Organization and Processing Streams

Neurons selective to the early elements of speech and music have indeed been identified in various species at the next stage of processing, which follows the primary (or *core*) auditory cortex and is often referred to as the auditory *belt* region. The belt surrounds the core areas and, together with the next stage, the *parabelt,* forms the totality of the auditory cortex proper in higher mammals with more than a dozen discrete auditory cortical areas (Figure 1, next page; see legend for abbreviations. See also color insert, Figure 2). In addition, auditory-responsive regions exist in the anterior superior temporal (aST) cortex (extending laterally into the superior temporal sulcus and beyond), premotor cortex, prefrontal cortex (ventrolateral [VLPFC], dorsolateral [DLPFC]), inferior parietal cortex (IPL), and even in the cerebellum (not shown).

Thus, many more auditory cortical areas exist than previously thought, and they are arranged in a processing hierarchy where discrete steps occur at every level. Auditory cortical areas form at least two major processing streams, an anterior-ventral one for the processing of *what* a sound represents, and a posterior-dorsal one for *where* in space a sound source is located (Figure 1; see also color insert, Figure 2). The two main functions of hearing, as defined earlier, therefore seem to be realized in two largely segregated cortical processing streams, similar to what happens in the visual system. Although the role of the ventral stream in object identification is virtually undisputed in either system, some researchers have sought to expand the role of the dorsal stream beyond spatial processing and have postulated its involvement more generally in sensory-guided action (i.e., *how* we perform certain acts).

Hierarchical models sometimes come across as simple feedforward models, neglecting the rich descending pathways at every level, from the cortex back to thalamus and brainstem, and the reciprocity of cortico-cortical connections. However, the existence of back-projections is often inherent in arguments made about *top-down processing,* whereby hierarchically higher structures by virtue of descending pathways influence activity in lower-order

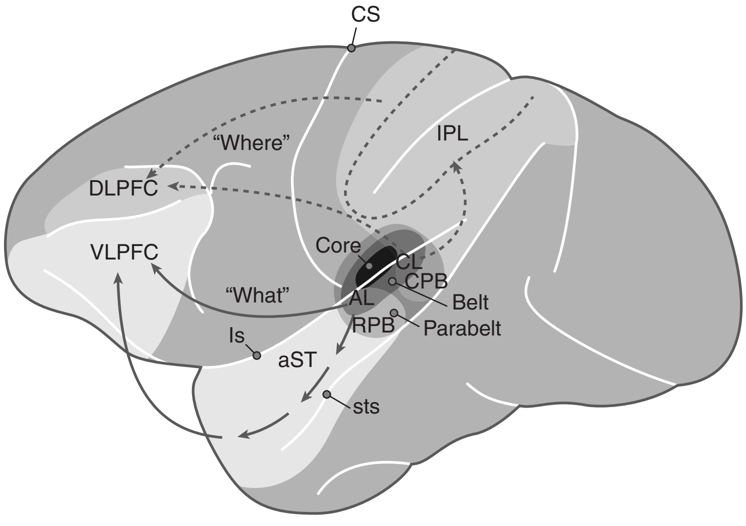

Figure 1 Schematic Illustration of Hierarchical Processing in the Auditory Cortex of the Rhesus Monkey and Processing Streams for "What" and "Where"

Notes: Auditory signals arrive first in the core areas (consisting of the primary auditory cortex, A1, and two rostral areas) from subcortical inputs in thalamus and brainstem. Activity then propagates to the belt (AL, CL, among others) and parabelt areas (rostral and caudal, RPB and CPB, respectively), which give rise to two pathways projecting to two largely segregated regions in the prefrontal cortex (PFC): the ventrolateral and dorsolateral (VLPFC and DLPFC) regions, respectively. The ventral processing stream is also relayed through the anterior superior temporal (aST) cortex, where regions or patches specialized for the processing of voices and communication sounds have been found in both monkeys and humans. The dorsal stream, in addition to its projection to the DLPFC, is relayed also through the inferior parietal lobule (IPL) of the posterior parietal cortex (PPC, particularly the ventral intraparietal region, VIP). Rich back-projections exist from the prefrontal cortex to the PPC as well as to the aST (not shown). See also color insert, Figure 2.

stations. Descending pathways also are able to adjust the response properties of neurons at lower levels and therefore mediate many forms of auditory plasticity.

Auditory Object Identification

This entry now discusses the processing hierarchy in the anterior-ventral auditory "what"-stream. Most notably, in the lateral belt areas of the superior temporal (ST) region in rhesus monkeys, a large proportion of neurons selective to brief frequency changes as well as neurons tuned to certain bandwidths of noise or combinations of tones have been found. When tested with whole monkey vocalizations, more neurons are found in the anterior than in the posterior part of the lateral belt that respond selectively to these calls. In the anterior parabelt and adjacent ST regions of rhesus monkeys, even more neurons respond well and quite selectively to monkey vocalizations. A region anterior and lateral to the primary auditory cortex also contains neurons that respond to the pitch of a complex tone even when the fundamental frequency is removed. The existence of such "pitch neurons" is important because pitch is critical for identifying and segregating auditory objects, especially in the context of music and speech.

The question arises by what neural mechanisms such selectivity for complex sounds is generated. Studies in which monkey calls are dissected into their constituent elements (both in the spectral and temporal domains), and the elements are then played to the neurons separately or in combination can provide an answer to this question. A sizable proportion of neurons in the anterior lateral belt respond much better to the whole call than to any of the elements. These results are indicative of nonlinear summation (*combination sensitivity*) in the frequency and time domain playing a crucial role in the generation of selectivity for specific types of calls. Similar mechanisms had previously been described in bats and songbirds. Coincidence detection in the time domain is perhaps the most important mechanism in shaping this selectivity. Temporal integration, the time window during which inputs are summed, extends 100 to 200 milliseconds, which fits well with the fact that most "syllables" in monkey calls (as well as in human speech) are of that duration.

Neuroanatomical studies have shown that anterior lateral belt projects to the VLPFC, which also receives visual projections and has a function in object working memory. Categorization of communication sounds and the solution of the invariance problem (i.e., the fact that we can recognize a particular speech sound regardless of pitch or accent of the speaker's voice) may be performed with the help of VLPFC. Thus, the lateral belt areas are not the ultimate stage in the processing of communication sounds. They only present an intermediate stage, similar to areas in the visual system that contain neurons selective for the size of visual stimuli. Visual cortical neurons selective for more specific objects, such as faces, are not found until even higher processing stages. In the auditory cortex, areas in the anterior ST regions (as part of the ventral processing stream) are the ones that seem to specialize in the processing of auditory objects, including voices and vocalizations. Functional magnetic resonance imaging (fMRI) studies in monkeys have confirmed the existence of a prominent patch in the anterior ST region that is activated selectively by species-specific communication calls. In humans, the anterior ST region (not its posterior part, as had previously been thought) also contains a processing hierarchy for phoneme identification as well as a "voice center" for the identification of human voices.

Auditory Space Processing

The second main task of hearing is to localize sound sources in space. The auditory periphery (the basilar membrane with its inner and outer hair cells), however, cannot a priori encode a two-dimensional (2-D) spatial signal, as do the visual and somatosensory peripheries (retina and skin surface, respectively), because it extends only along a single dimension. Auditory space, therefore, has to be computed from attributes of sound that vary systematically with spatial location and are thus processed differentially by the central auditory system. This problem is logistically similar to the computation of three-dimensional (3-D) spatial information from 2-D sensory information in the visual system, where the 2-D signals from each retina are combined to render 3-D perception (stereoscopic vision). Sound attributes most commonly assigned to spatial quality are differences between sound arriving at the two ears. Both the intensity (level) and the time of arrival of sound originating from the same source differ when the sound source is located outside the median plane, such as to the left or right. A sound to the right reaches first the right ear, then the left (and vice versa), which leads to an interaural time difference (ITD). Sounds are also less intense on the other side of the head, which leads to an interaural level difference (ILD). ITD and ILD are registered and mapped already in areas of the brainstem, such as the superior olivary complex, and are passed along to higher centers, including the cortex, from there. In addition to these binaural cues, monaural spectral information contributes to auditory space perception: The frequency composition of a sound arriving at the eardrum from different directions in space varies because the external ears (pinnae) and the head have certain spectral filter characteristics. In other words, sound bouncing around in the pinnae leads to the amplification of certain frequencies and the attenuation of others. Specific spectral "fingerprints" can be assigned to different spatial locations, with attenuation of particular frequency bands ("spectral notches") varying systematically with azimuth (left/right) or elevation (up/down). Spectral cues are the most important cues for determining the elevation of a sound and for resolving front/back confusions, where binaural cues would be identical.

The information computed by lower brainstem structures is used by higher centers of the midbrain, such as the inferior and superior colliculi, to guide orienting movements toward sounds. For more "conscious" spatial perception in higher mammals, including humans, however, the auditory cortex is indispensable, as cortical lesions almost completely abolish the ability to judge the direction of sound in space. Neurons in the primary auditory cortex show tuning to the spatial location of a sound presented in free field. Many more neurons that are sharply tuned to spatial location are found in the posterior (or caudal) regions of lateral belt and parabelt of monkeys. Lesions in these regions cause a marked deficit in sound localization, whereas lesions in anterior parts of the belt cause auditory pattern recognition deficits. Functional neuroimaging studies in humans also demonstrate specific activation in the posterior auditory belt and parabelt (leading into the inferior parietal cortex) while subjects localize sounds in space or listen to sounds moving in space.

Neuroanatomical studies confirm that posterior lateral belt gives rise to a processing stream that is largely segregated from the one originating in anterior lateral belt: the posterior lateral belt projects to the DLPFC, which is known to be important for spatial working memory.

Dual Processing

Both animal and human studies suggest that information about auditory patterns or objects is processed, among others, in the aST region. By contrast, auditory spatial information is processed mainly in posterior ST and parietal regions of the cortex. Both pathways continue into the PFC, where they innervate largely segregated target regions in the ventrolateral and dorsolateral PFC, respectively. This dual processing scheme is reminiscent of the visual pathways, where a ventral stream has been postulated for the processing of visual object information and a dorsal stream for the processing of visual space and motion. Of course, in neither system is the separation between functional streams complete. Whether one thinks of such "crosstalk" as technical imperfection or necessary convergence of information is a matter of interpretation. There are also alternative accounts of this functional segregation in both sensory systems, which argues more for perception than action. In this view, the role of the dorsal stream would be extended from purely spatial processing to providing feedback in auditory-motor transformations.

AUDITORY PROCESSING: PERIPHERAL

The auditory periphery—the outer ear, middle ear, and inner ear—is designed to collect and amplify sound waves and to separate their different frequencies into nerve pathways that can allow the brain to determine the meaning of a sound (see color insert, Figure 3). This conduction pathway is crucial to surviving in a rich auditory environment. This entry first describes the process of sound conduction and then discusses the elements of the auditory periphery.

Sound Conduction

The vibrations caused by sound stimuli are converted by the auditory system into electrical signals that are sent along the auditory nerve to the brain. The outer ear and middle ear ensure that the vibrations are transmitted efficiently to the inner ear where fluid movements occur that can be detected by the sensory apparatus in a way that means that different frequencies and amplitudes can be distinguished; these two sensations correlate with the pitch and the loudness of the sound. This process relies on a sensory structure called the organ of Corti that rests on the basilar membrane. (The cochlea is a spiral-shaped structure shaped like a snail-shell, hence its name, which is taken from the Greek word for "snail"). The basilar membrane vibrates in response to the fluid movements set up in the cochlea by sound.

The final conversion of these vibrations into electrical signals is performed by sensory cells called hair cells that are embedded in the organ of Corti. At various stages along this pathway, the vibrations are selectively amplified giving rise to fine frequency discrimination and to a wide sensitivity range.

The Outer Ear

The protrusions at the sides of our heads that most of us think of as our ears are called pinnae; these structures are the first stage of the auditory pathway, the outer ears. An inner funnel-like entrance leads to the external auditory canal. Some animals (e.g., cats) can move their outer ears to direct them toward a sound source more effectively. Most humans cannot move their outer ears but nevertheless the reflection of sounds caused by their shape leads to significant information being sent to the brain about where a sound is located in space, especially about whether it is coming from in front of or behind or one or the other side of the head in the horizontal plane.

The tapered shape of the auditory canal, the tube that conducts sound into the head (the outer side is wider than the inner side) slightly increases sound transmission to the eardrum (tympanic membrane) and, in different animals, the length and cross-sectional areas of this external auditory canal favor different frequencies, that is, sensitivity to low, middle or high notes. In humans, this favored frequency is near that used in speech, 1 to 2 kilohertz (hertz are the number of sound wave cycles that occur per second).

The Middle Ear

The *tympanic membrane,* a translucent white (when healthy) membrane, is the boundary between the outer ear canal and the middle ear. On its inner side, the tympanic membrane is connected to one of a chain of small bones called *ossicles* that transmit the vibrations set up by sound through the middle ear to the inner ear. The ossicles connect the tympanic membrane to another membrane called the oval window membrane that vibrates the fluids in the inner ear. The difference in the size of the larger tympanic membrane to the oval window membrane results in an amplification of sounds by approximately 17 times. The tympanic membrane is susceptible to injury by high sound levels (e.g., explosions) but can recover from lower levels of damage.

The three ossicles are called (from the outermost to the innermost) the *malleus* (Latin for "hammer"), the *incus* ("anvil"), and the *stapes* ("stirrup") because of their respective shapes. They are attached together by cartilage, and muscles—the tensor tympani and the stapedius—suspend the ossicles from the skull lining of the middle ear. The muscles have separate nerve connections with the brain, but their simultaneous activation can contract them and lead to "locking" of the ossicular chain. This middle ear reflex helps to prevent loud sounds from causing damage to the inner ear.

The middle ear is otherwise an air-filled cavity that is kept at the same air pressure levels outside the skull by means of the Eustachian tube, which runs from the middle ear to the mouth. If this tube is blocked by saliva, "popping" of the eardrum (rapid movements) can be detected if the external air pressure changes such as during the ascent or descent of aircraft. These are not normally dangerous but sometimes can be alarming. However, if bacteria enter the middle ear by means of this route, infections can occur that lead to a build-up of pus that prevents the ossicular chain of bones from moving. This condition is termed *glue ear* and is a common cause of hearing impairment in small children. It is treated by allowing air back into the middle ear by the insertion of grommets (small ring-like devices) that hold open gaps made surgically in the eardrum. As the bacteria are anaerobic, this influx of fresh air helps to destroy them. The grommets can then be removed and because the holes that have been made are small and carefully placed, the eardrum can heal over when they are removed.

Another problem that can occur in the middle ear is ossification (bone overgrowth) of the ossicles, primarily with ageing. The ossicles can sometimes be replaced with artificial, often ceramic, substitutes that can help to restore the transmission of the vibrations set up by sound in the middle ear.

The Cochlea

The cochlea is a spirally fluid-filled tube; it is coiled to save space in the skull. When sound vibrations result in movements of the ossicles in the middle ear, the vibrations are transmitted to the cochlear fluids by these bones pressing on a membrane stretched across an opening in the bone at cochlear base called the oval window. The fluid movements in the cochlea cause vibration of the basilar membrane, which runs along the length of the cochlear tube.

The basilar membrane changes in its physical characteristics along the cochlea. Researchers have known since the 1930s that the basilar membrane's mechanics result in the conversion of the sound frequency to coding as a position of excitation along its length, a process that results in a tonotopic (sound-to-place) map. The main discovery was made by Georg von Békésy in the 1930s. He observed that the stiffness of the basilar membrane was greater toward the basal (middle ear) end of the cochlea than at its apex. The stiffness of the basilar membrane is graded and, as a result, different sound frequencies, although they set up a "traveling wave" along the basilar membrane, cause maximal vibrations at different points along the basilar membrane. Low frequencies vibrate the membrane most at the apex of the cochlea and high frequencies most at the base, with intermediate frequencies being represented systematically along its length.

Another membrane, Reissner's membrane, stretches from the center of the cochlea to the side of the cochlea attaching to its outer wall above the basilar membrane. Thus, the cochlea has three fluid filled compartments, the central one of which is filled with a different fluid from the other two. This central fluid is called *endolymph;* it is rich in potassium ions and importantly contains calcium ions. The other two compartments, the scala vestibuli and scala tympani, contain a fluid called *perilymph.* The principal ions in perilymph are sodium ions, and the difference in the ionic composition of the endolymph and perilymph sets up an electrical gradient that is necessary to the operation of the sensory cells of the cochlea. These cells are embedded in a sensory structure called the organ of Corti. They are called *hair cells* because protruding from their apical surface are bundles of tiny protrusions called *stereocilia* that early observers thought were hairs but that are actually modified microvilli. When the basilar membrane is deflected by fluid waves in the cochlea, deflection of the stereociliary bundles produces electrical signals in the body of the hair cell to which they are attached. This is because the shape of the bundles results in the opening of ion channels in the tips of the shorter rows of stereocilia. Potassium and calcium ions flow in rapidly depolarize the hair cell (making the electrical charge inside the cell more positive). This electrical change causes the hair cell to increase the rate of firing of the nerve fibers from the auditory nerve that are connected to its base. This process is known as mechanoelectrical transduction because a mechanical signal (sound vibration) is converted into electrical signals that can be sent to the brain. This is basically a rapid switch mechanism by which the nervous system turns a mechanical stimulus into a nerve signal to the brain. The calcium ions close the mechanoelectrical transduction channels as they enter the stereocilia, a mechanism that enables the hair bundles' sensitivity to be reset via a mechanism called adaptation. This process preserves the response of the hair bundle to deflection even if they are already deflected. A second slower mechanism also occurs that regulates the tension being placed on the mechanoelectrical transduction channels by moving the upper attachment point of the tip link along the side of the stereocilium. It has been suggested that this motion is driven by the climbing and slipping of a protein called myosin (which is also involved in muscle contractions) along the actin core of the stereocilium.

There are four rows of hair cells. One row is nearest to the central spire of bone in the cochlea, the modiolus; these are called the inner hair cells. Three rows lie toward the outer edge of the organ of Corti, the outer hair cells. These cells have different functions. The inner hair cells have large numbers (16–20) of nerve fibers attached to their bases that conduct electrical signals along the auditory nerve to the brain. The outer hair cells have fewer of these afferent nerve endings (terminals that send information to the brain) and instead receive signals from the brain that affect their activity from the efferent nerve terminals. The inner hair cells are principally responsible for conveying information about characteristics of the sound that is conducted from the cochlea to the brain. The outer hair cells boost this signal in a frequency specific way by rapidly changing their length; they exert contractile and extensible responses into the basilar membrane at the frequencies being transmitted in the sound. This mechanism only works in living animals because the outer hair cells need to be physiologically active to produce these movements. This process is known as the *cochlear amplifier* because the muscle-like responses of the outer hair cells increase the movement of the basilar membrane at appropriate points along its length, thus boosting the signal at the correct frequency position and decreasing the response at the remaining points and increasing the basilar membrane's ability to separate different frequencies. The outer hair cells thus amplify the sound signals in the inner ear for whichever frequencies they are detecting, an important function because most environmental sounds are complex; that is, they consist of many frequencies that determine their meaning in the brain.

AUDITORY RECEPTORS AND TRANSDUCTION

Hearing begins with the transduction of sound energy into electrical signals in the inner ear, through a sequence of events so fast and sensitive as to be limited only by the thermal noise of molecules moving in inner ear liquids. This entry reviews that sequence with particular focus on the remarkable properties of auditory receptor cells.

Sound originates in the motion of vibrating objects, such as the vocal cords during speech. The vibration energy—a form of mechanical energy—is transmitted to air molecules and thence to the eardrum. Vibrations of the eardrum in turn move the bones of the middle ear, which push in and out, piston-like, on the liquid-filled chambers of the hearing organ in the inner ear. The mammalian hearing organ, called the cochlea, is coiled in a spiral of several loops. Membranes running the length of the cochlea subdivide it into three tubes, or chambers, filled with liquid. The bone enclosing the upper and middle chambers has membranous, elastic windows in it. Middle ear bones push in and out on the upper chamber's window, creating pressure changes that deflect the elastic middle chamber and distend the window on the lower chamber.

The middle chamber (see color insert, Figure 3a) houses a long sensory epithelium (the organ of Corti) containing thousands of auditory receptor cells, called hair cells for their most striking feature: a "hair" bundle of fine, interlinked columnar structures. The hair cells form four long rows on top of the bottom (basilar) elastic membrane of the middle chamber. As illustrated in Figure 3(a) in the color insert, sound-driven motion of the basilar membrane bends the hair bundles against a delicate tectorial membrane. Viewed along the length of the cochlea, the motion of the basilar membrane takes the form of a traveling wave, which peaks at different places for different sound frequencies. The hair cells convert the mechanical energy of hair-bundle bending into electrical signals called receptor potentials. The electrical signals are transmitted from the inner ear to the brain via auditory nerve fibers (color insert, Figure 3a).

The mammalian cochlea has a single row of inner hair cells and three or more rows of outer hair cells (color insert, Figure 3a). Despite the small number of inner hair cells, it is their sound-evoked signals that are conveyed to brain neurons. Inner hair cells transmit signals to auditory nerve fibers across specialized points of close contact called synapses (color insert, Figure 3b), stimulating the brief electrical events (action potentials) that neurons commonly use to transfer information over long nerve fibers. The sound-evoked action potentials travel along auditory nerve fibers to neurons in hearing centers in the brain.

Outer hair cells are unique to mammals. Surprisingly, given their large numbers, they have weak contacts with auditory nerve fibers. Nevertheless, they are essential to good hearing. They amplify sound-evoked motions within the cochlea by a remarkable mechanism, electromotility, which refers to the fact that the outer hair cells change their length in response to movement of the cilia. The resulting amplification of the motion of the basilar membrane is considered critical for the unusual high-frequency capability of the mammalian ear. Other vertebrates can hear sound frequencies ranging from about 0.1 kilohertz (kHz, thousands of cycles per second) to as high as 10 kHz in some birds. Children can hear frequencies as high as 20 kHz (until hearing damage sets in), and other mammals can hear up to 50 or even 100 kHz. The entire frequency range is represented smoothly along the cochlear spiral such that the highest frequencies strongly activate hair cells at the base, next to the middle ear, and the lowest frequencies strongly activate hair cells at the top of the spiral. This systematic variation in the most effective sound frequency (best frequency or characteristic frequency) with cochlear location arises from smooth variation in the properties of the basilar membrane and hair cells.

Outer hair cells are important targets of negative feedback from the brain to the ear. Efferent signals originate in brain neurons and travel along different nerve fibers from those carrying afferent signals from the ear to the brain. Inside the cochlea, efferent signals are transmitted across synapses to afferent nerve fibers and to outer hair cells (color insert, Figure 3a). By these connections, brain neurons can reduce the electrical activity of auditory nerve fibers or the amplifying effect of outer hair cells on afferent signals.

To recapitulate, hearing begins with translation of the mechanical energy of sound into hair-bundle deflections. The hair cells transduce the deflections into electrical signals, which are amplified by outer hair cells, modulated by efferent feedback, transmitted to auditory nerve fibers, and conducted to the brain. Hearing requires further processing of the incoming signals by specialized centers in the brain; nevertheless, many important properties of hearing are determined or shaped by the inner ear. To appreciate this, we first consider in more detail how hair cells transduce the energy of sound into receptor potentials and transmit these signals to auditory nerve fibers.

Mechanoelectrical Transduction and Synaptic Transmission by Inner Hair Cells

The initial stages of transduction take place within the stereocilia, the columnar components of the hair bundle. Stereocilia are arrayed in rows of graded heights between about 1 and 10 micrometers (color insert, Figure 3c). Deflections of the hair bundle toward the tallest row are excitatory (positive); opposing deflections are inhibitory (negative); orthogonal deflections have no effect. Sound deflects the hair bundle back and forth along the preferred axis, stimulating a change in the electrical current flowing into the hair cell. This transduction current in turn changes the voltage across the hair cell's membrane, producing the receptor potential.

How does deflecting a hair bundle evoke a transduction current? The current is carried by positively charged potassium and calcium ions from the liquid bathing the hair bundle (color insert, Figure 3c). The ions enter the stereocilia through pores in special proteins (transduction channels) in the stereocilium's surface membrane. Even when the bundle is at rest, the transduction channels are open some of the time, allowing a small inward current. Deflecting the bundle positively further opens the channels, increasing the inward current. According to a widely cited model of hair cell transduction, positive deflections stretch hypothetical elastic structures, referred to as gating springs, which pull the transduction channels open. Negative deflection relaxes the gating springs, allowing the channels to close and so decreasing the inward current. Figure 3(c) in the color insert illustrates this idea in cartoon images by showing springy structures (gating springs) attached to trap doors (gates) on the external surfaces of the transduction channels. Two channels are shown closed and two are shown open with potassium ions moving through them.

The increased influx of positive ions during an excitatory stimulus creates a positive receptor potential across the hair cell membrane. The receptor potential secondarily affects the flow of current across the hair cell membrane through channels that open in response to voltage change rather than mechanical energy. These additional currents have several important effects on the afferent signal. They affect the time course of the receptor potential. The extra open channels also reduce the electrical resistance of the hair cell membrane, expanding the frequency range over which the receptor potential can follow the stimulus. One class of voltage-gated channels is critical to the transmission of the sound-evoked signal across the synapse. Voltage-gated channels that selectively pass calcium (color insert, Figure 3c) translate the receptor potential into calcium changes inside the hair cells. During a positive receptor potential, the calcium channels open and entering calcium ions activate the secretion of transmitter molecules (glutamate) from the hair cell onto the afferent nerve ending. Similar events occur at excitatory synapses throughout the brain, although transmission from hair cell to afferent neuron is remarkable for its high speed and volume. The secreted glutamate molecules cross the synaptic gap to bind to another type of ion channel, glutamate receptor channels, in the membrane of the auditory nerve fiber. The channels open, admitting positive ions into the nerve fiber; the positive voltage change then triggers action potentials. Thus, a cascade of steps involving mechano-sensitive, voltage-sensitive, and glutamate-sensitive ion channels converts the deflection of the hair bundle into the common neural code: a change in the number of action potentials per second.

Experiments that isolate components of this cascade have characterized properties, such as sensitivity and speed, that set limits on our hearing capabilities. Hair cell transduction is studied by viewing the hair bundle through a microscope and recording transduction currents with a miniature electrode while deflecting the hair bundle with a fine glass probe. Hair cells produce measurable responses to angular deflections of less than one degree. This extraordinary sensitivity allows us to detect sound intensities that move the basilar membrane by less than 1 nanometer (nm). Indeed, thermal (Brownian) motions of the cochlear liquids are the limiting noise within the system. At mammalian body temperature, transduction channels open within microseconds (10^{-6} s) of the start of a deflection, allowing such hearing specialists as sonar-using bats and certain whales to hear up to 60 to 100 kHz. The short latency is possible because of the directness and efficiency of the mechanoelectrical transduction process; the multistage transduction mechanisms of photoreceptors and olfactory neurons take much longer.

Positive hair-bundle deflections elicit transduction currents as much as tenfold larger than negative deflections of the same size. Surprisingly, this asymmetry is critical for our ability to hear at high sound frequencies. This can be seen by considering the receptor potential response to pure tones, which have a sinusoidal waveform that deflects the hair bundle back and forth symmetrically. For low-frequency tones, the transduction current and receptor potential oscillate at the same frequency as the tone. As tone frequency increases above about 1 kHz, the oscillations of the transduction current become too fast for the receptor potential to follow, so that the voltage oscillations get smaller and smaller. Because of this effect, hearing would fade away with increasing frequency above several kHz if transduction current were symmetric. Instead, the asymmetric transduction current is integrated by the membrane to produce a steady positive receptor potential, allowing us to hear at frequencies that are too fast for our receptor potentials to follow in time.

When the hair bundle is rapidly deflected to a new position and held there, transduction current activates within microseconds but then decays (adapts) with a time course ranging from tens of microseconds to tens of milliseconds. Sustained bundle deflections do not occur in the cochlea but low-frequency sounds do move the bundle slowly enough to trigger significant adaptation. Adaptation is a ubiquitous feature in sensory systems, reflecting the evolutionary advantage in emphasizing novel stimuli over background stimuli. Calcium ions that enter open transduction channels as part of the transduction current (color insert, Figure 3c) activate at least two processes that tend to close the channels. In addition to reducing the transduction current (hence, adaptation), closing the channels affects the overall stiffness of the hair bundle and therefore how much it responds to a new stimulus. This effect is most pronounced for stimuli with a similar time course as the calcium-mediated channel closure. In this way, adaptation processes help tune the hair cell to stimuli with a certain time course—that is, in a specific frequency range.

Amplification by Outer Hair Cells

Outer hair cells enhance cochlear sensitivity via a unique process that transduces receptor potentials into motions of the hair cell body. The underlying mechanism may be a voltage-induced change in the size of prestin molecules in the outer hair cell membrane. The moving outer hair cells exert force on the basilar membrane, amplifying the relative motion between basilar and tectorial membranes and therefore the deflection of the bundles of inner hair cells. The summed vibrational effect is so large that it can be detected as a sound in the outer ear canal. Measurement of these "otoacoustic emissions" is now used to screen infants for hearing loss originating in the cochlea.

AUDITORY SCENE ANALYSIS

When we listen, we effortlessly hear the separate sounds of our environment—voices, musical instruments, cars—each coming from its appropriate direction and having its own characteristic qualities such as pitch and timbre. This simple perceptual experience is the result of the complex brain mechanisms of auditory scene analysis (ASA), described in this entry. ASA addresses the problem of grouping together those frequency components that have originated from the same sound source, thereby separating them from other sounds that happen to be present at the same time. The problem of ASA can be conceptually divided into two parts: deciding which simultaneous frequency components belong together to form a sound source, and then sequentially tracking a particular sound source across time. These mechanisms make it possible for us to function in an auditorily cluttered environment by perceptually separating sounds that are physically mixed together in the sound waves that enter our ears. The limits of our ability to separate different sound sources are exploited in music, and our inability to fully understand the processes involved impairs the automatic recognition of speech by computer, and the effectiveness of hearing aids.

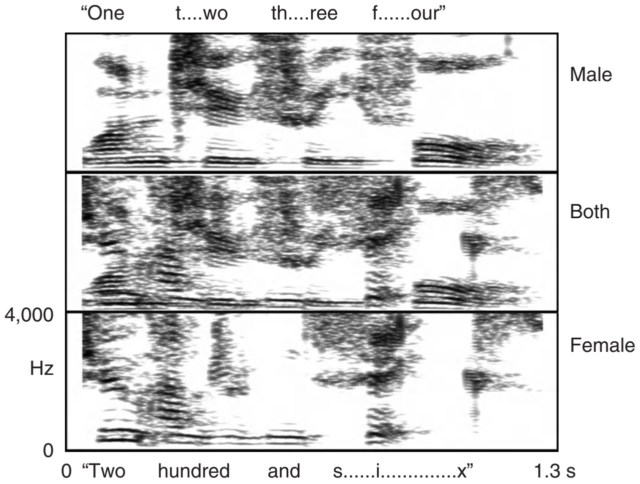

Figure 1 Narrow-Band Spectrograms

Notes: (Top) a male talker saying "One two three four"; (bottom) a female talker saying "Two hundred and six," and (middle) both utterances mixed together. The darker the spectrogram, the more energy there is in the sound at a particular frequency and time. The horizontal axis is time; the vertical axis frequency goes as high as 4,000 Hz. The roughly horizontal parallel thin dark lines denote the harmonics of the voice, closely spaced for the low-pitched male voice and more widely spaced for the higher-pitched female. The difference in pitch helps the brain perceive the two separate sounds in the mixture.

As an example of our ability to separate simultaneous sounds, Figure 1 shows spectrograms of three sounds. A spectrogram plots as a function of time how much energy is present in a sound at different frequencies; it broadly represents the pattern of activity that sound produces in the inner ear and that is signaled to the brain by the auditory nerve. The upper spectrogram is of a male voice saying "One two three four," the lower spectrogram is of a female voice saying "Two hundred and six," and the middle spectrogram is of those two sounds added together. When we listen to this mixture, we clearly hear the two voices as separate yet simultaneous sounds, and we have no difficulty in following a particular voice over time. Yet it is not obvious to the eye which parts of the mixture belong to one voice and which to the other. The brain uses a variety of cues to pull apart these two sounds from the mixture.

Simultaneous Grouping: Harmonic Structure and Onset Time

One of the cues that is useful for both speech and music is harmonic structure. Any sound apart from a pure tone (resembling a whistle) consists of many different frequencies. For a sound with a distinct pitch, such as a musical note, or a sung or spoken vowel sound, these frequencies will all be whole-number multiples (harmonics) of the fundamental frequency. So, for example, when the oboe plays the A above middle C to tune-up an orchestra, its sound contains frequencies that are all multiples of 440 Hz—it has a harmonic spectrum. If the oboe played the A an octave lower, then the fundamental would be 220 Hz and the harmonics would all be multiples of the lower fundamental of 220 Hz. The harmonic structure of the voiced parts of male and female speech is visible in the spectrogram of Figure 1. The harmonics appear as groups of roughly horizontal parallel lines. For the male voice, these are closely spaced, reflecting its low pitch; for the higher-pitched female voice, they are more widely spaced. The brain is adept at separating mixtures of differently spaced harmonics, as for example at the beginning of the mixed spectrogram where the low-pitched male voice and the high-pitched female voice are sounding simultaneously. If two voices are speaking or two instruments playing on the same pitch rather than on different pitches, it is much harder to separate them because their harmonic frequencies coincide.

Natural sounds that do not have a distinct pitch are less constrained in their frequency content: They may have a continuous range of frequencies rather than a set of discrete harmonically related frequencies. For example, the "f" of "four" in the male speech or the "s" of "six" are noisy, unvoiced sounds and so do not show harmonic structure—there are no parallel horizontal lines on the spectrogram. One of the cues that the brain uses to separate mixtures of sounds like these is the common onset time of a group of frequencies. The "t" of "two" in the male speech of Figure 1 is an example. The abrupt increase in energy of some of the frequencies in the sound mixture indicates that a new sound has started, and the brain then hears those frequencies that have abruptly increased in energy as a new sound in addition to the continuation of the sound that was previously present (the "un" of hundred" in the female voice). This principle has been called the *Old+New heuristic* by Albert Bregman. Harmonicity and common onset-time are examples of relatively simple, low-level properties of sound that the brain uses to help to segregate into separate sources the mixture of sounds that is occurring at a particular time.

Music exploits both our abilities and our inabilities to separate sound sources. Sometimes the composer wants us to hear separate sounds, at other times the composer wants us to hear different sounds blend into a single composite sound. Polyphonic music, such as a Bach fugue in which there are two or more separate melodic lines, strives to keep each of the different voices distinct to the listener; music students are taught the principles of "voice leading," which if followed help listeners keep the different voices of the music perceptually separate. David Huron has demonstrated the close links between these musical principles and the results of well-controlled psychological experiments on listeners' abilities to separate simple sounds. For example, voicing leading principles prohibit simultaneous pairs of notes from occurring in consecutive unisons, fifths, and octaves. Sounds at these consonant intervals tend to blend because they have many harmonics in common. For the unison, all the harmonics are in common; for the octave, every harmonic of the higher note coincides with every even harmonic of the lower note. The perfect fifth (for example, from C to G) has a frequency ratio of 3:2 so every third harmonic of the lower note is at the same frequency as every second harmonic of the higher note. When two sounds are played on less consonant intervals (such as the minor third), or if they start at different times, then they are much easier to keep perceptually distinct. Polyphonic music thus avoids sounds that have the same onset time and similar harmonic structures.

On the other hand, composers frequently capitalize on our inability to separate sound sources to create a novel timbre or sound quality that fuses two or more separate instruments. At the beginning of his *Unfinished Symphony,* Schubert merges the sound of the oboe and clarinet playing in unison to give a novel timbre that does not sound like either instrument. Played badly, out of time or tune, the timbres of the individual instruments emerge. Another example is the "12th" or "octave quint" organ stop, which produces a tone at an interval of a 12th (octave plus 5th, giving a frequency ratio of 3:1) above the note played on the keyboard. When coupled with a traditional stop, the "octave quint" stop thus adds a tone at triple the frequency of the original note. The harmonics of this higher note thus coincide with every third harmonic of the original and so simply modify the timbre without producing the impression of a separate pitch. Were the "12th" to be sufficiently out of tune (or out of synchrony) with the original played note, it would stand out as a separate note at the higher pitch and both notes would maintain their original timbre.

Common harmonic structure and a similar onset time are examples of heuristics that are used to group sounds into simultaneous wholes. They contribute to what Bregman in his influential 1993 book, *Auditory Scene Analysis,* describes as low-level grouping cues. These cues are simple properties that are more likely in components that originate from a common sound source than in those that have come from independent sources. Although their use does not guarantee a complete and appropriate organization of sounds, it provides a better starting point than the raw mixture.

An interesting current experimental question is to what extent the transformations that take place early in auditory processing (for example in the cochlea, the brain stem, and the mid-brain) facilitate such low-level grouping.

Sequential Streaming: Continuity

So far, this entry has looked at how the brain separates the mixture of sounds that is occurring at a particular time into appropriate groups that correspond to different sources. Another aspect of ASA is the problem of how we track a *particular* sound source across time to produce a single auditory stream. The problem is illustrated in an early paper from 1950 by George Miller and George Heise on the trill threshold. When two notes of similar timbre but different pitch alternate, the sequence can be heard in two ways: either as a trill—a single auditory stream rapidly varying in pitch, or as two separate streams each consisting of repetitions of one of the pitches. If the two notes are close in pitch, as is the case with a musical trill, a single, trilling, stream is heard. But if the notes are wide apart in pitch but still played rapidly, then the single stream splits into two, and you hear a sequence of repeating high notes, together with a sequence of repeating low notes. The faster the repetition rate of the notes, the closer together in frequency must the two pitches be to maintain the single stream, trill percept. The brain interprets large discontinuities in pitch in terms of different sound sources.

Abrupt discontinuities in other sound properties can also produce a similar split into different streams. David Wessel demonstrated such an effect with changes in timbre. The sounds he used are illustrated in Figure 2.

The upper panel A of Figure 2 illustrates the pitches of a sequence of notes played on the same instrument (solid lines). It is heard as a rapidly repeating ascending three-note figure. If the alternate notes are now played on a different instrument (dashed lines), the percept is dramatically changed. Now each instrument forms a separate stream. The rapid ascending figure is no longer heard, but instead each instrument plays a descending figure at half the original speed. A similar result can be obtained if the solid and dashed notes denote different spatial positions rather than different instrumental timbres.

In the 1970s, Bregman demonstrated an important consequence of this sequential streaming: Listeners find it much more difficult to tell the order of individual notes across streams compared to within streams. For example, in Figure 2, listeners would hear clearly whether the second note came before or after the third in the top panel, but would find it difficult in the lower panel because the two notes are heard in different streams.

Sequential streaming takes a few seconds to build up. Overcoming our initial default assumption of a single source requires accumulating evidence. A surprising result from Robert Carlyon and Rhodri Cusack's research is that attention is necessary for this accumulation to take place; if the sequence of tones is presented as an unattended background to a primary task, such as watching a video, no accumulation of evidence takes place. The result is surprising within Bregman's framework, which proposes that low-level grouping takes place pre-attentively, and has led to suggestions that unattended auditory material might undergo only limited separation into separate sources.

Schematic Knowledge

So far we have seen how relatively simple properties of sound can help to organize sound mixtures into their component sources or streams. But the brain likely uses more specific knowledge about sounds or sound types to help it to carry out this difficult task. A simple example involves listening to two simultaneous vowels spoken on the same pitch, starting and stopping at the same time, coming from the same direction in space. Here, there are no low-level grouping cues to help a listener to separate the two sounds, yet when asked to identify what the two vowels are, listeners' responses are well above chance. Knowing something about possible speech sounds helps the listener to assemble the appropriate components.

ASA and Hearing Impairment

Our ability to attend to different sounds that are present simultaneously generally passes unnoticed while we enjoy normal hearing, but those suffering from sensorineural hearing loss caused by a damaged or ageing cochlea are often aware of a disproportionate impairment in listening to one sound in the presence of others. Their difficulties arise partly from a loss of frequency selectivity in the cochlea, which increases the range of frequencies in the background sound that can mask the sound of interest. This loss of frequency selectivity, which is also present with cochlear implants, can in addition impair the brain's ability to use harmonic structure to separate different sound sources. Were hearing aids able to separate wanted from unwanted sounds, these problems would be reduced. Unfortunately, there is no effective general solution to sound separation either in a research implementation or in the much more demanding context of a wearable hearing aid. In practice, the problem is addressed by making modern aids directionally sensitive, so that sound coming from a particular direction (usually straight ahead) is amplified more than that from other directions. This approach can work well in a relatively uncluttered, dry acoustic environment, but is much less successful when even moderate amounts of reverberation are present because echoes of unwanted sounds will come from the amplified direction.

The difficulty of using spatial direction in generally useful ways in hearing aids is reflected in the difficulty that listeners with normal hearing show in exploiting some spatial differences to separate simultaneous sounds. For example, John Culling and Quentin Summerfield revealed a surprising inability of listeners to use the main localization cue in the horizontal plane (the difference in time of arrival of sounds at the two ears) to separate simultaneous sounds. If no other grouping cues are present, giving two sounds different interaural time differences does not help the listener to hear them as separate sounds or in different locations.

Computational Auditory Scene Analysis

Research during the last 20 years into ASA has proved challenging for theories addressing some of the classic issues in hearing such as pitch perception or sound localization. Theories that have been developed to cope with the perception of the pitch or direction of a sound when it is the only sound present often do not generalize well to the problem of determining the pitches and directions of multiple simultaneous sounds. The last 20 years have also seen the development of computational auditory scene analysis (CASA). A primary motivation behind CASA is the presently brittle nature of automatic speech recognition. Recognition algorithms generally use overall measures of the sound from the input microphone to match stored templates of words. Additional sounds corrupt these parameters and give poor recognition. Again, a general solution to the sound segregation problem would improve matters, but has proved elusive. However, the development of sophisticated CASA models and their integration with speech recognition algorithms is now leading to stimulating insights into how the low-level cues and schematic knowledge distinguished by Bregman might in practice be combined in the analysis of auditory scenes.

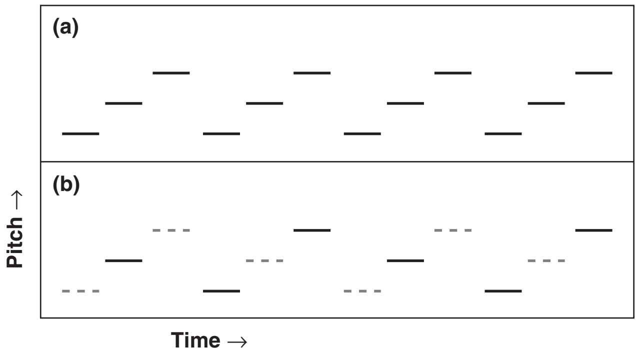

Figure 2 The Wessel Illusion

Notes: The upper panel (a) represents the pitches of a sequence of notes played on a single instrument. Listeners hear a repeating rapidly rising three-note figure. The lower panel (b) shows a similar sequence of pitches but with the even notes (dashed lines) played on a different instrument from the odd notes (solid lines). Listeners hear this sequence as two separate sound streams, each with a slowly descending three-note figure. The brain uses continuity of instrumental timbre to separate the mixture into two streams.

AUDITORY SYSTEM: DAMAGE DUE TO OVERSTIMULATION

Sound is the stimulus that activates the hair cells in the inner ear and starts the sequence of chemical and electrical processes that activate auditory nerve fibers and ultimately lead to perception. Sound that is too loud and lasts too long can severely damage the hair cells, can reduce or abolish activation of auditory nerve fibers, and can lead to impaired perception. This entry discusses damage to the auditory system caused by overstimulation.

Noise exposure levels are strictly regulated in the workplace to prevent hearing loss; typically a level of exposure of about 80 to 85 dB(A) is allowed for 8 hours, depending on the jurisdiction, and assumes the remaining 16 hours per day to be noise free. Every 3 dB(A) increase in sound level would halve the allowed exposure time. However, exposure to recreational noise in bars, sport venues, and concert halls may also lead to gradually accumulating hair cell loss and thus to hearing loss. For instance, the average noise levels in a hockey arena can be more than 100 dB(A) during the 3-hour game. Taking the 80–85 dB(A) industrial norm, this would then result in an allowable exposure time of only 5 to 15 minutes. Often, these games are watched in addition to the 8-hour allowable workplace noise, and the cumulative effect of these exposures can result in hair cell damage.

Hair cells come in two types, the inner and outer hair cells. Both inner and outer hair cells function as microphones, converting vibration into membrane potential changes. In addition, the outer hair cells function as mechanical amplifiers that increase both basilar membrane vibration amplitude as well as fluid motion near the inner hair cell stereocilia. Hair cell damage as a result of noise exposure typically starts with the outer hair cells in the high frequency region of the inner ear and, when the overstimulation is even more severe, is followed by loss of the inner hair cells in that same region. Complete loss of outer hair cells leads to the loss of amplification and produces about 40 dB hearing loss, and loss of frequency selectivity; combined, this results in deteriorated (speech) perception. When the inner hair cells are also damaged, the auditory nerve fibers that synapse with these cells commonly degenerate. In regions without hair cell damage, overstimulation also leads to excess inner hair cell release of the excitatory neurotransmitter glutamate, which in turn opens receptor channels in auditory nerve fiber terminals and allows excess calcium to flow into these terminals.

This causes damage to the inner hair cell auditory nerve fiber synapse resulting in loss of stimulation of the auditory nerve fibers and, hence, hearing loss. This neurotoxic process can be reversed under certain conditions, and the synapses may be fully repaired in less than a week. This neurotoxic damage is one of the substrates for the so-called temporary threshold shift following noise trauma. Hair cell damage, however, is irreversible and leads to a permanent threshold shift. Whereas the hearing loss can be compensated by amplification provided by hearing aids, the loss in frequency selectivity that results from outer hair cell loss cannot be ameliorated.

Noise exposure typically damages the outer hair cells in the high-frequency region of the cochlea, leaving the inner hair cells intact. Auditory nerve fibers that innervate the inner hair cells in regions with damaged outer hair cells typically have lower spontaneous- and driven-firing rates than do auditory nerve fibers innervating regions without any hair cell damage, which are typically tuned to low frequencies. Hence, the firing-rate profile across all auditory nerve fibers after noise exposure is no longer frequency independent as it is in normal ears, that is, is no longer balanced across the frequency range of hearing.

In several auditory cortical areas, there is a frequency-place map, also called tonotopic map. This map reflects the frequency analysis of the inner ear. An imbalance in the output of the auditory nerve fiber array results in changes in the levels of inhibitory and excitatory activity at the various stations in the central auditory system and ultimately leads to changes in the organization of the auditory cortex. Cortical neurons that would normally be most sensitive to the high frequencies that are affected by the hearing loss (e.g., above 6 kilohertz [kHz]) will after noise trauma become most sensitive to frequencies representing the edge of the hearing loss range (i.e., 6 kHz). As a result, a large part of the auditory cortex becomes sensitive to this edge frequency and this frequency becomes overrepresented in the tonotopic map. The same imbalance that gives rise to change in the frequency representation in the auditory cortex will also lead to increased spontaneous activity in the cortex and other parts of the central auditory system. This could be the cause for tinnitus (ringing in the ears), which often accompanies noise-induced hearing loss.

Damage to the auditory system is not restricted to hair cell loss. Degeneration of auditory nerve fibers underneath missing inner hair cells may subsequently occur; even as late as 8 months after the noise trauma. This degeneration is accompanied by newly formed synaptic endings in the cochlear nucleus. Therefore, noise-induced hearing loss may progress as a neurodegenerative disease with the capacity for synaptic reorganization within the cochlear nucleus. Any beneficial aspects of this reorganizational plasticity have yet to be shown.

AUDITORY SYSTEM: EVOLUTION OF

In the broadest sense, hearing is the detection, classification ("what"), and localization ("where") of mechanical disturbances of the surrounding medium. Such disturbances include sound—properly defined as longitudinal pressure waves propagating in an elastic medium—and other mechanical waves. Other sensory systems detect mechanical disturbances such as touch, vibration, and pressure sensors, and the origin of hearing is entwined in their evolution, but dedicated sound-receiving structures have only evolved in arthropods and vertebrates. The ancestral sensory cells in all hearing organs can be traced back to mechanoreceptors in organisms at least in the Cambrian (about 500 million years ago) period. This entry describes the evolution of the auditory system.

In insects, hearing organs developed independently at least 19 times from mechanoreceptors in the cuticle coupled to tympanic membranes. By contrast, the vertebrate inner ear originated only once. The vestibular structures that provide information about orientation and gravity are essentially unchanged during the course of evolution, but the hearing structures of the inner ear originally evolved for underwater hearing and show significant changes with the transition from water to land. In water, the similar density of water and tissue allows sound to travel through the body and stimulate auditory sense organs either directly or via mechanically coupled structures such as gas bladders. When vertebrates moved onto land, their ears may have resembled those of their fish ancestor's, responding to sound-induced vibrations of the skull (similar to bone conduction) and to substrate vibrations. On land, however, the impedance mismatch between the air and tissue causes most sound energy to be reflected, and physical constraints on detection and increased importance of detecting airborne sound probably led to the emergence of the eardrum (tympanum) and middle ear. Tympanic ears evolved during the Triassic period, probably when the spiracular openings were covered by a layer of tissue contacted by the middle-ear bone. Tympanic ears were previously assumed to have originated once, but the current consensus is that they emerged independently at least five times, in the lines leading to amphibians, turtles, lizards and snakes, archosaurs (crocodiles and birds), and mammals. Consequently, the auditory sense organs and nuclei in the central auditory pathways of land vertebrates are not necessarily homologous, but have emerged in parallel, subject to similar selective pressures for communication and localization.

In the early ear, the spiracles opened into the mouth cavity, leading to acoustically coupled eardrums. Thus, a sound wave that pushed in the eardrum on one side would travel though the mouth cavity and push out the eardrum on the other ear. These coupled ears can be extremely directional, as exemplified by modern lizard ears. The formation of a closed middle ear cavity in mammals and birds is a derived condition and would have profoundly changed the operation of the ear by decoupling the eardrums. Evolutionary processes that might have led to closed middle ears are numerous and may include requirements to shield the eardrums from respiratory noise. Additionally, although coupled ears provide exquisite directional information, they also exhibit nulls, or areas of low sensitivity. Whatever the cause(s) of the isolation of the middle ears, these changes would have led to a nondirectional ear, and selection for features that improve localization, such as external ears. External ears generate a robust, directionally dependent sound shadow, especially at high frequencies, and mammals have developed the three-ossicle middle ear with increased sensitivity to higher frequency sound, allowing improved detection of these sound shadows. On top of these peripheral changes, additional neural processing of interaural time and level differences would have been needed to compensate for the loss of directional information from the eardrum, leading to specialization for central processing of sound source localization information. Thus, many of the features of the avian and mammalian central auditory systems may reflect modifications of existing structures in already functioning land vertebrate systems. The increased sensitivity to airborne sound and higher frequencies may have provided the major evolutionary pressures for refinement of central auditory processing at a time when the major land vertebrate groups had already separated.

In the hindbrain, major differences among vertebrates are related to temporal and binaural processing. The auditory midbrain, the inferior colliculus or torus semicircularis, is a major processing site, especially in amphibians. Here, response properties such as selectivity for specific combinations of frequencies, specific temporal patterns, specific sound locations, or specific pulse-echo delays (bats) emerge. In birds and mammals, the greatest changes are in the forebrain auditory centers. Specialized communication systems based on vocal learning have evolved in parallel in humans, songbirds, parrots, and hummingbirds. Both humans and songbirds learn to produce their complex vocalizations early in life, exhibiting a strong dependence on hearing the adults they imitate, and have dedicated forebrain centers for vocal production and learning. Mammals are distinguished from other vertebrates by the evolution of the cortex in place of the more usual nuclear organization. The mammalian auditory cortex is characterized by both precisely tuned cortical systems with multiple auditory areas and specialized "where" and "what" pathways. Thus, the selection pressures that shaped the auditory system through evolution may be related to localization, communication, and specializations such as echolocation.

AUDITORY SYSTEM: STRUCTURE

When the ancestors of land animals first left the sea, they faced many new challenges; one of which was the detection of airborne sounds. Animals have many types of vibration receptor but, like most cells in the body, they require a fluid environment. This posed a problem because, when sound waves meet a solid or liquid, most of the sound energy is reflected and less than 10% is transferred into the solid or liquid. This problem (impedance matching) has been overcome by the evolution of structures that take the highly dispersed energy of the air molecules and focus it onto a small solid point to produce vibrations in the fluid around the specialized vibration receptors. This entry describes the structure of the ear and the pathways within the central nervous system that process its input.

Structure

The external ear, or pinna, acts as a funnel directing sounds into the external auditory canal to produce movement of the eardrum (tympanic membrane). The pinna can become greatly enlarged as in the long-eared bat, and in species such as the horse or cat, the pinna is independently movable and can be directed toward the source of a sound. Human pinna movement is vestigial but the pinna still generates a characteristic notch in the intensity of higher frequencies. The distinctive ridges and curves of the pinna form reflective surfaces that lead to some frequencies having a longer pathway into the ear canal. This introduction of a small delay or phase change can produce a waveform cancellation and a reduction in sound level among some high frequencies. The precise frequencies that are reduced in the notch are altered by the direction of the sound source, and this is thought to be important in estimating sound elevation and in sound localization for people with unilateral deafness.

The tympanic membrane is stretched taut across the auditory canal (see color insert, Figure 4). Pressed against it is the first of three tiny bones (the ossicles) that act as a lever to amplify and focus the force exerted by the air molecules. These bones are the malleus (mallet), incus (anvil), and stapes (stirrup). The malleus is attached to the eardrum while the stapes is pressed against the oval window: a membrane-covered opening in the fluid-filled inner ear. The long arm of the malleus takes the weak movements of the tympanic membrane and transfers them to the small base of the stapes in a process that amplifies the pressure by almost 15 times. The joints between the ossicles are conventional ball and socket joints and are susceptible to pathological processes and the base of the stapes can become fused to the wall of the inner ear (otosclerosis) and produce a conductive hearing loss. In conductive hearing loss, the ear is still sensitive to vibrations that come directly through the bone, and so a person would still be able to hear a train from several miles away if the person pressed his or her head against a railway track. This type of hearing impairment is more easily treated than is sensorineural hearing loss, which involves the permanent loss of the hair cells of the inner ear that detect the vibrations, or the nerve cells that contact them. The actions of the ossicles are controlled by tiny muscles called the tensor tympani (to malleus) and the stapedius (to stapes). These muscles can act via the stapedius reflex to reduce the amplitude of the vibrations produced by loud, low-frequency sounds. Paralysis of the stapedius muscle can produce hypersensitivity to sounds.

The sensory structures of the inner ear are contained in a labyrinth of interconnected tubes within the dense bone at the base of the skull. The sensory cells for hearing are located at the base of one of the membrane-bound tubes and form the organ of Corti. This spirals around for two and a half turns in the part of the labyrinth called the cochlea. The mechanical properties of the membrane on the floor of the organ of Corti (the basilar membrane) mean that the membrane at the base of the cochlea is taut and narrow (blue line) and tuned to high frequencies, and the wider, more floppy membrane at the apex (red line) is tuned to low frequencies (see color insert, Figure 5). This is counterintuitive because the base of the cochlea, which resembles the shape of a snail shell, would be expected to have the wider part of the membrane. The membrane at the base is actually stretched across a narrower gap because there is a spiral shelf of bone protruding from the center of the cochlea. This shelf is broad at the base and narrow at the apex.

Sitting on the basilar membrane are a single, spiral row of inner hair cells (IHC) and three rows of outer hair cells (OHC). The IHC are the sensory receptors that transform (transduce) the mechanical sound energy into neural impulses via synapses with type I nerve fibers that make up about 90% of the cochlear sensory fibers. Progressive changes in the width and tension of the basilar membrane mean that the IHC at any particular point are most sensitive to one particular frequency. This means that the frequency components making up the sound wave are coded by the position of the nerve endings contacting IHC as well as by the rate at which the hair cell vibrates. The OHC appear to function primarily as a cochlear amplifier to modify the properties of the basilar membrane and actively increase the amplitude of its vibrations by changing their length in time with the vibrations of the membrane. Thus, the cochlea is not a passive listening device but has a feedback mechanism for actively amplifying small vibrations. The OHC are contacted by some thin, type II sensory nerves but these are much less numerous than the type I nerves.

Pathways

The sensory nerve fibers have their cell bodies in channels in the conical bone at the center of the cochlea (the modiolus) and form the spiral ganglion. The central processes of these cells form the cochlear branch of the VIIIth cranial nerve and enter the brain where they immediately split into ascending and descending branches. The ascending branch of the type I fibers forms specialized synapses on the spherical bushy cells (SBC). These are giant synapses that engulf the spherical cell bodies and permit secure and accurately timed synaptic transmission. The descending branches also produce giant synapses around the cell body of globular bushy cells (GBC) and regular synapses with the dendrites of other, usually larger, nerve cells.

The primary nerve fibers enter the cochlear nucleus in an ordered sequence with the low-frequency (red, LF) fibers being more ventral and lateral and the high-frequency (blue, HF) fibers being more dorsal and medial. This regular frequency gradient is maintained at all levels of the ascending auditory pathway right up to the cortex.

Small cells such as the bushy cells, with their small "bush" of stunted dendrites, are all sharply tuned as they are primarily driven by a single sensory fiber. By contrast, some large nerve cells have widely branching dendrites and receive inputs from many fibers that represent a wide range of frequencies. This means that they can simultaneously compare the inputs over a wide spectral range and possibly code for changes in the relative intensity of different frequency components within a sound (important for determining the elevation of a sound). By synapsing on a variety of output neurons in the cochlear nucleus, the input from the sensory nerve is split up into at least five different output pathways. As cells in the cochlear nucleus also receive inputs from the auditory cortex, the contralateral cochlear nucleus, and vestibular and somatosensory nuclei, along with intrinsic excitatory and inhibitory neurons, their output has already undergone significant central processing.

Most of the output from the cochlear nucleus is destined for the main auditory nucleus of the midbrain (the inferior colliculus), but the routes by which the information get there are varied and reflect the importance of binaural (two-ear) comparisons. Some cells project directly to the inferior colliculus, but most are involved in indirect pathways. Two of these involve the small bushy cells whose outputs are involved in localizing low-frequency sounds. Sounds off to one side of the head will arrive at the near ear slightly sooner than at the far ear, and by comparing the time of arrival at the two ears, the brain can determine if the sound is coming from directly ahead or is off to one side. The two types of bushy cells both project to the brainstem structure called the superior olivary complex (SOC), which in turn projects to the inferior colliculus. The spherical bushy cells project bilaterally to the medial superior olivary nucleus (MSO) and the recipient cells act as coincidence detectors to compare the timing of the signals from the two ears. These cells are sensitive to differences as short as 20 millionths of a second even though the action potentials that carry the neural information are each about one thousandth of a second long. This is rather like using a grandfather clock with a one-second pendulum to measure the time taken by athletes in a time trial! By marking the position of the pendulum, you could measure times much shorter than a second, and in the same sort of way, the MSO cells will only fire an action potential if the inputs from the two cochlear nuclei are coincident. If the action potentials from the two input cells arrive at slightly different times, then they can cancel each other out and the MSO cell will not fire. The globular bushy cells also project bilaterally to the superior olivary complex: to the lateral nucleus (LSO) on the same side but to an adjacent nucleus (the medial nucleus of the trapezoid body or MNTB), that contains inhibitory cells, on the opposite side. These inhibitory cells project to the adjacent lateral nucleus. Thus, the cells of the lateral nucleus also act as binaural comparators to compare the arrival time of input from the two ears. In this case, coincident arrival of an excitatory and an inhibitory input means that the two inputs cancel each other out. If the inhibition is delayed slightly, then the LSO cell has time to fire before the inhibition takes effect.

The information contained in the different ascending pathways is selectively recombined within the central nucleus of the inferior colliculus. This nucleus is organized into laminae that are stretched out at right angles to the frequency gradient. Thus, the top lamina in the central nucleus responds to low frequencies, and the deeper laminae respond to successively higher frequencies. Within the laminae, there are both excitatory and inhibitory cells, and most project to the thalamus.

The main auditory nucleus in the thalamus is called the medial geniculate body and it has three main divisions: medial (MGM), dorsal (MGD), and ventral (MGV). The ventral nucleus receives the bulk of the output from the central inferior colliculus and projects to the core auditory areas that include the primary auditory cortex and adjacent areas that maintain a representation of the frequency gradient in the cochlea. These core areas then project to the surrounding belt areas, and in primates at least, the belt areas then project to parabelt areas. Different cortical areas have separate functions and the specialized human language areas may correspond to the parabelt. In the rhesus monkey, three core areas receive parallel input from the MGV, and there are parallel processing streams between cortical areas. Thus, the belt and parabelt areas project to multimodal areas of the frontal and temporal lobes in separate streams.

The ventral stream ("what" pathway) is more concerned with sound identification, and the dorsal stream is more concerned with sound localization ("where" pathway).

All neocortical areas have six layers, and the only types of projection neurons are the excitatory pyramidal cells (PC). Cells located in the deepest layers (V and VI) project back down to the auditory thalamus and these descending fibers outnumber the ascending ones by about four to one. The layer V pyramidal cells also project to the dorsal and lateral nuclei that form the periphery of the inferior colliculus as well as most other auditory structures including the SOC and the cochlear nucleus. The projections to the SOC appear to contact scattered cells that project back to the cochlea and modulate the activity of the inner and outer hair cells. Thus, powerful descending pathways arise in the cortex as well as in the thalamus and inferior colliculus that provide feedback and can potentially affect hearing sensitivity and mediate the effects of selective attention.

AUDITORY THRESHOLDS

The term *auditory threshold* usually means the minimum sound pressure level needed to sense the presence of an acoustic stimulus. Most of us are familiar with this type of auditory threshold through the experience of having a hearing test. In the most common type of hearing test, the minimum sound pressure level (SPL, specified in decibels or dB) needed to detect the presence of pure tones (sine waves having clear pitches) is measured for tones varying from low to high frequencies (frequency is the physical attribute of sound most closely corresponding to perceived pitch). Usually, this type of hearing test is performed while the listener wears earphones so that each ear can be tested separately.

Representative population values for the minimum detectable SPL for pure tones presented through earphones have been obtained by testing large groups of listeners thought to have normal hearing sensitivity. These normative values (called minimum audible pressures) reveal that humans are most sensitive to sounds in the middle range of hearing (e.g., from about 1–4 kilohertz [kHz]) and less sensitive to low- and high-frequency sounds. The general shape of this function is largely determined by the acoustics of the outer ear and the power transfer characteristics of the middle ear, although other factors such as biological noise (heart beat, respiration, etc.) can influence those values. The plot of normal thresholds in SPL as a function of frequency resembles a somewhat asymmetric bowl shape with a low-frequency slope that decreases fairly gradually (roughly–20 dB per octave or doubling of frequency), whereas the high-frequency slope is much steeper (as much as 80 dB/octave). Furthermore, the location in frequency of the high-frequency slope is highly dependent on age and may decrease substantially even in the early years of adulthood. This apparently "normal" decrease in high-frequency hearing sensitivity has been the basis for several recent commercial products (e.g., high-frequency ring tones) that emit high-frequency sounds audible to teenagers and young adults but not older adults.

The audiogram that is generated by the type of hearing test described is taken as an estimate of a person's auditory sensitivity. The normative values of SPL are the basis for hearing threshold levels (HTLs) such that the just-detectable SPL across frequency is set to 0 dB HTL essentially flattening out this bowl-shaped function. Thus, on the audiogram, thresholds are plotted in reference to these normative values. Hearing loss results in auditory thresholds that are elevated relative to normal (although paradoxically an audiogram plots increases in sound level as decreases along the ordinate). The most common types of hearing loss result from infections of the middle ear or in pathology affecting the sensory cells of the inner ear. Comparing thresholds for sounds presented by earphones with those presented by a bone-conduction vibrator often provides an indication of which type of hearing loss is present. This entry describes absolute, differential, and other types of thresholds and how to make sense of threshold levels.

Absolute Threshold

Many other types of thresholds for acoustic stimuli are referred to in the auditory literature. One helpful distinction in sorting through these various threshold measures is that of an absolute threshold versus a relative or differential threshold. The type of threshold mentioned earlier that would typically be measured by an audiologist administering a hearing test is an example of an absolute threshold. No sounds other than the pure-tone signal are presented to the test ear, and the judgment made by the listener is simply whether the tone is present or absent. Before discussing differential thresholds, it is useful to describe what the term *threshold* itself actually means.

A threshold is usually expressed as a single number. So, continuing the previous example, if an audiologist measures a person's threshold for a 500-hertz (Hz) pure tone, a single number is usually recorded; for example, 20 dB SPL (SPL will continue to be used in the example while acknowledging that an audiogram is plotted in HTL). It is almost never the case, however, that the 500-Hz tone would always be heard if it were played at 20 dB SPL or that it would never be detected if it were presented at 19 dB SPL. Detection thresholds usually refer to the point where a stimulus is detected an intermediate percentage of the time. More commonly, the percentage of times a listener detects the presence of an auditory signal varies with SPL.

Suppose one measured the percentage of times a listener detected a tone at five different SPLs, let's say 16, 18, 20, 22, and 24 dB SPL. The tone normally would be presented several times at each level so that a reliable estimate of performance is obtained. At 16 dB SPL, the listener detected the tone 10% of the time; at 18 dB SPL, it was detected 25% of the time; at 20 dB SPL, 50% of the time; at 22 dB SPL, 75% of the time; and at 24 dB SPL, 90% of the time. The mathematical expression describing how performance changes as SPL is varied is called a psychometric function. So, rather than there being a single value of SPL dividing performance between inaudible and audible sounds, the likelihood that the signal was detected is different for different presentation levels. Thus, the *probability of detecting* the presence of the signal is a function of signal SPL. Any of the levels mentioned could be considered a "threshold" because the signal was detected at that level at least some of the time. However, there is usually an agreed-upon criterion value—such as the example of the SPL producing 50% correct used previously—that yields the single number reported for "threshold."

In the earlier example, little information was given about the way the test was administered. However, it is easy to imagine that different listeners might react differently depending on their own tendency to respond one way or the other when they are uncertain about their answers. Suppose the listener was told that the signal would be presented during the interval of time a light was illuminated and that many such "trials" would be tested. Furthermore, the signal tone would only be present on one-half of the trials and the probability it would occur on any given trial was 0.5. After each trial, the listener must answer "yes" a tone had been presented or "no" it had not. It is easy to imagine two listeners whose sensitivity to the test tone is the same but their response behavior is different. One listener, for example, feels that it is important never to miss a signal when it is presented. This listener might be inclined to respond "yes" even if not sure that a tone had been presented. This type of behavior or *response bias* would lead to detecting the signal most of the time it was presented (a high proportion of "hits"), but it also would lead to a relatively large number of "yes" responses when no signal was presented. Those incorrect "yes" responses are called *false alarms*. The second hypothetical listener has a much more conservative approach and only votes "yes" when he or she is absolutely sure the signal was present. This listener would probably have few false alarms but would also miss the signal when it was present on more presentations than the other listener. Thus, specification of performance beyond simple percent correct should consider listener response behavior such as computing the ratio of hits to false alarms. A common measure or index of the detectability of a signal is referred to in *signal detection theory* as d' (pronounced "d prime").

Differential Threshold

Now we return to the idea of a relative or differential threshold. Suppose we were interested in the smallest difference in frequency a listener could discriminate. Let's assume that the stimuli are pure tones and that one tone is 2,000 Hz and the other tone is 2,000 Hz plus some small increment in frequency. The listener hears the two tones in sequence one in each of two observation intervals of a trial with the order of presentation chosen randomly. The listener then must indicate which of the two observation intervals contained the tone that was higher in pitch. If the difference in frequency between the two tones is small, the listener may not be able to tell which one is higher and simply must guess. In that case, the percent correct performance may be no better than chance (i.e., 50% correct). However, if the difference in frequency between the two tones is increased, performance should improve with percent correct scores increasing above chance until, with a sufficient difference in frequency, performance may approach 100% correct.

As with the previous example, we can specify a percent correct point on this psychometric function to define as the criterion performance for "threshold." For example, it could be that a frequency of 2,020 Hz was discriminable from 2,000 Hz 75% of the time. That value is considered a relative or differential threshold. It is also called a just-noticeable difference (JND) or difference limen (DL). Another common expression for a differential threshold is the ratio formed by the JND relative to the standard stimulus, which in this case would yield 20 Hz/2,000 Hz or 0.01. This ratio is also called a Weber fraction after the famous psychophysical scientist who proposed that this ratio was a constant value for many types of sensory discriminations. Many types of differential thresholds are reported in the auditory literature reflecting the discriminability of various aspects of simple tones or of more complex stimuli such as modulated tones or speech.

Other Types of Thresholds

As a final illustration of the various types of auditory thresholds, consider the following. A listener is presented with a sequence of individual words that initially are so soft as to be inaudible. The task of the listener is to report whenever a word is heard. The listener does not have to understand the words, only indicate that he or she was aware a sound had been presented. As the level of the sounds is raised, the probability of detection increases. As with the two earlier examples, detection performance would take the form of a psychometric function that varied from chance to nearly perfect performance. And, it would be possible to specify an SPL yielding a specified level of performance that we could call a speech detection threshold.

Now suppose the listener is not asked to indicate detection but instead must identify the spoken words. Typically, the level of the sound would have to be raised a few decibels above the just-measured threshold for speech detection to find the point where the speech was understandable a specified percentage of the time. So, a second psychometric function is obtained for the same stimuli, but this time for the task of speech recognition. Here we have two psychometric functions for the same sounds but for different tasks: one for detection and the other for recognition. Finally, suppose this speech detection/recognition experiment is repeated but now the words are not presented in quiet but instead a continuous "white" or Gaussian noise is played at a moderate SPL. Now the speech would not be detectable or recognizable at the same SPLs as before but instead the level of the speech would have to be increased so that the words could be heard above the noise. The psychometric functions would be shifted to these new levels, and the threshold points obtained from the psychometric functions would be considered "masked thresholds" because the noise acted to mask the speech signals. Thus, the values of threshold obtained for a given stimulus—speech in this example—may be affected by the presence of other sounds.

Making Sense of Threshold Values

To summarize, although the most familiar auditory threshold is for detection of pure tones, many other types of thresholds for different stimuli and tasks are possible and occur frequently in the auditory literature. Many variables affect the threshold values obtained in an experiment or clinical procedure, including the nature of the stimulus, the experimental technique, the instructions given to the observer, and the specific task. To make sense of the threshold values (particularly for comparisons across laboratories and clinics) that are obtained requires careful specification of these variables and how they were controlled.

BAYESIAN APPROACH

The *Bayesian approach* to perception focuses on whether the computations that the brain performs in perceiving the world can be described as forms of Bayesian inference. *Bayesian inference* is the process of optimally extracting information from noisy inputs and, if needed, combining this information with prior knowledge. The Bayesian approach to perception typically involves mathematically precise modeling of perceptual experiments in humans. Central to Bayesian inference is *Bayes' rule* (also called *Bayes' theorem*), named after the 18th-century British mathematician and Presbyterian minister Thomas Bayes. Bayes' rule is a general equation directly derived from the basic tenets of probability theory, but in the context of perception, it is based on the fact that the brain's observations of physical stimuli (such as the orientation of a line or the identity of an object) are noisy. The rule states that the probability that a stimulus had a particular value given a set of noisy observations (the *posterior probability* of the stimulus) is proportional to the probability that a stimulus of that value generated those observations (the *likelihood* of the stimulus), multiplied by the probability of the stimulus value independent of the observations (the *prior probability* of the stimulus). In mathematical notation,

$$p(\text{stimulus} \mid \text{observations}) \ \alpha \ p(\text{observations} \mid \text{stimulus}) \times p(\text{stimulus}).$$

In this equation, p stands for probability, "|" means "given," and "α" means "proportional to." (In more abstract notation, Bayes' rule is written as $p(\mathrm{A}|\mathrm{B}) \ \alpha \ p(\mathrm{B}|\mathrm{A}) \ p(\mathrm{A})$, where A and B are random variables that could refer to the stimulus and the observations, respectively.) This entry discusses several concrete examples. Ernst Mach and Hermann von Helmholtz were among the first to apply the idea of Bayesian inference to sensory perception, although a similar notion can be found in the writings of Pierre-Simon Laplace. Strong experimental evidence for Bayesian inference in perception started emerging only in the 1980s, and some of it is discussed here. The Bayesian approach to perception should not be confused with Bayesian data analysis, which is an area of statistics with applications in neuroscience.

Perception as Information Extraction

Our percept of the world is a complex composite of pieces of uncertain knowledge extracted from noisy and ambiguous sensory inputs. The brain is different from a recording device such as a camera, which accurately captures the light in a visual scene but will not be able to tell, for instance, whether there is an animal in the scene. Indeed, in computer vision, sophisticated algorithms are used to extract that information. To humans and other animals, such higher-level knowledge can be of great ecological importance—for example, an animal in the scene could be a predator. To extract information from sensory inputs, the brain has to perform many different manipulations, including combining signals that come from the same source, making decisions, planning movements, allocating attention, and storing and retrieving information. Manipulations of sensory inputs that aim to extract behaviorally relevant information can be called *perceptual computations.* A key question in neuroscience and cognitive science is what algorithms and mechanisms the brain has developed to perform perceptual computations in the presence of uncertainty.

Uncertainty in Perception

Sensory information is uncertain. A lion chasing a giraffe must judge its position, speed, and direction of motion to decide when and how to attack, but because the giraffe is running fast, these judgments come with large uncertainty. A basketball player trying to pass the ball must keep track of the positions of his teammates and of the members of the opposing team, sometimes only seeing them out of the corner of his eye. When someone approaching you looks familiar, you need to use visual information to decide whether to greet your friend or avoid an awkward moment. When you are hiking in the forest and need to decide whether to jump over a stream, you have to judge the width of the stream as well as how far you can jump. When you are driving on the freeway and the car ahead of you brakes, you determine how to react based on uncertain variables such as your car's distance to it. The central idea of the Bayesian approach is to acknowledge this omnipresent uncertainty and ask how the brain can consider it optimally when performing perceptual computations.

An Analogy: The Apple Tree

Because sensory information is noisy, the brain constantly has to make guesses about the state of the world. Some guesses are better than others. Computing the goodness of possible guesses is known as Bayesian inference. Imagine you are shown the locations of some apples lying scattered in a field. You are told that the apples fell from a tree recently and are asked to guess the location of the tree. Your best guess will probably be somewhere in the middle between the apples because you know that apples don't fall far from the tree and tend to fall roughly evenly in all directions. You will be able to report a best guess of the tree location, and you will have an idea how probable each other location in the field is. For example, the farther outward a location is, the less you will believe that the apple tree was there. This changes if you know that there was a strong wind blowing from the west when the apples fell. Your best guess about the location of the tree would then be more to the east than it was before, and probabilities assigned to other locations will change accordingly. If you have additional information, for example that some areas of the field are swampy, you will be able to adjust your probabilities, because you know apple trees tend to grow on solid ground.

This example illustrates that one can use noisy observations (the locations of the apples) to obtain the probability of each of their possible causes (apple tree positions). However, for this to work, you need to know how a given cause generates observations (for example, that apples don't fall far from the tree). You might also have prior information about causes (such as that apple trees tend to grow on solid ground). Using these pieces of knowledge when you are given a particular set of observations will allow you to infer the goodness of possible guesses about the stimulus. This is exactly the logic expressed by Bayes' rule—in this example, it would state that the probability of an apple tree location given locations of apples in the field can be computed by multiplying the probability of those apple locations given that tree location with the prior probability of that tree location. This multiplication is followed by a *normalization,* which is the division by a constant factor to ensure that the total probability of all possible causes is equal to 1—a defining property of a probability distribution. One can write this as $p(\text{tree location} \mid \text{apple locations}) \propto p(\text{apple locations} \mid \text{tree location}) \times p(\text{tree location})$.

Bayes' rule is not just about apple trees, however. It is general and widely used in fields as different as statistics, economics, computer science, computational biology, and neuroscience. Moreover, it has practical applications, such as in Bayesian spam filters, which calculate the probability that an e-mail is spam based on the words it contains. These filters multiply the probability of finding those words in a spam e-mail by the prior probability that any e-mail is spam, followed by a normalization: $p(\text{spam} \mid \text{words}) \propto p(\text{words} \mid \text{spam}) \times p(\text{spam})$.

Bayesian Inference in Perception

This entry now discusses what Bayes' rule means in the context of perception. The apple tree in the previous example is analogous to a feature of an event or object in the world, often called the *stimulus* (in a somewhat confusing terminology, the event or object itself is sometimes also called the stimulus. This can be a simple variable such as the orientation of a line, the color of a surface, or the direction of motion of an object. It can also be more complicated, such as whether a desired object is present in a scene, what your coworker just said, the identity of the person approaching you, or how safe it is to change lanes on the freeway.

The apple locations are analogous to observations of the stimulus made by the brain. There are different ways of conceptualizing these. In their simplest form, the observations are variable measurements of the stimulus. For example, when the stimulus is a line oriented at 60°, a measurement of its orientation on a single trial could be 58° or 61°. This is sometimes called the *internal representation* of the stimulus. It is often assumed that internal representation of a stimulus is distributed around the true value of the stimulus, according to a roughly Gaussian (normal) distribution. Alternatively, the observations could be the variable activities of neurons in a population responding to the stimulus. For example, if the stimulus is an oriented line, then the observations could be the numbers of spikes emitted by the neurons in the primary visual cortex (V1) that are sensitive to orientation at that location. These numbers vary because you do not get the same pattern of response every time you present the same stimulus. Which description of the observations is most appropriate depends mostly on whether you study a perceptual phenomenon from a behavioral or a neural point of view: Psychologists tend to use noisy measurements, whereas neuroscientists tend to use neural activities. Most Bayesian models of perception are at the behavioral level.

Now that we have described what the stimulus and the observations are, we can formulate the central hypothesis of the Bayesian approach in perception: In many perceptual tasks, the brain computes the posterior probability distribution over the relevant stimulus variable based on the observations it has available, as expressed in the equation on page 201. One can think of this equation as a formalized description of a key task that the brain faces: to infer aspects of the world based on noisy sensory input. The lion infers in which direction the giraffe is moving, the basketball player where his teammates are, and the forest hiker whether he can jump over the stream. From the point of view of the observations, $p(\text{observations} \mid \text{stimulus})$ is sometimes called the *noise model,* the *variability* in the observations, or their *generative model.* In the apple tree analogy, the clue that there is a strong wind from the west is an element of the generative model. In the example of the oriented line, the Gaussian distribution or the form of the variability of the population of V1 neurons constitutes the generative model. When the observations are the activities of a population of neurons, one can think of that population as *encoding* the probability distribution over the stimulus (see Figure 1).

The posterior probability distribution, $p(\text{stimulus} \mid \text{observations})$, reflects the uncertainty about the stimulus: If this distribution has a single sharp peak, it means that based on the observations, only one of a few stimuli are plausible, and uncertainty is small. For example, when you are driving on the freeway on a sunny day and there is another car a short distance in front of you, the posterior probability distribution over your distance to it will be narrow. If, on the contrary, the distribution has a flat and broad peak, or multiple peaks of similar height, it means that based on the observations, many stimuli are plausible, and uncertainty is high. For example, if the same car is far ahead of you at nighttime, the posterior probability distribution will be broad. This is an important point because it means that, through Bayes' rule, the brain can encode not only the most likely value of a stimulus (compare: the most likely location of the apple tree, the most likely distance to the other car), but also the uncertainty about that value (compare: how large the area is where you believe the apple tree could still stand, how wide a range of distances to the other car is plausible).

Bayesian inference in perception is seldom a matter of perceiving a single stimulus. As already discussed, perceptual computation can involve elaborate manipulation of sensory information,

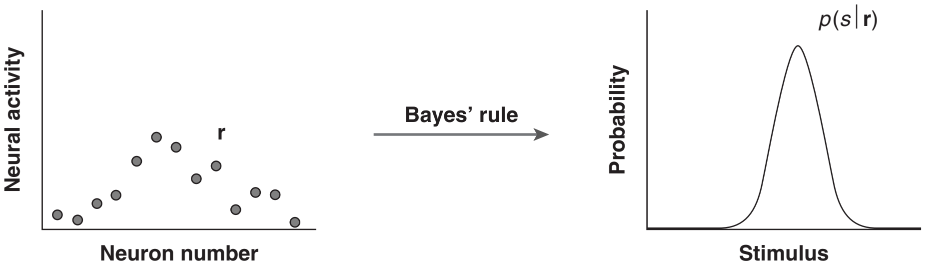

Figure 1 Schematic Illustration of Bayes' Rule in Perception (Neural Version)

Notes: A stimulus (e.g., orientation of a line) elicits activity in a population of neurons (left), whose activities (e.g., spike counts) we collectively denote by **r**. Based on these noisy observations, Bayes' rule computes the probability distribution $p(s|\mathbf{r})$ over the stimulus (right), providing the most likely value of the stimulus, as well as its uncertainty. One can think of the probability distribution being encoded in the pattern of activity.

which in many cases has to be done in multiple stages. For example, when you are deciding whether there is a predator hiding in the bushes, your brain has to infer the features of objects in the scene, as well as make the higher-level judgment about animal presence. In such situations, Bayesian inference can become complex, but the key feature remains that at every stage, a probability distribution is computed over the variables at that stage. Using Bayes' rule to compute with uncertainty and probability during a perceptual task guarantees the best possible performance; therefore, Bayesian inference is often referred to as *optimal inference,* or "optimally taking into account uncertainty." The Bayes-optimal strategy ensures that an organism makes fewer mistakes and is more efficient in perceiving the world and generating behavior.

Experimental Evidence

Perception researchers have found a large amount of evidence that the brain performs Bayesian inference, that is, computes posterior probability distributions over stimuli. This evidence is commonly provided by showing that those probabilities are used by humans in solving certain behavioral tasks. No experimental paradigm has contributed more to this than that of cue combination. The basic idea of this perceptual computation is that an observer is presented with two or more cues providing information about the same stimulus, and has to estimate the stimulus. For example, you might have a cat that likes to hide in the backyard. To find her, you use the movement you see as well as the faint meowing you hear. Because of noise, both in the world and inside the brain, cues from the same source are often not in complete agreement. For example, the best guess about the location of the cat based on its meowing may be slightly different from the best guess based on its image. One way to combine such cues would be to take the average of these guesses. However, this is not a good idea when one cue is much less certain than the other: if the cat is barely visible, the best combined guess may be close to the one based on what you hear. Indeed, the formalism of Bayesian inference applied to cue combination predicts that the best combined estimate is a specific combination of the individual guesses that gives less weight to the less certain cue. This prediction has been tested in a wide variety of cue combination experiments in which the disagreement between two cues is artificially varied. The general conclusion has been that humans do consider uncertainty in a close to Bayes-optimal way when combining cues. Evidence for Bayesian inference has been found in many other areas of perception as well, including decision making, visual motion estimation, color perception, and sensorimotor behavior.

Neural Basis

Even though Bayesian inference has become a fixture in behavioral descriptions of perception, the neural basis of Bayes-optimal computations has only recently started to receive scrutiny. The challenge here is to discover which operations the brain performs on neural activity so as to produce behavior that is close to Bayes-optimal. This problem is directly related to one of the central questions in neuroscience, namely that of the relation between brain and behavior. Eventually, predictions from this approach might be tested in physiology. Research into Bayesian inference in perception is expected to be of wide interest in the coming years.

BINDING PROBLEM

Objects have different features such as color, shape, sound, and smell. Some, such as color and sound, are represented separately from the instant they hit our sensory receptors. Other features, such as color and shape, are initially encoded together but subsequently analyzed by separate areas of the brain. Despite this separation, in perception the brain must represent which features belong to the same object. This is the *binding problem.* Any case of the brain representing as associated two features or stimuli that are initially represented separately can be called binding, but this entry focuses on a subset of these: the pairing of features that belong to a common object.

Solutions to the Spatial Binding Problem

A simple solution to the binding problem is to have a single neuron (or other representational unit) for each possible combination of features. However, considering that different feature dimensions such as color, shape, and texture may each have hundreds of values, it is impractical to dedicate a unit to each combination. Still, the visual system does contain neurons selective for certain combinations of features, and these may suffice to solve the binding problem in certain cases.

Wolf Singer has championed the theory that binding is represented via synchronous rhythmic firing of the neurons selective for the paired features. The idea is that the joint activity of the feature representations allows other brain areas to process the features together, excluding features belonging to other objects. Groups of neurons in many parts of the brain frequently do synchronize their responses, and attention to visual stimuli can enhance the effect, but the precise relationship of the phenomenon to perceptual binding remains unclear.

For experimental psychology researchers, two papers on binding by Anne Treisman in the 1980s set the course for nearly two decades. Treisman's feature integration theory (FIT) became the most influential theory of binding and the most influential theory of attention. FIT posits that binding is accomplished by an act of selective attention and has three elements.

1. Features such as color and shape are represented separately in the brain, but each feature (such as red) has a feature map indicating the location of each instance of the feature in the visual field. By virtue of the position of the units that represent the feature relative to the others in the map, a location tag is implicitly included and

activity of a unit signals both feature identity and location.

2. The objects of a visual scene initially cause representations of the various features of all the objects to become active. The system does not yet represent which features belong to the same object.
3. Binding happens when attention is directed to a particular location. The neurons corresponding to this location in each feature map become active, excluding those in other locations, and the features occupying the location are bound.

Spatial Binding: Evidence

The results of thousands of visual search experiments have been interpreted in the framework of FIT. In one case, people were tested on the time needed to find a red "X" target stimulus among a large array of red "O"s and blue "X"s. Because the target is defined by the combination of color and shape, the task requires binding of these features. If there were no binding to determine whether any instances of red were in the same location as the X shape, the target could not be found. Searches that require binding are usually more time-consuming than are searches for a target containing a feature different from those of all the other items. In this latter case, a feature map alone is sufficient to solve the task. According to FIT, the reason for the greater difficulty in the binding search is that the binding step takes time and can only be performed in one location at a time. Attention is hypothesized to visit each location in turn, binding its features until the target is found.

FIT has been useful for explaining visual search results; however, a number of other models, models without any role for attention in binding, can also explain visual search performance. These alternative models imply that the nature of the binding process cannot be determined from visual search results alone. Visual search results are affected by many factors such as image segmentation mechanisms, local salience processing, and crowding, making it difficult to isolate the binding process.

In experiments relying on fewer assumptions, Treisman documented clear binding mistakes with simple displays, in a phenomenon she called *illusory conjunctions*. In one illusory conjunctions experiment, two black digits and three colored letters were flashed briefly on the screen. Participants attempted to report the digits and the letters and the letters' associated colors. They usually reported the correct letters and colors, but occasionally with the wrong pairing. Treisman suggested that the short presentation duration, in combination with the attentional demands required to also report the digits, meant that the attention available was sometimes inadequate to correctly bind the features. Subsequent work verified that illusory conjunctions are perceptual errors rather than an artifact of guessing strategies, and illusory conjunctions are more common when perceptual demands are high, but it remains unclear whether this reflects a critical role for attention or just that binding requires additional sensory processing beyond that required for identifying the features.

To probe the role of attention more directly, Jochen Braun and colleagues devised a quantitative measure of the attentional resources shared by two tasks. Results from this paradigm indicate that contrary to FIT, some feature bindings are perceived at little or no cost to attentionally demanding visual tasks. For example, accuracy in reporting the orientation and color of two line segments in the periphery was almost completely unaffected by the demands of a concurrent task of searching for a T among L's or an L among T's. Results from Braun's paradigm do, however, support the idea that attention is critical for linking features to particular spatial locations. Ability to judge the spatial configuration of adjacent red and green patches (whether red is left of green or right of green) traded off linearly with performance in concurrent central tasks, supporting a critical role for attention. Interestingly, other discriminations that may also rely on configuration do not show this property, for instance, discrimination of face gender or identity. Apparently, the binding required for certain discriminations can proceed with little to no attention. However, even when full attention and extensive processing time is available, binding can fail profoundly, as described in the next section.

Location Tagging of Features: A Prerequisite for Binding?

In her feature integration theory, Treisman suggested that bindings between features are mediated by the features' links to a location in common. Psychophysical demonstrations of binding failures under conditions of full attention provide support for this idea that binding is accomplished through common location tags.

In a display devised by Steven Shevell and colleagues, two separate objects are presented at the same location but in different eyes. For example, a vertical array of orange and gray stripes is presented in one eye, and a horizontal array of gray and blue stripes in the other eye. The conflict between the eyes causes different perceptions to occur alternately, including some involving misbinding of the color and form features. Specifically, arrays of orange with blue stripes of either orientation are perceived. This phenomenon suggests that pairing of features is not fully resolved until after the representations of the two eyes come together. That presentation of multiple instances of a feature in a single location can confound binding supports the notion that binding relies on location tags.

Even when features are perceived in their correct locations, binding can still fail profoundly. Still, this too may reflect a location tagging failure that arises when the spatial scale of analysis of one feature is larger than that of another, allowing the location tag of the larger feature to correspond to more than one instance of the smaller feature. In a display devised by Hugh Wilson and Frances Wilkinson, a pair of dots defines a local orientation. Hundreds of such pairs of dots are scattered across the screen and oriented such that globally, a spiral is perceived. If all these dots are white and unrelated black dots are randomly interspersed with them, then under brief presentation conditions binding fails—people are unable to say whether the dots forming the clearly visible shape are black or white. This phenomenon suggests that the mechanisms for a feature (here, shape) extracted by combining a number of local components do not preserve information about other aspects of its constituents (here, color). Rather, the global shape is assigned to a large area, with multiple colors tagged with locations within it.

Rare neuropsychological syndromes further highlight the role of location tagging. Some patients with bilateral parietal damage erroneously pair color and shape much more frequently than they misperceive the constituent features. Damage to the pulvinar, a subcortical structure, can cause similar binding problems. Both disorders are accompanied by a deficit for localization of even an isolated feature, consistent with the thesis that binding of visual features is accomplished through common location tags.

Temporal Binding

Certain binding failures documented in healthy observers suggest that the binding process is quite slow relative to feature identification. Two dot patterns—each forming a different global shape (such as those mentioned earlier) and each a single color (e.g., red or green)—were set in alternation. The two shapes were constructed such that their shapes could not be determined when the alternation rate exceeded the temporal resolution of the shape identification mechanism. The two global shapes were easily perceived at 15 hertz (Hz), implying rapid grouping of the dot pairs and extraction of the global shape, and the color of each dot was perceptually obvious. However, without extensive scrutiny, observers were unable to determine which shape was formed of green dots and which shape formed of red dots unless the patterns alternated slower than 3 Hz. Binding of color and motion also shows a slow limit of less than 3 Hz, even when both features are local. The alternation of colors and motions causes the display to contain more than one feature of each type in a single perceptual location. With binding based on location tags, this yields binding ambiguity when the displays are alternated fast enough to exceed the temporal resolution of the binding process. The 3-Hz result indicates that binding is slow and requires much more time than does identification of the constituent features.

Even at slow rates, binding of the features that occur together in time may pose problems beyond those faced by spatial binding. For spatial binding, linking features based on common location works well thanks to the large number of spatially organized areas in the visual system. In contrast, no chronotopically organized visual areas have been found, raising the issue of how features might be tagged temporally. Temporal tagging would be unnecessary if all features were processed in the same amount of time. But features have different sensory latencies and processing times. Perhaps the perceptual systems have a scheme for tagging the time that features actually occurred in the world, as opposed to when they are identified by the brain, but this is not yet understood.

From Perception to Memory and Cognition

Once features are bound by perception, these bindings must be maintained by visual short-term memory if we are to do such simple tasks as detect changes in scenes. But visual short-term memory has a limited capacity, and for moving objects, the pairing of object to features may easily be lost. Jun Saiki has used a display with a triangle, circle, and square of different colors moving about the screen and briefly disappearing behind occluders. Sometimes the objects switch colors or shapes while they are behind the occluders, but people are poor at detecting this, even though they do well at detecting a new color or a new shape. Understanding the role of bound object representations versus individual feature representations in real-world behavior requires more investigation of the demands binding places on initial perception and on sustained attention and memory.

BINOCULAR VISION AND STEREOPSIS

Animals such as rabbits and horses have two eyes, one on each side of their heads (binocular vision) that provide them a panoramic view and awareness of the world all around them. For instance, rabbits are able to see potential predators approaching from behind because of the lateral position of their eyes. Humans and a number of other species have forward-facing eyes that do not allow for a view behind the head. What evolutionary advantage could make up for the sacrifice in field of view? One enormous advantage is that the two forward-facing eyes receive images of the same portion of the visual world, but the left and right eye images differ because the eyes view from slightly different positions. These image differences on the two retinas (called binocular disparity) are used by the brain to provide a precise estimate of the depth of objects in the world, relative to where the eyes are looking. This transformation of two images into the perception of depth is called *stereopsis* (Greek for solid sight), and for animals that seek camouflaged prey that are able to remain still, stereopsis can be essential.

Modern humans do not typically use binocular disparity for hunting prey; however, they do rely on this depth cue for daily tasks such as navigating stairs, reaching for the handle of a coffee cup, or threading a needle. Without stereopsis, such tasks become surprisingly difficult; it is only through time and practice that someone who loses stereopsis late in life becomes adept and confident by relying on other, monocular, cues to depth. In conversations with individuals who do not have stereopsis, a common complaint is that, even though long periods have elapsed since they lost stereopsis, they find it difficult to catch a baseball, or they might feel slightly unstable going down stairs. Such losses are experienced by people who once had stereopsis, but then are forced to function without it because of sudden illness or injury. In contrast, many individuals who are born without stereopsis are able to rely on other cues, such as motion parallax, to perform daily tasks and even play competitive sports such as cricket. Unfortunately, others suffer permanent visual deficits, such as amblyopia (often called lazy eye), resulting from the early disruption of their binocular vision.

Although stereopsis is one of many potential cues to depth used by the brain, it is the only one that, on its own and without head movement, provides such a compelling sense of the volume or space between points in the world. It is not known whether individuals who lack stereopsis experience the space between objects in the same way as people with stereopsis do. In a recent case study, Oliver Sacks recounts the story of a woman named Sue who regained stereopsis while in her 40s. She describes the difference in her world, and in her experience of visual space. In one instance, Sue describes eating a meal, looking at her fork and suddenly, for the first time, being aware of the space between the fork and the food she was eating. Her description of this and other experiences of the space between objects and surfaces provides rare insight into a world devoid of stereoscopic depth.

Although scientists and philosophers have studied binocular vision since the time of Euclid (ca. 300 B.C.), it is remarkable that the link between the percept of depth from stereopsis and the two slightly offset images received by each eye was only realized about 150 years ago. For centuries, it has been known that the left and right eyes' images differ but natural philosophers considered it a challenge to explain how the visual system produced an impression of a single world from them. Sir Charles Wheatstone discovered that these differences allow for the perception of a single *three-dimensional* world. He invented a "stereoscope" that used mirrors to present separate images to the two eyes and provided simple stereograms that produced compelling depth when viewed in this way. Wheatstone's 1838 presentation to the Royal Society of London was the starting point for the empirical study of stereoscopic vision. Not only did he give scientists a way to present stereoscopic images to the two eyes, but in doing so, he provided a means of carefully manipulating the input to the binocular visual system. Since then, much research has been focused on the nature of stereopsis, and what stimulus attributes influence this process. His stereoscope was also one of the most successful consumer products of the 19th century and became a fixture in Victorian parlors. The new field of photography provided exciting stereoscopic photographs of natural wonders, exotic places, and the spectacles of the age.

This entry describes the information used for stereopsis, measuring stereoscopic depth perception, and the neurophysiology of stereopsis.

The Information Used for Stereopsis

Stereopsis is based on relatively simple geometry. Figure 1 illustrates this geometry and the information that forms the signal for stereopsis, binocular disparity.

In Figure 1, the observer is fixating object F, and there is a separation between it and another object N. Keep in mind that when we look directly at an object we are positioning the image of that object on the high-resolution portion of the retina, the fovea. The fovea is defined as the reference for a set of geometrically corresponding points (i.e., if you were to slide one retina on top of the other, these points would align) and is itself a corresponding point. The other point, N, is closer to the observer than F is, and the image of this object falls on non-corresponding points: In the left eye, it is to the left of F, and in the right eye, it is to the right of F. The difference in distance between the position of the image of the object and the fovea in each eye is its retinal disparity, which can be represented either as the distance on the retina or in geometric terms as the difference in angular separation of F and N between the two eyes. Because binocular disparity is always relative to fixation, the computation of disparity is the same whether the object is in front of, or behind, the fixation point.

Measuring Stereoscopic Depth Perception

Wheatstone's invention provided a means of presenting and carefully controlling stereoscopic images, while holding other cues to relative depth constant. Much of the research in the 20th century used simple line and dot stimuli to investigate the limits of stereopsis and the factors that determine these limits (see Figure 2, second row). In 1960, Bela Julesz, who was seeking a perfectly camouflaged stereoscopic stimulus, introduced what he called a random-dot stereogram (RDS). He showed that if identical patterns of random dots were presented to the two eyes, and a region in one of the

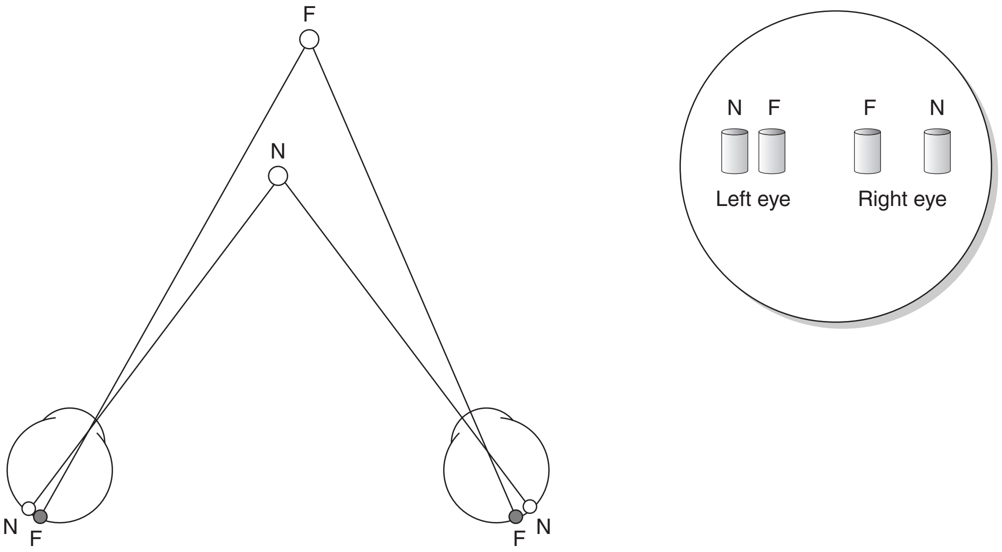

Figure 1 Corresponding and Noncorresponding Points

Notes: The two eyes fixate on object F, and object N sits closer to the observer. As shown in the inset, and by the circles indicating where each object lies on the retina in each eye, the images of N stimulate non-corresponding retinal points. Also, as shown in the inset, the separation between N and F is larger in the right eye because N is shifted away from the midline, toward the left eye.

pairs was shifted laterally (to create retinal disparity), then that region would appear to float above or recede behind the background. Critically, the shape of the shifted region was not visible in either of the monocular views; it could only be seen in the combined or cyclopean view (Figure 2, top row). Further, the amount of depth perceived was proportional to the size of the shift. He argued that this demonstration formed a definitive rebuttal to Gestalt psychologists who believed that the binocular combination required for stereopsis occurred after prior neural processing which extracted form from an image.

Julesz's introduction of the RDS initiated a shift in focus of the experimental community from the relationship between binocular disparity and perceived depth to an issue called the correspondence problem. As argued by Julesz, RDS contain many identical elements, and no obvious contours or form to match in the two eyes. How does the stereoscopic system determine the appropriate disparity given that there are so many possible matches? Julesz proposed that the visual system identifies regions or clusters of elements in two images that are highly correlated, and then extracts a disparity estimate from their relative positions in the two eyes. This cross-correlation approach formed the basis for many subsequent models of stereopsis.

Thresholds and Limits

Under ideal conditions, with high contrast sharp edges and lines, some observers can see the depth provided by disparities as small as 2 to 6 seconds of arc. These disparities are much smaller than that of the spacing of photoreceptors on the retinas and stereopsis has therefore been referred to as a hyperacuity. At a distance of 57 centimeters (cm), such disparities allow discrimination of the depth of objects separated by less than the width of a typical human hair! Such stereoscopic thresholds, or stereoacuities, reveal the extraordinary ability of the stereoscopic system under ideal conditions, and with some practice. Experiments in which large numbers of young adults, without additional training, have been assessed have shown that 80% of those tested can reliably discriminate disparities as small as 30 seconds of arc, which is less than the thickness of a fingernail at arm's length. Such fine stereoacuity judgments depend on a number of stimulus attributes such as visibility, viewing time, and blur.

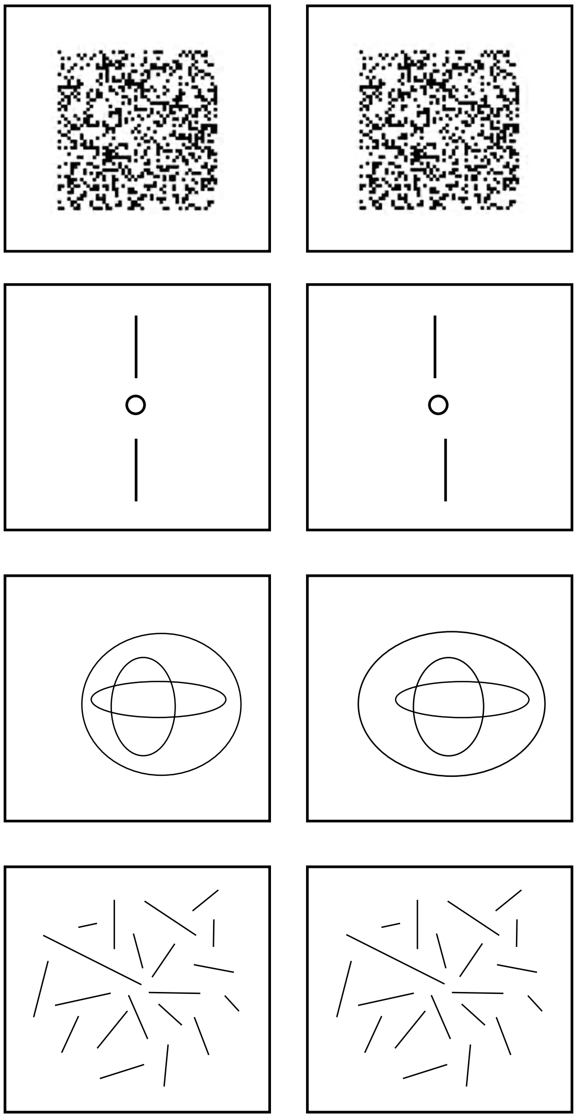

Figure 2 Stereograms

Notes: The stereo pairs shown here illustrate how space and form can be created simply from lateral shifts in images presented to the two eyes. The easiest way to view stereograms is to put them in a stereoscope, which presents the two images separately to each eye. You can also view these without an optical device by first crossing your eyes, and as the images become doubled in the two eyes, allow the central pair to overlap. Then, fixate on this central fused image. Gradually it will sharpen, and you will be able to see the three-dimensional (3-D) relief in the figures. In the first row is a random-dot stereogram, like that created by Julesz, which contains a central square protruding in depth. Row two contains a simple line stereopair; the top bar should recede in depth and the lower bar will come forward. Row three shows circles at different positions in depth. In row four, two of the line elements are displaced in depth, one near and the other far. (Note that these perceptions may be difficult to achieve without a stereoscope.)

The stereoscopic system, although useful for making high-resolution depth judgments, also provides relative depth information for stimuli that have much larger disparities. In fact, the binocular disparity can be so large that the images of the objects in the two eyes cannot be fused, and are seen as double, but still the observer can reliably judge the position in depth of the object relative to fixation. Investigators have shown that the upper limit for stereopsis, or the largest disparity that produces a percept of depth, generally occurs when the binocular disparity is near three times the width of the object. Thus, the upper limit scales with object size. However, this limit, unlike stereoacuity, is not affected by the amount of high-contrast detail within the object, stimulus contrast, or the viewing time.

Development of Stereoacuity

Studies of stereoacuity in infants in the 1980s used a variety of stimuli (RDS and line stereograms) and methodologies (e.g., behavioral measures and visual evoked potentials) to show that stereoscopic depth percepts do not reliably appear until approximately 4 months of age. Evidence suggests there is a critical developmental period between 4 and 24 months of life. If normal binocular vision is prevented by disease or visual defects during this time then development of stereopsis is highly improbable in later life. From this age on, it appears that stereoacuity continues to improve until 9 to 12 years, at which point performance reaches adult levels. However, some studies suggest that further improvements in stereoscopic vision occur with age until 21 years.

The Neurophysiology of Stereopsis

Electrophysiology

At about the time that Julesz was developing the RDS, David Hubel and Torsten Wiesel were conducting groundbreaking research, recording the responses of binocular neurons in the cat visual cortex. Their Nobel-prize winning research identified and classified cells in the primary visual cortex (known as V1 or striate cortex in primates) according to eye dominance. They found that a large portion of the cells received input from both eyes.

These binocular neurons were subsequently shown by Horace Barlow and colleagues to be disparity tuned, responding to specific retinal disparities between objects on the two retinas. Subsequent experiments with awake monkeys suggested that disparity-selective neurons could be classified as tuned excitatory, tuned inhibitory, near or far. The tuned neurons respond to small disparities, near fixation, whereas the near and far cells respond to coarser disparities in front of and behind fixation, respectively. More recent experiments show that these are not strict categories, but that the cell types fall along a continuum.

Electrophysiological studies have shown that V1 cells respond to anti-correlated RDS in addition to the traditional correlated RDS described. In anti-correlated RDS, the polarity of the elements (black/white) is reversed in the two eyes so that a white element in the left eye would correspond to a black element in the left eye and vice versa. The response of V1 cells to anti-correlated RDS suggests that these units do not code depth percepts per se (humans do not see reliable depth via disparity in these anti-correlated patterns). However, neurons in area V2 do distinguish between these types of stimuli, and respond to correlated patterns in a manner that is consistent with behavioral reports. Other studies of the disparity selectivity of extrastriate neurons have shown disparity processing in areas thought to be dedicated to other visual attributes, such as motion in the middle temporal (MT) cortex. Investigators have influenced monkeys' behavioral responses to the location in depth of a stimulus by applying a mild current to MT neurons. In these experiments, only coarse disparity tuned neurons were influenced by the microstimulation, suggesting that there is a distinction between coarse and fine disparity processing at this level in the system. It has been proposed that the dorsal pathway, which includes MT, is specialized for processing coarse disparities and driving eye movements. According to this description, the ventral stream, which terminates in the inferotemporal cortex (IT), is responsible for fine disparity and high-resolution depth judgments.

fMRI Studies

The study of the neural basis for stereopsis in human subjects has grown rapidly with the advancement of brain scanning technology such as functional magnetic resonance imaging (fMRI). Investigators had previously shown that individuals with damage to the parietal region suffered deficits in stereoscopic depth perception, and subsequent studies using fMRI confirmed this relationship. However, more recent work by Ben Backus and colleagues demonstrates that, as electrophysiology has shown in the monkey cortex, processing of binocular disparity information occurs throughout the human visual cortex. To date, the results of fMRI studies in humans map well onto the electrophysiological results. Particularly interesting is recent work that suggests that MT is involved in the combination of disparity and motion for the perception of 3D form.

Although researchers are beginning to understand the neural and behavioral basis of stereopsis, many questions remain. For instance, is stereopsis processed differently in the dorsal and ventral streams, is surface perception a critical component of stereoscopic processing, and can stereopsis be regained by individuals previously believed to be stereoblind?

BISTABLE PERCEPTION

Human perception is amazingly efficient and usually stable despite the intrinsic ambiguity and uncertainty of sensory input. However, occasionally our sensory systems do fail to reach a single interpretation for a given input. Sometimes, our percepts fluctuate between two distinct interpretations or states, although more than two interpretations are also possible. This is called *bistable* (or multistable for more than two states) *perception.* The perceptual alternations are spontaneous and stochastic, and the alternating percepts are often mutually exclusive. This entry describes varieties of bistable perception, binocular rivalry, mechanisms for perceptual switching, and tools used for studying mechanisms of object perception and visual awareness.

Varieties

Several varieties of stimuli can lead to bistable perception. Many bistable phenomena are generated from a set of common factors, some of which are listed here.

Unspecified Depth Relationship

Retinal images are fundamentally two-dimensional, but objects in the real world are three-dimensional, thus the depth relationships between different parts of an image are ambiguous. The Necker cube—a wireframe cube that can be seen as switching back and forth between two different viewing angles—falls into this category. The depth of the different wire segments is intrinsically unspecified.

Unspecified depth information can also lead to bistable perception of dynamic images. For example, varying speed of motion across different parts of an image can lead to the perception of a three-dimensional structure (structure-from-motion, motion parallax cue). Two sets of random dots sliding sideways across each other within a rectangular area, their speeds following a sinusoidal function, slower near the boundary and faster in the center, would be seen as a transparent rotating cylinder. However, the depth relationship of the two surfaces is ambiguous and bistable. Observers can see either the leftward moving dots or the rightward moving dots as the front surface, and as a consequence, perception of the cylinder alternates between clockwise and counter-clockwise rotation motion. A rotating silhouette figure is also bistable and can be perceived as rotating either clockwise or counter-clockwise. This is also because the depicted person could have two possible viewpoints (facing direction) at any moment, essentially also a problem of unspecified depth relationship.

Ambiguous Border Ownership

Boundaries between different regions of an image can have ambiguous ownership. The familiar Rubin's face-vase illusion belongs to this category. Here the space between a pair of facing profile faces can be seen as a vase. When the percept of the vase arises, the faces recede, and vice versa. This perceptual alternation occurs automatically. In this case, the borders between the two outer faces and the middle vase can be seen as belonging to the faces (face percept) or belonging to the vase (vase percept). In essence, the ambiguity of border ownership is also an ambiguity in depth assignment—which surface area is in front and occludes the other regions?

Competing Grouping Possibilities Between Image Components

Image components can be grouped in different ways. A simple example is a matrix of evenly spaced dots that can be seen either as rows of dots or columns of dots. The bistability can be enhanced when different Gestalt cues lead to different groupings (e.g., color alternating across rows and size alternating across columns). Similarly, moving components can be grouped in different ways, resulting in bistable (or multistable) percepts, as exemplified by the motion quartet demonstration, in which case grouping (or correspondence) occurs over time.

More generally, bistability can result from components fluctuating between organized and unorganized states. A good example is the well-researched component versus pattern motion: two gratings sliding across each other can be seen as just that, or they can stick to each other and form a plaid. Under the right conditions, perception clearly alternates between component grating motion and grouped plaid motion. Another excellent example is a moving diamond placed behind three invisible occluding bars so that no corner can be seen. The four visible edges of the diamond can be seen as moving relatively independent of each other (sliding up and down in the space between occluders), or they could be seen as parts of a single diamond shifting sideways.

Bistable Perception in Audition and Tactile Perception

Although less common, bistable perception also occurs in other sensory modalities. For example, bistable streaming can occur with two repetitive tones when the frequency difference between them is moderate. Over time, perception alternates between one combined stream and two independent streams. Similar to apparent motion experienced visually, alternate tactile stimulation at two nearby locations generates a tactile apparent motion. Interestingly, a tactile version of the bistable motion quartet can be experienced as well. For example, if pairs of brief vibrotactile stimuli are applied to the finger pad with short intervals, and with each successive stimulus pair alternate between the opposing diagonal corners of a small square, observers will experience switches between the two motion paths, one that moves up and down and another left and right.

Binocular Rivalry

A special yet intriguing type of bistable perceptual phenomenon is binocular rivalry. Normally, our two eyes' retinal images are similar. However, when the images at corresponding retinal locations of the two eyes are different, observers tend to see an alternation between these two images, a phenomenon called binocular rivalry. For example, if a horizontal grating and a vertical grating are projected to the left and right eyes' corresponding locations, respectively, observers would see an alternation between the horizontal and the vertical grating.

One of the central questions with regard to binocular rivalry has been "what rivals during binocular rivalry?" Two main answers have been provided to this question. (1) Rivalry is a mutual inhibition between the two sets of eye-specific neurons (eye rivalry); (2) rivalry is an alternation between two stimulus representations (stimulus rivalry). Each view has its own strong supporting evidence. More recently, the consensus has been that binocular rivalry involves both early (low level) and late (high level) processes, and both eye rivalry and stimulus rivalry are possible. Whether it is primarily eye rivalry or stimulus rivalry is determined by specific stimulus conditions.

The visual system consists of multiple and parallel pathways, and growing evidence indicates that rivalry occurs in the parvocellular rather than in the magnocellular pathway. For example, in the absence of form and color conflict, two flickers with a dramatic difference in temporal frequency are not engaged in rivalry, and fast motion signals are much less likely to rival than are slow motion signals, even with conflicting directions of motion between the two eyes.

Mechanisms for Perceptual Switching

A hallmark of bistable perception is that one has little voluntary control over the switching process. Attention can modulate the dominance duration of a percept to some extent, more so for certain bistable pictures than for binocular rivalry, but perceptual switching cannot be halted. The dynamics of bistable perception is usually characterized as a stochastic process. The distribution of percept durations has often been described (or fitted) with a gamma distribution; however, alternative models have been suggested, among them that the gamma distribution is better fit to switching rates than to percept durations. The neural mechanisms responsible for perceptual switching during bistable perception remain poorly understood. However, adaptation to the currently dominant percept/stimulus plays an important role. The idea is that over time the dominant percept/stimulus would become weaker and succumb to the previously suppressed percept/stimulus. Reducing the effect of local adaptation (e.g., by slowly moving the pair of competing stimuli) significantly slows binocular rivalry alternations. Another interesting proposal is that bistable perception, including binocular rivalry, results from switching dominance between the two hemispheres. Loosely related to this proposal, rivalry switching rates in certain clinical populations (e.g., bipolar patients) were found to be much slower than were normal controls.

Although perceptual switching cannot be halted voluntarily, manipulating the context (spatial, temporal context, or cross-modal context) of the bistable stimuli can have strong effects on the dominance durations and switching dynamics. For example, placing a Necker cube in the middle of unambiguous cubes consistent with one of the percepts would significantly increase the probability of seeing the Necker cube the same way as those unambiguous ones in the context. Intermittent presentations of bistable stimuli, with stimulus on-times less than the average dominance duration and stimulus off-times a little longer, can lead to a dramatic reduction in switching. In some observers, such a temporal manipulation can even completely abolish the perceptual switching, thus stabilizing the bistable stimuli. With intermittent presentations, the forces (e.g., adaptation) that drive switching from one percept to another are apparently much weaker than the facilitation (e.g., priming of some sort) from prior experience of the dominant stimulus. Unambiguous cues from other sensory modalities can bias the percept of an ambiguous stimulus. For example, touching a rotating cylinder can significantly bias the percept of a visual bistable rotating cylinder so that the two cylinders match rotation direction.

Tools to Study Mechanisms of Object Perception and Visual Awareness

Bistable stimuli have received renewed interest in recent years partly because they afford the opportunity to isolate neural mechanisms more closely related to awareness. The logic is relatively simple: With bistable perception, the stimulus stays constant but perception changes, thus correlated changes in neural activity in the brain must have more to do with the perceptual change. Conversely, binocular rivalry can be used to create a complementary situation where monocular stimuli presented under suppression are not explicitly detected by the observer, and the neural mechanisms registering the unperceived stimulus would less likely serve as the neural mechanisms directly involved in generating perceptual awareness. The observed neural signal change is not necessarily the so-called neural correlates of consciousness (NCC), but we can at least conclude that neural mechanisms with activity more in sync with perceptual states are better candidates for NCC than are neural mechanisms that are more in sync with stimulus states. For the goal of presenting stimuli under interocular suppression, an interesting modification to the rivalry paradigm is the so-called continuous flash suppression paradigm in which one eye is presented with high-contrast dynamic noise and the corresponding retinal region in the other eye is presented with interesting images. Often, the goal in this situation is to check at what level in the processing hierarchy as well as in which pathway the suppressed images can be processed.

Certain bistable stimuli can also be used to study visual neural mechanisms of object perception. As described earlier, a class of bistable stimuli fluctuates between an unorganized collection of components (features) and an organized perceptual pattern (object). Examples include the moving stimulus that could be seen as either two sliding gratings or a single plaid. Such stimuli allowed the discovery of motion sensitive neurons that are selective for direction of component motion and motion neurons selective for the direction of pattern motion. In the case of a diamond moving behind invisible occluding bars, the alternate bistable percepts correspond to either a coherent shape (diamond) or elementary features (moving bars). With this stimulus, an interesting finding is that when observers report seeing the diamond, activity in the early visual cortex decreases while activity in high-level object sensitive areas increases. This observation provides insight into the interactions between the primary visual cortex and object sensitive cortex.

BODY PERCEPTION

Body perception refers to the detection and recognition of an animate body and its postures. The body is a special object of perception because unlike other objects, it refers to perception of the self as well as to perception of others. Our own bodies tell us what we are doing now and help us figure out how we should perform actions that give us what we want. Visual perception is integrated with additional sensory channels that provide tactile, proprioceptive, and kinesthetic information for multimodal processing. We see it, feel it, and control it. This online body information organizes current body information with stored spatial and structural body information. Because of the body's unique structure, other people's bodies are also special objects of perception. They give us information about what they are doing and whether we need to respond to what they are doing. We frequently observe other people's bodies, imitate them, interact with them, and predict their movements. Hardwired brain circuits capture specific body configurations, postures, and actions. Finally, body perception involves understanding the relation between the two sources of body information. The influence of one's own body on the perception of other people's bodies defines embodied perception. This interaction of body information from one's own body with information from other people's bodies helps us understand how other people are like us and helps us learn new skills.

Two types of representations are specific to the body and are not used for other objects: an online representation that coordinates sensorimotor inputs about our current body configuration and a long-term body representation that organizes information about the structure and spatial properties of the human body in general. Although terms such as *body percept, body image,* and *body schema* have been used interchangeably to refer to both of these concepts, the term *body schema* is most frequently used to refer the online representation, and the term *body structural descriptions* is used to refer to the long-term, spatial properties of the body. This entry describes perception of one's own and other people's bodies, specialized body processing, and the significance of body perception.

Perception of One's Own Body

Perception of our own body relies on the integration of information from multiple senses into a common framework. These sensory inputs combine to form an online body representation that tells us about the configuration of our body parts in a particular body position at a certain point in time. This helps provide the information needed to produce successful actions. This dynamic representation changes every time the body changes position. Inputs from the senses and muscles (e.g., touch, kinesthesis, proprioception, and vision) modify the immediate, online body representation and update it to keep track of current body positions and current locations of sensation. Thus, the online body representation represents one's own body exclusively because it contains privileged information about present body status, sensory feedback, and motor intention for performing actions in the environment.

A number of studies have documented the joint contributions from visual, tactile, and proprioceptive inputs to our perceived location and identity of body parts. For example, when a person is presented with the simultaneous presentations of tactile and visual stimulation, her response speed to the *tactile* stimulus is slower when the *visual* stimulus is close to her hand compared with when it is far from her hand. The same pattern of responses occurs even when the viewed arm and hand are replaced with a fake arm and hand in an anatomically possible posture.

Moreover, the relative contributions of vision and touch to body perception can be revealed by introducing sensory conflict. Distorting devices such as prisms, mirrors, and video monitors can be used to artificially displace the visual location of body parts to varying degrees from natural viewing conditions. In other words, the visual image of our hands can be displaced to appear somewhere else in space or time. People experience a conflict between the seen and felt positions of their body parts when their visual fields are distorted or displaced by wearing prism glasses. This exposure to sensory conflict leads to a shift in the perception of the body part so that it "feels" like it is located where it is "seen." These findings indicate the importance of visual contributions to body perception.

The importance of proprioception and kinesthesis to body perception can be demonstrated through a body perception illusion. Vibrating the tendons of arm muscles induces illusory arm movements. For example, it feels as though one's bent arm is straightening if the biceps muscle is vibrated. If the biceps muscle is vibrated while the hand of that arm holds the nose, the experienced sensation is that one's nose "grows" or lengthens like Pinocchio's when he tells a lie. This illusion constitutes a resolution of sensorimotor conflict with the long-term body representation. Because the head and body are stationary, the combined sensory input from the hand and the arm is perceived as the nose elongating. Thus, the configuration of the whole body is inferred from the various inputs rather than from the direct perception of the body parts. Our structural body representations interact with online representations even without vision.

The perception of one's own body in some ways is different from the perception of other people's bodies. For example, these perceptions differ in visual and proprioceptive inputs. Despite these apparent differences, however, the perception of one's own body and of other bodies is closely related.

Perception of Other People's Bodies

Body representations also assist in the organization and perception of other people's bodies. The interface between the perception of one's own body and the perception of other people's bodies is the long-term, body structural representation. This representation is a dedicated, internal representation of the spatial organization of body parts and the invariant properties of human body structure. The representation incorporates information about the relative locations among body parts, the degrees of freedom for movement at joints, and anatomically possible body function. It is multimodal, incorporating information about one's own and others' bodies from multiple senses, especially vision, touch, and proprioception. In contrast to the online body representation, the long-term body representation is used to represent body information about other people as well as oneself.

One source of evidence for a long-term, multimodal spatial representation of body comes from the adult neuropsychological literature. Patients with autotopagnosia often have brain damage in the left parietal lobe. Although patients can identify individual body parts by themselves, they cannot locate the same body parts within the context of the complete body. Patients cannot localize body parts on themselves, on the experimenters, or on dolls. This deficit is not limited to vision because patients cannot find specific body parts on bodies whether they look for them or feel for them. Further, it is specific to the body because patients can find named parts on other objects such as trucks or trains. Finally, the deficit affects the spatial body representation specifically because patients can demonstrate good knowledge of bodies, naming of body parts and relatively intact general spatial abilities. Patients with autotopagnosia appear to have lost their spatial body representation that is used for organizing information from their own bodies and other people's bodies.

The structural similarity between one's own body and other people's bodies helps the visual system make inferences about other people and their actions. From these similarities, it can determine whether one's own body could perform movements similar to those of someone else. For example, people spontaneously use their own body to make judgments about other bodies. In one study, people were given pictures of bodies rotated to various degrees away from vertical and were asked whether a dot was on their left or right hand. Response times varied depending on the discrepancy between the angle of the illustrated hand and the person's own hand. The response times indicated that people mentally simulated the movement of their own hand to match the picture before making the left or right hand judgment.

The use of one's own body to interpret the visual world is especially important for perceiving other human and animate bodies and their actions from impoverished visual information. The phenomenon of biological motion refers to our ability to readily perceive a solid human or animal walking and performing complicated actions such as running, yoga, or dancing from moving dots or point-light displays. Point-light displays are created from filming a person moving in the dark with lights attached to his or her joints. Only the moving lights against a dark background are visible; no explicit body structure information is provided in the stimulus. Even with such minimal body information, people can identify human and animal body structure and movement almost immediately. Although humans can perceive the biological motion of animals, they are most efficient at recognizing other humans. They can even distinguish themselves and friends from strangers. It is proposed that people use their representations of their own bodies and visual experiences to interpret the displays.

Other people's motions influence body perception, but our own movement influences body perception as well. What we do with our own bodies affects how we perceive the bodies of others. In one study, people performed a memory task in which they compared two sequentially presented postures of another person. At the same time, they either moved their arms or their legs. Performance in the posture memory task depended on what limbs were moved. If participants moved their arms, their memory for other people's arm postures was selectively improved. When participants moved their legs, their memory for other people's leg postures was selectively improved. Importantly, the interaction between body movement and memory is specific to the body. When people compare two nonsense objects (e.g., made from LEGO toys), movement has no effect on memory. Thus, the same body representation appears to be used to encode the body positions for the self and others.

The integration of one's own body information with other people's body information is important for learning new skills and social interactions. We learn from other people through imitation. Imitation unites the perception of another human's action with one's own production of that action. For example, when learning a tennis serve, a person perceives the action visually, and reproduces the action motorically. The commonalities between what people can do and what they perceive other people doing suggest that a similar mental code and neural system support the learning of new skills and understanding what other people are doing. The mirror neuron system has been proposed as a neural network that responds similarly when a primate observes the execution of a goal-directed action (e.g., reaching for a peanut) and when the primate physically executes the action. Ultimately, these systems help organize body information into meaningful perceptions that tell us how to prepare ourselves for responding appropriately to what others are doing.

Specialized Body Processing

In addition to having body-specific representations, human bodies and their postures are visually perceived using "special" recognition processes that are not used by most common objects. Like faces, bodies are recognized using configural processing mechanisms. There are good reasons why bodies are perceived more as faces are than like other objects. For example, both faces and bodies are important social stimuli for which recognition has evolutionary importance. Humans have extensive experience viewing faces and bodies from birth. Both are identified at the individual level (e.g., Joe) rather than as just a category (e.g., face or body). Importantly, humans can configure their faces and body postures to convey emotions, intentions, and other meaningful information.

The visual perception of body postures (and faces) depends on configural processing rather than on the part-based processing used to recognize most objects. To recognize a body posture, one cannot rely on the presence or absence of a particular part. Bodies usually have two arms, two legs, a head, and a trunk. Instead, different body postures are identified by differences in the precise spatial relations among the shared object parts, or their configuration. In contrast, part-based recognition processes are used for most common objects. Recognition time and accuracy are largely independent of where parts are located or in what orientation the object is situated. A widely used empirical indicator of configural processing is the inversion effect: the recognition of upright items is faster and more accurate than is the recognition of inverted items. Inversion disrupts the configuration or spatial relations among features. For bodies, inversion disrupts the basic body-part relations because heads are no longer above the trunk, which is no longer above the legs. Robust inversion effects have been found for both body postures and faces, suggesting that they are processed configurally. In contrast, most objects (e.g., houses) do not show inversion effects.

The inversion effect can also be used to indicate what body information is necessary to define the body. Researchers manipulated the body stimulus to find out what changes in body information lead to the breakdown of configural processing as indicated by the loss of the inversion effect. When bodies were divided in half along the vertical axis (dividing left from right), the inversion effect was robust. It appears that the visual system was able to reconstruct the body from the long-term body representation because the body is largely symmetrical along its vertical axis. However, when bodies were divided in half along the horizontal axis (at the waist), the inversion effect disappeared. Individual body parts (e.g., arm, leg, head) did not produce inversion effects either. Of interest, when body-part relations were scrambled and limbs were placed on the trunk in alternate locations (i.e., arms put in the head position, legs in arms, etc), not only were no inversion effects found, but the visual system's ability to distinguish between scrambled body positions plummeted. In other words, when the spatial locations of limbs on the trunk violate the long-term spatial body representation, body posture perception is severely impaired.

In addition to functional processing mechanisms, the brain provides a special status to perceptual stimuli that correspond to the human body. Neuronal populations in the superior temporal sulcus and fusiform gyrus are selectively sensitive to bodies compared with other objects and faces. One neuroimaging study compared neural responses to images of headless bodies and body parts to control images. A region of the lateral occipitotemporal cortex, known as the extrastriate body area or EBA, responded selectively to static images of human bodies and body parts. In contrast, the EBA had only a weak response to face, object, and object parts. The response of the EBA also generalized to line drawings, stick figures, and silhouettes of bodies. It appears that the EBA represents bodies at an abstract level that does not rely on visual features.

Thus, the way we view the human body is distinctive from the way we view most other objects. Behavioral and neural evidence suggests the body appears to be defined by its hierarchical structure and that the specific configuration of body parts is important for recognition.

Development of Body Perception

Developmental researchers have investigated what aspects of human bodies allow infants to distinguish them from other objects. A sensitivity to human bodies appears early in development. Evidence from phantom limb patients points to the existence of primitive spatial body representation that may be hardwired in the brain. Despite a lack of sensory input and experience using limbs, individuals with aplasia (e.g., born without limbs) often experience phantom limb sensations and perceive movements of other people's limbs no differently from typically developing individuals.

In typically developing children, a sensitivity to the configuration of body parts appears sometime after the first year of life. Infants younger than 18 months are unable to distinguish between normal and scrambled images of bodies. Although infants' perceptual expectations about normal human faces develop earlier than do those about human bodies, a human body template is shared among infants.

During the first year of life, infants also acquire a sensitivity for the biomechanics of how humans move within the organization of the human body. Three-month-old infants prefer point-light walker displays of upright walking humans relative to inverted walking humans. By 5 months, they are able to distinguish a global body form as long as it provides a context in which the body parts are salient. Infants' visual sensitivity to the structure of the human body corresponds with the infants' acquisition of a basic set of motor skills during the first 18 months. Thus, the development of sensitivity for the visual perception of human bodies corresponds with the development of motor production.

Researchers have proposed that infants, like adults, use body representations to integrate and process stimuli across sensory modalities. Newborns are able to copy gestures. For example, when an adult opens his mouth, the infant opens his mouth in response. When an adult sticks out his tongue, the infant sticks out his tongue. The ability of infants to view another person's movements and reproduce them with their own bodies indicates that infants have body representations that link the infant's actions (proprioception) to the actions of another (vision). These rudimentary imitation skills suggest that neural systems, such as the mirror neuron system, are in place early in development to facilitate learning from other humans.

Significance

Humans are embodied and optimized for processing "like me" information. Perceptual processes integrate information about the observer's own body and other's bodies. Further, visual processing changes if stimulus features resemble information in the observer's own body representations. Specialized body representations and mechanisms help organize information from other people's bodies and aid in body perception. Why is efficient body perception important? The significance of interpersonal action suggests that a key function of these mechanisms is social perception. People's perceptual goals are functionally based around what other people are currently doing; knowing what another is about to do increases the chances that one's own actions will be appropriate.

BODY PERCEPTION: DISORDERS

The brain computes at least three distinct types of representation of the human body. One type of representation, known as *body semantics* (or *body image* in the classical literature) codes long-term explicit knowledge about body parts, their functions, and their associates (e.g., the wrist is the place where a watch or bracelet is worn). The second type of representation provides a dynamic, constantly updated ("online") mapping of the current locations of body parts in space (the *body schema*). The third kind of representation codes more stable, long-term topological information about the structural positions of body parts on the body surface (*body structural descriptions*). Although the brain structures mediating these representations are not firmly established, several lines of evidence suggest that the body schema and body structural descriptions rely on the integrity of the parietal lobes, whereas body semantics are likely mediated primarily by the temporal lobes. Damage to the body schema or body structural descriptions results in a diverse group of disorders of body perception, to be described in this entry.

Body Schema Disturbances

The body schema is an online representation of the body derived from numerous motor and sensory inputs (e.g., proprioceptive, vestibular, tactile, and visual). It is used to generate accurate representation of body posture, to guide action, and to aid in the perception of the body postures and actions of others. Patients with disorders of the body schema have difficulty performing such tasks.

Personal Neglect and Associated Phenomena

Hemispatial neglect is a common consequence of stroke, particularly to the brain's right hemisphere, but also occurs on occasion following left hemisphere stroke, as well as subsequent to traumatic brain injury or tumor. Patients with neglect fail to attend to or act in the side of space opposite the brain lesion and may fail to attend to one side of their bodies. Thus, for example, patients with left neglect caused by right hemisphere lesions may fail to wash their left hands, comb their hair on the left of their heads, or shave the left sides of their faces. Even when looking in a mirror, they frequently fail to recognize that the left side of the body is poorly attended. This is known as *personal neglect.*

A well-known phenomenon in the neglect syndrome is that of *tactile, auditory, or visual extinction.* It has recently been demonstrated that the extinction phenomenon is observed within single body parts. For example, if a neglect patient is touched simultaneously in two spots on the back of the same hand, one spot slightly to the left of the other, he or she will frequently only report the right-most touch. There is thus a "gradient" of attention that spans individual body parts.

Neglect patients often exhibit *anosognosia* for (i.e., unawareness of) their motor and spatial deficits. For example, patients with weakness of an arm or leg after stroke may frankly deny that there is a problem, even when asked to demonstrate the limb's function. Finally, and less commonly, patients with neglect may exhibit *somatoparaphrenia,* or delusions that the limbs on the side of the body opposite the stroke do not belong to them, and may even belong to others. It is not known precisely how such body-related delusions may emerge, but it is likely that they are the product of a mismatch between intact and damaged parietal lobe sectors that code different aspects of perception and action of the limbs.

These deficits all appear to be different facets of a disturbance in the body schema. Treatments that act on the integration of body and space, such as irrigating the ear on the damaged side with cold water to stimulate the vestibular system, may temporarily ameliorate the deficits. Longer-lasting effects have been difficult to obtain.

Ideomotor Limb Apraxia

Ideomotor apraxia is a disorder common in left-hemisphere stroke and degenerative dementia (e.g., Alzheimer's disease, corticobasal degeneration) that is characterized by spatiotemporal errors in pantomime (e.g., "pretended" use of a tool, without the tool in hand), imitation, or recognition of complex movements and postures. For example, a patient with ideomotor apraxia might imitate a hammering gesture with an increased-frequency, low-amplitude movement in the horizontal plane, with the hand open rather than clenched. Such patients are often also impaired in the imitation of meaningless movements and postures, and some of these patients are unable to position a mannequin to copy the same meaningless poses. This indicates that the problem in imitation of meaningless movements and postures is at least partly a problem in perception, and not just in execution. The performance of patients with ideomotor apraxia frequently improves considerably when they are permitted to actually hold and use a tool rather than simply pantomiming the action.

At least some of the differences between pantomimed and actual tool use may be explained because pantomime relies heavily on a form of spatiomotor coding of limb position, called *intrinsic spatial coding,* which is different from the *extrinsic spatial coding* that is strongly involved in tool-use tasks. In an intrinsic spatial coding system, the positions of the limbs and joints are coded with respect to an internal space centered on the body parts, that is, without reference to the external world.

Intrinsic spatial coding must be used, for example, when positioning the body parts into a desired configuration with eyes closed (for example, try pantomiming a "sawing" motion with eyes closed. The fact that you maintain a fairly fixed set of coordinates during the process indicates that your intrinsic spatial coding is intact). In contrast, *extrinsic spatial coding* systems explicitly code the position of body parts with respect to the external world. The latter is particularly useful, for example, when planning and executing reaching and grasping movements, or movements in which a tool such as a hammer needs to contact a recipient object such as a nail. Ideomotor apraxic patients show a marked deficit in their ability to perform tasks heavily reliant on intrinsic coding (Figure 1).

Phantom Limb Phenomena

Amputees frequently experience the sensation that an amputated limb is still a part of the body. This sensation is accompanied by pain in most patients. Sensation of a phantom body part may also occur following removal of other body parts, such as after breast or eye surgery. The missing limb may feel shortened or distorted, and may seem to move, gesticulate, or twitch. A number of investigations indicate that the phantom sensations arise because of decreased input from the amputated body part to the somatosensory cortex of the brain. Areas of the somatosensory cortex that are near to the original area will take over, or "remap" the cortical region that no longer has input.

The most successful treatments of phantom limb phenomena include use of a mirror box or virtual reality to create false visual feedback about the movement of the phantom limb. When the good limb moves, participants perceive another limb moving at the location of the phantom limb. Essentially, this treatment appears to work by coupling the movement of the good limb to the tactile and proprioceptive sensations of the phantom limb, thus causing a remapping of input-output connections. Spinal cord stimulation with an electric current emanating from an electrode near the spinal cord may also be an effective treatment.

Disturbances of Body Structural Descriptions

Structural descriptions represent objects' shapes in terms of their parts, and the relationship among parts; in turn, these parts are explicitly represented as shapes in their own right. A number of lines of evidence suggest that shape primitives such as cones, cubes, and cylinders may be invariant to viewpoint (i.e., recognizable from many perspectives) and can generalize to novel objects. *Work* with patients with *autotopagnosia,* a deficit in body-part localization, suggest, that there is a specialized structural description system for the representation of human body parts.

Autotopagnosia

Patients with autotopagnosia are unable to localize body parts on themselves or others, whether cued by verbal command or instructions to model the performance of another person. Thus, for example, if an examiner points to her ear, an autotopagnosic patient may be unable to point to his own ear in turn. Although the disorder is quite rare, there are several reports of patients who show the cardinal signs of the disorder: inability to localize human body parts by pointing, but no difficulty localizing parts of animals or inanimate objects. In addition, many of these patients are able to name body parts pointed to by an examiner, and to name the functions of body parts. These data indicate that a discrete representation of the human body is separate from semantic knowledge-based representations.

Several accounts propose that autotopagnosia reflects impairment in a spatial map of the body, but only relatively recently has it become clear that this map is different from the body schema discussed in the previous section. Several interesting autotopagnosic patients, for example, have been unable to point to body parts on command, but could readily point to small objects taped to the same body parts. This indicates that the patients could perform all of the spatiomotor operations needed to localize points on the body surface and to program a reaching movement to those locations, but could still not identify discrete body parts. One of these patients had difficulty matching pictures of body parts (e.g., a nose and a different nose) when they were presented from different views. This suggests that this patient was unable to access stored representations of body parts that would permit him to judge whether the parts are the same even with occlusion of specific details. These and other data indicate that these patients suffer damage to a representation that encodes the appearance and topological location of body parts; that is, a "structural description" of the body.

Gerstmann's Syndrome

One circumscribed instance of a deficit in body structural descriptions may be seen in Gerstmann's syndrome, a relatively common group of symptoms that occurs frequently after left inferior

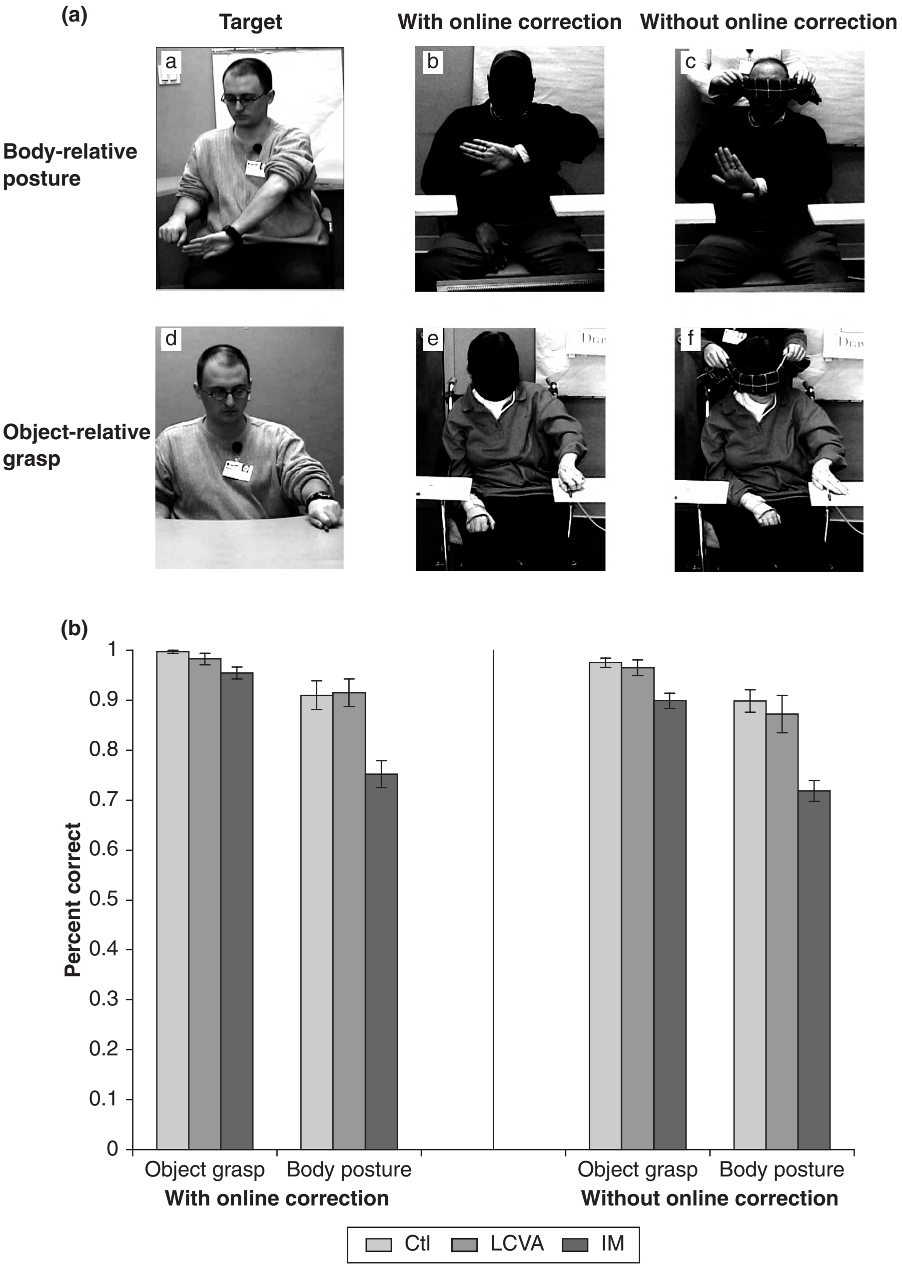

Figure 1 Ideomotor Apraxia

Source: Jax, S., Buxbaum, L. J., Moll, A. D. (2006). Deficits in movement planning and intrinsic coordinate control in ideomotor apraxia. *Journal of Cognitive Neuroscience, 18*(12), 2063–2076.

Notes: (a) Examples of performance of patients with ideomotor apraxia, from a study by Steven Jax and colleagues on a task requiring imitation of body-relative postures (top row) and object-relative grasps (bottom row). Left column: target posture. Middle column: examples of performance with full vision, where online correction is possible. Right column: performance without vision of the hand or target, where online correction is not possible. (b) Data from the task shown above. Light gray data bars are healthy control subjects (Ctl), medium gray are patients without apraxia who have suffered left-hemisphere cerebrovascular accidents (LCVA), and dark gray are patients with ideomotor apraxia (IM). Note the poor performance of apraxic patients for body-relative postures both with and without online correction, as well as for object-relative grasps without online correction. Ideomotor apraxics have difficulty positioning the body parts with respect to one another (*intrinsic coding,* explained in text), and are abnormally dependent on visual feedback.

parietal stroke. Although there is ongoing disagreement about whether Gerstmann's syndrome is a "true" syndrome, the components of the disorder are commonly observed together, and include a writing disability (dysgraphia), an inability to distinguish right from left, a lack of understanding of the rules for calculation or arithmetic (dyscalculia), and an inability to identify fingers (finger agnosia). The symptoms frequently occur in the context of a number of other neurological impairments, including *aphasia* (language disturbance), but have also been reported in pure form.

Gerstmann himself believed that a deficit in knowledge of the body was the common core underlying these symptoms. He based this hypothesis on observations that right–left disorientation is often particularly marked regarding the hands and fingers, finger differentiation is required for writing, and fingers play an important role in early learning of arithmetic operations in children, as well as in counting in some adults. Given that patients with the syndrome are impaired with others' bodies and not just their own, Gerstmann argued that knowledge of one's own body was necessary to understand another body. However, given the strong resemblance of the finger agnosia observed in Gerstmann's syndrome to the deficits exhibited with the entire body in the autotopagnosia syndrome, it remains quite possible that Gerstmann's syndrome reflects a deficit in mental manipulation of body structural descriptions.

Emerging Issues

Recent advances in research on monkey physiology indicate that there are prefrontal and parietal brain regions containing so-called mirror neurons that fire both when the monkey observes another's actions as well as when the monkey performs the same actions. Thus, these neurons may encode equivalence between the bodies of self and others. These interesting observations are likely to be the tip of the iceberg in our understanding of the encoding of body perception by the human brain. The range and variety of disorders of body perception indicate that there is considerable depth, complexity, and variability in human body processing. However, many details remain to be elucidated. It is known, for example, that some regions in the human temporal lobe—the extrastriate body area and fusiform body area—respond to the sight of human bodies, but lesions in these regions do not commonly cause problems with body perception. What, then, is the cognitive function of these regions? Conversely, as reviewed here, evidence from patient studies indicates that there are three dissociable types of body representation, each causing distinct body representation disorders, yet more work remains to clarify the precise brain regions that mediate these representations, how the representations act alone or in concert in the context of various tasks, and whether there are evolutionary antecedents as would be revealed in studies of the monkey brain.

BRAILLE

Braille, described in this entry, is a useful system for reading and writing by touch that was developed by Louis Braille in 1829. Before that time, some of the available systems attempted to mimic the shapes of letters. Braille is derived from a 6-millimeter (mm)-high dot matrix and does not copy letter shapes. The use of embossed letter shapes was not a successful strategy because evidence indicates that Braille patterns are far more discriminable than letter shapes, according to Jack Loomis. Although it is certainly possible to use touch to read embossed print shapes, the patterns need to be much larger than Braille characters to be useful. One would need to enlarge embossed letters to at least 1 centimeter (cm) to make them easy to feel.

Braille is an abstract code that is derived from a 2 (across) by 3 (down) rectangular matrix of embossed dots. The letters A through J are represented by the top 2 × 2 cells of this matrix, and the rest of the alphabet is produced by adding dots to the bottom two cells. Thus, the entire alphabet is produced by varying combinations of the six dots. Many blind people learn to identify the individual characters at rapid rates when they learn the code early in life.

Reading Braille Text by Hand

Most blind people are not fluent readers of Braille. The reason for this is rather simple: Namely, most people lose their sight later in life rather than in early childhood. As one ages, the frequency of visual impairment increases, and a common cause of visual impairment is diabetes, often accompanied by neuropathy and reduced tactile sensitivity. It is difficult to learn to read as an adult, and the difficulty is magnified for learning to read with one's fingers. Acquisition of skill in reading Braille is most readily accomplished in an educational environment where a child has access to good educators who have been trained in this area. However, this is less common today, given mainstreaming of visually impaired students. Former visual print readers also have considerable difficulty making the translation to reading Braille because Braille text is highly contracted. According to Susanna Millar, Braille text uses a large number of contractions to save space and time, and older visual habits may show interference effects and cause difficulty because of the presence of visual reading habits. Learning to read visually entails connecting sound patterns with visual patterns. Millar, however, contends that reading Braille requires that one attend to dot density patterns or patterns of textures, rather than letter shapes.

According to Millar, slow Braille readers tend to try to treat each character as an individual pattern or shape, and show vertical tracing patterns. For example, a letter B is represented by two vertical dots, and naive readers may move their fingers up and down as they feel the dot pair. These "scrubbing" behaviors interfere with rapid reading, which can reach more than 200 words per minute (wpm) in skilled, long-term readers. The novice is also likely to trace the shape of each character, and has a great deal of difficulty reading entire Braille words. However, skilled readers show rapid scanning of the lines of Braille, with few hesitations. Note that tactile acuity is increased in persons without sight, according to K. Sathian. Some of the difficulty that late blind persons have with learning to read Braille may be motivational. Older individuals often have difficulty coping with their loss of sight and the related restrictions in mobility. The necessity to acquire new mobility skills may limit the time available for learning to read Braille.

Laterality and Braille

The most common way that blind people read Braille is with the index finger of the right hand for reading and scanning the text. Most blind people use two hands when reading Braille skillfully. The right hand is generally used for reading the text and the left hand is used for keeping place and finding the next line of Braille as the reader completes scanning of the preceding line.

The large literature on laterality effects in vision provides evidence that the left brain excels at verbal tasks and the right hemisphere is better suited for pattern perception. This literature has led some educators of the blind to insist that students use their left index fingers for scanning Braille. This cumbersome reading method is questionable at best. It assumes that reading Braille primarily depends on the ability to perceive the individual patterns that constitute the Braille. Evidence indicates that rapid Braille reading depends on perception of texture patterns, or dot density, according to Millar. In any event, reading Braille is a complex skill that includes perceptual and higher-level cognitive, verbal components.

Multimodal Influences and Cross-Modal Plasticity

Researchers have adopted a variety of methods of studying Braille, and these have included the involvement of sighted persons and blind persons. Although the results of studies with sighted persons are interesting and informative, an important caveat should be remembered. Sighted persons are not skilled at reading Braille, and few, if any, sighted individuals can read normal Braille text by hand. For example, one finds less than 47% correct reading of two-letter uncontracted Braille words by sighted individuals according to Morton Heller, but 100% correct for two-letter words by blind persons.

Some evidence indicates that identification of Braille is enhanced in sighted individuals when they are allowed sight of the hand as it feels the Braille characters, even when they cannot see the dots themselves, according to Heller. This advantageous combination of the senses may derive from providing blindfolded sighted persons with spatial reference information about the location of the patterns in space, and the horizontal orientation. Patterns such as letters or Braille are defined by orientation, and it is easy to confuse Braille configurations when they are tilted. For example, if one rotates a Braille C (. .) by more than 90 degrees, it becomes a B (:).

Recently, researchers have been interested in how the brain processes Braille characters in blind and sighted individuals. According to Lofti Merabet and colleagues, the visual cortex is active when blind people process Braille. This indicates a reorganization of the brain owing to experience. Moreover, evidence indicates visual cortical involvement in the sighted according to Sathian and Simon Lacey. It is presently not clear exactly how the functioning of the visual cortex may differ in blind and sighted individuals, but future research will likely provide clarification of this question.

New Technology

A variety of new devices facilitate Braille output from computers, and input of Braille to the computer for blind persons. These devices are expensive, but extremely useful to the fluent reader of Braille. In addition to refreshable Braille displays that permit immediate translation of text on a computer screen to lines or pages of Braille, screen readers will read the text aloud that appears on a computer screen for the blind user. Text may be scanned using sophisticated optical character recognition (OCR) technology. Moreover, electronic Braille printers have become more widely available. However, out of convenience and cost considerations, some blind persons still use old technology (e.g., the Perkins Braille typewriter or other mechanical devices). Although voice recorders, scanners, and screen readers are helpful, they are not complete substitutes for a system of reading and writing.

BRAIN IMAGING

One of the fundamental challenges in understanding the human central nervous system is characterizing how its various functions are localized and how they interact with one another. Imaging technologies enable neuroscientists to visualize the structure of the human brain and to measure biological activity through the skull, revealing the living brain at work. Functional localization of human perception and cognition are conventionally achieved either by recording the activity during behavior or by measuring the deficit in performance after lesioning specific regions.

At least six different families of techniques are used to investigate different aspects of human brain function: positron emission tomography (PET), functional magnetic resonance imaging (fMRI), electroencephalography (EEG), magnetoencephalography (MEG), transcranial magnetic stimulation (TMS), and lesion analysis. Each technique provides different information about brain function and affords particular strengths and weaknesses. The most spatially precise methods for localizing brain responses during mental activity are PET and fMRI. Both of these methods take advantage of the local coupling between neuronal activity and the hemodynamic response; specifically, local increases in neuronal activity lead to local changes in cerebral blood flow, blood volume, and blood oxygen concentration. Neurovascular coupling provides an indirect measure of brain activity that is fundamentally limited by the characteristics of the hemodynamic response on which the activation signal is based. Nevertheless, these methods have revolutionized the field of cognitive neuroscience during the past 10 to 20 years primarily because the activation results can be visualized as an appealing three-dimensional image that can be interpreted by the expert and layperson alike.

Finer temporal information about the millisecond time course of brain activity is achieved through EEG and MEG techniques. EEG is sensitive to scalp-surface electrical activity produced by synchronous neural firing in the brain, and MEG is sensitive to scalp magnetic fields directly generated by this electrical activity. These methods are commonly used to measure brief changes in electrical potentials or magnetic fields that are time-locked to a perceptual or cognitive event. However, the sources of the electrical generators giving rise to the transient evoked changes have to be estimated using modeling techniques, and so spatial mapping typically requires the experimenter to make certain assumptions about the underlying neural activity.

Demonstrating an association between neuronal activity and performance using any of these four methods does not necessarily mean that the brain region of interest is *required* for perception or cognition, but merely that it is engaged by the mental process. The final two methods, TMS and lesion analysis, are best suited to proof of causality (i.e., demonstrating what regions of the brain are necessary for sensation, perception, or cognition), as well as for studying the circuitry and connectivity of the brain. They both concern the suppression of neural activity, by electrical interference or brain damage, respectively. This entry describes in more detail the most popular noninvasive tools for investigating the neurophysiological basis of perception: PET and fMRI.

Positron Emission Tomography

PET is a radiotracer imaging procedure using nuclear technology to create two- and three-dimensional maps of neural activity in the brain. The term PET refers to a general method for measuring tissue metabolism by detecting the local tissue concentration of biologically important compounds, such as glucose or water, that have been labeled with small amounts of radioactivity, such as C11 or 015. A machine called a cyclotron labels these specific compounds with the positron-emitting isotopes that are then injected into the participant's bloodstream. By using different compounds, PET can quantify the amount of blood flow, oxygen and glucose metabolism, and drug concentrations in the tissues of the working brain. Sensors in the PET scanner detect pairs of gamma rays emitted indirectly by the positron-emitting radioisotope as the compound accumulates in different regions of the brain and body. These data are used to produce two- or three-dimensional images of the distribution of the drug molecules or tissue metabolism.

Blood flow and oxygen and glucose metabolism reflect the amount of brain activity in different regions and enable scientists to learn more about the physiology and neurochemistry of the working brain. Brain function is typically measured using a "fast" blood flow method. This particular technique commonly uses an isotope of oxygen incorporated into water that is injected into the blood stream and quickly perfuses the brain tissue. The concentration of the isotope builds up over a period of about 30 seconds while the participant is presented with stimuli or is performing a task. Safety guidelines on the radiation dosage typically restrict the type of participants that can be recruited, often excluding females of childbearing age, for example. Guidelines also limit experiments to a small number of scans, thus permitting the presentation of only a small number of experimental conditions. Another disadvantage of PET concerns the spatial specificity of its functional localization. Although the functionally related blood flow signal is local, it is not possible to determine how precisely it is localized to the cortical grey matter because upstream and downstream large diameter blood vessels can also display detectable changes. Spatial specificity is often reduced further during analysis by spatially smoothing the image data (up to 18 millimeters [mm]) and averaging across different brains to improve the signal-to-noise ratio. Consequently, there has been a shift during the last few years away from the use of PET for neuroscience and toward fMRI. This rapidly evolving technique conveys certain advantages including lower cost, greater accessibility, lack of radiation burden, enhanced spatial precision for localization, and the possibility of conducting single-subject investigations.

Functional Magnetic Resonance Imaging

This major branch of MRI refers to a method for generating two- and three-dimensional images of neural activity that are based on the measurement of minute changes in blood oxygenation levels in the brain. A photograph of a typical fMRI experimental setup is shown in Figure 1. Functional MRI is just one of a family of techniques developed from nuclear spectroscopy. These methods rely on the resonant properties of different atomic nuclei, and so, unlike PET, the signal contrast has an intrinsic origin. The most common signal is derived from the behavior of hydrogen nuclei (protons) because hydrogen (in the form of water, H_2O) is a major component of living tissue. In fact, the human body consists of between 45% and 75% water. Negatively charged electrons orbiting the atomic nucleus generate a spinning charge that exerts its own small magnetic field. When a participant is exposed to an external magnetic field, there is a net increase in the number of protons that are aligned with the direction of the static field.

One of the main components of an MR scanner is its huge superconducting magnet. For example, 3 Tesla refers to a field strength that is 60,000 times greater than that of the earth's magnetic field. The orientation of the net magnetization of the protons can be flipped perpendicularly by applying a short burst of radiofrequency energy that has the same resonant frequency as the hydrogen nucleus itself (i.e., 42.58 megahertz (MHz)/Tesla). When the radiofrequency pulse ceases, the protons lose energy by emitting their own radiofrequency signal that is received by a conductive field coil placed around the participant. This measurement is reconstructed to obtain a set of two-dimensional slices that can be used to create a three-dimensional image. MRI provides exquisitely detailed images not because of the high energy of the individual proton signals that are available to make the MRI signal, but because of the huge number of protons found in body tissue. The strength of the static magnetic field is important because it determines the number of excess protons and, hence, the strength of the MR signal. For example, at 1.5 Tesla, the total number of excess protons within a volume of tissue that measures 2 × 2 × 5 mm is about 6 million billion! A 3 Tesla scanner would produce an even greater excess of proton signals, hence generating brain images with an even better signal-to-noise ratio.

The rate of the return to equilibrium magnetization is determined by the magnetic state of the

Figure 1 The Whole-Body, 3 Tesla Philips Intera MR Scanner

Source: Photograph taken by D. A. Hall.

Notes: This scanner is based at the Sir Peter Mansfield Magnetic Resonance Imaging Centre at the University of Nottingham, United Kingdom. The participant is lying on the patient bed with his head positioned inside the radiofrequency receiver coil and the experimenter is moving the bed into the bore of the MR scanner. In this auditory fMRI experiment, the participant was required to discriminate between different sound stimuli that are presented over headphones. Verbal responses are not possible during fMRI and so responses were recorded using a 10-button keypad that is resting on the participant's leg.

surrounding tissue. fMRI capitalizes on the fact that deoxygenated hemoglobin affects this magnetic environment, with the rate of decay becoming more rapid as the neighboring concentration of deoxyhemoglobin increases. Given that the metabolic demands of neuronal activity determine the oxygenation state of the blood in localized regions of the brain, the MR signal provides a convenient measure of neuronal activity. The component of the MR signal that is associated with the underlying neural activity is referred to as blood-oxygenation-level-dependent (BOLD) contrast. BOLD contrast provides the basis for fMRI. The size of the BOLD signal is small, accounting for only about 1 to 2 % of the overall signal variance, and so experiments involve averaging image data acquired during several tens of repeated presentations of the stimulus. Physiological noise, such as the cardiac and respiratory signals and movement of the cerebrospinal fluid, are the main contributors to the MR signal variance.

In reality, the relationship between neuronal activity and the BOLD signal is complicated because the contrast is based on combined changes in relative blood flow, volume, and oxygenation. The precise coupling between the BOLD response and neural activity is still in debate, but it is generally accepted that the BOLD signal is reasonably well correlated with population synaptic activity (including inhibitory and excitatory activity). Not all of the BOLD signal comes from hemodynamic changes within the smaller venules and capillaries that are most closely located to the site of neuronal activity. Some of the BOLD signal comes from larger draining veins and so the BOLD activation maps probably extend a few millimeters beyond the underlying neural activity. The spatial resolution of the functional image itself is also in the order of several millimeters, with fMRI scans generally having a spatial resolution of about 3 × 3 × 3 mm.

Brain Imaging Studies

The functional data that are acquired during PET and fMRI are too noisy to construct an activation map from a single brain scan and so experiments typically involve repeating the same stimulus or task many times while the participant undergoes a series of brain scans. Figure 2 (see also color insert, Figure 37) illustrates some of the key aspects of a brain imaging experiment using an example taken from auditory fMRI. The upper time line represents one of the simplest paradigms for mapping neural activity, one in which the experimenter seeks to contrast the brain response during a stimulation condition (such as listening to a particular sound stimulus) with that during a baseline condition (such as listening to no sound stimulus at all, or to a different sound stimulus). A single PET scan takes many seconds to produce and so each scan tends to capture the ongoing neural activity pattern that is sustained across a stimulus condition of about 30 to 90 seconds in duration. In contrast, a single fMRI scan can be acquired rapidly (within 1–2 seconds), and so a series of scans are typically acquired over time. fMRI is therefore more sensitive to both transient and sustained hemodynamic changes and provides much more flexibility about the choice of stimulus duration (from a brief event lasting 100 milliseconds (ms) to a longer epoch of 30 seconds or so). Another difference between the two brain imaging methods concerns the total number of scans that can be acquired for each participant. PET is limited by safety guidelines that limit the overall radioactivity dosage for an individual and a maximum of 12 scans is typical for most experiments. In contrast, the BOLD signal is generated via the endogenous contrast mechanism provided by proton resonance, and there are no known safety risks. The main practical constraint for fMRI scanning time is the total amount of time that the participant is able to lie still and concentrate on the task (between 10 and 30 minutes).

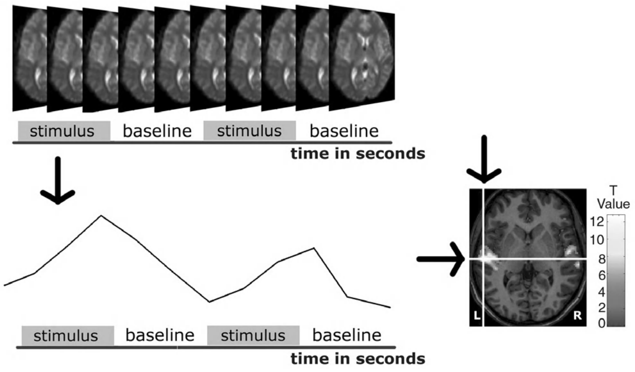

Figure 2 Several Key Aspects of an (Auditory) fMRI Experimental Design and Image Analysis

Source: Original figure created by D. A. Hall.

Notes: The upper time line represents a segment of the experiment showing how repeated scans are acquired at regular intervals over time, while the participant listens to an alternating sequence of sound stimulation and baseline conditions. Each scan is represented by one horizontal slice through the brain. In this example, each stimulus condition lasts about 9 seconds, with scans occurring every 3 seconds. The lower time line presents a schematic diagram of the stimulus-correlated variability in the MR signal measured in arbitrary units. Such a time course is representative of a voxel (individual point) that responds strongly to the sound stimulus. The spatial distribution of the activated voxels is shown in the right panel, with the most significant voxel highlighted by the crosshairs. The color scale reflects the statistical significance of the activation across the auditory cortex. Note that the activation is overlaid onto the anatomical scan, which has a finer spatial detail than the functional scans shown in the upper time line. In this figure, the activation reflects the greater contralateral auditory cortical response to a sound stimulus that was presented to the right ear. See also color insert, figure 37.

Activation maps of the BOLD signal are generated from a statistical analysis of the image data. However, statistical analysis follows a series of image processing steps that are carried out after the data have been acquired by the MR scanner. Each image processing step is rather computationally intensive and must be completed off-line. The analysis makes the assumption that the position of the brain is constant throughout the time series, so first, the effects of small head movements over time are corrected so that each and every scan represents the same set of brain slices. If the pattern of neural activity is to be directly compared across different participants, or if the data from different participants are to contribute to a group analysis, then the shape of the individual brains must be spatially transformed to match a common stereotactic space. An official standard brain template is used to provide an international reference that includes both a set of three-dimensional coordinates and anatomical labels for the corresponding brain regions. Most often, image analysis uses a parametric statistical approach. The General Linear Model (GLM) is applied to each point in the image (individual points are called voxels). The model describes the changes in the amplitude of the MR signal over time as a linear sum of the different experimental effects (corresponding to the BOLD signal), the expected confounding effects, and the residual variability. The pattern of neural activity is estimated by contrasting the GLM parameter estimates at each voxel for the different stimulus conditions (for example, by applying a T-test to the stimulation and the baseline conditions). In the example shown in Figure 2 (also color insert, Figure 37), the "baseline" scans are subtracted from the "stimulation" scans using a T-test procedure and the regions of the brain that show a statistically significant difference in signal between the two conditions ($p < 0.05$) is defined as functionally active. The statistical significance of the contrast is calculated using classical statistical inference. Often the color scale of the activation map represents the statistical value (such as the T value) for each voxel that exceeds the chosen significance threshold (see Figure 2; see also color insert, Figure 37). The activation maps obtained using fMRI represent a relative increase in the response to one stimulation condition compared with another. The maps do not represent an absolute measure of neural activity. In contrast, activation maps obtained using PET can represent an accurate estimate of the actual change in local regional cerebral blood flow. Activation maps are often overlaid onto a high-resolution anatomical brain scan that is acquired using MRI. The anatomical scan maximizes the contrast between gray and white matter in the brain by choosing a different set of gradient and radio frequency pulse parameters of the MR scanner compared with those used in BOLD imaging. The anatomical scan typically has a spatial resolution of at least 1 × 1 × 1 mm and is used to facilitate the interpretation of precisely where in the brain the activation is located.

CAMOUFLAGE

The most common kinds of camouflage make one thing appear to be two, two things one, and so on. The occurrence of camouflage predates human history, in the sense that abundant examples exist of concealment and deception in nature. Some plants are often mistaken for stones, some birds have feathers that look like bark, and some insects resemble twigs (called *mimicry*). There are also natural textures that closely match their surroundings (called *blending* or *crypsis*), or forms that are so visually broken that they defy recognition (*disruption*) (see Figure 1; see also color insert, Figure 13). This entry describes natural camouflage, military applications, Gestalt psychology and camouflage, and more recent developments.

Natural Camouflage

Scientists became particularly interested in camouflage in nature in the 19th century because they saw it as tangible evidence of the theory of natural selection, which Charles Darwin had proposed in 1859. Research of the subject advanced in the 1890s, when the U.S. artist and naturalist Abbott H. Thayer claimed to have determined why so many animals are colored lightest on their undersides, where they are the least sunlit, and darkest on their upper parts. It is now widely believed that animals with such *countershading* (also known as Thayer's law) appear to be less solid and less dimensional because their markings cancel out the shading effects of the overhead sun.

During the Spanish-American War, Thayer proposed unsuccessfully that countershading should be applied to U.S. ships. In 1902, he patented the idea, which he claimed to have derived from the coloration of a seagull. His research intensified and, in 1909, he and his son (Gerald H. Thayer) published a groundbreaking volume, titled *Concealing Coloration in the Animal Kingdom,* in which (among other things) they suggested ways to use "protective coloration" for military purposes. In addition to countershading, the book described and illustrated natural and humanmade examples of blending, disruption, and mimicry.

Military Applications

During World War I, partly through Thayer's revelations, hundreds of artists, architects, theater designers, and others were deployed by various armies as consultants in wartime deception. The French, who were the first in history to establish a military unit for that purpose, referred to this practice as *camouflage,* and a camouflage advisor was a *camoufleur*.

Initially, most ground-based or field camouflage was concerned with concealing artillery from airborne observers, who relayed the location of targets to their own long-distance artillery. In 1917, however, British attention shifted to the heavy loss of their ships from attacks by German submarines (called U-boats). This led to a new way of thinking about naval camouflage as distinct from field

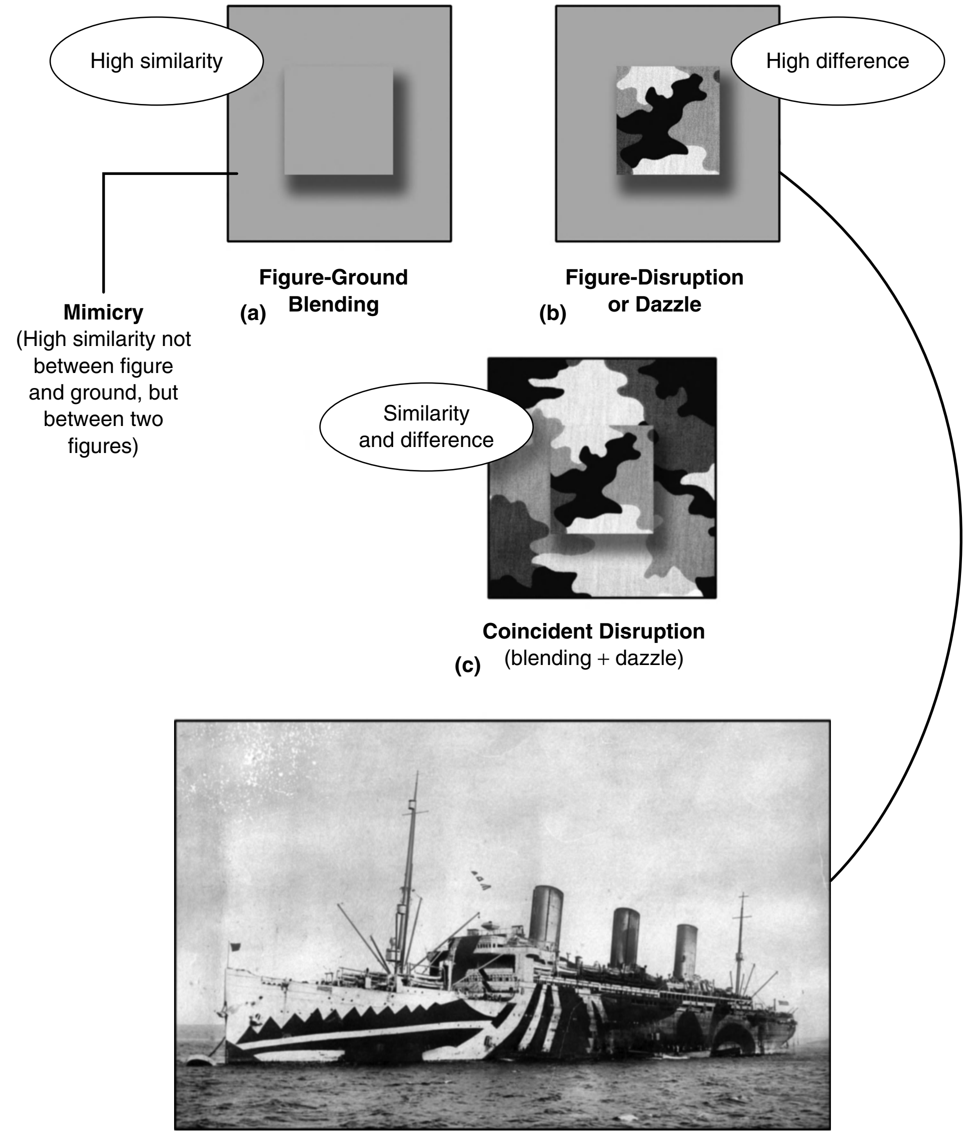

Figure 1 Three Categories of Camouflage

Source: Illustration © by Roy R. Behrens, 2008. Reprinted with permission.

Notes: Although there are any number of ways to categorize examples of camouflage, perhaps the three most common kinds are figure-ground blending (a), in which an object blends in with its setting (also sometimes known as crypsis); figure disruption ([b] and photo below it), in which the surface of the figure is broken up by highly contrasting components, a method that was used widely for ship camouflage during World Wars I and II; and coincident disruption (c), in which the figure is broken up, but parts of it blend in with the background. In the system shown here, mimicry is said to be a subcategory of blending or high similarity camouflage. See also color insert, Figure 13.

camouflage, with the result that the British began to apply erratic, abstract patterns to the surfaces of their ships. First proposed by the British artist Norman Wilkinson (who called it *dazzle painting*), the purpose of this method was not to conceal the ship, but rather to throw off the accuracy of the U-boat gunner, who was positioned at a considerable distance and had to aim ahead of the target. It was never scientifically confirmed to what extent this actually worked, but the U.S. government was sufficiently convinced that it deployed its own camouflage expert (the artist Everett Warner) and adopted a parallel strategy in the last year of World War I.

Gestalt Psychology and Camouflage

The findings by Thayer and others about camouflage and its military applications were more or less concurrent with the birth of a branch of psychology called Gestalt theory. Founded in Germany around 1910 by three psychologists (Max Wertheimer, Kurt Koffka, and Wolfgang Köhler), this movement was chiefly concerned with the psychology of vision and with problem solving. Notably, the Gestaltists investigated *figure-ground phenomena* (the extent to which a shape is seen, in relation to various backgrounds), the conditions of which are of central concern in the visibility of objects. Gestaltists identified the *principles of perceptual organization* (similarity and proximity grouping, good continuity, closure, etc.), which did not differ greatly from the principles Thayer had earlier called the *laws of disguise* (e.g., countershading, figure-ground blending, and shape disruption). Gestaltists also brought attention to the holistic or synergistic aspects of experience, as expressed by the oft-quoted maxim (derived from Aristotle), "the whole is greater than the sum of its parts."

English translations of writings about Gestalt psychology became available in the mid- to late-1920s. In some of their publications, the Gestaltists used examples of camouflage as proof of their earlier findings. They were particularly interested in children's puzzles called *embedded figures* (also known as a *camouflaged figures* or *puzzle pictures*) in which one is asked to find a figure or other shape in a purposely complex setting, a task that one of their students, Kurt Gottschaldt, used extensively in his research of problem solving. Later, in 1940, the British zoologist Hugh B. Cott (who had been a camoufleur during World War I, and a camouflage instructor in World War II) published a comprehensive book on *Adaptive Coloration in Nature,* in which he argued persuasively that embedded figures are ubiquitous in natural camouflage. He referred to this as *coincident disruptive coloration,* by which he meant the combined use of blending and disruption.

More Recent Developments

Throughout World War II, those trained in art-related fields continued to be called on to contribute to camouflage, both military and civilian. By the end of the war, this had lessened, partly because of developments in surveillance technologies that were not based on vision (such as radar). In addition, because the effectiveness of dazzle camouflage had never been proven, it was no longer cost efficient to painstakingly design and apply bewildering abstract patterns to thousands of ships.

After World War II, military applications of camouflage evolved, on the one hand, toward electronic, nonvisual deception (such as the illusive technology of the Stealth bomber). On the other hand, initially as an adaptation to the jungle setting of the Vietnam War, the camouflage patterns on military uniforms became increasingly visual, to the point that some might regard them as advertising rather than as concealment.

In recent years, there has been a heightened interest in camouflage, as shown by the adoption of camouflage patterns in civilian clothing styles. There has also been increased discussion about the pertinence of camouflage (both literal and metaphorical) to art, architecture, philosophy, and literature. Additionally, in the biological sciences, there has been a resurgence of research about natural camouflage.

CAUSALITY

One is tempted to believe that perception is limited to the reconstruction of meaningful objects such as rocks or chairs on the basis of raw sensory information. The topic of perceptual causality shows that one should resist that temptation and be open to widen the scope of perception. Subjective causality is by no means a mere reflection of physical causality, but is our interpretation of whether one event is causing another event. It often approximates reality and sometimes deviates substantially from it. The function of this subjective and immediate sense of causality is to make sense of the world and to guide our actions. Albert Michotte has in many ways become the father of perceptual causality by arguing that the phenomenal impression of causation is a fundamental building block of perception and that causality is perceived in a direct manner that is not qualitatively different from that of perceiving rocks or chairs. Before describing the work of Michotte and his followers, this entry looks more closely at causality and its context of event perception.

Efficient Versus Final Causes

Causality can be conceived in two different manners, one relating to internal events, such as goals, opinions, and cultural settings. The other relates to the observation of external events that happen in the world. Aristotle proposed this distinction between causation from within and external causation. He called the former *final causation* and the latter *efficient causation.* Take, for instance, the event of a player's leg making contact with a ball, upon which the ball proceeds to move into the direction of a box. In terms of efficient causation, one could say that the leg has caused the ball to move. The leg moved first and somehow imparted its motion or impetus to the ball. We observed one motion as the cause of another subsequent motion.

David Hume has extensively discussed this type of causality. Besides temporal succession, one has to assume additional mechanisms that distinguish a true cause from coincidental succession. For instance, in the case of a collision of two billiard balls, the ricochet motion of the target ball has been caused by the cue ball via such intermediate mechanisms as friction and energy transfer. A soccer fan would not agree to this description. She would describe the same event as a forward player intending to score a goal. The intention causes the player to aim for the goal, and this intention causes the ball to move. Unlike the efficient cause, the final cause relates to an involved observer, for whom the simple chain of events (1) intention (2) leg movement (3) ball movement is no longer a chain. The intention does not end when the leg starts to move, nor does it disappear when the leg has stopped moving.

Cause and effect cannot easily be narrowed down in temporal or spatial terms. Although the conditions that must be met to perceive an efficient cause can be described with comparative ease, the conditions for perceiving a final cause are more intricate because they do not fit into straightforward descriptive categories. Not surprisingly, psychologists have put their primary focus on the efficient cause although the final cause is in many ways more important for us as acting individuals. In the world of a human actor, actions are caused by the intended environmental effects. The final cause for our fingers flipping the light switch is our intention to turn on the lamp. This intention stretches to the point in time where the lamp is on, and thus the succession of cause and effect is no longer valid. To make things even more difficult, the technological advances of our time require us to perceive causal relations between goals and events that appear to be dissimilar. Where our ancestors pulled a mechanical lever to set a switch, we achieve the same effect by means of a mouse click on the computer or even a verbal input.

Phenomenal Reality of Efficient Causes

Since the days of Hume, our understanding of an efficient cause has been shaped by the idea of associationism. We see A as the cause of B because

A precedes B with regularity. Turning the switch is perceived to cause the light to go on because the switch action has become associated with the light. In contrast to this associative concept of causality, Michotte put forth a fundamentally different concept of visual causality, claiming that we have direct phenomenal access to causality. It requires neither learning nor conscious or unconscious inferences. He was able to demonstrate that observers perceive the motion of two simple objects as causally related as long as surprisingly few boundary conditions are met. Take, for instance, the case of an actual billiard shot. The cue ball moves toward the stationary target ball and abruptly stops at the moment of collision, instantly setting the target ball into motion. Michotte discovered that impoverished renditions of such an event suffice to convey the impression of causality. The motion of a painted dot toward another painted dot on a screen and the subsequent motion of the second dot are readily and immediately perceived as causally connected.

Michotte did most of his experiments using a turntable. Two lines were drawn on a rotating disk, which was covered by a mask except for a small slit that served as a viewing port. Changing the distance between the circular lines at different stages would produce different dot motions. Whenever the first dot moved toward the second dot, followed by motion of the second dot, the stimulus was perceived as "dot 1" launching "dot 2." Despite the artificial nature of the stimuli generated with this method, a stable impression of causality was readily produced. Depending whether the first dot stopped after contact with the second, Michotte distinguished among a launching effect proper, entrainment, launching across a spatial or a temporal gap, and others. Some of these effects are illustrated in Figure 1.

Infants readily perceive launching and entraining, which suggests the innate nature of phenomenal causality. Michotte's insights remain valid, albeit with considerable elaborations. Efficient causality has turned out to be more complex than thought by Michotte. In some cases, observers are reluctant to make causal attributions where they should according to Michotte, and in other cases, observers perceive causality even outside the conditions he put forth for launching and entrainment. For instance, judgments of causality change depending on the perceptual attitude and experience of the observer. Observers who adopt an analytic attitude tend to

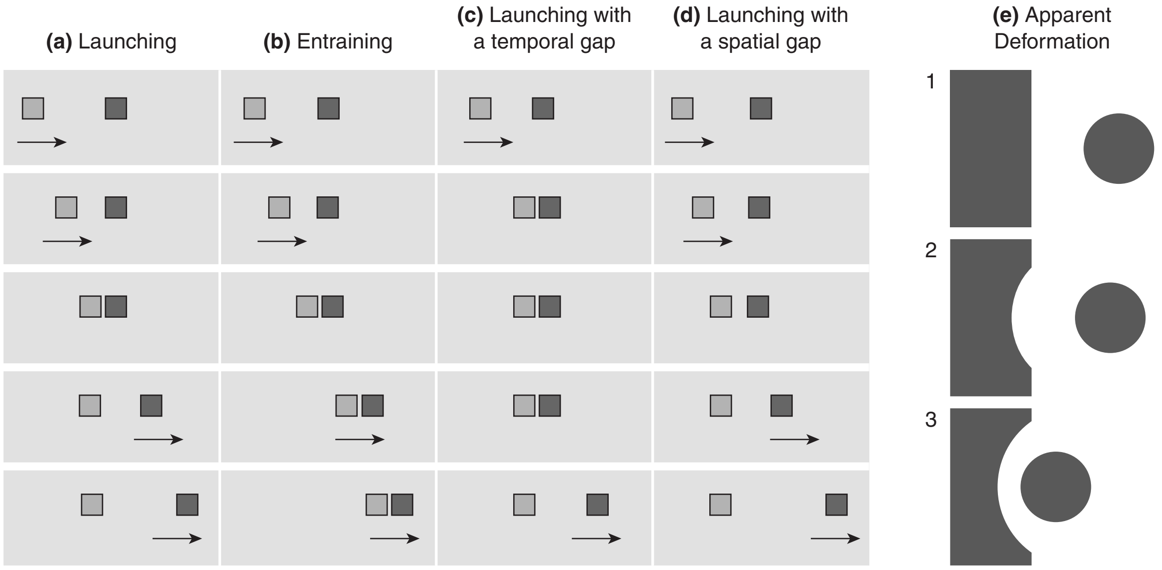

Figure 1 Schematic Illustration of Michotte's Stimuli

Notes: (a) Launching, (b) entraining, (c) launching with a temporal gap, (d) launching with a spatial gap. In (e), the observer has the impression that the motion of the circle causes the deformation of the rectangle although neither launching nor entrainment is the case.

describe the standard launching stimulus as a sequence of independent movements, rather than cause and effect. Conversely, the sequence of events shown in column (e) of Figure 1 is readily seen by most observers as the gray circle putting a dent into the grey rectangle although the two never touch. This suggests that the boundary conditions for perceptual causality may be even wider than originally thought.

Intuitive Physics

From an evolutionary point of view, one could argue that true causal relations have only been discovered by the perceptual system inasmuch as they have been internalized to secure the survival of the species. Whenever erroneously perceived causal relations did not have any adverse consequences, errors were not corrected. Thus, our direct access to efficient causes should be limited by the needs of the hunter and gatherer who moved around in a world determined by the laws of classical mechanics. According to the field of intuitive physics, the approximation of perceptual causality to physical causality has not progressed any further than what was known about physics in ancient Greece. For instance, when asked to indicate the trajectory of an object dropped from a moving carrier, many observers believe that it will fall straight down. Accordingly, when being moved on a conveyor belt, many adults and most children will release a ball directly above the stationary target on the ground when intending to hit it. They overshoot the target because they act as if they were stationary and the ball moved straight down. Instead, it moves down and in the direction of self-motion. After a few trials, the behavior adjusts quickly, but the causal relations that are expressed by Newton's laws remain opaque. The understanding of classical mechanics seems indeed limited to pre-Newtonian theory. The direct access to causation has clear limitations that are well described by intuitive physics. In other words, human observers have internalized causal relations that hold in the environment, but only to a rough approximation. This approximate internalization would also explain the inclination to perceive causal structure in mere graphic illustrations.

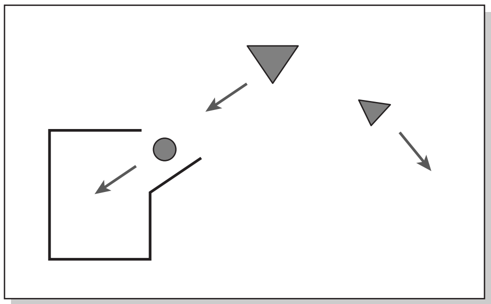

Figure 2 Geometric Figures Used by Fritz Heider and Georg Simmel in a Cartoon

Notes: The arrows indicate the direction of motion and were not present in the experimental stimuli. Movements of the figures are seen as actions and the figures take on particular traits.

Overestimation of Action Goals

When it comes to final causes, a new domain of perception opens up, one that is sometimes dramatically removed from physical causality. The laws of physics and mechanical causality are being bent dramatically when it comes to the perception of causes for willed events. For example, in the case of ballistic movements, a large number of observers believe that a cannon ball accelerates after it has left the cannon. Similarly, observers judge a thrown ball that increases its speed after leaving the pitcher's hand to look more natural than a ball that decelerates in accord with physical law. This surprising but stable finding can be explained by the projection of an intention into the object itself. Rather than limiting the effect of the intentional cause to the movement of the effector—the arm that throws the ball—the effect migrates to the ball. In Aristotle's terms, a person's goal to throw the ball to a particular target causes the ball to move, not just while it is being held in his or her hand but also beyond this point on its way to the target.

Final causality also leaves the domain of perception proper and enters the realm of emotion and cognition. We spontaneously "see" intentions, emotions, and social relationships in simple movements of geometrical objects as Fritz Heider and Georg Simmel have demonstrated. When the geometric drawings in Figure 2 are animated, as indicated by the arrows, observers spontaneously describe the actions in social terms. They may readily see the large triangle as a villain chasing the circle while the small triangle is the friend of the circle (apparently a female), and the large rectangle is a house. We cannot help but experience inanimate motion within a framework of social meaning.

Interestingly, even stationary objects tend to be interpreted in a causal manner that considers the history of the object's deformations, as Michael Leyton has pointed out. A crumpled piece of paper readily reveals that its prior state was uncrumpled and that it has been put into its crumpled state by an actor.

CELL PHONES AND DRIVER DISTRACTION

Operating a motor vehicle is an activity engaged in by more than one billion people on an annual basis. Given that each year there are more than one million fatalities worldwide associated with motor vehicle accidents, driving represents one of the more risky activities undertaken on a regular basis by adults between the ages of 25 and 65. Estimates suggest that as many as 80% of accidents on the roadway are the result of some type of driver distraction, and it has been noted that one of the basic road errors is a failure to see and react to another road user in time. Driver distraction associated with visual processing can be divided into two general categories: Situations where drivers fail to look at roadway hazards in the driving environment (i.e., failures to look or fixate upon an object) and situations where drivers look at objects in the driving scene, but show degraded processing of the driving environment because attention is directed elsewhere (i.e., failures to see or attend to the object). This entry describes the relationship between cell phones and driver distraction.

Driver distraction associated with a failure of visual processing can be attributed to situations where drivers fail to direct their eyes to hazards in the roadway. This source of impairment can be the result of distractions from outside the vehicle (e.g., an electronic billboard with sudden onsets or movement that results in a reflexive orientating of the eyes to the billboard) or to distractions within the vehicle (e.g., dialing or text messaging on a cellular phone). In both situations, driving is impaired because the eyes are diverted from the roadway and the information necessary for the safe operation of the vehicle is not fixated on for a sufficient duration to allow for its processing. This results in a source of driver distraction wherein the driver fails to look at critical information in the driving environment. Research indicates that the concurrent performance of ancillary visual tasks often compromises driver safety; however, some drivers are more impaired than others. Compared with more experienced drivers, novice drivers are less able to interleave the performance of a concurrent visual task with driving. For example, novices tend to allocate longer epochs of visual processing to a secondary task than do more experienced drivers who exhibit frequent and short glances between the two tasks. In sum, the first source of distraction occurs if the driver does not look at an object, and thus, he or she cannot see and react in a timely fashion.

Driver distraction can also be caused by attention being diverted from driving to some other activity (e.g., a cell phone conversation), resulting in a form of inattention blindness. In such cases, critical information in the driving environment may be fixated upon, but the driver does not "see" the information because attention is directed elsewhere. For example, when drivers converse on either a hand-held or hands-free cell phone, they fail to subsequently recognize as much as 50% of the information that they would have recognized had they not been conversing on a cell phone. In addition, the impaired recognition is equivalent for both items of high and low relevance to safe driving, suggesting that there is little or no semantic prioritization of the information that is impaired by the cell phone conversation (i.e., drivers are as blind to a billboard on the side of the road as they are to a pedestrian standing on the curb). Moreover, recordings of brain activity indicate that cell phone conversations suppress the initial registration of information in the driving scene. In particular, the amplitude of the P300 component of the event-related brain potential elicited by imperative events in the driving environment (e.g., brake lights) is reduced by half when drivers are conversing on a cell phone. Thus, drivers using a cell phone fail to see information in the driving scene because they do not encode it as well as they do when they are not distracted by the cell-phone conversation. In addition, the diversion of attention from the driving environment increases the time it takes for drivers to respond to changes in the driving scene (e.g., lead vehicle braking and red-onset traffic lights). In situations where the driver is required to react with alacrity, the data indicate that drivers using a cell phone will be less able to do so because of the diversion of attention from driving to the phone conversation. The net result is that activities such as conversing on a cell phone increase the likelihood and severity of accidents on the roadway.

Several other multitasking activities share surface similarities with conversing on a cell phone but do not lead to significant driver distraction. For example, listening to radio broadcasts or books on tape does not impair driving. Evidence also indicates that speech production results in significantly greater interference than does speech comprehension. These findings are important because they demonstrate that listening to verbal material, by itself, is not sufficient to produce the dual-task interference associated with using a cell phone while driving. Moreover, in-vehicle conversations do not interfere with driving as much as cell phone conversations because there is a greater ability to synchronize an in-vehicle conversation with the processing demands of driving than there is with a cell-phone conversation.

Whereas the fact that driver distraction is associated with failures to fixate on objects in the driving environment and failures to attend to objects that are fixated, the mechanisms underlying the latter source of interference are not well understood. In particular, models of dual-task performance that invoke concepts such as "attentional resources" or "code conflict" would seem to predict that an auditory/verbal/vocal task such as conversing on a phone should not interfere with a visual/spatial/manual task such as driving. It is possible that the interference stems from a central processing bottleneck associated with the concurrent tasks of driving and talking on a cell phone. Further specifying the mechanisms for this source of dual-task interference is an ongoing focus of research.

CHANGE DETECTION

Change detection is the noticing of change in the world around us. For example, when driving in traffic, the vehicles around us constantly change their positions, and sometimes their speed and direction as well. To avoid collisions, we must notice any such changes and respond to them. More generally, the ability to detect change is important for coping with everyday life; humans (and most animals) are consequently quite good at it. However, our knowledge of how changes are detected remains incomplete. The progress that has recently been made owes its existence to two related developments: (1) a realization of some of the confusions and assumptions built into our previous ideas about change, and (2) new methodologies that allow it to be more effectively isolated and studied.

An important step is to clarify the meaning of the terms themselves. As used here, *change detection* is restricted to the noticing of a change (i.e., the observer seeing that a change *exists*) via the use of vision. This can include the related abilities of identifying the change (i.e., seeing *what* it is), as well as localizing it (i.e., seeing *where* it is), although these abilities likely involve somewhat different mechanisms.

An adequate understanding of change detection has been difficult to achieve. Part of this is because of the nature of change itself. Although the concept of change appears simple, attempts to formalize it have shown otherwise. For example, change requires that some aspect of an object remain constant but another aspect does not, a situation that has not been completely resolved by present-day philosophers. Furthermore, our intuitions about change detection are often highly inaccurate. For example, we generally believe that we could easily detect any change in front of us provided that its size is sufficiently large. But we can be amazingly "blind" to such changes, failing to detect them even when they are large, repeatedly made, and are expected. Such *change blindness* is a phenomenon strikingly at odds with our intuitions about how change detection should work. However, such counterintuitive results have taught us much about what change detection is and how it works, as this entry describes.

Background

Insight into change detection has been obtained from a variety of sources. Some of the earliest discoveries occurred in Hollywood studios in the 1930s, where filmmakers found that an audience could fail to notice a sudden change (e.g., the appearance of a new character) if this occurred at the moment they made an eye movement (or saccade) from one side of the screen to the other, or when they blinked their eyes in response to a sudden noise. Filmmakers also discovered their own blindness to changes made during a film cut (e.g., the change in length of cigarettes in different shots), with such continuity errors often going unnoticed until long after the film had been released.

Controlled investigations of this phenomenon began in the 1950s. One line of research examined simple displays composed of about a dozen dots with random positions; observers were found to be surprisingly poor at determining if one of these dots had changed in a later presentation of that image. This work ultimately formed the basis for the proposal of a limited-capacity visual short-term memory (VSTM), an important part of current theories of visual perception.

A later wave of studies in the 1990s extended this in several important ways: images were more realistic, repeating changes were often used, and change blindness was also induced in other ways, such as making changes during an eyeblink. These developments allowed change detection to be more deeply investigated, and connections made to other aspects of visual perception. One of the more important findings in this regard was the discovery that *attention is needed to see change.*

Methodologies

All studies of change detection use essentially the same design: An observer is first shown an initial stimulus (e.g., a picture of a harbor with some ships in it), followed by a modified version of this (e.g., the same picture with one of the ships removed). The ability of the observer to detect the change is then measured, usually in terms of speed or accuracy.

In real life, the motion signals produced by a change automatically attract attention, causing it to be easily seen. (For example, waving at your friends usually makes them see you right away.) To study the mechanisms involved in change detection, the process is slowed by eliminating this automatic drawing of attention. This can be done in several ways.

Gap-Contingent Techniques

In this approach, the initial image is presented for a short time (e.g., a half second), followed by a brief blank field or mask (typically about 100 milliseconds [ms]); the modified image is then shown (see color insert, Figure 14). The change therefore occurs during the gap between the original and modified stimuli. If this gap is longer than about 80 ms, changes can be extremely difficult to see—indeed, some can require more than a minute to be seen, even though continually repeated.

The explanation for this is that the “flicker” created by the gap overwhelms the local motion signals created by the stimulus change, making it impossible for them to automatically draw attention to its location. The observer must then carry out a time-consuming scan of the image until the change is found.

Saccade-Contingent Techniques

Here, the initial image is again presented to the observer, but the transition to the modified image is made during an eye movement (or *saccade*) to a new location. The stimulus on a retina is smeared during a saccade. Thus, from the point of view of the retina, the pattern encountered here is this: initial image—smeared image—modified image. This is similar to that encountered in the gap-contingent techniques, and so induces similar amounts of change blindness.

Shift-Contingent Techniques

In this approach, the initial image is shown to the observer for a short time, and the modified image then shown immediately afterward, with its location shifted somewhat—for example, moved right or left a few degrees of visual angle. Changes made under these conditions are again difficult to detect, even when they are large and expected.

The reason for change blindness here is much like that for the gap-contingent techniques: the shifted image means that there is mismatch at most points in the original and modified image, generating motion signals that swamp those created by the change itself. Note that this is closely related to the blindness found for changes made during film cuts, where the signals created by the mismatch of the images swamp the local signals created by the change, requiring a time-consuming attentional scan of the image.

Gradual-Change Techniques

These techniques have the initial image gradually fade away, with its place taken by the modified image. If the transition occurs over several seconds, the change will be extremely difficult to see. The reason for change blindness here is essentially the same as that for the other conditions: the ability of the motion detectors to guide attention to the location of the change has been eliminated, in this case, by making the change slowly enough that the motion detectors don’t fire.

Implications for Perceptual Mechanisms

The failure to see large changes under various experimental conditions can be explained by the proposal that attention is needed to see change. However, the story does not end here. New distinctions and new questions arise, many of which have more general implications for how we see. These include the following.

Change Versus Motion

Work on change detection motivates a more careful distinction between change and motion. Here, *motion* is the temporal variation in a property at a given point in space. For example, the flow of muddy water in a stream can be described by its velocity at each point. There is no object here, no sophisticated structure—only unstructured “stuff” extending over part of space. Simple motion detectors in the human visual system respond to exactly such variation.

In contrast, *change* refers to the transformation of a particular object or event over time—for example, the wing movement of a bird overhead. Here, there is a constant structure (the bird) in which a transformation (wing movement) occurs.

Attention is important here, being used to form a coherent representation that persists during its transformation.

In this view, any dynamic variation in the world is picked up by two separate perceptual systems: one for *motion* (variation in a particular location) and one for *change* (variation in a particular structure). Both systems will generally be in play. One of the key insights of recent work is the need to separate the contributions of each system, so that their operation can be studied independently.

Mechanisms of Change Detection

Another set of issues involves the mechanisms of change detection itself, and how attention enters into their operation. An important finding is that only 3 to 4 items can be seen to change at a time. Indeed, it appears that the items held by attention may be not independent, but may instead be parts of a single structure that corresponds to a single object.

Recent work is beginning to explore the components involved. Contrary to our intuitions, change detection need not be an elementary process. It can be divided—at least conceptually—into a sequence of distinct operations: (a) load the information into a memory store (such as VSTM), (b) put it into a coherent form, (c) hold it across a temporal gap, (d) compare the contents of memory to the new stimulus, (e) unload this memory, and (f) shift processing to the next candidate item(s). Results indicate that distinct mechanisms for at least some of these do exist.

Scene Perception

Given that our representation of a scene contains no more than a few coherent structures at a time, an important question is why we have the impression that we see everything in coherent form. (Note that much of a scene is represented—at least while our eyes are open—but this is not necessarily in coherent form.)

Recent work supports the view that scene perception is based on a dynamic process, rather than on an accumulation of detailed information. More precisely, attention appears to be allocated on a "just-in-time" basis, with the representation of an object formed at the moment it is needed, and dissolved once attention has been withdrawn. Longer-term visual memories are still needed to coordinate this process. But these may contain relatively sparse amounts of information—perhaps just the information from the items currently attended, along with some properties from the locations used in the management process.

Implications for Individual Differences

Change detection can help explore the general mechanisms involved in visual perception, as well as how particular individuals (and cultures) perceive the world around them. One approach to this is based on the *priority* given to items in a display. Given that attention is first allocated to interesting items, the speed at which a change is detected can indicate if the associated item is considered interesting. For instance, observers addicted to a substance such as alcohol or cannabis are faster and more likely to detect changes to items associated with that substance than are observers who are not addicted.

Individuals also differ in the *way* they encode items, something that depends at least partly on training. Experts at U.S. football are better able to spot meaningful changes to football scenes than are novices, indicating that the experts have learned to see aspects of the scene not perceived by others. In addition, some studies suggest that U.S. residents may be less able to detect changes in the surrounding context (e.g., the surrounding elements in a scene) than are Japanese, indicating a difference in the encoding of foreground and background elements.

Finally, individuals can also differ in the *mechanisms* at their disposal. For example, some individuals can have a "gut feeling" that something is changing, even though they do not yet have a "picture" of the change. Although there is still dispute about the basis of this phenomenon, the fact that observers can show differences in the way they experience change may provide an interesting new perspective on how we perceive our world.

COCHLEAR IMPLANTS: CONTROVERSY

Cochlear implants have been dogged by controversy since the earliest stages of their development. In the mid-1970s, when French otologist Claude-Henri Chouard, a pioneer in implant surgery, was implanting on average one deaf patient per month, the French Deaf community protested against the procedure, staging rallies in 1977 and 1978. About that same time, another implant pioneer, Graeme Clark of Australia, found himself greeted by Australian Deaf protesters who resented the negative portrayal of deaf people and their lives that Clark promoted in the media as he sought to sell the public on his research. He reported that he was "surprised" to find that deaf people were upset with his efforts to "cure" them. This entry describes the controversy regarding cochlear implants.

Many in the Deaf community—meaning those people who participate in Deaf culture, have a deep appreciation of Deaf history and traditions, and use a signed language to communicate—do not consider deafness a medical condition in need of a cure. They believe deafness is a necessary precursor to Deafness, and Deafness is about being a member of a cultural and linguistic minority group. This smaller Deaf community, it should be noted, is distinct from the millions of people who have some degree of hearing loss. For instance, although some 13 million U.S. residents have varying degrees of hearing loss, only about 600,000 of them call themselves Deaf.

These Deaf Americans, like their international counterparts, reacted negatively to cochlear implants. The Greater Los Angeles Association of the Deaf (GLAD) published a position paper on implants in 1985. That report expressed concern that the medical profession generally failed to acknowledge the existence of a Deaf perspective about deafness, let alone about implants. The National Association of the Deaf (NAD) issued a position paper on implants in 1991, condemning the use of implants in children and objecting to the oralism that the technology promotes.

It is not simply the audiological intervention, the imperative to hear, that draws the ire of many in the Deaf community. Members also object to the pressure to speak. The cochlear implant technology promotes speech, and only speech, as the expected communication method for implantees. For example, Web sites of both implant manufacturers and surgical centers stress that the goal of the procedure is to promote speech and listening. Some also recommend the complete abandonment of any signed language with a deaf child, arguing the continued use of signs will interfere with the acquisition of speech.

Many in the Deaf community view this as an attack on their language and their culture, as much as on their physicality. This is not the first time such issues have been raised. Oralists at the beginning of the 20th century believed that sign language should be banned from deaf education altogether, and only speech and lipreading should be used with deaf schoolchildren. From the point of view of many in the Deaf community, cochlear implants are a high-tech weapon in an old battle against American Sign Language, a prominent marker of Deaf culture. To many, this technology is trying to do what oral education techniques alone could not, that is, make deaf people over in a hearing image.

Culturally Deaf people have historically been quite uninterested in the project of being made over as hearing people. Rather, they took pride in their Deafness. To many, such implant technology would eliminate deafness but suppress signed language, and thereby undo Deaf culture. However, this threat to the Deaf culture was largely lost on the wider hearing public in the same decade. Many hearing people believed, and arguably still do, that deafness is a medical condition in need of a cure.

As the rates of implantation increased in the 1990s, reactions to cochlear implant technology became more strident. However, at the beginning of the 21st century, the Deaf community shifted its focus from contesting the issue with the hearing community to making implanted deaf people feel welcome in the Deaf world. That is, if implants continued to grow in popularity, the Deaf community wanted those implanted to join them, and claim their place in the Deaf world. Accordingly, the NAD revised its position paper on implants in 2000. It spoke of recognizing the "diversity within the deaf community" and stressed that the Deaf world "welcomes all individuals regardless of race, religion, ethnic background, socioeconomic status, cultural orientation, mode of communication, preferred language use, hearing status, educational background, and use of technologies." The statement also stresses that "implanted children are still deaf" and they should be encouraged to develop both speech and sign skills accordingly. It is too soon to tell whether this call to inclusion will bring implant users into the Deaf community.

COCHLEAR IMPLANTS: TECHNOLOGY

A *cochlear implant* (CI) is an auditory prosthesis developed to treat severe-to-profound sensorineural hearing loss (SNHL). Hearing loss is sensorineural (rather than conductive) when the hearing dysfunction is located at the inner ear (cochlea) or along the neural pathway that connects the cochlea to the brain. SNHL can occur congenitally from genetic causes or from complications during the prenatal or early postnatal periods. It can also be acquired as a result of disease, injury, tumors, ototoxic drugs, noise exposure, or aging. SNHL usually involves damage to the cochlea's hair cells, which vibrate in response to sound. These vibrations induce nerve cells to send signals to the brain that cause the sensation of hearing. Damage to the hair cells is permanent and cannot be repaired by any medical or surgical means available today. When hair cell damage is relatively mild, hearing aids can compensate for the reduced sensitivity by amplifying sound. However, if the hair cells are damaged beyond responsiveness, hearing aids are ineffective and cochlear implantation becomes a viable alternative.

Rather than amplifying sound, CIs bypass the hair cells and directly stimulate auditory neural fibers connected to the cochlea with electrical impulses. The auditory neural fibers (as well as the corresponding hair cells) are organized tonotopically in the cochlea; neural fibers at the front (apical) end of the cochlea respond to the highest frequencies in the environment, and nerve cells at the back (basal) end of the cochlea respond to the lowest frequencies. CIs divide sound into frequency bands and then stimulate the cochlea tono-topically according to the intensity of the auditory input in each frequency band. Today, approximately 120,000 people worldwide have received a CI, among which more than 6,000 have two. This entry discusses how CIs work, the process of cochlear implantation, CI effectiveness, and new directions.

How Cochlear Implants Work

Components

A cochlear implant system has external and internal components. The external components shown in Figure 1, sit behind the ear and on the side of the head. A microphone, worn behind the person's ear (A), sends signals to a sound processor (not shown), a small unit about the size of an MP3 player that can be worn on a pocket or specially designed pouch. The sound processor converts incoming sounds into electrical pulses. The electrically processed sounds are sent to a transmitter (B), which is held in place by a magnet just behind the ear. These signals are transmitted from the transmitter through the skin to a receiver, implanted under the skin (C), and from there, the signals are sent to the electrodes (as many as 22) in the electrode array (D). The electrical pulses directly stimulate auditory neural fibers that help the cochlear implant recipient hear.

Notes: The external components sit behind the ear and on the side of the head. A microphone, worn behind the person's ear (A), sends signals to a sound processor (not shown), a small unit about the size of an MP3 player that can be worn on a pocket or specially designed pouch. The sound processor converts incoming sounds into electrical pulses. The electrically processed sounds are sent to a transmitter (B), which is held in place by a magnet just behind the ear. These signals are transmitted from the transmitter through the skin to a receiver, implanted under the skin (C), and from there, the signals are sent to the electrodes (as many as 22) in the electrode array (D). The electrical pulses directly stimulate auditory neural fibers that help the cochlear implant recipient hear.

Sound Processing

Although different types of sound processing strategies exist across the manufacturers of cochlear implants, the basic principles for each strategy are similar. Specifically, the environmental sounds are sent through a bank of filters (i.e., electronic circuits that remove specific frequency components of the signal) based on their frequency or pitch. Low frequency sounds or components of sounds are maintained in the low-pass band filters, and high-frequency sounds are represented in the high-pass band filters. Each filter then outputs a series of electrical pulses or pulse trains, which are electrical representations of the input signal or sounds. These electrical pulse trains are used to stimulate the auditory neural fibers.

Cochlear Implantation

Candidacy Criteria

To receive a CI, adults and children over the age of 2 must have a severe-to-profound hearing loss (i.e., ability to minimally detect the loudness of signals that are comparable to the loudness of a lawn mower or a subway train), and children 12 to 24 months old must have a profound hearing loss. Also, both children and adults must demonstrate through audiological testing that their spoken word comprehension is poor when using hearing aids. Individuals must have an intact auditory nerve and no medical contraindications for surgery. Finally, it is recommended that children undergo a psychological evaluation to identify any confounding factors that may affect the successful use of a CI. In the United States, the FDA has approved cochlear implantation for children 12 months of age or older. There is no upper age limit for implantation.

Surgery

Skin incisions are made to provide access to the mastoid process (protruding bone behind the ear) while preserving the blood supply of the skin. The implant electronics and induction coil are placed in a pocket under the skin. A hole is drilled in the mastoid so the electrode array can be inserted into the middle ear through the facial recess and then into the cochlea through an opening made anterior and inferior to the round window membrane of the cochlea. The insertion is performed to position the electrode into the scala tympani of the cochlea. Following the insertion, the hole into the cochlea is sealed with connective tissue and the skin incision is sutured.

Programming the Cochlear Implant

Approximately one month after surgery, the CI is programmed for each individual and his or her hearing capabilities. Typically, the threshold levels (i.e., the lowest signal intensity a person detects) and the comfort levels (i.e., strongest signal a person can tolerate comfortably) are determined for each electrode along the electrode array. After programming, the electrodes stimulate the auditory nerve at near threshold levels for soft sounds, and stimulation will be greater with louder sounds but never greater than comfort levels. Within the first 6 months, the audiologist modifies these levels regularly as the patient adapts to the new signal.

For children and adults who can communicate when they are hearing the electrical signals, programming the device can be accomplished efficiently and reliably. For infants, however, programming the implant is more challenging because infants cannot reliably report when they are hearing. To overcome these difficulties, implant manufacturers have developed their devices and software such that neural activity from the auditory nerve can be directly measured in response to electrical stimulation. This neural activity can provide an indication of loudness levels where the infant first hears the input signal. Audiologists can then use this information to program the CI.

Cochlear Implant Effectiveness

Variability in Outcomes

Most adults who receive CIs had normal hearing during childhood. They can use linguistic knowledge to help interpret the new sound input from the CI. As a result, most adults with CIs have near-normal scores on a variety of outcome measures after a period of adaptation. Many adult CI users report that at first voices sound more high-pitched and mechanical than normal. This improves with adaptation; however, CIs never restore hearing to the natural quality that adults remember. Congenitally deaf children, on the other hand, do not have a memory of spoken language. Thus, there is a large amount of variability in outcomes among children with CIs: Some children do very well whereas others receive little benefit from the CI.

Predictors of Outcome Variability

There is an enormous amount of variability in language outcomes among children with CIs. Some of this variability can be predicted by several demographic factors. One of the most important is the age at which children receive a CI. Earlier implantation predicts better language development. For example, recent investigations suggest that toddlers who receive an implant before 1 year of age learn words more quickly than do toddlers who received their implant at 1 to 2 years of age. Electrophysiological measures, which can measure the development of natural auditory responses from infancy to adulthood, have revealed that there is likely an important window of time during early childhood in which it is crucial to acquire spoken language.

Another factor that predicts language outcomes is the amount of hearing at the time of implantation. Children with more hearing before implantation tend to acquire language better than do children with less hearing before implantation. Characteristics of the CI and the surgery also matter. Outcomes are affected by the number of electrodes inserted and the depth of CI insertion.

After surgery, the type and amount of speech therapy is crucial. Children who receive frequent speech therapy support develop better speech and spoken language skills than do those who receive little or no speech therapy. Children who undergo therapy that focuses more exclusively on spoken language tend to perform better on tests of speech perception and speech production than do children enrolled in therapy that combines sign and spoken language. Also, children's language skills improve as they gain more experience with the CI.

In addition to demographic predictors of outcome, researchers have recently investigated other factors that might contribute to success. For example, children who have better cognitive, motor, and lipreading skills before receiving a CI have been shown to have better speech and spoken language outcomes.

Effectiveness for Other Sound Perception

Recently, researchers have begun to investigate the effectiveness of CIs for perceiving other types of sound. Studies of music perception and production have shown that CI users are good at rhythm but not melody. Research on different qualities of speech has shown that CI users have a difficult time identifying individual talkers and dialects. Pitch cues in speech, such as rising pitch at the end of a question or lexical tone in some Asian languages, as well as complex non-speech sounds in the natural environment, such as animal or insect sounds, are also challenging for CI users.

New Directions

New Configurations

Until recently, all patients received a CI in only one ear and the other ear was saved for future technology. Now, some investigators are reporting advantages in locating sounds and speech understanding in noise with bilateral implantation, and many people believe that the benefits of binaural hearing may outweigh the benefits of waiting for a new technology. As a result, increasingly more patients are requesting a second CI, and some receive two CIs simultaneously.

CIs eliminate all acoustic ("natural") hearing in the implanted ear. For CI candidates who have some residual hearing for low-pitched sounds, it is desirable to preserve their acoustic hearing while using the CI to gain access to high-pitched sounds. One way to accomplish this is to implant one ear and fit the other ear with a hearing aid. Recently, CI manufactures have created a "short electrode array" that preserves the hair cells in the cochlea that respond to low-pitched sounds, allowing a mix of electrical and acoustic hearing in a single ear. Some evidence indicates that both of these approaches result in better speech understanding than does unilateral implantation.

New Measures of CI Effectiveness

Today, measures of CI effectiveness primarily involve tests of speech and language comprehension and production during the first several years after cochlear implantation. One direction for future research is to assess the long-term effect of CIs on education level and general quality of life. Another future direction is to investigate how early deafness and subsequent cochlear implantation affect cognitive, social, and emotional outcomes.

Assessing Effectiveness in Infants

Because earlier implantation predicts more successful outcomes across several measures, the candidacy criteria for CIs have expanded to include increasingly younger children. Currently, the FDA approves implantation down to 1 year, and some surgeons are implanting infants as young as 5 months.

Cochlear implantation during infancy presents new challenges. Current clinical instruments for assessing language skills in children involve instructing the children to perform tasks that are impossible for infants, such as pointing at a named picture or repeating what the clinician says. To assess early linguistic skills in infants, clinicians must currently rely on parental reports, which are indirect and highly dependent on the parents' ability to objectively assess their child's performance.

To develop more direct measures of performance, researchers are currently adapting behavioral measures that have been used to investigate normal-hearing infants' speech perception and language skills for use in the population of infants with hearing loss. For example, one methodology assesses infants' ability to distinguish different syllables or words using the following procedure. Infants are presented with an image of a checkerboard pattern on a TV monitor and a repeating speech sound until the infant looks away from the checkerboard pattern. Their looking times are monitored by an observer and recorded on a computer.

The presentation of the checkerboard pattern and speech sound is repeated until the infant's looking time to the checkerboard pattern has decreased by 50%. Then, the same checkerboard pattern is presented but now with a different speech sound. Infants who can distinguish the new speech sound from the old one will tend to increase their looking time to the checkerboard pattern in response to hearing the new speech sound. However, infants' performance on these types of tasks is highly variable and affected by things such as fussiness and attention. Current research continues to hone these techniques to improve their reliability.

COLOR: GENETICS OF

Normal trichromatic color vision in humans is afforded by the presence of three types of light sensitive cone photopigments in the retina. The underlying genetics of the short-, middle-, and long-wavelength sensitive (abbreviated S, M, and L) cone photopigments has been the topic of research for nearly 300 years. However, only during the past 20 years, through the use of modern molecular genetic techniques, has precise information about the genes underlying normal and defective color vision become available. This entry examines the current understanding of the genetic basis for human color vision, genetic variability in the system, and its behavioral consequences.

Genetic Basis of Human Color Vision

Cone photopigments in the human retina have two components—a protein component (opsin) and a chromophore (11-*cis*-retinal, a vitamin A derivative). Each of the cone photopigments has different spectral sensitivities; that is, they vary in the efficiency with which they absorb the different wavelengths of light. These cone photopigments differ only in their opsin component, and a different gene encodes for each of the opsin molecules. The gene encoding the S opsin is located on chromosome 7. The genes encoding L and M opsins are located on the X chromosome, in a head-to-tail tandem array (i.e., they lay right next to each other). This arrangement is the primary reason there is variation in these genes in humans. Just adjacent to this array is an important genetic regulatory element called the locus control region (LCR). The LCR is required for any of the genes in the L/M array to be expressed. The L and M opsin genes are about 96% identical, though they show only about 43% identity with the S opsin gene; many of these genetic differences are responsible for the different spectral properties of the photopigments. Mutations in these opsin genes result in differences in the structure of the associated opsin. This alters the functional properties of the photopigment; for example, the sensitivity of the photopigment to different wavelengths of light might be shifted, or the photopigment could be altogether nonfunctional. The functional consequences of genetic variation are discussed later.

The location of the L and M genes on the X chromosome means that color vision defects associated with mutations in these genes are inherited in an X-linked recessive pattern. These defects are commonly called "red-green" color vision defects. Females have two X chromosomes, whereas males have only one; therefore, in males, one mutated copy of the X chromosome is sufficient to cause a red-green deficiency, whereas in females the mutation must be present in both copies of the X chromosome. Thus, males are about 25 times more likely to have red-green defects than are females; however, nearly 15% of women will be carriers of a red-green color vision defect. Interestingly, there is rarely any behavioral indication of a female's carrier status. Thus, these red-green defects might pass through many generations without any family member exhibiting a defect.

In contrast, the autosomal (not sex-linked) location of the gene encoding the S opsin means that color vision defects associated with mutations in the S-opsin gene (referred to as "blue-yellow" color vision defects) are inherited in an autosomal dominant fashion. As a result of their autosomal location, humans normally have two copies of each of these genes; yet, a defect in a single S pigment gene is sufficient to cause a blue-yellow defect—there are no carriers. Thus, blue-yellow defects are equally prevalent in males and females, though they are much more rare than the red-green defects in general.

Genetic Variation Within Normal Color Vision

Most mammals have only a single L or M gene on the X chromosome; their color vision, therefore, is based on an S photopigment and an L or M photopigment, giving them dichromatic color vision. Most Old World primates (including humans) possess both L *and* M genes; their color vision is based on three photopigments (S, M, and L), rendering them trichromatic.

Among humans with trichromatic color vision, the number of genes in the L/M array varies from two (the minimum required to confer trichromacy) to as many as nine, with a mode of three. Curiously, other trichromatic Old World primates show nowhere near this degree of variability in gene number, even though they too are trichromatic. The relevance of the variability in gene number for human color vision is not clear, especially given evidence suggesting that only the first two genes in the L/M array can be expressed.

The location of the L/M gene array and their high homology allow for frequent unequal homologous crossovers (intermixing of the genes). This can occur between the genes (intergenic crossover) or within the genes (intragenic crossover) between two parental X chromosomes. Such recombination events are responsible for the observed variation in L/M gene number on the X chromosome. In addition, genes with "intermixed" L and M sequences are produced from intragenic crossover events. These genes encode photopigments that have spectral sensitivities intermediate of the normal L- and normal M-cone photopigments (and are sometimes called hybrid pigments). To date, there has been no measurable real-world consequence for having these hybrid pigments in individuals with normal color vision, although their presence can be revealed through careful color vision testing where subtle differences in spectral sensitivity can be revealed. The combined variability in gene number and gene sequence means that in a group of 100 males, the probability that any 2 will have identical L/M arrays is less than 2%.

Genetic Variation and Red-Green Defects

Two main genetic causes of inherited red-green color vision deficiency have been identified. The most common cause is rearrangement of the L/M genes resulting either in the deletion of all but one of the genes, or in the production of a gene array in which the first two genes both encode a pigment of the same type (L & L or M & M). The second general cause is the introduction of a mutation in either the first or second gene in the array, rendering one pigment nonfunctional. The most prevalent mutation results in the disruption of a highly conserved disulfide bond that is essential for the proper folding of the protein into its functional three-dimensional form. The same mutation, when it is present in the rod photopigment, causes an aggressive form of blindness called autosomal dominant retinitis pigmentosa.

Although all red-green deficient individuals have compromised color discrimination compared with normal trichromats, significant variation correlates with the underlying genetic variation. On one end of the spectrum are *dichromats* (individuals with a single spectral type of L or M gene). They have the worst color discrimination, as evident with a Rayleigh color match where they accept all mixtures of the red and green primaries as matches to the monochromatic yellow. The remaining individuals (who have either multiple types of L pigment and no M pigment or multiple types of M pigment and no L pigment—referred to as *anomalous trichromats*) fall along on a continuum of deficiency. In some cases, the deficiency is so mild that the individual is unaware of it only until genetic or behavioral testing; however, the most severe individuals behave almost like dichromats. This variation in behavior can be reliably linked to the underlying genetics of anomalous trichromacy, though exceptions can arise from differences in experience or performance issues on behavioral tests. The L and M photopigments differ in their peak spectral sensitivity by almost 30 nanometers (nm). Consider an anomalous trichromat with two L genes. If the L genes encode for L photopigments that are nearly identical to each other in their spectral sensitivity, the defect will be quite severe (nearly dichromatic). However, if these genes encode for an L photopigment and a hybrid photopigment (with disparate spectral sensitivity), the resultant defect can be mild. Nevertheless, it is now possible to examine the L and M genes of an individual and reliably determine whether he or she has a red-green defect and, if so, to make a prediction about the severity of the defect.

COLOR: PHILOSOPHICAL ISSUES

Why does the apple on the table before you look red? A commonsense answer: You are looking at a red apple in good natural light and you have normal color vision. It may seem hard to quarrel with this statement, but it is not particularly informative. A scientific account might go something like this: The apple selectively reflects more of the longer wavelength rays in daylight than those of shorter wavelengths. As a result, the kinds of light sensors in the retina of your eyes that are more sensitive to longer wavelengths respond more strongly than do those that are more sensitive to shorter wavelengths. This imbalance in response is coded and re-coded, exciting appropriate neural networks in the brain. Properly fleshed out, as it presumably will be in the future, such an account is indeed informative, but it would seem to lack something important. Nowhere in it is there a reference to the red quality of the apple or to your experience of that quality. The philosopher's task is to try to put the commonsense and the scientific accounts together to get a picture that accounts for the red quality and relates it to an informative causal analysis. The main philosophical attempts to do so are briefly discussed in this entry.

Physicalism, Dispositionalism, and Primitivism

Our only access to the colors of things is through our visual experience. As the *physicalist* sees it, the red of the apple is that physical property of the apple that causes us to experience red. This would seem to be its selective reflectance of light rays across the spectrum. However, the three sensor types of the retina are limited in their ability to resolve the spectral details of the light arriving at the eye. Consequently, things with different spectral reflectances can look red. A comparable situation applies to the spectra of light-emitting objects such as LEDs. The causes of experiences of red are so physically diverse that it is not clear what or whether they have anything in common.

To secure a property that all red things have in common, *dispositionalists* propose that we take the redness of an object to consist in its disposition to look red to color-normal observers under normal conditions, regardless of the physical mechanisms that underlie that disposition. Unfortunately, this proposal has problems of its own. The color appearance of some objects varies significantly with variation in the spectral composition of the light source, even if the source is considered "normal." For example, two surfaces that match in color in sunlight may look distinctly different in north daylight. In addition, the visual background and the distribution of colors in the scene will always affect the color appearance of the object to some extent, and sometimes quite dramatically. Furthermore, color-normal observers do not see colors of things in exactly the same way. So what viewing conditions and which observers shall we use to determine the "true" colors of an object? There seem to be no convincing reasons for choosing one set of conditions or observers rather than another. Once more, we are without a unitary objective feature that we could identify with redness.

Primitivists are dissatisfied with the candidates for physical redness proposed by physicalists and dispositionalists, but still want to retain the intuition that colors are properties of the material world outside of our consciousness. They propose that colors be understood as primitive, irreducible *qualitative* features of the physical universe. Such primitive qualities would exist over and above the elementary particles and fields that, according to contemporary physics, compose the furniture of the world and are exhaustively describable in quantitative terms.

But if we were thus to adorn the naked world of quantitative physics with color qualities, doing so would not seem to bring us any closer to answering the question of why the apple that you see looks red. The original quantitative scientific account tells us in a perfectly adequate way how the light with a particular spectral power distribution stimulates the receptors in the retina. We know that, with a properly functioning nervous system, this process is both necessary and sufficient for seeing object colors. Adding the supposed primitive qualitative redness of the apple to this account seems to play no additional role in helping us to understand how it is we come to see the apple as red.

Subjectivism

Confronted by these obstacles, we might consider abandoning our original supposition that the apparent redness of the apple is a property of the apple. Instead, we might think of the redness as our *subjective,* mental response to some feature of the physical apple. This suggestion goes back to the scientific revolution of the 17th century. It had been voiced some 2,000 years earlier by the Greek atomist Democritus, and repudiated by Aristotle, who preferred to locate colors outside of living creatures, in the interaction of light and matter. Medieval as well as ancient thinkers had followed Aristotle in this. For them, the qualities that objects are seen to have are by and large the qualities that they do have; these thinkers held that the business of our senses is to reveal Nature's finery rather than to clothe things with raiment of our own devising. Galileo introduced a new view of the Book of Nature: It is, he was fond of saying, written in the language of mathematics. The objects of mathematics are *quantitative:* number, structure, and motion. The powerful new mathematical physics seemed not to allow for the *qualitative* features of experience. Colors, sounds, and odors were thus swept from the physical world of matter in motion into the dustbin of the mind. There they joined thinking, purpose, and consciousness, which the new physics had likewise dispossessed from the world of matter. This sharp division of nature into a mental and a physical domain, famously advocated by René Descartes, served science well, but left obscure the nature of mind and its relationship to the physical world.

Although science and philosophy have become more sophisticated than they were in the 17th century, the basic picture of a divided nature remains with us. As some of its early critics remarked, this picture offends common sense. How could it be that the shapes that we see are inherent features of the physical world, whereas the colors that we see are constructions of the mind? Can we even imagine a shape with no color whatever? Furthermore, there are grave difficulties in understanding in what sense colors could be "in the mind." Colors are not, literally speaking, *in* minds as raisins are *in* cookies. We need more than a figure of speech. We need to know how color perception is to be understood if we are to think of colors as properties of mental items. Suppose that when you look at the apple that you take to be red, the direct object of your perception is an apple-shaped red color image. Your awareness of the redness of the apple—and, indeed of the apple itself—would be inferential awareness rather than the direct awareness that it seems to be. Worse still, because the physical apple is, by hypothesis, not colored at all, your supposed perception of its color is always illusory. But putting this aside, if mental objects are colored, we must be able to see them. And just how does that seeing take place? Is seeing a red image like seeing a red apple? If so, we will fall into an infinite regress because seeing an apple involves having a visual image of an apple, and if that is to be seen, there must be an image of that image, and so on. But if seeing a red image is not like seeing a red apple, then how do we see red images?

Epiphenomenalism, Eliminativism, and Mind and Body

If we suppose that there are neither red apples nor red mental images of apples, we must consider a more radical approach. Perhaps there are no color properties at all, just physical color stimuli on the one hand and mental color experiences (not red images, but experiences *as of* red) on the other. Taken together, these are sufficient to give us the appearance if not the reality of a world of colored objects. If we are willing to accept this position, we must still confront the most difficult problem of all: the relation of mental experiences to brain events. If experiences are identical to brain events, the brain as a physical entity must have qualitative as well as quantitative characteristics. And yet, qualitative characteristics have no more part to play in neuroscience than they do in physics. We might think of them as idle by-products, mere *epiphenomena,* of neural activity. If so, it is unclear how they could have come into being as a result of processes of natural selection because they can confer no advantage on the organism that possesses them. For this reason, we might be tempted to *eliminate* qualitative experiences altogether from our picture of the world, as previous generations of scientists eliminated other explanatorily useless items such as phlogiston and the electromagnetic ether. This would mean that we human beings are nothing more than biochemical computing machines. It would seem that to take this path is to turn our backs on our problem rather than solving it. We know what it would mean for a machine to act as if it perceives color, but it is hard to conceive how one could go about constructing a machine that actually experiences color (or feels pain, or falls in love). Would it make a difference if the machine were made of wetware rather than hardware? If so, why?

Our investigation of the place of color in the world has led us to confront the classic philosophical problem of the relationship between mind and body. One of the motivations of those who want to think of colors as being items in the physical world is to bypass, or even partially dissolve, this formidable issue. But even if this could be achieved, we would still have to deal with colored afterimages, color illusions, color experiences of migraine sufferers, and a whole host of chromatic phenomena that are not part of the world outside of our skins.

The problems we have touched upon are difficult and their solutions are evasive, but they cannot be brushed aside. The fact is that we are physical beings as well as beings that think, and feel, and see colors. There must be a unitary picture of ourselves and of our world that accommodates and explains this fact. It is up to us to construct that picture. Once we understand what it is to see the apple as red, we shall have gone a long way to understand what we are.

COLOR CONSTANCY

We would rather eat a banana that looks yellow than one that looks green because the banana's color appearance carries reliable information about its ripeness. In general, color appearance is a useful percept because it provides reliable information about object identity and state. When we search for our car in a large parking lot, we rely on color to pick out likely candidates; our driver's licenses list the color of our eyes and hair for identification; we detect that a friend is embarrassed by the blush of his or her face.

For color appearance to provide useful information about objects, it must correlate with properties intrinsic to objects and be stable against transient features of the environment in which the objects are viewed, such as the illumination. This stability, which is provided in good measure by our visual systems, is called *color constancy*. That we have generally good constancy is consistent with everyday experience. We are content to refer to objects as having a well-defined color, and only rarely (e.g., when looking for our car in a parking lot illuminated by sodium vapor lamps) do we observe large failures of constancy. This entry describes the problem of color constancy, empirical observations, and theories of constancy.

The Problem of Color Constancy

Vision obtains information about objects through the light reflected from them. If the reflected light were in one-to-one correspondence with physical object properties, then extracting stable object percepts would be straightforward. But the reflected light confounds properties of the illumination with those of the object. In the case of color, the relevant object property is its surface reflectance function $S(\lambda)$: the fraction of incident illuminant power that is returned to the eye at each wavelength λ. The relevant property of the illuminant is its spectral power distribution, $I(\lambda)$: the amount of power at each wavelength that arrives at the object. The spectrum reflected to the eye is thus $C(\lambda) = I(\lambda)\,S(\lambda)$. $C(\lambda)$ is called the color signal. Ambiguity arises because of the symmetric role played by $I(\lambda)$ and $S(\lambda)$ in the formation of the color signal. For example, a banana seen in skylight might reflect the same spectrum to the eye as does grass under direct sunlight because the effect of the illuminant change on the color signal can be counteracted by the change in surface reflectance. The perceptual challenge of color constancy is to make object color appearance stable against changes in $I(\lambda)$ while making it sensitive to changes in object reflectance $S(\lambda)$.

Empirical Observations

To what extent does the visual system actually stabilize object color in the face of illuminant changes? This has been studied with scaling and naming paradigms where observers describe the color appearance of objects seen under different illuminants, as well as with matching paradigms where observers adjust a test object seen under one illuminant to match the appearance of reference object seen under a different illuminant. A few generalizations may be drawn from the large empirical literature. First, color appearance does vary somewhat when the illuminant is changed: color constancy is not perfect. Second, the variation in object appearance is small compared with what would be predicted for a visual system with no constancy.

That constancy is generally good is often characterized by a constancy index, which takes on a value of 0 for a visual system with no constancy and 1 for a visual system with perfect constancy. For natural viewing conditions when only the illuminant is changed, experimentally measured constancy indices are often in the range 0.8 to 0.9, and sometimes higher.

Constancy is not always good, however. For example, constancy fails for simple scenes. Indeed, when a scene consists only of a single diffusely illuminated flat matte object, changes of illumination and reflectance are perfectly confounded, and changes of illumination lead to large failures of constancy. More generally, the degree to which the visual system exhibits constancy depends critically on what is varied in the scene. Under natural viewing conditions, constancy tends to be good if only the spectrum of the illuminant is varied. But if the surface reflectances of the other objects in the scene are covaried with the illuminant, constancy can be greatly reduced. For example, suppose the illuminant is shifted to have more short wavelength power and less long wavelength power. If at the same time, the surface reflectances of objects in the scene are shifted to compensate (i.e., to reflect less at short wavelengths and more at long wavelengths), color constancy is impaired. In laboratory studies of this manipulation, constancy indices drop into the range 0.2 to 0.4, a result that needs to be explained by any theory of constancy.

Theories

Theories of constancy should account for the general empirical observations described previously.

They should explain why constancy is often good, but also why it sometimes fails. Essentially all current theories share in common the general notion that visual processing of the color signal reflected from a single object is affected by the color signals reflected from the other objects in the scene. That is, our perception of object color is constructed by analyzing the reflected color signal relative to the rest of the retinal image.

Fundamentals of Color Vision

To understand theories of constancy, it is necessary to review a few fundamentals of human color vision. The color signal arriving at each retinal location is not represented completely. Rather, its spectrum is coded by the responses of three classes of light-sensitive photoreceptors. These are referred to as the L, M, and S cones, where the letters are mnemonics for long-wavelength-sensitive, middle-wavelength-sensitive, and short-wavelength-sensitive. Each cone class is characterized by a spectral sensitivity that relates the cone's response to the intensity of incident light at each wavelength. The three classes of cones differ in the region of the spectrum they are most sensitive to. Thus, the information about color available to the brain consists of the responses r_L, r_M, and r_S of the L, M, and S cones at each image location.

Contrast Coding

The simplest theories of constancy postulate that the initial representation of the image is processed separately for each cone class and that at each image location the cone responses are converted to a contrast representation. For the L-cones, contrast is based on the difference between the overall L-cone response r_L and the L-cone responses in its local neighborhood, and it expresses this difference relative to the magnitude of the neighboring responses. Let u_L represent the average of the L-cone responses in a spatial neighborhood of an L-cone whose response is r_L. Then the contrast is given by $c_L = (r_L – u_L)/u_L$. Parallel expressions apply for the M and S cones.

Experiments that assess the visual system's response to spots flashed against spatially uniform backgrounds support the idea that cone responses are converted to a contrast representation early in the visual system. These experiments include measurements of appearance, of visual discrimination thresholds, and direct measurements of electrical activity in retinal ganglion cells.

How does contrast coding help explain color constancy? Consider a change in the overall intensity of the illuminant spectrum. This will increase the cone responses equally to the light reflected from every location in the scene. Thus contrast, which depends on the ratio of cone responses across locations, is invariant to such illuminant changes.

When a change in the illuminant is not characterized as a simple scalar change in intensity, contrast is not guaranteed to be exactly invariant across the illuminant change. Nonetheless, analyses of the light reflected from natural surfaces indicate that contrast computed separately for each cone class (i.e., c_L, c_M, c_S) is quite stable across naturally occurring illuminant changes, even those that are not pure intensity changes. When the objects in the scene are held fixed and only the spectrum of the illuminant is varied, theories based on local contrast coding do a good job of accounting for experimental color constancy data.

Challenges for Contrast Coding Models

Although contrast coding can explain constancy across illuminant changes, it also predicts strong failures of constancy when the reflectances of some of the objects in the scene are changed. Suppose we fix one test object of interest, and then vary the objects around it at the same time as the illuminant is changed. Manipulations of this sort can be arranged so that the local means (u_L, u_M, u_S) near the test object remain fixed across the illuminant change. In turn, this means that the contrasts of the test object (c_L, c_M, c_S) vary with the illuminant, and contrast theories thus predict large failures of constancy under these conditions. Although experimental tests do reveal that color constancy is reduced when this type of manipulation is performed, the reduction is not as great as contrast theories predict. In addition, contrast is a quantity computed independently of the three-dimensional scene being viewed. Experimental manipulations that affect perceived depth relations without changing cone contrasts have been shown to affect how color is perceived. Contrast-based theories are incomplete.

Theoretical Approaches and Considerations

The current theoretical challenge is to develop models that can account for the full range of experimentally measured performance, when stimulus manipulations include changes in the illuminant, in the reflectances of other objects in the scene, and in geometric aspects of the scene.

One approach to model development is mechanistic. The idea underlying mechanistic models is that the cone responses corresponding to each object are subjected to a series of transformations as they propagate from the retina to the cortex, and that the end result of these transformations is a neural representation that is more directly correlated with object reflectance than are the cone responses. The contrast coding idea reviewed earlier is an example of a mechanistic approach, and contrast coding is generally taken as the first stage of modern mechanistic theories. Current research along mechanistic lines seeks to incorporate additional stages. For example, most models postulate that signals from the separate cone classes are recombined at second-stage opponent sites, which code differences between cone contrasts. Signals leaving the opponent sites are then further modified in an image-dependent fashion. For example, the overall magnitude of cone contrasts across the image are thought to control the gain applied to second-stage signals, and such processes have been shown to have the effect of further stabilizing color appearance across natural illuminant changes. To the extent that mechanistic models eventually account for color constancy across a wide range of experimental conditions, they have the attractive feature that they simultaneously provide an account of the chain of neural processing that underlies the color perception.

A second modeling approach is computational. Here the idea is to step back from the details of human vision and ask instead how to design an algorithm that, if it had access to the cone responses, could in principle achieve approximate color constancy. The algorithmic work lies within the domain of computer vision and has led to methods that explicitly estimate the physical scene illuminant $I(\lambda)$ and surface reflectances $S(\lambda)$ from the spatial array of cone responses. Although the resulting algorithms do not have any necessary connection to human vision, they may be elaborated into models that predict how object colors will be perceived. For example, one can link algorithm and human performance by predicting that two objects viewed in different scenes and under different illuminants, but whose surface reflectances are estimated by the algorithm to be the same, will also have the same color appearance. Modeling efforts of this sort have been successful at accounting for experimental measurements of object color appearance across a wide range of experimental conditions and particularly at accounting for both successes and failures of constancy in a unified fashion.

Computational modeling typically incorporates constraints derived from analysis of what surfaces and illuminants occur in natural scenes. In the Bayesian approach to developing computational methods, such constraints are expressed explicitly as probability distributions. This in turn allows a precise statistical formulation of how to optimally estimate surface and illuminant properties from the cone responses. In the context of developing models for human vision, the motivation for incorporating optimality principles into the development of algorithms is that evolution has driven the visual system toward information processing optimized for natural scenes, so that a computational method that is optimized with respect to the same set of scenes is likely to mimic human performance.

The mechanistic and computational approaches are complementary. Any computation that correctly predicts performance must have a mechanistic expression (because the human visual system implements it), and conversely, any mechanistic formulation that describes performance must express a computation that does an excellent job of achieving color constancy for natural viewing (because we are only rarely surprised to see a fixed object appear a different color.) The current challenge is to elaborate both of these approaches to describe the full range of performance, and to bring them together into a single model that connects mechanism (including contrast coding), performance, and a computational understanding.

COLOR DEFICIENCY

Color vision is the capacity to distinguish objects based on the wavelengths of light they reflect or emit, and color vision is one of the most salient features used to describe objects in our environment. Consider a few things that exquisite color discrimination enables—being able to determine the ripeness of fruit, to rapidly detect your car in a parking lot, or to determine if your steak is cooked to your liking. Each individual's perception of color is a private sensation and, for those individuals who possess a "normal" ability to perceive color, this sense is often taken for granted. Conversely, individuals with color deficiency are often aware of their defective color discrimination throughout daily life. For example, people with color vision deficiencies can have difficulty telling whether a piece of meat is raw or well done, or might have difficulty seeing that they have been in the sun too long and are getting sunburned. They may also have a different sense of what looks good—be it their clothing or the food in front of them. This is because the color cues allowing individuals with normal color vision to distinguish between two objects may not be present for color-deficient individuals. For example, ketchup and chocolate syrup might look about the same color to them. This entry examines the range of color vision deficiencies present in humans, including their genetic origins, receptoral mechanisms, associated perceptual consequences, and incidence in the population.

Photoreceptor Mechanisms

The four types of photoreceptors in the human retina initiate the process of vision, and these types can be separated into two main classes (rods and cones). Rods are effective only at low light levels and can detect even a single photon of light, thus affording our scotopic vision (i.e., nighttime vision). Cones are less sensitive than rods are and therefore operate at higher light levels (serving photopic, or daytime, vision), and are responsible for our ability to perceive color. Thus, most of our visual experience is mediated by the cone photoreceptors (paradoxically, however, the cones constitute only about 5% of the total number of photoreceptors). There are three different classes of cone photoreceptor, each one with a different spectral sensitivity (i.e., plot of sensitivity of the photopigment vs. wavelength). Each of the four types of photoreceptor contains a single type of photopigment molecule, which gives the photoreceptor its characteristic spectral sensitivity.

As hypothesized 200 years ago by Thomas Young, we now know that trichromatic color vision is afforded by the presence of three spectrally distinct cone photopigments in the retina. Each cone type can be classified by the wavelength of light that the photopigment it contains is most sensitive to: short-, middle-, and long-wavelength sensitive (abbreviated S, M, and L). All humans with normal color vision have the same S-cone pigment, with peak absorption around 417 nanometers (nm). The M-cone pigment varies slightly between individuals, but peaks around 530 nm. Interestingly, there is widespread variation of the L-cone pigment among humans with normal color vision, but the peak of the L-cone pigment is approximately 559 nm. Rods are maximally sensitive to 500 nm light, but do not contribute significantly to our color vision.

The absorbance spectrum of a photopigment represents the probability of a photon of light being absorbed as a function of wavelength. In other words, each cone photoreceptor is simply a photon "counter"—an individual cone does not have access to information about the wavelength content of a given light stimulus. At the most basic level, the signal from a photoreceptor depends on the number of photons caught, not on their wavelength. For example, even though an L-cone is about two times more sensitive to 559-nm light than to 500-nm light, if the 500-nm light is more than twice as bright, it will elicit a higher quantal catch in the L-cone, and thus, a stronger neural response.

Consequently, the ability to discriminate colors arises from the neural channels that extract the *ratios* of the photon catches in the different spectral cone types. As such, possession of one cone type from each of the three spectrally distinct classes (S, M, L) provides the basis for normal color vision. However, if input from one or more of the cone classes is missing, the result is a compromised ability to make chromatic discriminations, that is, a color vision deficiency. Although these individuals are often called "color blind," in most cases, this is an inaccurate description of their color vision. With rare exception, these deficiencies do not involve a loss of sensitivity to all colors—as implied by the phrase *color blind;* rather, certain colors that can be easily discriminated by a "normal" observer look the same to the color-deficient observer.

Red-Green Color Vision Deficiencies

The most common form of inherited color vision deficiency is one that affects the red-green (L–M cone) system. Among individuals of Western European ancestry, about 7 to 10% of males have a red-green color vision defect. The incidence is lower among Africans as well as smaller isolated populations such as Fijian Islanders and the Inuit. The incidence in females is much lower (approximately 0.4%) because the defects are inherited as X-linked recessive traits, though approximately 15% of females are carriers of a red-green defect. The general genetic causes of red-green color vision deficiency involve a disruption of the L/M gene array on the X chromosome, which occurs either through a physical rearrangement in genes in which one type is missing or through the introduction of an inactivating mutation in one of the genes. In both cases, the result is an absence of function of either the L- or M-cones. This is because a cone cannot absorb light without a functional photopigment.

Within the red-green color vision defects, there are two broad subcategories—dichromacy and anomalous trichromacy (Figure 1). Red-green dichromats base their vision on an S pigment and a single L *or* M pigment. Individuals with an absence of L-cone function are said to have a *protan* defect, and individuals with an absence of M-cone function are said to have a *deutan* defect. Individuals with less severe forms of the red-green defects, known as anomalous trichromats, do not have the normal M or L photopigments; instead they base their vision on an S pigment and either two spectrally distinct M pigments (*protanomals*) or two spectrally distinct L pigments (*deuteranomals*). They are trichromats, in that they have three different pigments, but are different from normal (anomalous). Deuteranomalous defects are by far the most prevalent of any of the congenital color vision defects, affecting nearly 5% of men.

Perceptually, the absence of a cone type can have differing effects (see color insert, Figure 15). Individuals with a protan (L-cone) defect are less sensitive to light in the long-wavelength (red) portion of the spectrum. Therefore, the brightness of red, orange, and yellow are reduced compared with that of a normal observer. Furthermore, these individuals may have problems in distinguishing red from green, as well as difficulties differentiating a red hue from black. In contrast, individuals with deutan (M-cone) defects exhibit a reduction of sensitivity to colors in the green region of the spectrum. Deutans suffer similar hue discrimination problems as the protans, but without the abnormal dimming. These discrimination errors are exploited in the design of color vision tests; however, the real-world consequences of having certain red-green deficiencies are minimal. Some individuals go unaware of their defect until tested in a laboratory setting.

Tritan Color Vision Deficiencies

Tritan defects are an inherited autosomal dominant abnormality of S-cone function. Individuals with tritan defects base their vision on an L and an M pigment; they are dichromats. Unlike the red-green defects, there is no evidence for anomalous trichromats with tritan color vision defects. These defects occur in both males and females with equal frequency and are believed to affect approximately 1 in 10,000 people. Because the S-pigment gene is on chromosome 7 and humans are diploid (i.e., they have two copies of each autosome), each S-cone photoreceptor expresses the S-cone pigment genes from both copies of chromosome 7. Consequently, a defect in one S-pigment gene is sufficient to cause tritanopia,

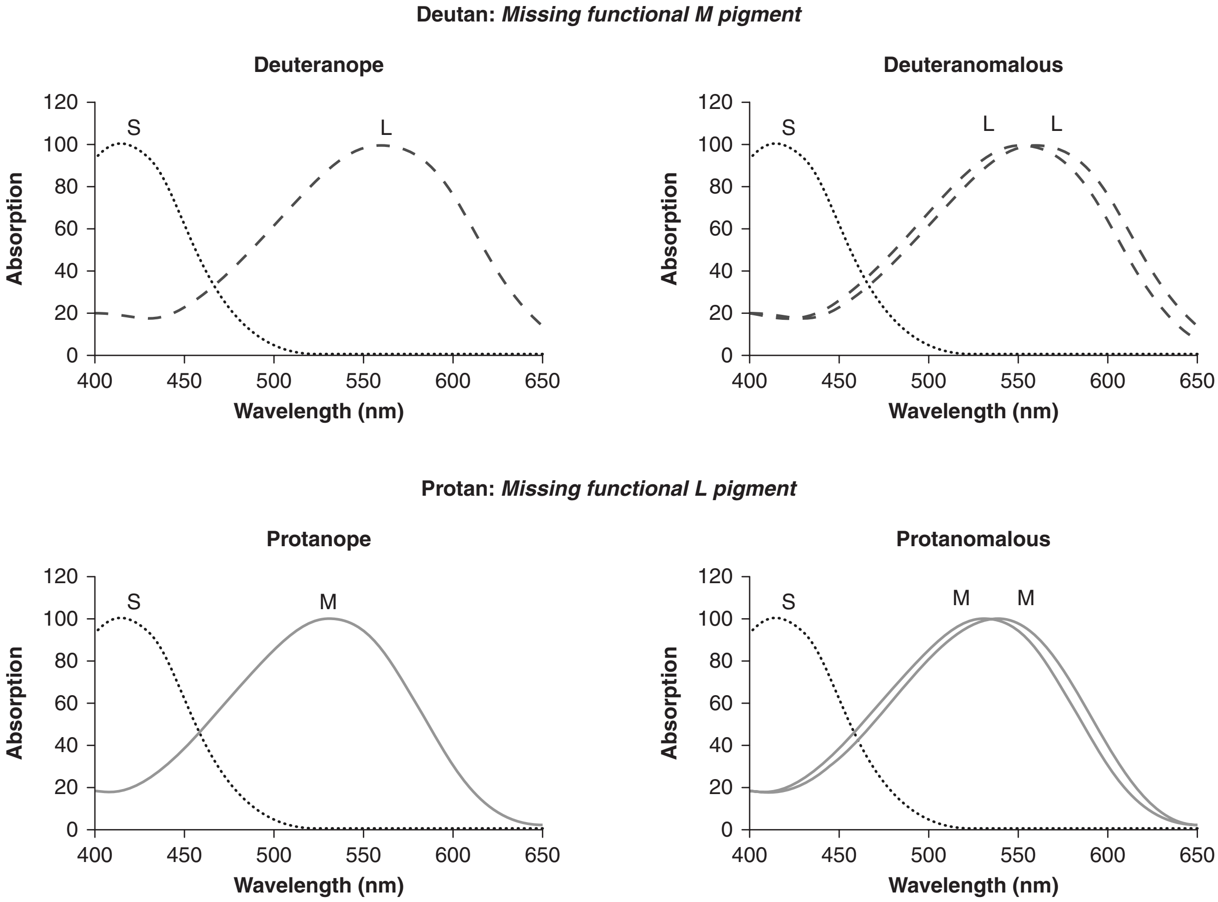

Figure 1 Photopigments Underlying Defective Red-Green Color Vision

Notes: Red-green color-deficient individuals are missing either all members of the M class or all members of the L class of pigment. Dichromats have only one pigment in the L/M region of the spectrum, whereas trichromats have two pigments in the L/M region of the spectrum. The degree of color vision deficiency in persons with anomalous trichromacy depends on the magnitude of the spectral difference between their pigment subtypes. Deuteranopes and deuteranomalous trichromats have no functional M pigment, though deuteranomals have two slightly different L pigments. Likewise, protanopes and protanomalous trichromats have no functional L pigment, though protanomals have two slightly different M pigments.

just as a mutation in one rhodopsin gene is sufficient to cause retinitis pigmentosa, a retinal degeneration that involves the degeneration of the rod photoreceptors. Furthermore, this disorder exhibits incomplete penetrance, meaning that individuals with the same underlying mutation can have different degrees of color-vision impairment, even between siblings.

Blue-Cone Monochromacy

Blue-cone monochromacy (BCM) is a condition where both L- and M-cone function is absent; therefore individuals will be able to function at normal light levels but will not be able to distinguish different hues. Any residual color vision in these individuals must be based solely on the S cones and rods. This means that under most conditions, they are monochromatic, though under mesopic (dim light; between photopic and scotopic levels) conditions, they may gain some additional discrimination capacity. This disorder affects approximately 1 in 100,000 individuals.

As with the red-green defects, there are two main genetic causes of BCM, sometimes referred to as one-step or two-step mutations, though both lead to the complete absence of functional L and M photopigment. In one-step mutations, there is an inability to express the L and M pigment genes—as such, no L or M photopigment is made. In the two-step mutations, the L or M pigment genes can be expressed; however, the pigment that is made is nonfunctional because of some other mutation. In both the one-step and two-step mechanisms, individuals have poor visual acuity, myopia, nystagmus (involuntary eye oscillations), and minimally detectable electroretinogram (ERG) responses. Because of the X-linked nature of the condition, female carriers are spared from a full manifestation of the associated defects, but they can show abnormal ERG amplitudes.

Achromatopsia

Complete achromatopsia (i.e., rod monochromacy) is a congenital vision disorder in which all cone function is absent or severely diminished. This disorder affects as many as 1 in 30,000 people and is thought to result from mutations in one of two components of the cone phototransduction cascade (transducin or the cyclic-nucleotide gated channel). Rod monochromacy is typically characterized by a complete lack of color discrimination, photophobia (light sensitivity), reduced acuity, visual nystagmus, and a nondetectable cone ERG. Because these individuals lack all cone function, perception is dominated by the rod system and vision at normal light levels can be difficult.

Acquired Defects

As described earlier, most color deficiencies are inherited and result from disruptions in the genes encoding the cone photopigments. However, color vision deficiencies may be acquired through exposure to toxins (such as heavy metals), cortical defects (occurring from a stroke or shaken baby syndrome), or other disease (diabetes, optic neuropathy, glaucoma). As a generalization, these defects are predominantly tritan, have an equal incidence in males and females, and are typically accompanied by a reduction in visual acuity. Acquired defects can be categorized by the perceptual color vision deficit or by the mechanism. Perceptual categorization can be broken into three basic categories: a nonspecific loss of color vision, a loss pertaining to the red-green axis, or a loss corresponding to the blue-yellow axis. There are also three mechanistic categories: absorption, alteration, and reduction. Absorption defects affect the absorption of a particular hue. For example, the normal aging process affects the lens of the eye, causing a selective absorption defect in discrimination in the blue-yellow axis. An alteration defect is one that shifts the normal color match, and normally reflects a destruction of the macular cones. A reduction defect occurs typically as a result of diseases of the optic nerve and causes perceptive reduction of saturation within the red-green axis as well as a milder blue-yellow loss.

Testing and Assessment

When screening for color vision deficiency and attempting to make diagnoses, no one test should stand in isolation. Over the last few centuries, several different methods for diagnosis and testing of color vision deficiencies have been developed, and using a battery of tests will help the examiner to assign a more accurate diagnosis. Furthermore, the use of a standard illuminant ensures reliability and repeatability of the test(s).

The anomaloscope, discovered by Lord Rayleigh in 1881, is a color-matching test in which subjects view a small bipartite field and compare a mixture of red (670 nm) and green (546 nm) wavelength light on one half to a spectral yellow (589 nm) on the other half. The *Rayleigh match* takes advantage of the fact that normal trichromats behave dichromatically for lights with wavelengths longer than 550 nm (because the S cones are not sensitive at these wavelengths). Thus, by restricting the lights employed to the longer wavelengths, a normal trichromat can achieve a perfect color match to the monochromatic light by mixing two "primaries." A subject's *match range* can be any range of numbers between 0 and 73, with most subjects matching two to four of the numbers in the range of 38 to 42. Individuals do vary in the relative amounts of the primaries needed to achieve the match, altering their match range slightly (this variability has been linked to individual variation in the L- and M-cone pigments). However, individuals with missing or altered L or M pigment will match a much larger and distinctly displaced range of mixtures of the two primaries because of their relative insensitivity to one of the wavelengths of light. Therefore, the extent of the matching range is directly representative of the severity of the defect. For example, deuteranomals need less red than normal in the red-green mixture to match the spectral yellow (matching a wide range of numbers in the 0–40 range), whereas protanomals need more red in the match (matching a wide range of numbers typically in the 40–73 range). A subject matching the entire 0–73 range is diagnosed as dichromatic. This test is considered by many to be the gold standard in diagnosing type and severity of red-green defects.

Because the Rayleigh match uses wavelengths to which the S cones are relatively insensitive, it only can be used to detect red-green defects (defects associated with disrupted L- or M-cone function). To evaluate S cone function, which provides the basis for color vision along the blue-yellow axis, one can use a color matching test called the *Moreland match*. The test field consists of a cyan (480 nm) and yellow (580 nm) light, and the matching primaries are blue (440 nm) and green (488 nm). This color match is often employed in the evaluation of acquired color vision because they more often affect the blue-yellow system.

In the interest of speed and convenience, printed pseudoisochromatic plate tests are a widely used screening tool, of which there are several varieties. Mostly these tests specialize in detecting red-green deficiencies; however, a few include plates to detect tritan defects. These tests operate on the pseudoisochromatic principle by using a field of dots that vary in luminance, and embedded within the dots is a number or other recognizable shape differing in chromaticity from the background. Four different types of plates can be included. Vanishing plates contain a figure that is correctly recognized by a color normal observer, but is not recognized by a color defective observer because the figure is confused with the background. The diagnostic plates are more sophisticated in that, based on the type of error, they can differentiate between a protan and deutan observer. One of the more advanced plate types is the transformation plate in which two figures are embedded: one figure recognized by a normal observer, and the other recognized by a color defective observer. Finally, in the hidden plate, the figure is seen by the color defective observer rather than by the normal observer. Current versions of these tests include Ishihara, AOHRR plates, and the Neitz Test of Color Vision.

Another type of test is the arrangement test in which subjects order materials in a specific hue or saturation order. The stimulus is prearranged in a random order and subjects are instructed to arrange the stimuli according to color. Correct arrangement of the various color samples requires normal color vision, as well as good discriminative ability. Some versions are so difficult that even individuals with trichromatic color vision can make significant errors. These tests vary in the number of colored samples used in the test; current versions of these tests include Farnsworth D15, Lanthony's desaturated D15, and the Farnsworth-Munsell 100 hue test.

An emerging tool for assessment of color vision is molecular genetic analysis. From a small blood sample, it is possible to isolate a person's DNA, which can be used to analyze the genes encoding the S, M, and L photopigments. The presence of mutations or deletions in one or more of these genes provides predictive information relevant to the subjects' color vision capacity. This means that in nearly every individual with a color vision deficiency, it is possible to determine a precise genetic cause for the deficiency.

COLOR MIXING

Differently colored lights can be mixed together optically to produce lights of another color. Which lights and which mixtures perceptually match each other can be predicted from a few relatively simple rules. The simplicity of these rules, discussed in this entry, derives from the properties of the visual photoreceptors in our eyes that convert arriving photons into neural signals, rather than from physics.

Overview

The visible spectrum is that part of the electromagnetic spectrum that we can see. It covers wavelengths from about 390 to 730 nanometers (nm). When viewed alone, the appearance of *monochromatic* lights made up of single wavelengths varies across the spectrum from violet at short wavelengths through blue, blue-green or cyan, green, yellow-green, yellow, orange to red at long wavelengths. Sodium street lighting, which appears yellow, is a commonly encountered example of lights that are nearly monochromatic. Most lights that we encounter in the natural environment are *broadband* in the sense that they consist of lights of many different wavelengths covering broad regions of the spectrum.

Mixtures of monochromatic lights or mixtures of broadband lights can be perceived as identical even when the components in the mixtures are physically different. For example, a mixture of red and green monochromatic lights can appear identical to a yellow monochromatic light, and a mixture of blue and green monochromatic lights can appear identical to a cyan monochromatic light (see color insert, Figure 16, left panel). The relationship between the physical characteristics of lights or mixtures of lights and whether or not they appear to match can be investigated in simple color matching experiments.

Properties of Color Mixing

In a typical color matching experiment, an observer looks at a circle, half of which is illuminated by a "test" light of variable wavelength (λ) and the other half by a mixture of three "primary" lights usually chosen to look red (R), green (G), and blue or violet (B). For each test light, the observer adjusts the intensities of the three primary lights, so that the test field is perfectly matched by the mixture of primary lights. With the proviso that sometimes one of the primaries must be added to the test light to complete the match and that the primaries must be independent (in the sense that none of the primaries can be matched by a mixture of the other two), only three primaries are required to match any test light. The upper panel of Figure 1 shows the mean red, green, and blue color matching functions (CMFs) for primary lights of 645, 526, and 444 nm (denoted by the vertical dashed lines) as a function of test wavelength, λ. Each function defines the amount of that primary required to match a monochromatic light of λ nm. That any light can be matched by a mixture of just three primary lights reflects a fundamental property of normal human vision: it is *trichromatic*. The operation of color television, computer monitors, and projection systems, which produce colors by mixing together red-, green- and blue-appearing lights in different proportions (as you can see for yourself by looking closely at the screens), relies on our color vision being trichromatic.

Another important property of color mixing is that it behaves linearly as reflected in a set of descriptive laws known as Grassmann's laws. Color matches are symmetric (if light A matches light B, then B matches A), transitive (if A matches B, and B matches C, then A matches C), obey the proportionality rule (if A matches B, then n × A matches n × B), and are additive (if A matches B and C matches D, then the combination of A and C matches the combination of B and D).

The Biological Basis of Color Mixing

The origins of trichromacy and the linearity of color mixing are mainly biological. They occur because there are only three classes of cone photoreceptor in the human eye, each of which responds *univariantly* to light. Once a photon is absorbed, its effect is the same whatever its wavelength, as a result of which photoreceptors are, in effect, sophisticated photon counters.

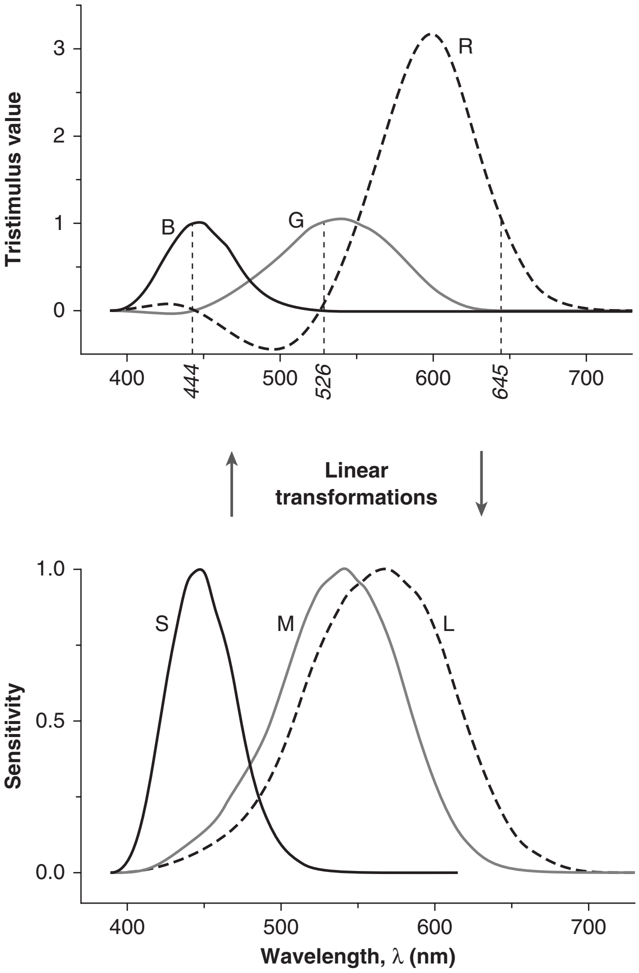

Figure 1 Color Matching Functions and Cone Spectral Sensitivities

Notes: The red (R), green (G), and blue (B) CMFs (upper panel) can be linearly transformed to the long-wavelength (L), middle-wavelength (M) and short-wavelength (S) cone spectral sensitivities and vice versa. The CMFs for primaries of 444, 526, and 645 nm are from Stiles and Burch, and the cone sensitivities are their linear transformation proposed by Stockman and Sharpe. By convention, CMFs are defined for test lights of equal energy across the spectrum.

Photoreceptors, however, are more likely to absorb some wavelengths than others (see Figure 1, bottom panel). A change in photoreceptor output could result from a change in wavelength, from a change in light intensity, or from both, so individual photoreceptors are color blind. Our ability to perceive color depends on the comparison between the outputs of the three cone photoreceptor types.

When observers match the test and mixture fields in a color matching experiment, the two fields are matched for each of the three cone types. In other words, the two lights that perceptually match generate the same pattern of cone outputs. Matches depend on the three cone spectral sensitivities. As illustrated in Figure 1, the red (R), green (G), and blue (B) CMFs (upper panel; shown as dashed, gray, and black lines here) are a linear transformation of the spectral sensitivities of the long- (L), middle- (M), and short- (S) wavelength-sensitive cone spectral sensitivities (lower panel).

Color Mixing and Color Appearance

Cone spectral sensitivities and CMFs tell us which pairs of lights match, but they do not tell us what the color of the matched pair looks like to the observer; that is, they do not tell us about color appearance. Color appearance depends also on the context within which the lights are presented. For example, lights that are identical can look different when surrounded by areas of different color. The effect on color appearance of changing the color of a surrounding area from blue to yellow is shown in the color insert, Figure 17. The two squares are printed with the same ink, but the square with the yellow surround looks much bluer than the square with the blue surround does. Color matches reflect trichromatic univariance at the cone photoreceptors, whereas color appearance depends on previous light exposure and, in addition, on the complex activity of post-receptoral mechanisms in the retina and brain that act on the outputs of the cone photoreceptors.

Additive and Subtractive Color Mixing

What this entry has discussed so far is the *additive* mixing of visually superimposed colored lights. Additive color mixing produced by mixing lights is illustrated in the left panel of Figure 16 in the color insert. In contrast, the mixing of paints, dyes, and pigments depends on the lights reflected by pigments (i.e., on the wavelengths that are not absorbed or “subtracted” by the pigment) rather than on the addition of projected lights. Thus, a yellow pigment appears yellow because it absorbs short-wavelengths and reflects middle- and long-wavelengths, and a cyan pigment appears cyan because it absorbs long-wavelengths and reflects short- and middle-wavelengths. When predicting the effects of mixing pigments, the lights that are subtracted by the mixture pigments must be considered. For example, a mixture of yellow and cyan pigments will appear green, because the two pigments absorb, respectively, short- and long-wavelengths, leaving only green-appearing, middle-wavelength light to be reflected. Subtractive color mixing is illustrated in the right panel of Figure 16 of the color insert.

COLOR NAMING

Color naming in the broad sense is giving a color name such as "red" to an object of a particular color. This task is not as trivial as it sounds. We commonly use only a few color names but can distinguish millions of different colors. The colors of an object such as a banana may differ to some extent in all perceptual color dimensions of hue, saturation, and brightness: Parts of the banana may be darker and less saturated because of shading, parts may be more yellow-greenish or more yellow-orangish. Yet we perceive all these different shades of colors as belonging to the same category "yellow" and speak about the "yellow" banana. Color naming thus involves a partitioning of the continuous color space into distinct color categories, to which we assign a word. In the narrower sense, color naming refers to a method used in psychological experiments where observers have to name the color of the stimuli presented. This entry describes the universality of color names, psychophysical experiments, the Stroop effect, and neural correlates.

Universality of Color Names

Color names in different languages are remarkably consistent. It has been proposed that 11 basic color terms are strikingly similar across different languages and cultures. The English words for these basic color terms are *black, white, red, yellow, green, blue, gray, orange, brown, pink,* and *purple.* These color names may be grouped and ordered to approximately reflect their appearance during child development and cultural development as follows: (black, white) → (red) → (yellow, green) → (blue) → (gray, orange, brown, pink, and purple). An analysis of data from 110 languages of nonindustrialized societies gathered in the World Color Survey confirmed the idea of universal color names. Although there are some small variations of the focal colors (those colors that provide the best example of a basic color term) across languages, the focal color fell on average close to the colors found for English speakers. Despite these similarities, different languages may differ in the number of basic color terms. For example, some languages such as Russian, Polish, and Italian have a basic color term to distinguish between "light blue" and "dark blue"; some languages merge green and blue into a single "grue" category, and members of the Dani of New Guinea have only two basic color terms to distinguish between light-warm and dark-cool colors. Interestingly, when asked to remember colors, the Dani were better across the same color boundaries (e.g., blue-green) than English observers were, even though their language does not have any corresponding color terms. Another New Guinea language, Berinmo, deviates from the universal pattern: Berinmo has a "nol"/"wor" category that goes right across the green category of English speakers. Overall, the issue of the universality of color names and categories is still controversial.

Psychophysical Experiments

Color naming used as a method in psychophysical experiments gives a direct report of the color sensation evoked by the stimulus. Color naming seems to be an inherently coarse method because there are only a few color names but millions of distinguishable colors. One way to overcome this limitation is to use a technique called *hue scaling,* where observers rate the amount of red, green, blue, and yellow in the stimulus. The shapes of the hue scaling curves have been found to be highly similar across observers, and only the amplitude differed. Further, observers almost never rated a color as being both red and green, or both yellow and blue, in agreement with the notion that red-green and blue-yellow are opponent colors. Another way to overcome the limitations of color naming is to let observers name a large number of color samples and to infer the partitioning of color space based on the naming results of all color samples arranged on the color plane according to the chromaticities of the color samples. This method has been used to investigate color constancy, showing that observers can achieve almost perfect color constancy (the ability to see objects in the same color, independent of the illumination).

The Stroop Effect

The naming of a color interferes with the reading of a word (the so-called Stroop effect): For example, people take longer to name the blue ink color of the printed word *RED* than if the blue ink is used to print the word *BLUE.* In general, the naming of the ink color of a printed word is harder if the word is a color name that is different from the ink color. The Stroop effect occurs even though the observers were instructed to ignore the letters and to pay attention only to the ink. The Stroop effect shows that color naming is tightly coupled to reading, another learned linguistic skill. The Stroop effect occurs also when observers have to name the color of objects with a characteristic object color shown in a "wrong" color. In the reverse Stroop task, observers are instructed to ignore the ink color in which a color word is printed and to respond to the meaning of the color word. Again, reaction times are generally faster with congruent combinations than with incongruent combinations.

Neural Correlates

The neural correlates of the color categories have not yet been found and are a topic of intense research. The present results support the view that in early visual areas V1 to V4 basic color categories do not have a special status. A potential candidate area for the representation of color categories is an area in the inferior temporal (IT) cortex.

COLOR PERCEPTION

Color vision is defined as the ability to discriminate differences in the wavelengths of light. Yet, like all vision, the *perception* of color is ultimately not about seeing wavelength or light but about seeing the objects that light illuminates. Color provides powerful cues to object recognition. For example, it can help reveal what sort of surface we are viewing (e.g., leaf or bark) and the particular state that the material is in (e.g., dry or lush foliage, ripe or unripe fruit, or a pallid or glowing complexion). To make these judgments, the color percept must be tied to properties of the object (how it reflects light) rather than simply to the light reaching the eye (which can change as the illumination changes). The strategies and extent to which the visual system achieves this perceptual goal is the subject of color constancy.

Color can tell us what we are looking at and where it is by helping to segment different parts of the scene based on their colors (see color insert, Figure 18). Black and white photography shows that color is not necessary for seeing the layout of a scene, and many studies have found that color cues on their own do not support the perception of fine spatial details nor as strong a sense of motion as luminance cues. Indeed, the chromatic equivalent of a black and white image—where only differences in color but not in luminance are shown—is often unrecognizable. Yet color is nevertheless one of the most salient cues for segregating objects. A ripe fruit pops out from green leaves, and the leaves in turn appear grouped together to form trees, because differences in color set objects apart whereas similarities in color bind them. Thus, color vision plays an important role in spatial vision. Chromatic cues may be especially important for seeing shapes in the presence of shadows. Cast shadows produce much larger changes in brightness than in color, and thus the ability to link together parts of the scene that have a common color allows the underlying objects to be delineated more clearly. Individuals with color deficiencies often find spatial tasks, where items must be located or grouped by their color, most difficult. This entry discusses color appearance and contextual influences on color appearance

Color Appearance

The seemingly limitless variety of colors we can experience (estimates suggest that humans can discriminate among millions of different shades) rests on detecting the responses from only three types of cone photoreceptors with different sensitivities to wavelength. This trichromatic representation fundamentally determines what information the brain can extract about a light's spectrum, and it is probably not coincidental that the perceptual representation of color is itself three-dimensional. The principal psychological attributes of a color are its hue (e.g., whether it is red or blue), saturation (the degree to which it appears mixed with white, as in pink versus red), and brightness (the perceived intensity). Perceptual color spaces attempt to capture the relationships between different colors—typically in terms of these attributes—and these arrangements are thought to reveal how color percepts are built by the visual system.

In modern color spaces, hues are arranged around a circle with white at the center, an idea that may have first appeared in 1704 with the publication of Sir Isaac Newton's *Opticks*. In this color circle, different hues thus correspond to different directions from white, while saturation is captured as the distance from the achromatic center (see color insert, Figure 19). If these circular planes are stacked according to their brightness from dark to light, then the space becomes a three-dimensional color solid such as a cone or sphere. The actual structure of the solid can be complicated because of limits imposed by the realizable gamut of colors and because the perceptual distances between colors can vary in complex ways. A further complication is that the different attributes of color do not vary independently. For example, the hue of many wavelengths changes when they are desaturated by adding white light (a phenomenon known as the Abney effect), or when their intensity is varied (the Bezold-Brucke effect). Specifically, the hues of wavelengths tend to become more blue or yellow as intensity increases.

Among all the hues around the circle, some appear special or more fundamental. Experiments with color appearance suggest that red, green, blue, and yellow seem psychologically pure, in that they cannot be reduced to more basic sensations. In contrast, all other hues appear to be mixtures of two of these primaries. For example, orange appears to contain both red and yellow, and purple is a mixture of red and blue. A striking feature of color experience is that some mixtures are never perceived together. We cannot (under simple viewing conditions) perceive a color that is both red and green, or both blue and yellow, in the same way that we cannot see a light that is both bright and dark. Such observations led the 19th-century physiologist Ewald Hering to propose the opponent process theory of color vision. This held that color is represented by three mechanisms that signal red versus green, blue versus yellow, or bright versus dark. Because red and green are represented by the same mechanism responding in opposite ways (e.g., exciting to red and inhibiting to green), the red and green primaries are mutually exclusive sensations, but can co-occur with the sensations carried by the mechanism opposing blue and yellow.

By this model, the sensation of a pure red (one not tinged by blue or yellow) occurs at the unique point where the blue-yellow response is zero. In turn, a pure gray is perceived when both the red-green and blue-yellow responses are zero. The stimuli corresponding to the unique hues of red, green, blue, and yellow have been studied extensively because they help define the responses of the opponent processes to different wavelengths (their spectral sensitivities). Three of the unique hues can be seen at wavelengths within the rainbow spectrum of visible light. Unique blue is roughly at 470 nanometers (nm), green at 510 nm, and yellow at 580. (However, as noted later, the actual locations vary widely among individuals.) Unique red is instead known as an extraspectral light. The longest wavelengths we can see appear too orange (red tinged with yellow), and thus, a pure red requires mixing these wavelengths with a bluish, short wavelength to cancel out the yellowness. More generally, the yellowness at any wavelength can be cancelled by adding blue light, whereas redness can be cancelled by adding green light. This hue cancellation technique was used by the psychologists Leo Hurvich and Dorothea Jameson beginning in the 1950s to map out the sensitivities of the red-green and blue-yellow responses to different wavelengths, work that prompted a modern revival of Hering's opponent process theory.

A different approach to studying how the spectrum of hues is parsed was developed by the anthropologists Brent Berlin and Paul Kay in the 1960s. They asked observers to label the colors falling on the surface of a perceptual color space (the Munsell color solid) and to pick out the chip that provided the best example of a color label. Berlin and Kay's work was designed to ask how color naming varies across speakers of different languages. This method defines a set of primaries corresponding to basic color terms—terms that are used reliably by most speakers of a language and that refer to colors independent of objects (e.g., unlike salmon or lilac). The English language has 11 basic terms, including the Hering landmarks (red, green, blue, yellow, black, white, and gray) and additionally brown, orange, purple, and pink. This suggests a more complex representation of color than would be conveyed by independent responses along the three opponent dimensions. For example, pink and red may represent separate focal points in color appearance even though they are both shades of red. Moreover, the color categories of yellow and brown occur only for light or dark colors respectively, and thus require an interaction between the Hering's red-green, blue-yellow, and light-dark dimensions.

In the late 1950s, researchers including Russell De Valois and his colleagues began recording the color responses of single cells in the visual pathway of primates. Many cells in the eye's retina and in the lateral geniculate nucleus to which retinal cells project gave responses of opposite polarity to different parts of the spectrum—exciting to some wavelengths while inhibiting to others. This provided a physiological basis for color opponency. These post-receptoral cells could build opponency simply by receiving inputs of opposite sign from the different classes of cones, similar to the way that spatial opponency was known to be built by receiving signals of opposite sign from the center and surround of the cell's receptive field. This helped reinforce opponent color theory, which remains a cornerstone of modern color science.

The actual links between color appearance and color coding have remained elusive. Specifically, it remains unclear how color sensations are represented by the responses of visual neurons. Among the two principal types of cells responding to color in the geniculate, one responds best to color changes that vary between red and blue-green, and the second signals color changes that perceptually vary from purple to yellow-green. Thus, the perceptually pure axes of red-green and blue-yellow cannot be tied to a single cell type at this level of the visual system. Moreover, the basis for unique hues becomes even less clear when signals from the geniculate are passed on to the visual cortex, where cells are found tuned to many different color directions. Whether there is a subset of cells or a transformation at further stages in the visual pathway that culminate in neurons with the responses predicted by perceptual opponency remains an area of active interest and debate.

Because of such discrepancies, many color scientists have also begun to look for the unique hues in another place—outside the observer. Some colors may look more special because they correspond to special properties of the environment rather than to special states in the neural response. For example, the phases of natural daylight vary along a blue-yellow axis, and thus unique blue and yellow could reflect learning about a prominent physical characteristic of the world. Similarly, red (and pink) might be special because they are the ecologically important colors of blood and skin tones and are colors that signal ripening fruit among the foliage. The idea that color appearance is determined by the color environment has been bolstered by the findings that the wavelengths corresponding to the unique hues cannot be predicted from the visual sensitivity of observers. For example, humans vary dramatically in the relative number of different cone types, yet this variation is not correlated with observers' choices for unique hues. Large individual differences in sensitivity also occur because of differences in the amount of inert pigments in the eye screening the receptors. The lens contains a yellow pigment that steadily increases with age, blocking progressively more of the short wavelength light reaching the retina. Yet, the unique hues and the white point remain stable across age, suggesting that color appearance is continuously recalibrated to compensate for sensitivity changes in the observer.

Finally, all accounts of color appearance—physiological, environmental, and cultural—are plagued by the problem that individual differences in the unique hues and in color naming are enormous, even among individuals living in a common environment and speaking a common language. This raises the possibility that the perceptual representation of color is not strongly determined by any factor. Why people describe colors the way that they do thus remains an enigma.

Contextual Influences on Color Appearance

The dimensions of hue, saturation, and brightness are adequate to describe color appearance under simple conditions, when observers view a single uniform spot in an otherwise dark room. Percepts in this viewing mode are known as unrelated colors and appear to describe attributes of light. Yet, when stimuli are instead judged in the presence of other colors and in spatially varying contexts—as is typically the case in natural viewing—then the experience of color becomes much richer and more complex. These related colors more closely reflect how we see colors in the real world and point to the importance of perceiving color as a property of objects and surfaces.

A clear example of the perceptual changes that can emerge from this change in viewing context is the distinction between brightness and lightness. As noted, brightness refers to the perceived intensity of light coming from a spot, whereas lightness corresponds to the perceived reflectance of the spot—what percentage of the incident illumination is returned from the spot. The paper on this page has a high reflectance and appears white, whereas the print absorbs most of the light and appears black. Note these are perceptions of the surfaces themselves and not simply of the amount of light at a point on the page. Whether the page is viewed in a dim room or bright sunlight—an intensity change that can be many orders of magnitude—the print and paper still appear black and white, and the reason the print looks dark is that it reflects less of the incident light than the paper does. If a spot from the print could be viewed through a tiny aperture that left the rest of the scene in darkness, then the spot would suddenly appear bright, a phenomenon known as the Gelb effect. The change occurs because the print is now the only point with light. Any light on a completely dark background is an increment and will be perceived as light. Dark colors can only be perceived when there are decrements (i.e., when the background is brighter). As a result, the color brown can never be seen as an unrelated color, and only arises when there are other elements in the scene that are brighter.

How do surrounding colors affect color appearance? One process is simultaneous contrast or induction. When a spot is placed on a uniform surround, the perceived lightness depends roughly on the ratio of the center and surround intensities rather than the absolute intensities (see color insert, Figure 20a). Thus, the same gray appears darker on a bright surround but brighter on a dark surround. Perceived hue is similarly biased, so that a gray becomes greenish or reddish when placed on a red or green background. Context can also bias color appearance in the opposite way, by reducing the perceived color differences between surfaces in the scene. These effects are known as assimilation, and typically occur in finely varying patterns where the colors begin to blend. Finally, color appearance can be affected by the average color in the background and by its variance. For example, a color will appear less saturated when the gamut of surrounding colors varies widely, even though the average color in the surround remains neutral.

For simple patterns, these contrast effects depend largely on the local differences between the center and surround, and are an example of a general principle that the visual system tends to emphasize relative differences in stimuli. However, the contextual effects may also reflect much more sophisticated inferences about the stimuli. A number of recent (as well as some classic) illusions have shown that subtle changes in the spatial arrangement of patterns can lead to dramatic changes in the perceived lightness and color of the elements. These changes tend to be those that alter the perception of transparency or shading, suggesting that the perception of lightness and hue includes computations that factor in the three-dimensional structure and illumination in the scene. One striking illustration of these effects is neon color spreading, where the perceived color of line elements tends to diffuse into the surround areas to give the impression that the lines are being seen through a colored filter.

Context can also affect color over time rather than over space. Like all sensory systems, the visual system is highly adaptable and adjusts its responses whenever the stimulus changes. These adaptation effects are well known in color vision. To a person who has just viewed a red square, a gray square appears greenish. This occurs because the visual system becomes less sensitive to the adapting color, thus biasing the response to other stimuli away from red and toward its opposite, green. A second effect is that the red itself becomes less saturated and thus more neutral. With careful fixation, a blurry blob of color will completely fade to gray (see color insert, Figure 20b). This adaptation re-centers color space so that the white point corresponds to the average color we are exposed to, discounting the changes in color appearance that would otherwise result from a change in the average color of the lighting. Many of the contextual influences in color appearance can be seen as processes that are designed to compensate for variations in the environment or in the observer so that the perceptions of color remain faithful to the properties of surfaces.

As these examples illustrate, in natural viewing situations, the perceived color of a patch cannot easily be predicted simply from the light spectrum because it also depends on the surrounding colors and context. Yet even these contextual influences fail to capture the full richness of color perception. Real surfaces have many perceptual qualities and can, for example, appear rough or smooth, or lustrous or dull. These attributes cannot be reproduced by uniform spots in surrounds because they depend on the spatial and spectral variations within rather than between surfaces. The surface statistics that the visual system uses to judge the actual material properties of surfaces is currently an active area of research.

COLOR PERCEPTION: PHYSIOLOGICAL

When we view the world around us, we attribute color to the individual objects we look at. But, as was discovered by Sir Isaac Newton, the light rays being reflected from these objects into our eyes are not colored. How we see color depends on the visual processing going on in the eyes and the cortex. Color vision starts with the absorption of light in three different types of light sensitive receptors in the eye, which convert electromagnetic energy into electrical signals, which in turn are transformed into action potentials by a complicated network of cells in the retina. The information is sent to the visual cortex via three independent channels with different chromatic preferences. In the cortex, information from these channels is mixed to enable perception of a large variety of different hues. Furthermore, recent evidence suggests that color analysis and coding cannot be separated from the analysis and coding of other visual attributes such as form and motion. Although some brain areas are more sensitive to color than others are, color vision emerges through the combined activity of neurons in many different areas. This entry describes the physiological mechanisms of color perception.

Cone Receptors

Human color vision is characterized by three different classes of cone photoreceptors, denoted long- (L), middle- (M), and short-wavelength-sensitive- (S) cones. Light is absorbed in the cones and converted by a complex photochemical reaction into an electrical signal, whose magnitude is determined by the number of photons absorbed by each cone. Figure 1 shows the most recent and precise estimates of the cone absorption spectra. Thus, although the light stimulus is determined by its intensity at an infinite number of wavelengths between approximately 400 and 700 nm, the output of the cones can be characterized by only three numbers—the absorption for each cone class. This is the principle of *trichromacy*. The three classes of cone therefore drastically reduce the dimensionality of color vision. Several characteristics about the human cone absorption spectra are worth noting. Figure 1 shows that all types of cone are sensitive to a wide range of wavelengths. L- and M-cones are sensitive nearly over the whole visible spectrum. The L-cones have their peak sensitivity at a wavelength that would appear yellowish and the S cones have their peak sensitivity at a wavelength that would appear violet under neutral viewing conditions. Therefore, the common labeling of the cones as red, green, and blue is misleading because these labels do not correspond to the wavelength to which the cones are maximally responsive. Thus, there is no simple relationship between the excitation of a single class of photoreceptors and the color we perceive.

Instead, photons of different wavelengths have different likelihoods of being absorbed by the three cone classes. Once absorbed, the only remaining information is the photon count in each cone, not the wavelength of the absorbed photons, a principle termed *univariance*. An increase in the photon count of a photoreceptor can thus result from an increase in light intensity, a change to a more favorable wavelength for that cone class, or both. Therefore, to compute the color of an object unambiguously, the magnitudes of the output signals of the three cone classes have to be compared. This starts at the

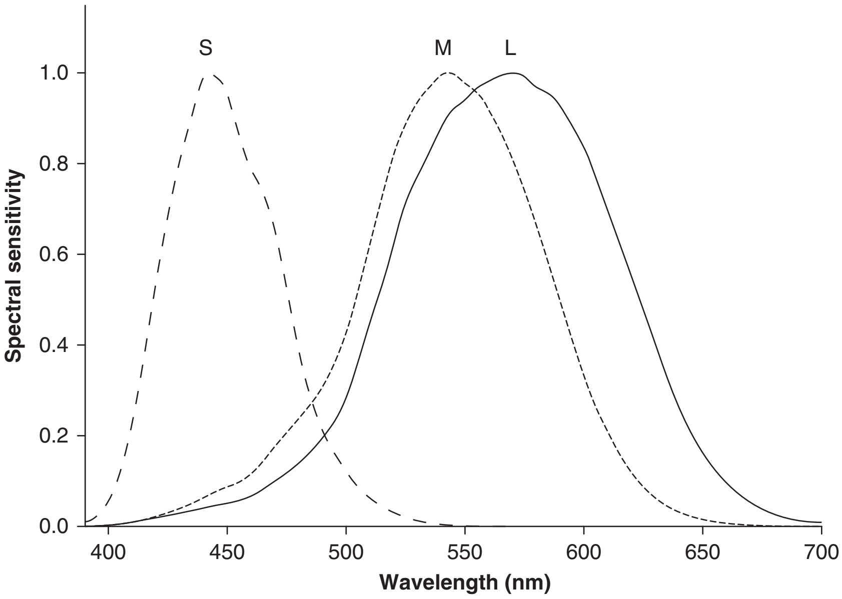

Figure 1 Cone Absorption Spectra

next stage of processing, which is performed by bipolar cells and ganglion cells in the retina.

Retinal Ganglion Cells and Lateral Geniculate Nucleus

Three channels of information from the retina to cortex are distinct from each other in their chromatic properties, as well as in their anatomical substrate. These three channels do not simply correspond to the signals conveyed by the three different classes of photoreceptors. Instead, the signals from the cones are repackaged into three new types of signals. It is assumed that the major reason for this transformation is the high degree of correlation in the signals from the L- and the M-cones, which results from the high degree of overlap in their spectral absorption functions.

One of these channels is called the luminance channel because it simply computes the intensity of stimulation by taking a weighted sum of the outputs of the three different cone types. This channel does not convey information about the color of things. The other two channels are called cone-opponent because they take differences of the output signals of the three different cone types. Ganglion cells in all three channels have circularly symmetric receptive fields with excitatory and inhibitory subregions.

There is one type of ganglion cells in the retina, called M-cells as in magnocellular, with relatively large dendrites. The M-cells do respond to luminance only, similar to the way a black-and-white printer would represent an image by taking a weighted mixture of signals from L- and M-cones. Interestingly, the weights that have been found physiologically by recording from individual M-cells are identical to the weights determined for photometric luminance in flicker-photometric experiments on human observers. About half of M-cells have a region at the center of their receptive field where they receive excitatory input from a group of L- and M-cones, whereas the surrounding parts of the receptive field receives inhibitory inputs. These are called ON-center cells. The other half has the opposite receptive field arrangement and therefore responds best to dark spots on a white background. These cells are called OFF-center cells.

More interesting from the viewpoint of color vision are the other two types of cells. Ganglion cells that contribute to the P-channel are called parvocellular and have smaller dendritic fields. In and near the fovea, the centers of their receptive fields are formed by single L- or M-cones, making these ganglion cells suitable for high acuity vision. The receptive field surround is formed mostly by the other cone class, that is, if there is an L-cone in the center, the surround would be dominated by M-cones. As with the M-cells, center and surround have opposing signs. For the P-cells, this has two consequences. First, if the stimulus is a white spot on a dark background, ON-center P-cells would respond quite well to it. Second, if the input is a large long-wavelength uniform field of light, an excitatory center with an L-cone would be maximally stimulated, and the inhibitory surround with M-cones would be maximally suppressed, leading to a maximal activation of the cell. Therefore, P-cells respond best to structured luminance stimuli and to uniform colored stimuli. They are said to fulfill a "double-duty" because they potentially underlie both color vision and high acuity luminance vision. Note, however, that P-cells do not respond to structured color stimuli, such as a small spot of red surrounded by a green of the same luminance. Actually, P-cells will not respond at all to such a stimulus because the excitation at the center is matched in that case by the inhibition in the surround.

Finally, it was recently discovered that there is another color opponent channel to the cortex, the so-called koniocellular (K) pathway that carries signals from S-cones to a large degree. These ganglion cells take the difference of the signals from S-cones and a summed signal of the L- and M-cones, and these cells are usually not spatially opponent. Therefore, these cells respond to large blueish or yellowish fields of light, but not to luminance patterns.

Thus, three channels of information from the retina to cortex are distinct from each other both in their chromatic properties and in their anatomical substrates. The differences in the chromatic properties of P- and K-cells is shown in Figure 2(a), which shows a distinct clustering of the chromatic preferences of lateral geniculate nucleus (LGN) cells along the L–M, and the S–(L+M) axes of color space. When these cone-opponent mechanisms were first discovered in the monkey retina, it was assumed that these would be the neural substrate of

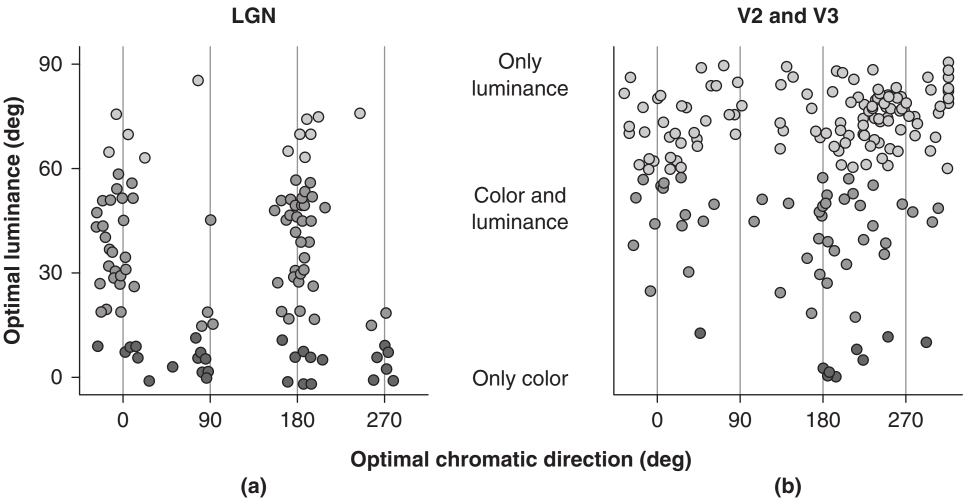

Figure 2 Color and Luminance Preferences of Neurons in the LGN and in the Cortex (V2 and V3)

Notes: The *x*-axis denotes the optimal chromatic direction; the *y*-axis denotes the preferred luminance as elevation above the isoluminant plane. Neurons in the LGN cluster around the cardinal directions, neurons in the cortex do not. Most neurons in the LGN and the cortex respond to both luminance and color.

the color-opponent mechanisms that Ewald Hering had proposed at the beginning of the 20th century. Hering had defined his "unique hues" purely phenomenally by observing that a color perceived as red never contained green as well, even though it could be a blueish red (purple) or a yellowish red (orange), and vice versa. Analogously, blue would never appear yellow. These opponent colors strongly suggested a link with the cone-opponent retinal mechanisms. However, many years of research showed that these two concepts are clearly distinct. For example, the S–(L+M) retinal cone-opponent mechanisms respond best to colors that appear purple and greenish-yellow, but not so much to colors that we would typically call good examples of blue and yellow, such as in the Swedish flag.

Hering's unique hues are formed at the level of cortical color processing, presumably at the stage where we group different colors into categories. For example, when we view a rainbow, we do not perceive a gradual transition from one wavelength to the next, but we see a typical stripe pattern. The physiological basis for this categorization process is still unclear. Several high-level visual cortical areas of the monkey brain have been suggested as the neural basis, but at this time, it is not even clear that monkeys have the same color categories and unique hues as humans.

Processing of Color in the Early Visual Cortex

Initial studies of the functional architecture of the primate visual cortex found only a small percentage of about 10% of all neurons devoted to the analysis of color signals. In these studies, the quest was for neurons that would only respond to stimuli defined by color, and give no response to luminance. According to a view promoting a functional segregation, it was thought that these neurons would analyze the color of objects, and other specialized neurons would deal with form, motion, and depth. In contrast to these results, later neuroimaging studies observed a strong and vigorous response to color that exceeded the response to luminance stimuli. The solution to this seeming contradiction was found when the color properties of single neurons in the primary visual cortex were investigated in more detail. A large proportion of neurons responds well both to color and to luminance. This is in line with anatomical findings that the three streams that arrive in the visual cortex from the retina do not remain segregated but become mixed to a large degree. Along these lines, many recent studies failed to find a strong segregation of functional properties in the primary and secondary visual cortex. Rather, it seems that the tuning of each cell for different visual stimulus attributes is more or less statistically independent. For example, knowing that a cell is selective for color does not allow a prediction about the orientation selectivity of that cell.

Although it was initially thought that the chromatic properties of V1 cortical cells are quite similar to those of the retinal cells, more details have been discovered in recent years. In the retina, responses of a neuron to all colors can be predicted just by the knowledge of the cells' preferred color because these neurons sum their cone inputs in a linear manner, and the preferred colors fall into two clusters of L–M and S–(L+M). Although most cells in V1 still follow the linear model, the color preferences are more widely distributed, as shown in Figure 2(b). These cells still show quite a broad tuning to color, responding to many different hues. In V2, a subpopulation of neurons was found that has more restrictive responses limited to a rather narrow range of hues, mimicking the behavior of higher order color mechanisms observed psychophysically. Similar effects have been reported in V4, and there seems to be a progression from V1 via V2 to V4 and the inferotemporal (IT) cortex in the specificity of the chromatic response.

Another important characteristic of color cells that emerges in V1 is double opponency. As mentioned earlier, the single opponent cells in the retina and LGN cannot signal spatial and chromatic properties at the same time. They respond to color without considering the spatial context. Double opponent cells are both spatially and chromatically opponent, and are therefore able to signal chromatic boundaries—for example, a red fruit next to a green leaf. These cells effectively compute color contrast—the difference between two colors, so their response would be independent of the average color in the scene, which is mostly determined by the illumination color. Therefore, this would be an ideal mechanism to achieve color constancy, which is the ability of the primate visual system to assign a stable color to an object, independently of how it is illuminated. Only recently have these double-opponent cells been found in the primate's visual cortex. They are members of the class of cells that respond equally well to luminance and color.

Evidence for Specialized Cortical Regions

Early evidence for the existence of a unique color center in the visual cortex came from single-unit recordings of macaque monkey area V4. It was argued that area V4 is uniquely specialized for color because it contains an unusually large proportion of color selective cells, some of which exhibit the property of color constancy. Initial estimates of the proportion of color selective cells in V4 were as high as 100%. Subsequent studies found significantly lower estimates, some as low as 20%. Although a consensual estimate is still lacking, it is likely that V4 contains approximately the same proportion of color selective cells as do V1, V2, or V3. Moreover, the color selectivity of V4 cells appears to be similar to that of neurons in earlier areas. Most V4 neurons are not more narrowly tuned in their wavelength selectivity than retinal ganglion or LGN cells. However, a subpopulation of V4 neurons exists that is more narrowly tuned. In that respect, V4 is not different from V1 or V2.

The major argument against V4 as the color center of the monkey brain comes from lesion studies. Lesions of extrastriate area V4 do lead to mild deficits in color vision and to a variety of other visual deficits. Monkeys with V4 lesions are severely impaired in shape discrimination, object recognition, texture discrimination, and in their ability to focus attention. Lesions to the next processing stage, the inferotemporal cortex, seem to mimic the human condition of cerebral achromatopsia, that is, a specific loss of color perception. However, the color deficit depends on the removal of the entire IT cortex, which has a variety of other dramatic effects on higher-level vision. In the IT cortex, the proportion of color selective cells is believed to be high as well—somewhere between 50% and 70%. The distribution of preferred colors in the IT cortex was reported to be rather uniform, with a subpopulation of cells being selective to a narrow range of colors. These results suggest that the IT cortex could be involved in the elaboration of perceptual color categories.

In humans, it has long been reported that bilateral cortical damage to the lingual and fusiform gyri on the ventromedial side of the occipitotemporal lobe could lead to severe color vision deficiencies. In analogy to earlier single-unit studies in monkey V4, this area has been called human V4 (hV4). Brain imaging studies show this part of the visual cortex to contain a representation of the contralateral hemifield and to be highly active during a variety of color vision tasks.

Although all these results imply that some region of the visual cortex, whether it is V4 or IT, has a high sensitivity to color relative to luminance, no single experiment has shown evidence for a region that does respond to color *only*. Similarly, the visual world of patients with cerebral achromatopsia is not the world of black-and-white movies. The patients typically show a variety of severe object- and pattern-recognition disorders. Some researchers think it more likely that color perception is the result of the simultaneous activity of neurons belonging to several cortical areas. That different aspects of color perception can be differentially affected by cortical lesions supports this view. Indeed, several patients have been reported with lesions outside the primary visual cortex; they had impaired color constancy but no deficits in color discrimination. Similar results had been reported for monkeys with V4 lesions. In addition, color-memory and color-constancy can be differentially affected in humans suffering from cortical lesions. Thus, as is the case for most other visual attributes, our experience of color probably depends on the activity of neurons belonging to a number of different cortical areas. This notion is further supported by the observation that most visual cortical areas are activated by exposure to chromatic stimuli, and in area hV4, the relative response to color might just be slightly higher than in other areas of the brain.

COMMON CHEMICAL SENSE (CHEMESTHESIS)

In 1912, G. H. Parker described the sensory system responsible for detecting chemical irritants as "the common chemical sense." Although Parker noted that the common chemical sense was mediated by irritant-detecting free nerve endings resembling pain receptors, he concluded that it was a separate sense with its own set of receptors that produced distinct sensation qualities different from taste and smell. Free nerve endings are axons that do not terminate in specialized structures and are devoid of myelin (fatty insulation around axons). Today, we know that the nerves that respond to chemical irritants do not constitute a separate, independent sense, as Parker hypothesized. Rather, they are part of the general somatic sensory system: a subset of pain and temperature sensitive fibers that can be found throughout the skin and mucosal membranes of the nose, mouth, respiratory tract, eye, and anal and genital orifices. Recently, the term *chemesthesis* has been used to describe the sensations elicited by the chemical stimulation of free nerve endings. Chemesthesis is thus analogous to somesthesis, which describes sensations produced by mechanical stimulation of the general somatic sensory system. We stimulate our chemesthetic sense every time we eat chili peppers, sniff ammonia, or cut onions. These same nerve endings respond to other environmental irritants that may affect our health and determine the food we eat and the personal products we buy. This entry describes trigeminal chemoreception, stimulation of nerve endings, solitary chemoreceptor cells, and reversal of aversion.

Trigeminal Chemoreception

In humans, chemesthesis is best represented by free nerve endings in the trigeminal (Vth cranial) nerve innervating the mouth, nose, and eyes. However, free nerve endings originating from other cranial nerves, such as the glossopharyngeal (IX) and vagus (X) in the oral cavity and throat, as well as spinal nerves innervating the skin, also respond to chemical stimuli. A great deal of the information on chemical irritation has been obtained from cells in the dorsal root ganglia of the spinal cord that give rise to the spinal nerves. Nevertheless, much of the research on chemesthesis as it relates to environmental irritants and especially taste and smell involves trigeminal chemoreception. One main reason is that trigeminal free nerve endings are accessible to chemicals, lying in areas that are directly exposed to the environment.

The trigeminal nerve is a mixed sensory nerve containing axons of different sizes. The cell bodies of these axons are found in the trigeminal ganglia situated near the base of the brainstem. Trigeminal nerve fibers have the ability to respond to touch, cold, heat, and painful stimuli. The fibers are of different diameters and conduct action potentials at different speeds. The largest fibers respond to touch and conduct action potentials rapidly. The smallest fibers (unmyelinated and small myelinated) respond to painful stimuli and conduct action potentials slowly. Fibers that respond to chemical irritants are polymodal—they respond to a variety of noxious, irritating stimuli (mechanical, thermal, and chemical)—and are especially sensitive to capsaicin, the active, "hot" ingredient in chili peppers.

Stimulation of Nerve Endings

A variety of sensations are elicited by stimulation of trigeminal chemesthetic nerve fibers, including those described as pungent, tingling, stinging, burning, cooling, warming, painful, and irritating. In addition to providing a sensory experience, chemical stimulation of trigeminal chemoreceptors activates protective reflexes, such as increasing secretions (e.g., saliva, tears, and nasal mucus), decreasing breathing, initiating sweating, and decreasing the size of the nasal passages. Anyone who has bitten into a chili pepper or taken a whiff of ammonia has experienced some of these reactions. These reflexes function to counteract the effect of the irritant by diluting it or preventing more of it from entering the body.

Numerous chemical irritants stimulate trigeminal free nerve endings. Some chemesthetic stimuli may affect human health and welfare by eliciting unpleasant sensations in the eyes, nose and throat and potentially harmful physiologic reactions (including respiratory and cardiovascular changes, and allergic reactions). Many indoor air contaminants fall into this category and may contribute to building-related illness or sick building syndrome. These compounds are called volatile organic compounds (VOCs). Some VOCs include nicotine and benzene (tobacco smoke), formaldehyde (pressed wood products), limonene (aroma and cleaning products), and toluene and xylenes (craft and building supplies).

Some of the best-studied irritants that elicit responses from chemesthetic trigeminal nerves are the pungent compounds found in a wide variety of plants. Pungent vegetables and spices contain irritating compounds such as allyl isothiocyanate (horseradish and mustard), eugenol (cloves), gingerol and zingerone (ginger), piperine (black pepper), menthol (mint), cinnamaldehyde (cinnamon), propanethial-S-oxide (onions), and capsaicin (chili pepper).

How these chemicals activate trigeminal nerve endings is actively being explored in many laboratories. Although the mechanism of stimulation is known for only a few compounds, researchers believe irritants interact with receptor proteins found on the chemesthetic free nerve endings. Receptor proteins are like locks that are opened by appropriate chemical stimuli, the keys. Once the locks are opened, ions (charged atoms) move into the nerve endings and initiate signals (action potentials) that are carried to the brain to be deciphered. Some of the best studied of these receptor proteins are activated by nicotine and acidic stimuli (low pH). The carbon dioxide in carbonated beverages is irritating, in part, because it undergoes a reaction that results in a low pH.

In the mid 1990s, a new class of receptor proteins that is activated by irritants was discovered. These proteins belong to the transient receptor potential (TRP) channel family. The first of these proteins was reported by David Julius and his colleagues at the University of California, San Francisco. This polymodal receptor protein, now called TRPV1, is activated by stimuli such as heat, low pH, piperine, eugenol, and capsaicin. Other TRP channels have now been discovered that are triggered by compounds such as allyl isothionate, cinnamaldehyde (TRPA1), and menthol (TRPM8).

Many chemesthetic stimuli activate olfactory and taste receptor cells at low concentrations and are non-irritating. At higher concentrations, they elicit responses from chemesthetic trigeminal nerve fibers in the mouth, nose, and eyes and are described as irritating. For example, although benzaldehyde (which smells like almonds) and NaCl (table salt) are pleasant at low concentrations, both can become irritating at high concentrations. Researchers can determine at what concentration odorous compounds stimulate nasal trigeminal nerves by measuring the lateralization threshold—the concentration of the compound that can be detected in one side of the nose. For example, if a low concentration of an odorant such as benzaldehyde is delivered to one nostril and clean air to the other nostril, the nostril that received the odorant cannot be determined. However, once the concentration of the odorant becomes high enough to stimulate trigeminal receptors, the correct nostril can be resolved. That is, any concentration of the irritant that can be localized to one of the nostrils must be stimulating trigeminal nerves. Knowing the lateralization threshold has allowed researchers to make psychophysical measurements of chemesthesis.

Stimulation of nasal and oral trigeminal chemoreceptors may affect the perception of odorants and tastants. For example, chemical trigeminal stimulation could limit the access of odorant molecules to the olfactory organ reflexively by modifying breathing, nasal secretions, or the size of the nasal passages. Activation of nasal trigeminal nerve fibers by irritants may also directly inhibit olfactory receptor neurons by axon reflex. Cell bodies in the trigeminal ganglia send their axons to the nasal cavity where they may make several branches. One branch may go to the respiratory epithelium, but another may go to the olfactory epithelium housing the olfactory receptor neurons. Once an action potential is produced in the respiratory epithelium branch of the nerve, it travels to the brain and to the olfactory epithelium branch. Here, substances may be released that decrease the activity of olfactory receptor neurons. Similarly, evidence indicates that stimulation of oral trigeminal nerves may indirectly or directly decrease responses to taste stimuli. The purpose of this arrangement may be to keep high concentrations of chemical irritants from overwhelming the more sensitive olfactory and gustatory systems.

Solitary Chemoreceptor Cells

As described earlier, chemesthesis traditionally has been thought to involve only trigeminal free nerve endings in the nasal and oral cavities and the eyes. Recently, however, cells have been discovered that may change that idea. These cells, called solitary chemoreceptor cells (SCCs) are found scattered throughout the nasal cavity and the respiratory and digestive tracts. Many of these cells have the characteristics of individual taste cells that detect bitter compounds. The SCCs in the nasal cavity are contacted by trigeminal nerve fibers. Bitter substances activate nasal trigeminal nerve fibers, presumably through the SCCs. Other compounds may also stimulate trigeminal nerve fibers through the SCCs.

Reversal of Aversion

An interesting aspect of chemesthesis is that many substances that are initially (and probably innately) aversive eventually become preferred. Examples include the consumption of such substances as tobacco, chili pepper, mustard, curry, horseradish, ginger, and vinegar. Infants, children, and naive adults typically reject these stimuli on first exposure. However, most adults reverse their natural rejections and acquire strong positive preferences for at least one innately unpalatable substance. Indeed, whole cuisines, such as Mexican and Korean, are based on some of these chemesthetic stimuli. Why the reversal of the initial aversion occurs is not well understood.

COMPUTATIONAL APPROACHES

Perception is the analysis of sensory input in the context of our prior perceptual experience of the world. The goal of such analysis in visual perception is to infer the identities, forms, and spatial arrangement of objects in the three-dimensional (3-D) scene based on our two-dimensional (2-D) retinal images. *Computational approaches* to perception seek to elucidate the theoretical principles and to model the mechanisms underlying these analyses and inferential processes.

The theoretician David Marr suggested that computational accounts of perception should provide explanations at three different levels: (1) computational theory, (2) representation and algorithms, and (3) implementation. Accounts at the computational theory level clarify the purposes or goals of the computations underlying a perceptual phenomenon and explain the logic of the proposed strategies for achieving those goals. Next, representation and algorithm level accounts describe how information is represented and how it is transformed into the desired output given the input. The implementation level details the physical implementation of the transformation in neural circuits or in computers: notably, each implementation medium is associated with a set of unique constraints—for example, computers can manipulate numbers with high precision but in a step-by-step serial fashion, whereas neurons individually represent information in low resolution and slowly but process information in a massive parallel fashion. These three levels of computational account are coupled only loosely. There is wide choice available at each level, and the explication of each level involves issues that are rather independent of the other two. This entry describes stages and modules of perceptual computation, varieties of computational approaches, and contributions of computational approaches.

Stages and Modules of Perceptual Computation

Perceptual computation in our visual system can be roughly divided into three stages: early vision, mid-level vision, and high-level vision. Early vision involves the extraction of elementary visual features such as edges, color, and optical flow, among others, as well as the grouping of these features into useful aggregates. Mid-level vision deals with the inference of visible surfaces or Marr's so-called 2.5-D sketch. The objective here is to infer the geometrical shapes of the visible surfaces and the occlusion relationships between them in a visual scene. High-level vision concerns reasoning about objects, their identities, structures, and locations. It also concerns global scene information such as 3-D spatial layout and illumination direction. Although the three-stage division is motivated mainly by functional considerations, these computational stages correspond roughly to the different visual areas along the ventral visual pathway in the hierarchical visual cortex. Marr suggested that visual computation proceeds in a bottom-up, feedforward fashion, employing a series of loosely coupled, decomposable computational modules, each of which can be studied mathematically and computationally in isolation. Recent research, however, has begun to emphasize the functional roles of recurrent interaction among the different computational processes during perceptual inference.

Varieties of Computational Approaches

There are three major computational approaches in the study of perception: the *inverse optics* approach, the *dynamical system/neural network* approach, and the *statistical inference* approach. All three approaches consider perception fundamentally as a problem of *inference,* as proposed by Hermann von Helmholtz, for filling in the missing logical gap between the retinal images and the perceptual knowledge to be derived from them. Current research formulates perceptual inference in the Bayesian framework, which emphasizes the integration of prior knowledge in the inference process. To illustrate Bayesian inference, let us consider the following example. Suppose I saw a woman wandering around in my yard wearing a hat one evening when I got home. Normally, I would have concluded that it was my wife because she was the only woman in the house. On the other hand, grandma told me she would be visiting either that day or the next day. Thus, it could also be granny. In Bayesian terms, the prior probability of the woman being my wife was $p(wife) = 2/3$, and that of granny was $p(granny) = 1/3$. Now, from experience, I also knew granny loved wearing hats but my wife was not fond of it. Thus, the likelihood of observing granny in a hat was $p(hat|granny) = 0.2$, but that of observing my wife in a hat was much lower at $p(hat|wife) = 0.05$. The probability of a certain interpretation after combining the likelihood of a certain observation and the prior probability of that interpretation, called the posterior probability (i.e., $p(granny|hat)$, $p(wife|hat)$), can be obtained by the Bayes' rule,

$$\begin{aligned} p(granny|hat) &= p(hat|granny)p(granny)|p(hat) \\ &= 1/3 \times (0.2)/0.1 = 2/3 \end{aligned}$$

$$p(wife|hat) = p(hat|wife)p(wife)|p(hat) = 1/3$$

where

$$\begin{aligned} p(hat) &= p(hat|wife)p(wife)p(hat|granny)p(granny) \\ &= 2/3 \times (0.05) + 1/3 \times (0.2) = 0.1. \end{aligned}$$

The optimal Bayes' decision is one that chooses the interpretation with the maximum posterior probability, or the so-called maximum *a posteriori* estimate, which minimizes the probability of making a mistake. In this example, the optimal Bayesian estimate is "granny." Helmholtz suggested that such inferences are constantly taking place unconsciously in our brain, yielding perceptual conclusions about our environment.

The Inverse Optics Approach

The inverse optics approach starts the inquiry at the computational theory level by asking what physical processes are responsible for generating the observed images. This approach begins with a deterministic forward model of image formation that describes the behavior of light as it travels through space and interacts with surfaces, and then attempts to invert that model. This approach has been important in studies involving the computation of the 3-D surface geometry of objects such as depth from binocular stereo and shape from shading.

Figure 1(a) shows an image of a penny. We can effortlessly perceive the 3-D surface geometry of Lincoln's face based simply on the shading information. The inverse optics approach looks for a set of constraints based on our knowledge or models of image formation. One such constraint is that the relative luminance perceived at a particular location should depend on how the surface is oriented (slanted) away from the viewer, the lighting direction, and the reflecting properties of the surface. Figure 1(b) depicts the relationship between measured luminance and surface orientation, assuming light comes from the right and the reflectance property of the surface is Lambertian, which means any incident light will be reflected diffusely and equally in all directions. Each location in the so-called reflectance map in Figure 1(b) corresponds to a particular surface orientation. The drawn icons at the end of the x- and y-axes illustrate how the surfaces are oriented along those axes (p, q). The luminance at each point is the luminance seen at each corresponding surface orientation given a single specific lighting direction. A number of surface orientations can give rise to each particular luminance, so the surface orientation at each location in the image cannot be uniquely determined based on the measured luminance alone. Such ambiguity can be resolved with additional

assumptions such as that surfaces of objects tend to be smooth.

Optimization algorithms are typically used to find surface orientation, as defined by (*p, q*), at each image location that can explain the luminance measurement at that location based on information in the reflectance map, while requiring the estimate surface to be smooth. Figure 1(c) illustrates a recovered 3-D shape from the penny image, which is computed based on the maximum *a posteriori* estimate of surface orientation at each point in the image. Figure 1(d) shows a rendered image of the recovered shape, which almost completely explains the input image. Yair Weiss and colleagues also showed that with the prior assumptions that objects tend to move slowly, that each object is rigid and its different parts tend to move at the same velocity, the maximum *a posteriori* estimate of motion stimuli matches well to our percept, suggesting that our perceptual system is performing Bayesian inference with our percept being an optimal Bayesian estimate.

Studies based on this approach have yielded important insights into the physical constraints of the world that help shape our perception. A difficulty with this approach is that many physical processes responsible for generating images in natural scenes remain unknown or difficult to model mathematically. Furthermore, each observed image is generated by many processes (such as surface materials, 3-D surface geometry, lighting conditions) acting in concert and can be produced by a number of different combinations of these causes. Similar objects can give rise to many different images, whereas many different objects can give rise to similar images. Thus, the inverse optic approach tends to be highly under-constrained, and works only in restrictive and idealized situations.

The Neural Network/Dynamical System Approach

The neural network or dynamical system approaches focus on considerations at the neural implementation and mechanism level. Typically, neural circuits are constructed from simplified models of neurons with excitatory and inhibitory connections to explain perceptual or neurophysiological observations. The neural circuit developed by Stephen Grossberg and colleagues to explain the perception of neon-color spreading (color insert, Figure 31a) provides a beautiful example. In their boundary contour/feature contour model, the boundary detection system detects the abrupt black to red transitions in the lines as evidence of occlusion boundary. A boundary linking mechanism based on Gestalt laws completes the boundary, which in this case forms an invisible circular fence to constrain the diffusion of color from the red cross, producing an elusive reddish tinted surface percept. The intuition implemented here is that *a priori* our visual system assumes color to be constant over a continuous surface (color insert, Figure 31b and c).

This class of models has a strong intuitive and conceptual appeal to biologists and psychologists because of its obvious connections to perceptual observations, physiological data, and plausible neural circuits. The design of these models tends to be bottom-up, that is, wiring up the circuits by hand or by some learning rules, rather than being motivated "top-down" by computational theory and constraints. Hence, these models tend to offer explanations at the mechanistic levels, without necessarily explaining the underlying computational principles and rationales at the theoretical level. From a computational perspective, however, neural network model approaches do have an advantage:

Mechanistic learning rules implementing supervised and unsupervised learning can be applied to wire the circuits based on input data. That means that at least some inference mechanisms can be learned by implicitly extracting statistical regularities from the input data in the learning process without an explicit understanding of how images are formed in the natural environment. Kunihiko Fukushima's neocognitron model and Tomaso Poggio's HMAX model are well-known examples that combine unsupervised or supervised learning to achieve recognition of specific categories of objects in uncluttered scenes. Nevertheless, despite the success of such approaches in the detection of some specific object classes such as letters or faces, learning a general perceptual inference system that can fully interpret images from 3-D natural environments remains intractable with such approach because the parameter space for associating images with their underlying causes is extremely large.

The Statistical Learning and Inference Approach

The emphasis on understanding the causes of image formation in the inverse optics approach and the emphasis on extracting statistical patterns from natural scene data in the neural network approach have recently been united under the framework of statistical learning and inference with generative graphical models. The statistical approach seeks to model explicitly the statistical structures in the actual joint probability distributions between images and their underlying causes to incorporate our knowledge about the conditional independence between the causes. Statistical learning models the uncertainty about the image's underlying causes, which is easier than fitting precise physical models based on image formation.

An early success story of this approach is the modeling of the emergence of the primary visual cortex (V1) simple cells' receptive fields as being independent image feature factors for representing (or synthesizing) natural images efficiently. This idea of efficient coding, originally proposed by Horace Barlow, might be generalized to conceptualize perception as a process for seeking and learning the simplest and most parsimonious descriptions of the observed scenes. Decomposing image causes as independent factors allows irrelevant factors or causes to be ignored in efficient scene descriptions. The theoretician David Mumford suggested that the visual system computes and represents a hierarchy of efficient codes and that the recurrent feedback connections between the different visual areas provide a means for the higher visual areas to "hallucinate" interpretations that can help select and disambiguate representations in the lower visual areas. The generation of these hallucinations is not deterministic but probabilistic in nature. Each hallucination is effectively a sample drawn from the joint statistical distribution represented in this hierarchy. These distributions are encoded in the horizontal and feedback connections, furnishing *a statistical grammar* that allows the visual system to parse and interpret images in a way that relates how linguistic grammar is used to parse spoken or written sentences.

In this framework, visual processing involves iterative top-down and bottom-up processing. The broad interpretations of overall scenes (e.g., outdoor vs. indoor) are often much easier to compute than are early visual processes such as image segmentation, figure-ground segregation, and 3-D surface shape inference, so these interpretations could provide useful contextual information to disambiguate early visual processing. Top-down hallucinations based on these interpretations can exert two effects: enhancing relevant visual cues over irrelevant information or noise in the early representations, while explaining away or suppressing the redundant information in the low-level representation. Through this explaining away, the activation of the higher areas results in suppression of the overall activities in the early visual areas, resulting in a more efficient—in terms of overall neural activities in the brain—neural description of the environment. From this perspective, subjective perception corresponds to a synthesized mental representation that provides the most efficient scene description.

Learning such a hierarchical coding or statistical grammar structure is difficult. It has become more tractable when clever mathematical structures are introduced for the variables and their relationship and large amounts of data. Figure 2 illustrates an example of these ideas from the works of Stuart Geman, Song-Chun Zhu, and others. This example concerns how the concept of a bicycle could be represented hierarchically in terms of its parts and how statistical distributions in this structured hierarchical representation can be learned and used in the perceptual parsing of a bicycle. A typical bicycle is composed of four characteristic parts: seat, handle, wheels, and frame. The dependency relationship between the parts and the bicycle concept is specified by the so called AND edges, meaning that the concept of a bicycle requires the simultaneous observation of a seat AND a handle AND wheels AND a frame. The spatial relationships between these parts themselves are constrained by horizontal edges, each modeled by statistical distributions. For example, the distance between the center of the frame and the wheels follow a Gaussian distribution estimated from training data. Each part itself can have many possible instantiations— a wheel could be a thick wheel of a mountain bike OR a thin wheel of a racing bike. This relationship is expressed as OR edges in the graph, with each edge encoding the probability of a possible realization associated with that part. This AND/OR structure repeats itself iteratively down the hierarchy until the parts are basic image primitives such as corners, junctions, and edges represented in early visual cortex. Perceiving a bicycle in an image means linking image features to subparts, and ultimately to the concept of a bicycle, in the image processing process. The bottom row of Figure 2 shows the retinal input image and the ambiguous edge signals from bottom-up edge detection (left). The Gestalt laws embedded in the horizontal connections in the early areas suggest the presence of two circles, which lead to the proposal that a bicycle might be seen. This triggers the system to generate top-down hallucinations (sampling from the statistical distributions) consistent with the input. The seat and handlebar are hard to see in this particular input image, so the top-down hallucination can even hypothesize what the presence of those missing parts would look like. Such hallucinations or hypotheses can be realized as explicit mental images in the early visual cortex (three examples on the right of the bottom row). It

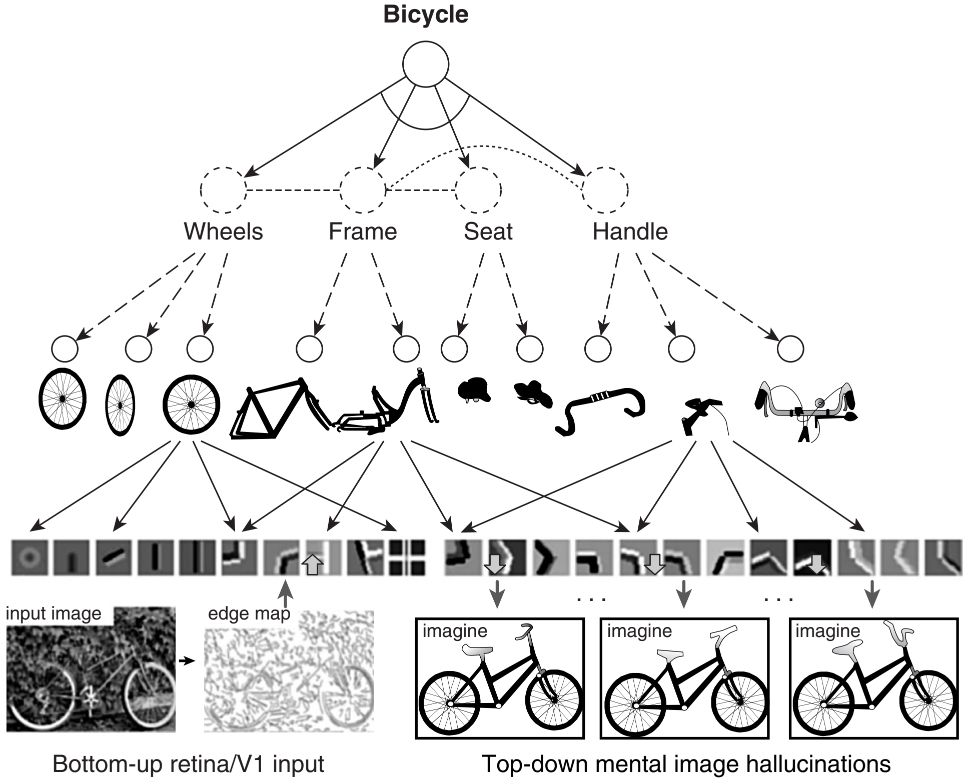

Figure 2 A Schematic of the Generative AND/OR Graph for Representing the Concept of a Bicycle

Notes: Based on Z arrows and horizontal arrows specify probability distributions relating the different structure variables. Random samples from the statistical distributions in this graph produced reasonable bicycles in different views and forms. Recognition of a bicycle in a cluttered and ambiguous natural scene (left, bottom row) is made possible by top-down and bottom-up interaction.

has been shown that bicycles in extremely ambiguous natural scenes can be segmented and recognized using this computational architecture, a feat unparalleled by other existing computational systems based simply on feedforward connections. Recently, it has been shown that this type of hierarchical network with many layers of representations can be learned in an unsupervised manner. However, it remains to be shown empirically that perceptual inference in our visual system is indeed based on these computational principles and mechanisms.

Contributions

Computational approaches have, over the years, provided a deeper, clearer, and more precise understanding of the computational principles and mechanisms underlying perception—why we perceive the world the way we do—by considering subjective perceptual phenomena as solutions to computational problems and by revealing how physical and statistical constraints on natural scenes shape our perceptual systems. Computational research has made clear the difficulties confronted by perceptual computation and have stretched the envelope of our imagination for the possible principles and mechanisms needed to resolve these difficulties. An emerging theme is that the perceptual computation can be conceptualized as a process of Bayesian inference of the underlying causes of the images. The objective of the inference is to provide us with a parsimonious and efficient description of the world around us so that we can ignore details irrelevant to the task and pay attention to details that are critical to our survival and task success. This inference could be facilitated by the mechanism of *analysis by synthesis,* which dynamically constructs the outcome of the inference as subjectively perceived mental images in our brain.

COMPUTER CONSCIOUSNESS

"I'm afraid, Dave." In Stanley Kubrick's classic film *2001: A Space Odyssey,* the computer HAL uttered these provocative words as it was being shut down. They remain provocative to this day: Can a computer really experience emotions such as fear? Can it really have an *I* that is afraid to be shut down? An *I* that is the subject of genuine conscious sensations? Or must a computer, no matter how sophisticated its program and convincing its behavior, be forever devoid of conscious experiences? These are key questions about computer consciousness, questions still debated by experts and explored in blockbuster films. This entry discusses some of these questions.

The Brain as Computer

Some experts answer, "Of course a computer can be conscious. The human brain, for instance, is a computer, and it has conscious experiences. So computer consciousness is not just possible, it is commonplace."

These experts differ, however, on why, exactly, the brain can be conscious. Some are *biological naturalists,* who claim that special properties of brain biology are critical. Precisely what these properties are, and how they can generate, or be, conscious experiences, is an open question with no scientific theories yet on offer. But one implication of biological naturalism is clear: If biology is necessary, somehow, for consciousness, then any complex system that lacks biology must also lack consciousness. Because the brain is a biological computer, it can be conscious. But a nonbiological computer, such as HAL, could not be conscious, no matter how compelling its utterances.

Other experts are *functionalists,* who claim that the critical properties are not fundamentally biological, but functional. The brain can be understood as running complex programs serial, parallel, and even quantum. Certain properties of these programs are critical for consciousness. Again, no scientific theory yet explains, precisely, what these functional properties are and how they generate consciousness; perhaps concepts from information theory or complexity theory will be useful. But functionalism is clear that biology, per se, is not essential to consciousness. A nonbiological computer, such as HAL, could be conscious if it is properly programmed.

Biological naturalists assert that progress in neuroscience is required to make progress in understanding consciousness. Functionalists can agree that progress in neuroscience is important because careful study of brain function might illuminate the functional properties that are critical to consciousness. Thus, both can profitably learn from neuroscience. But they debate about how this knowledge can be used. Functionalists claim that we can, in principle, use it to build conscious, nonbiological machines. Biological naturalists disagree.

Reductive and Nonreductive Functionalism

Functionalism is by far the more prevalent view among experts today. There are many versions of functionalism, and technical nuances within these versions. But functionalists can be grouped into two broad classes.

Reductive functionalists claim that mental states are identical to certain functional states: The conditions that define the different types of mental states of a system, whether biological or not, refer only to relations between inputs to the system, outputs from the system, and other mental states of the system. The relations among inputs, outputs, and mental states are typically taken to be causal relations. However, the reductive functionalist does not claim that these causal relations *cause* mental states. Instead, this functionalist claims that mental states *are* certain functional states. In particular, states of consciousness are mental states and are thus, according to the reductive functionalist, identical to certain functional states. If a computer, such as HAL, happens to have the right functional states, then it ipso facto has conscious experiences.

Nonreductive functionalists claim that mental states arise from functional organization but are not functional states. Consciousness, in particular, is determined by functional organization, but it is not identical to, or reducible to, functional organization. Nonreductive functionalism is, in one sense, a weaker claim than is reductive functionalism because it claims only that functional organization determines mental states, but drops the stronger claim that mental states are identical to functional states. But in another sense nonreductive functionalism is a stronger, and puzzling, claim: Mental states, and conscious experiences in particular, are something other than functional states, and therefore have properties beyond those of functional states. This proposed dualism of properties raises the unsolved puzzle of precisely what these new properties are and how they are related to functional properties. However, the nonreductive functionalist does agree with the reductive functionalist that if a computer, such as HAL, has the right functional organization, then it will have conscious experiences.

Spectrum Inversion

Reductive functionalism, although controversial, is the dominant view among experts today. One thought experiment at the center of the controversy is the so-called spectrum inversion problem, which goes back at least to John Locke. He asked, in his 1690 *Essay Concerning Human Understanding,* if it were possible that "the idea that a violet produced in one man's mind by his eyes were the same that a marigold produced in another man's, and vice versa." Are the colors you see the same as the colors I see? More specifically, suppose that you and I are functionally identical.

Would it still be possible that our color experiences differ, so that, for instance, the color I experience when viewing a ripe tomato is the color you experience when viewing fresh grass?

Functionalists, both reductive and nonreductive, answer that it is not possible for two people to be functionally identical and yet to differ in their color experiences. The reason, according to functionalism, is that every mental state, and therefore every color experience, is determined by functional organization. So, if two people have the same functional organization they must have the same mental states, and therefore the same color experiences.

If it could be shown that spectrum inversion were possible, this would falsify functionalism. It would challenge whether computer consciousness is possible because most arguments in favor of computer consciousness are based on functionalist assumptions. Thus, the possibility of spectrum inversion is still widely debated.

If reductive functionalism were true, then it would in principle be possible to build a nonbiological computer, a variant of HAL, that is functionally identical to you. In this case, if you and the computer were shown the same visual scene, then the conscious color experiences of this computer, indeed all its conscious experiences, would be identical to yours.

Technology will likely evolve to the point where computers behave substantially like intelligent, conscious agents. The question of computer consciousness is whether such sophisticated computers really are conscious, or are just going through the motions. The answer will be illuminating not just for the nature of computers but also for human nature.

COMPUTER-GENERATED SPEECH, PERCEPTION OF

The ability to generate synthetic speech under computer control provides an important tool for the study of speech perception as well as an important technology for interacting with computers. We generally think of speech as a uniquely human ability, even if qualified by the vocal mimicry abilities of other species such as parrots and mynah birds, but computer models of speech production make it possible to generate speech signals with specific acoustic characteristics. Speech is an extremely complex acoustic signal mixing periodic and aperiodic sounds and consisting of patterns of frequency change over time, bursts of noise, silent gaps, and brief steady state patterns. Understanding how listeners quickly and effectively understand this complex signal is the primary goal of speech perception research, and synthetic speech allows systematic control of these acoustic properties. This entry describes the scientific importance of synthetic speech, models of speech production, text-to-speech synthesis, resynthesis of speech, and applications and limitations of computer-generated speech.

Scientific Importance of Synthetic Speech

Although psychoacoustic research defines and manipulates the acoustic properties of stimuli exactly using formal mathematical descriptions, this has not generally been possible for speech research. No simple mathematical description of speech can be used to characterize the sound patterns that affect listeners' perception of speech. Phonetic research seeks to identify the acoustic patterns or movements and positions of parts of the speaker's mouth that determine perception of consonant and vowel sounds (i.e., phonemes). The development of the speech spectrograph allowed researchers to measure how the sound patterns of speech change over time. The x-axis of the spectrogram (printed by a spectrograph) shows time as an utterance unfolds and the y-axis displays the frequency with the amount of energy at each time point and frequency displayed by darkening the point. Thus, dark and light visual patterns depict the different frequencies and noises in the acoustic patterns of speech. Rising pitches are displayed as lines that slant upward and falling pitches are displayed as lines that slant downward. The development of the Pattern Playback Machine at Haskins Laboratories provided a way of turning those visual patterns into acoustic speech sounds. Different patterns painted onto acetate were converted into speech containing only those acoustic properties hypothesized to change perception of one consonant or vowel into another. By making slight variations on those visual patterns, small systematic changes in speech signals could be generated where it would be difficult or even impossible for a human talker to speak with such precise control.

Models of Speech Production

Speech synthesizers are the modern computational version of the Pattern Playback. Instead of drawing acoustic patterns in visual form, speech synthesizers take as input a description of the speech signal—for example, as numerical descriptions of acoustic properties or moment-by-moment physical positions of speech articulators such as the tongue. These descriptions are then input to a computational model of speech production that generates the actual acoustic output. Some synthesizers model the movements of the mouth whereas others model the acoustic properties of speech production through filters and resonators.

Despite the differences between the underlying models, however, speech synthesizers are used less often to test those models than to parametrically control the acoustic properties of speech tested in perceptual experiments. Synthesizers permit precise control of the pattern properties of speech, synthetic speech has made possible studies how these properties are used in recognizing spoken consonants, vowels, and words, how this ability develops from infancy, and how human perception of speech differs from perception of speech signals by nonhuman animals. For example, it is possible to make a series of test stimuli varying from one vowel to another (e.g., from EE as in *beet* to IH as in *bit*) or from one consonant to another (e.g., from B as in *bit* to P as in *pit*). In the case of vowel stimuli, this can be accomplished by varying the duration of the vowel or by changing the frequency of one of the components of the vowel. For consonant differences, it is possible to vary the timing relationships among different acoustic properties such as a burst of noise and the vowel of the syllable, or by changing frequency properties. In this way, small acoustic changes can be produced that can be classified by listeners (adult humans, infants, chinchillas) to understand the relationship between the acoustic properties and perception.

Text-to-Speech Synthesis

Speech synthesizers that model speech production can also be combined with linguistic rules to produce text-to-speech systems. A text-to-speech system (TTS) takes unrestricted text such as this article and "reads" the text aloud, or at least renders the text into a speech waveform. Linguistic rules are used to translate the text input into a symbolic representation of consonants and vowels, and then to translate these phonemes (organized into words and sentences) into acoustic parameters that would drive the speech synthesizer to produce acoustic output. In this respect, a TTS is more like a reader than like an extemporaneous speaker. Although speech synthesizers that work at the level of modeling speech production are important for fine systematic control of the acoustic properties of consonants and vowels, text-to-speech systems are more useful to study the perception of spoken words and sentences.

Resynthesis of Speech

Speech can also be synthesized directly from the model of a natural utterance such as a sentence. Any utterance can be analyzed (using a modeling technique called linear predictive coding) to measure acoustic properties of the talker's voice and the moment-by-moment acoustic properties of the talker's vocal tract. These measurements can then be input to a model that generates an acoustic speech signal that is closely matched to the original speech. These parameters can then be modified to produce variations in consonants or vowels or speaking rate or intonation, or even whether the talker sounds male or female. This approach generates intelligible and natural-sounding speech that can be used to study the perception of emotion and speaker attitudes or aspects of narration.

Applications and Limitations

In general, synthetic speech can sound artificial. Listeners detect that such speech is not naturally produced, either by the presence of extraneous sounds or by funny intonation or unintelligible syllables. This has not limited the usefulness of synthetic speech for the study of speech perception. Moreover, the intelligibility of synthetic speech has reached the point that it is routinely used in a variety of commercial applications including voice response systems in automated teller machines, announcement systems in public transportation, vocal prosthetic devices for people who cannot talk, and reading machines for the blind.

COMPUTER GRAPHICS AND PERCEPTION

Computer graphics has become pervasive in visual media and is the core technology in video games, whose revenues are now higher than ticket sales for movies. Movies wholly generated using computer graphics appear with regularity, and movies commonly have backgrounds or characters created using computer graphics. Print and broadcast media have been similarly affected, and computer graphics virtual worlds are becoming commonplace on the World Wide Web. Because the product of computer graphics systems is intended to be viewed by people, it is important to understand computer graphics in a perceptual context. Although perception of computer graphics is similar to that of photography, film, and the graphical arts, important aspects of image creation and display are unique to computer graphics and must be understood to understand the perceptual effectiveness of computer graphics. This entry describes how computer graphics is generated, limitations of display devices, spatial information in computer graphics imagery, pictorial perception, and non-photorealistic rendering.

How Computer Graphics Is Generated

A computer graphics program can be thought of as a synthetic camera that captures an image or sequence of images of a scene that is described virtually in the computer. The virtual description of the scene (model) contains information about the geometry of surfaces and objects, material properties affecting the appearance of surfaces and objects, and characterizations of the light sources. The complexity with which illumination and surfaces interact to produce patterns of light in the real world is so great that computer graphics must necessarily operate using at best rough approximations to actual physics. These approximations must strike a balance between appearance and computational efficiency.

Usually, computer graphics generates or renders images using the same perspective projection process that occurs in real cameras and in the human eye. In computer graphics, a mathematical specification of perspective projection is used to map positions in the scene to their corresponding image locations. A variety of techniques are available to ensure that objects and surfaces in the scene hidden (occluded) by nearer objects and surfaces do not affect the appearance of the final image.

In the real world, there is variation across surfaces in color and reflectivity. Real-world surfaces also have fine-scale geometric roughness. Computer graphics models surface variations in color and reflectivity using *texture maps,* which may be hand painted in an image-editing program, captured by a camera, or produced in some automated manner. Similar techniques are available to represent geometric textures in ways that can be efficiently used by rendering algorithms. These kinds of textures are widely used in both computer games and movies (see Figure 1).

The manner in which light reflects off surfaces is modeled using some form of *bidirectional reflectance distribution function* (BRDF), which relates the percentage of incident light that is reflected to the orientations of light sources and viewpoint relative to the surface. The nature of the most commonly used rendering process is such that adding shadows to the generated image is quite costly, though it is now feasible to do in real-time on high-end graphics cards. A fully accurate image must also account for indirect lighting that reflects in series from more than one surface. This is not currently possible for interactive systems such as vehicles simulators and video games, but is often done for computer graphics–generated movies.

Notes: On the left is an indication of lines making up the geometric model. The right image is produced using perspective projection, lighting, texture mapping, and shadow.

Limitations of Display Devices

Computer graphics images are usually presented for viewing using either some sort of display device such as a monitor or video projector or in printed form. This has important perceptual implications, which are shared with other visual media such as photography and movies that use the same mechanisms for presentation. Under normal viewing conditions, the human visual system is able to see detail two to three times finer than can be displayed on computer monitors or high-definition televisions (HDTVs), when these are viewed at normal distances. Dynamic range, sometimes referred to as contrast ratio, is the difference in brightness from the darkest black to the lightest white in an image. Except for a few exotic display technologies, it is not possible to present images with a dynamic range close to that encountered by the human visual system in everyday life. With adaptation, the human visual system is sensitive to a range of brightness of about eight orders of magnitude, and can easily deal with naturally occurring scenes in which brightness varies by a factor or 10,000. High-quality computer and HDTV monitors can display a range of brightnesses covering about three orders of magnitude and are incapable of simulating the light levels associated with either bright moonlight or darker, or outdoors in daylight. Print media are far more restrictive in the brightnesses that can be conveyed. Similarly, the range of colors that can be seen by the human visual system far exceeds the range of colors (color gamut) that can be displayed by computer monitors, image projectors, or print media.

To deal with the problem of presenting images that have luminances and colors not displayable on a monitor or in print media, some sort of *tone mapping* operation is required. Tone mapping involves generating an image that gives the impression of the real scene, but using only the available dynamic range of the display device. The simplest form of tone mapping—used in many computer graphics systems—is to multiplicatively scale brightness levels to bring them within the required range. Because this may involve reducing contrast by factors of 1,000 or more, the result rarely appears realistic. More sophisticated techniques exploit the insensitivity of the human visual system to show variations in brightness across the field of view by adaptively increasing or decreasing brightness and contrast in local areas of the image. Done correctly, this can dramatically increase the subjective sense of dynamic range in an image without any modifications to the display device.

Spatial Information in Computer Graphics Imagery

Vision is a powerful source of information about the three-dimensional structure of the visible environment. Much of this information is associated with what are called *pictorial cues,* which can be extracted from single, static views of the world. Pictorial information includes various perspective effects, shading, shadows, and the patterns that occur when one object partially hides another. Visual motion is pervasive in human experience, and often provides a powerful source of information about the three-dimensional structure of the world. Binocular stereo supports perception of depth, surface orientation, and occlusion, particularly at nearer distances. Focus (accommodation) can also indicate depth, but only at distances up to a meter or two.

The term *perspective* is used to apply to a range of visual effects, all associated with the fact that the size of the retinal projection of a given sized entity in the environment is smaller the farther away the entity is from the viewer. The best-known perspective effect is that parallel lines in the world, when viewed from an oblique angle, converge to a vanishing point as when looking down a long straight road. A retinal image of converging lines is often perceived as a surface receding away from the viewer. The location of the vanishing point affects the perceived slant of the surface and the perceived relative distances to various points on the surface. The world is full of *visual texture,* consisting of repeated patterns such as grass, forests, brick, carpet, and the like. When a textured surface is viewed obliquely, the patterns making up the texture become finer and finer with distance. The visual system can exploit this effect, perceiving textures that smoothly vary in scale as indications of a slanted surface.

Computer graphics renders geometric models using perspective projection as an integral part of the process. The generated image of geometric entities will correctly convey the visual cues that underlie perspective-based space perception. The effectiveness of these cues in generating a perception of depth and surface orientation will depend partly on the accuracy of the geometric models used to generate them, though the nature of perspective cues is such that they do not depend strongly on the detailed shape of objects and surfaces. Although most computer graphics systems render geometry in a perspectivally correct manner, the same is not true for texture maps used to specify the detailed appearance of surfaces. Approximations used to render texture maps efficiently slightly distort the spatial structure of the texture and can significantly deviate from the correct association of the scale of the texture with viewing distance.

As indicated previously, the brightness of a point on a visible surface seen by a viewer is a function of the brightnesses and locations of light sources, the reflectance of the surface, and the orientation of the surface with respect to the line of sight. In almost all cases, visible brightness changes substantially when the relative orientation of light source and surface is changed. For most materials, changes in the orientation of the line of sight to the surface also produce significant changes in brightness. The visual system often interprets smoothly varying changes in brightness of a viewed surface as being caused by smoothly varying changes in the orientation of the surface. These spatial changes in surface orientation are typically perceived as resulting from surface curvature. Sometimes discontinuous changes in brightness are interpreted as discontinuous changes in surface orientation, but visual interpretation of brightness discontinuities is complex and not well understood. The lighting models used by most computer graphics rendering systems approximate the change in brightness caused by changes in surface orientation, as indicated by the underlying geometric models or bump maps. The effect often results in a compelling sense of three-dimensional surface shape.

Shadows are another source of visual information about the spatial structure of the world. Most often, shadows indicate position indirectly. Objects casting shadows onto extended surfaces tend to appear at a distance from the viewer corresponding to the perceived distance of the location on the surface where the shadow falls. The way in which most computer graphics systems create images makes it extremely difficult to generate shadows in the correct location with the correct shape. Real-world shadows have a smooth transition for lit to unlit areas (penumbra), which is also difficult to render accurately. In computer graphics, this is referred to as a soft shadow. Algorithms for generating perceptually plausible approximations of shadows have been developed. These are most often used in situations such as computer-generated movies, where computation need not be interactive, but are also available on some high-end PC video cards.

Computer graphics can be used to produce animations. As in the real world, visual motion typically produces a strong sense of three-dimensionality, along with the appearance of object and viewer movement. The most direct way to animate computer graphics is to generate a sequence of image frames based on changing geometric models and viewpoints, and then display these images at a rate such that smooth motion is perceived. For movies, substantial time is often used in generating each frame because the resulting imagery is stored and then played back on video or film. Real-time interactive graphics requires that video frames be generated at roughly 30 frames per second or faster before the motion looks continuous. A few exotic display devices track the viewer's head position and use this to control the viewpoint in the graphical rendering, producing a strong sensation of motion parallax.

Although binocular stereo is a powerful three-dimensional (3-D) cue in normal vision, few display devices support viewing of computer-generated stereo images. In the human visual system, the eye motions that are part of stereo perception are affected by accommodation (focus of the eyes) to locations of interest. Even though stereo image displays can vary the views from the two different eye positions based on depth, accommodation is consistent with the fixed distance at which the images are displayed, reducing the effectiveness of the displays. Despite the limitations of stereo image displays, they are reappearing in 3-D movies.

Pictorial Perception

Although perception of computer graphics and other graphical media involves the same set of pictorial cues as does viewing the real world, there are important ways in which visual perception of pictures and visual perception differ. Motion is sometimes missing, and non-pictorial cues such as stereo and accommodation are almost always absent. All of these are important sources of spatial information. The visual extent of a viewed display screen or printed graphical image typically ranges from 20 degrees to about 45 degrees, much less than the near 180-degree horizontal field-of-view of the human visual system, though there is disagreement about the exact effect of limited field-of-view on space perception. Except for a few exotic display technologies mostly limited to vehicle simulators, there is visual information available indicating the location of the two-dimensional surface on which the image is displayed. This information conflicts with the pictorial cues in the image itself, typically resulting in compression of apparent depths in the rendered scene. Finally, perspective cues in a rendered image will be distorted if the location from which the image is viewed, relative to what is depicted in the image, differs from the location of the synthetic camera used in rendering, relative to the scene model (i.e., if the observer views the scene at an angle).

Nonphotorealistic Rendering

A relatively new type of computer graphics produces technical illustrations or artistic images that are not realistic. Such images are useful in applications that use the analogous human-produced graphics. For example, an automotive manual might use a line-based graphics rather than a real or synthetic photograph, and an animated film might use images with lines and brushstrokes. Because this type of graphics is distinguished from the more common realistic graphics, it is usually called nonphotorealistic rendering (NPR). A particular challenge in this area is that it often concerns itself with image-space features such as brushstrokes, so maintaining a good appearance under change of viewpoint or object position is a challenge.

COMPUTER SPEECH PERCEPTION

Many science fiction writers and electrical engineers have envisioned that one day people will be able to talk to appliances. “Washing machine on” would be the vocal shot to be heard round the world liberating humanity from mechanical enslavement to buttons and knobs. However, although the current performance of speech recognition systems might be compared favorably to the effectiveness of commanding a dog to sit—a significant improvement from past decades when recognition performance was more like commanding a cat—talking to appliances is not the killer application that is desired by most people. But even at the current level of performance, there are a number of important successful applications for computer speech recognition systems. Moreover, understanding why computer speech perception has not reached the level of human performance can give insight into the basic theoretical problems that still need to be solved to understand human speech perception.

In principle, by using speech technology, every telephone could become a computer system. The phone could allow access to information stored in databases, could allow the entry of data into such databases, and could be used for a number of applications that take place using a keyboard, a mouse, and a visual display screen. For every telephone to become a net-connected computer terminal, we simply need to replace the keyboard and mouse with speech input through a recognition system and voice output using synthetic speech. However, the level of speech recognition performance is still well below the requirement of speaking to a computer using natural speech as if talking to a human agent. This entry discusses the problem of speech recognition, speech understanding, using speech recognitions systems, the human factors problem, and learning about speech perception from speech recognition.

The Problem of Speech Recognition

Human listeners recognize fluent sentences under adverse listening conditions with a high degree of accuracy. In the presence of background noise varying from –6 decibels (dB) SNR to +6 dB signal-to-noise ratio (SNR), we can recognize spoken words in the range of 60 to 90% correctly, with fluent sentence intelligibility even higher. Computer speech recognition systems cannot operate at this level of performance under comparable circumstances with a similar high degree of uncertainty about what might be said by a talker. One reason for this is the knowledge we bring to the problem of speech recognition. Human listeners use knowledge of their phonology (sound patterns and the organization of sound patterns), the lexicon (word knowledge), and syntax to aid in recognizing spoken words. We use background knowledge about the domain of discourse to constrain interpretations. Moreover, perhaps, regarding our ability to recognize speech even in isolated syllables, we can use our substantial experience producing and perceiving speech to aid recognition. The acoustic patterns of speech sounds are restructured at different speaking rates, across talkers’ vocal tract architecture and articulatory control, and in different phonetic and linguistic contexts. A single acoustic speech pattern may be ambiguous between different phonetic categories, and any single phonetic category may have multiple acoustic realizations in production. This many-to-many mapping between speech sounds and linguistic categories is a fundamental problem that humans solve with linguistic knowledge, cognitive processing, and experience with speech.

Speech recognition systems before the 1970s stored a fixed and limited set of utterances that could be recognized (e.g., a vocabulary of commands or digits or letters) as a collection of acoustic properties. A vocabulary was defined when each utterance was recorded by a talker into the system and was then reduced to a set of acoustic features such as spectral properties at different times. These features were represented as a template for the utterance that each spoken input was compared with. The spoken input was analyzed acoustically in the same way as the stored representations and the specific spectral features were compared over the duration of the utterance to derive a similarity score. The most similar template would be chosen as the candidate for the recognition of the input. For vocabularies such as digits where the words differed acoustically, and for isolated words spoken carefully, such systems could achieve 95% correct recognition for a single talker whose speech provided the templates, when there was no noise in the environment. However, deviations from these narrow operating constraints could reduce performance substantially so that users became frustrated easily at the repeated failures of recognition. For example, using letters instead of digits includes the items B, C, D, E, G, P, T, V, and Z, which are easily confused, and recognition performance could easily drop to 20% correct. Having a head cold or speaking quickly could reduce performance significantly. Performance of a system would generally be measured as percent correct recognition or percent error—reporting percent error in the speech engineering community has always been popular because small reductions in error rate appear larger than do small increases in accuracy once performance is over 80 to 90% correct. Recognition errors could be scored as substitution errors in which the wrong response was given or as recognition failures. Because these speech recognition systems depended on a comparison of the acoustic properties of stored templates of a vocabulary to each input utterance, performance was fragile and different from the robust performance of human listeners.

All speech recognition systems must cope with the problem of variability in the relationship between acoustic patterns and linguistic categories. Most speaker-independent recognition systems have vocabularies that are determined by the system designer and the acoustic representations are compiled into the system from a large database of speech that is analyzed into spectrotemporal features and stored as part of the system. The vocabulary can be designed to maximize linguistic contrast among the items (still satisfying the needs of the intended task), and the acoustics can be measured and representations chosen that for a large database of talkers maximizes discriminability. For simple discriminable vocabularies such as digits, these systems can easily achieve levels of performance over a telephone that is near human recognition—more than 95% correct. By contrast, speaker-dependent recognition systems allow the user to define a vocabulary and record the speech tokens that are analyzed to establish the vocabulary. This process can be iterative, in which the system prompts for specific vocabulary items, tests recognition, and then recalibrates by prompting for more training tokens. In this way, some systems have been developed as hybrids starting with a large database of speech for a large vocabulary but, upon determining through user interaction that substitution errors are too frequent (e.g., more than 15%), can prompt the user to produce some training speech that can be used to tune or adapt the initially speaker-independent vocabulary to function more accurately with a particular user.

Speech Understanding

In 1971, the Advanced Research Projects Agency (ARPA, now the Defense Advanced Research Projects Agency or DARPA) initiated a research competition to develop speech understanding systems. The emphasis in this project reflected a shift from previous engineering attempts at speech recognition—matching acoustic speech patterns to stored representations of utterances—to speech understanding. Speech understanding was defined as successful transmission of an intended message from talker to computer, even if recognition of the words or phonemes was poor. The shift away from pattern recognition of speech sounds to understanding of intended communication reflected two important trends in speech engineering. First, it was recognized that the linguistic content of an utterance was not completely represented by the phonetic transcription of that utterance alone. Phonemes could be omitted, reduced, or misarticulated, syllables or words dropped, and human listeners can still understand speech. Second, this entailed a shift in technical approach from pure signal processing and pattern classification methods to new developments in artificial intelligence and the successes of expert systems and natural language processing in the 1970s.

The goals of the 5-year competition were to develop systems that understand connected speech using a vocabulary of 1,000 words with a limited sentential syntax in a particular task domain from multiple cooperating talkers with less than 10% error. Four systems were completed by 1976 with one clear winner. Harpy could understand sentences from five different talkers (after being trained on 20 sentences from each) with a 5% error rate. The model was built to represent sentences by a network of about 15,000 states corresponding to short-term (10 milliseconds [ms]) power spectra in the sequences that would be permissible for all acceptable sentences. The network compiled all phonological, lexical, syntactic, and domain-specific constraints into a single model, turning comprehension into a statistical classification problem. The 20 training sentences were used to tune the acoustic state representations to specific talker vocal characteristics. Unlike other systems that represented expertise in words or sentences or domain knowledge as separate processing systems that interacted to determine recognition, Harpy precompiled all this knowledge into a single finite-state network of acoustic features with transition probabilities estimated for the nodes based on talker-specific acoustic properties and the linguistic knowledge of words and sentences. Thus, all the linguistic knowledge and knowledge of the domain of discourse (e.g., chess), was compiled by programmers into the system.

One important consequence of the ARPA speech understanding project was the insight that recognizing the acoustic patterns of speech did not have to be perfect or even the primary source of performance accuracy. This brings computer speech perception more into line with 50 years of research on human speech perception showing that lexical and syntactic and semantic constraints on the meaning of sentences can improve overall understanding of speech even at poor signal-to-noise ratios. We understand a sentence such as “A stitch in time saves nine” better than “The old corn cost the blood” in noisy environments, and this needs to be part of computer speech recognition systems. Furthermore, by placing the problem of speech understanding in a particular task domain (e.g., flight reservations or chess playing), knowledge about the kinds of sentences and words used in that domain, the kinds of linguistic interactions, and the meaning of those interactions relative to the goals of the speaker could all be used to make up for the limitations of acoustic pattern recognition of speech. This resulted in the development of computer systems that were much more successful at higher-level tasks than could previously be achieved. However, the addition of new constraints also introduced new kinds of errors. One apocryphal story from the competition described Harpy playing chess. When the computer’s king was completely boxed in and threatened with checkmate at the next move, the situational constraints were so strong on what the talker could logically say that Harpy would resign even if the human talker merely coughed instead of describing a move. In other words, Harpy could “hallucinate” understanding simply based on what the most expected utterance would be regardless of what was actually said. It is important for the constraints provided by expectation and knowledge not to override the actual sensory information in the speech signal.

Using Speech Recognition Systems

Speech recognition technology is needed for several general applications and has been used for with varying degrees of success: Voice interaction with computer systems over the telephone, information transfer in eyes-busy, hands-busy situations, as a prosthesis for people with manual motor impairment, dictation, and in “command and control” systems. As a general rule, if people are unable to use their hands for typing or controlling devices, speech is viewed as the logical substitute. Thus, we can think about speech as useful for transmitting information and as a way of controlling computers and machinery.

To date, arguably the greatest impact and success of speech recognition technology has been to improve the effectiveness of human telephone operators by partitioning their tasks into those that can be responded to by a computer and those that require human interaction. Reducing the need for human operators in some information transactions such as retrieving flight status or financial information has become the paradigm case of the successful application of speech recognition systems. In cases of number entry (e.g., flight numbers, bank account numbers) and simple isolated words and phrases, speech recognition can work effectively and efficiently, even over the phone with potential acoustic distortion of the speech signal and with great variability in the vocal characteristics of talkers. This kind of application generally combines aspects of information transfer and control through menu selection. These kinds of interactions allow for only a few alternative words at any point in the interaction, thereby significantly constraining the recognition problem. This has proven to be an important aspect of the successful application of speech recognition systems: Task-level constraints are important in the successful application of speech recognition systems.

The Human Factors Problem

When first conceived for real applications, speech technology was thought to be transparent as a user-system interface, at least by comparison with a mouse or keyboard, because everyone knows how to talk. However, it has become clear that every interface technology introduces its own problems that must be studied systematically. For example, speech recognition systems make errors, and there must be some way of communicating recognition uncertainty to a talker and for the talker to signal to the computer that a recognition error has been made. Recognition systems require careful articulation and some care about physical position with respect to the microphone, control of voice levels, consideration of ambient noise sources and levels, and simple experience in using these systems. Some talkers (called "sheep") are more successful in talking to speech recognition systems than are others (called "goats"), and general knowledge about interaction with technology and computers interacts with this difference in ability.

Human-to-human speech communication is generally successful and robust but not on the basis of the recognition of the speech signal alone. We can ask a speaker for clarification if we do not understand a word or sentence. Listeners can repeat part of a talker's phrase to seek confirmation from the talker. Speakers can increase redundancy by rephrasing or repeating ideas or words, and can slow speech down, emphasize important parts, and increase the clarity of production. Speakers use these modifications of speech production to increase listener comprehension secure in the pragmatic knowledge of a common set of rules for speech communication. However, if speakers engage in these natural behaviors with a computer speech recognition system, this would increase pattern variability and decrease performance. Thus, speakers fight natural tendencies and experience and must relearn the rules of conversational interaction for recognition systems.

Although these problems are seen in isolated utterance recognition systems, computer dictation systems present all these problems and more. Today it is certainly possible to dictate a document to a computer, although the computer will not match the facility of a moderately skilled typist in entering text. Dictation systems can be tuned, through a training regime (i.e., saying specific training sentences to the system when prompted), to the specific vocal characteristics of a single talker, but this cannot overcome the loss of the constraints that benefit small vocabulary recognition systems. Dictation is given as fluent sentences rather than as isolated words. Variation in pronunciation from time to time, because of distraction, fatigue, carelessness, or simple moment-to-moment motor variability in articulation results in acoustic patterns that are less stable for words that may have many similar "neighbors." The vocabulary is relatively unconstrained so that acoustically similar words may be used (e.g., think and thing, bog and dog). The syntax is relatively unconstrained so that the number of possible words that may follow any particular word is large. Speakers may pause, hesitate, restate, and revise an utterance after false starts. Thus, the set of utterances is poorly defined and highly variable in linguistic and acoustic terms. Unfortunately, it is difficult to predict the actual performance of a dictation system in the real world, and impartial systematic studies are scarce. System vendors will generally report high levels of accuracy (more than 95% correct) for cooperative users, although anecdotal user experience is much less satisfactory. Although it is difficult to carry out controlled dictation tasks as such, studies examining recognition of fluent speech have reported word recognition error rates around 4% for human listeners and 43% errors for computer recognition.

Human dictation taken by humans is also less successful by comparison with the more constrained interactions that take place with the human telephone operator tasks that speech recognition systems have been applied to. Dictation is a much more open-ended process wherein the constraints on any particular word at any point in time are provided by the structure of language and the message of the talker. As in the ARPA speech understanding project, to make use of such constraints effectively, it would be necessary to model the structure and use of phonemes, words, and sentences, to understand the talker's ways of speaking, and have some kind of understanding of the talker's topic. With human dictation, the normal rules of vocal communication can apply and the listener can request clarification and correct errors in ways that a computer cannot. Following the success of the Harpy system in the ARPA project, computer dictation systems typically model language using statistical networks called Hidden Markov Models that approximate these constraints based on a limited sequence of words. (The "hidden" part is the assumption of postulated states such as phonemes that serve as part of the structure of the statistical Markov model.) For example, all the linguistic knowledge that constrains the recognition of spoken words in dictated sentences is often modeled by the transition probabilities of sequences of three or four words. Although sequences of four words approximate locally comprehensible sentences, humans can easily distinguish sentences that only obey this constraint from natural sentences. The database of language from which these transition probabilities are estimated may be specific to a certain kind of discourse (e.g., business correspondence) and requires millions of words of correspondence to develop statistically plausible models even for such a small sequence of words. The implications of this is that, although a particular domain of discourse will represent the broad structural constraints of the language of that discourse and thus model sentences generally well, the specific statistics of word usage and phrases in the domain of the correspondence database can influence recognition performance substantially. Words that are rare in one domain and are potentially confused (e.g., mesa and peso) might lead to substitution errors in which a letter home is transformed by the recognition system to be less about scenery and more about banking. Similarly low-frequency constructions that are perfectly legal, such as, "He saw that that was there," will have recognition errors.

Learning About Speech Perception From Speech Recognition

The development of speech recognition technology has only been weakly influenced by knowledge of human speech perception. The application of linguistic knowledge and task knowledge is one clear example and the use of recognition "competition" within a "neighborhood" of similar utterance representations is another. However, there has been scant effort to apply what we know about the details of human speech perception and spoken language understanding to improving these systems. Moreover, little has been learned about human speech perception from the performance limitations of speech recognition systems. The use of statistical learning and statistical modeling in theories of speech perception may arguably be one such example. Some theories of human speech perception have been influenced by these notions, which suggest speech perception is based on these statistics rather than abstract linguistic categories. There have been attempts to improve speech recognition systems by using more psychoacoustically plausible acoustic pattern representations. However, this engineering application of perceptual research has demonstrated the need to better understand the relationship between peripheral auditory processes and subcortical and cortical neural mechanisms of speech perception. The few theories of speech perception that are implemented computationally and take real speech input could be thought of as the first steps toward being able to bridge the engineering approach and the psychological approach. Unfortunately, the performance of such systems is typically much worse than is that of commercial speech recognition systems. The era of the ARPA project and the immediate aftermath produced the greatest substantive interactions between speech engineers and basic speech researchers. These interactions led to new conceptualizations of the nature of the mental lexicon and the process of word recognition, as well as interactions between top-down and bottom-up processes in spoken language understanding.

COMPUTER VISION

Computer vision is a field whose goal is to take as input images or video streams and to extract useful information about the objects and surfaces in the scene that gave rise to the image or video. Humans employ vision to acquire knowledge about the external world and to guide a wide range of actions, and the grand objective of computer vision research is to provide machines with similar capabilities. These can be divided into the following:

> *Segmentation.* This is the partitioning of an image into sets of pixels that correspond to single objects or parts of objects. In a video stream, tracking is the process of matching these groups over time.
>
> *Recognition.* This involves categorization, which operates at a more generic level (This is the image of a face), as well as identification of specific instances (This is the image of Barack Obama's face).
>
> *Reconstruction.* This is the recovery of depth, surface orientation, and shapes of the objects and surfaces in the scene that gave rise to the image.
>
> *Controlling action.* These include visual guidance of locomotion, such as of a mobile robot in a building, or a car on a freeway, as well as manipulative actions such as reaching, grasping, or insertion.

This entry discusses each of these in turn and then closes with a brief overview of the past and future progress of computer vision.

Segmentation

Although the input to the human visual system is just a collection of values associated with outputs of individual photoreceptors, we perceive a number of visual groups, usually associated with objects or well-defined parts of objects. This ability is equally important for computer vision, where the term *segmentation* refers to the partitioning of the image into these groups of pixels. When extended to spatiotemporal data, the term *tracking* is often used to refer to the process of matching these groups from one time frame to the next. This has a number of applications. In monitoring people at an airport or traffic in a freeway, the basic process involves segmenting out individual people or cars and tracking them over time. Grouping can be of curves, not just regions; the process of tracing axons and dendrites in neuroscience research to infer neural network connectivity is another example. Grouping and tracking can be viewed as two aspects of the same process, that of spatiotemporal segmentation of a video stream.

Computer vision techniques for segmentation are based on algorithms that implement various grouping factors first studied comprehensively by the Gestalt school of visual perception. The single most important grouping factor is similarity—pixels that have similar brightness, color, or texture tend to be grouped together. Conversely, sharp changes in one or more of these features signal boundaries between regions. This motivates edge detection—a technique based on marking boundaries where neighboring pixels have significant differences in brightness. This has a natural generalization to color. However, if objects are textured, such as a tiger against a grassy background, then brightness or color edges may be less useful than texture edges for finding object boundaries. These are found by computing descriptors of image patches centered at different pixels and computing the locations where these descriptors change most sharply. Examples of texture descriptors might be histograms of oriented edge responses or filters modeled after the responses of cells in the primary visual cortex of primates.

Similarity is only one of the factors that can promote grouping. Curvilinear continuity is another powerful grouping factor, suggesting linking edge segments whose directions are consistent with being along a smoothly curving contour. This is an example of progressing from local measurements to global groupings, for which a variety of mechanisms have been explored in computer vision.

Currently, the most effective techniques for going from local edge measurements to global segmentation decisions are based on mathematical formulations such as Markov random fields, or normalized cut techniques based on spectral graph theory. Markov random fields provide a probabilistic formalism—the goal is to find the most probable grouping based on a model that makes it more likely for pixels to be in the same group if their features are similar, and for neighboring pixels to be more likely to be in the same group. Spectral graph theoretic techniques have a different viewpoint—pixels are nodes in a graph, and edges between pixels have affinity weights that are measures of pixel feature similarity. The goal is to find groups that have high intra-group affinity and low intergroup affinity, which is done by finding eigenvectors of a matrix associated with the graph.

Quantifying the performance of these segmentation techniques can be done with benchmark datasets where human observers have marked the boundaries of the different objects. These reveal that current state-of-the-art algorithms, though much better than previous approaches, still fall short of human level performance. In many applications, such as, for example, in biomedical image analysis, an interactive segmentation approach is used where a human user provides hints to the computer program to complete the segmentation process. The long-term goal is to have fully automated approaches. Such algorithms would likely combine bottom-up processes driven by pixel similarity of brightness, color, and texture with top-down processes based on recognition of familiar objects to arrive at final segmentations of the image or video stream.

Recognition

Humans use vision to recognize people (“Barack Obama”), places (“Times Square”), objects (“chairs”), scenes (“beach”), and actions (“jumping”). Recognition can be of a category (“dog”), or of a specific individual (“my dog Rover”). Many actual and potential applications of computer vision are based on recognition. Examples include identification of humans by face recognition, detection of suspicious activities by surveillance cameras, searching for images of tigers on the Internet, organizing people’s personal photo collections, optical character recognition of ancient manuscripts, or finding a building entrance for a robot.

Recognition is challenging. There is enormous variability in the visual appearance of an object because of factors such as different poses with respect to a camera, differing shading patterns caused by variations in illumination, or for categorization tasks, the variation from one individual to another. Even identification of exactly the same person has to deal with, for instance, differences in clothing, effects of age, or the presence or absence of sunglasses.

Most computer vision approaches to recognition treat it as a problem of machine learning, specifically “supervised learning” or “pattern classification.” Consider the problem of detecting faces in an image, a capability that can assist automatic focusing in digital cameras. To learn to detect blocks of pixels in an image that contains faces, one must train a program to distinguish between positive examples (various images of faces) and negative examples (images of other objects such as chairs, trees, sky, etc.). Such programs are called classifiers, and they take as input a set of “features” derived from the portion of the image corresponding to the object. In the case of face detection, useful features might be the presence or absence of horizontally oriented dark bars roughly around the putative location of the eyes and mouth. The learning program has access to a large number of precomputed features; what it figures out is the weight, positive or negative, to assign to different features. There are a number of different methods for training classifiers such as neural networks, support vector machines, decision trees and nearest neighbors. Choices of features vary, but the most popular, such as the so-called scale invariant feature transform (SIFT) feature proposed by David Lowe, are based on spatial configurations of oriented edges, not too different from the representations that might be produced in the primary visual cortex of primates.

Continuing with the previous example because an image doesn't consist of just a single face, the face may be present at any location at an image, and it could be small or large (corresponding to the imaged person being far or near), the classifier has to examine candidate windows at different possible locations and scales. This is where image segmentation, if successful, could be of great help because it could directly pinpoint a small set of candidate locations and scales. Conversely, recognition, if successful, enables one to mark a region as corresponding to a single object. As mentioned earlier, the right approach will likely be a combination of top-down and bottom-up processing, a subject of much active research in computer vision.

Computer vision techniques for object recognition have a long way to go before they can approach the level of performance of humans. By 2009, leading approaches are able to distinguish among a hundred or more visual categories if objects were present in isolation, but performance degraded considerably when the objects are in scenes with multiple objects potentially occluding each other. Contrast this with humans who, it has been estimated, can distinguish on the order of 30,000 visual categories. There are some clear success stories of computer visual recognition, however: reading printed text, handwritten digit recognition for postal envelopes and bank checks, and face detection in general images. Progress in recent years has been rapid, aided by advances in computing power and the availability of large collections of images for training classifiers.

Reconstruction

The process of image formation, whether in the eye or in a camera, results in the loss of depth information. All points in the external three-dimensional (3-D) world that lie on a ray passing through the optical center are projected to the same point in the two-dimensional image. During reconstruction, we seek to recover the 3-D information that is lost during projection.

Humans use many different cues in the image or video stream, such as binocular disparity, optical flow, position on the ground plane, linear perspective, texture gradients, shading, and occluding contours to achieve this goal. In computer vision, researchers have developed algorithms for exploiting these cues with varying degrees of success.

Of these techniques, the most effective and widely used ones for 3-D reconstruction in computer vision are based on multiple views. For example, we might go around a building and take many photographs of it from different viewpoints. Key points are extracted from the different images, and their correspondences determined; that is, we match key points in the different views that correspond to the same point in the world. When the projections of a sufficient number of points in the world have been matched in multiple images, it is theoretically possible to deduce the 3-D locations of the points as well as the relative position and orientations of the cameras. These techniques have been applied in many different settings. Examples include the compositing of synthetic objects in natural scenes or vice versa for producing special effects in movies, the creation of computer models of real world objects and buildings for populating virtual reality environments, or the accurate 3-D tracking of cricket or tennis balls using multiple cameras for sports broadcasts.

Just as humans can recover 3-D information about a scene from a single image, based on so-called "pictorial" cues, there has also been work in computer vision on trying to exploit cues such as texture, shading, and contour in a single image.

- If the image contains visual texture, then assuming that the arrangement is periodic, or at least regular in a statistical sense, it is possible to recover surface orientation and shape from a single image.
- Shading, or spatial variation in the image brightness, is determined by the spatial layout of the scene surfaces, their reflectance properties, and the arrangement of light sources. If one makes some simplifying assumptions, then a number of techniques can invert the process and recover the surface orientation and shape.

- Even if the image is abstracted down to a line drawing, humans can infer 3-D shape. This results from a combination of cues. For example, upon recognition that the line drawing corresponds to a rectangular block shaped building, one can infer something about the 3-D orientations of the principal planes of the building. If objects are recognized as resting on a ground plane, then their two-dimensional (2-D) position on the image plane conveys their 3-D distance from the viewer. Higher objects, closer to the horizon on the image plane, are further away.

Current thinking on the problem of inference of 3-D structure from texture, shading, and contour tends to be in the framework of Bayesian inference. Given a single image, many possible 3-D worlds could project to the image. It therefore makes sense to choose the one that is the most probable, an insight dating back to Hermann von Helmholtz's notion of perception as "unconscious inference." The world we live in has certain statistical regularities—it contains distinct objects, they often rest on a ground plane, they often move rigidly, and so on. By modeling these in a probabilistic framework, we can start to exploit Bayesian inference methodology. This paradigm has proved to be quite productive in theorizing about human perception, but it should be noted that by 2009 computer vision algorithms for exploiting pictorial cues were still not as general and robust as those based on multiple view analysis.

Controlling Action

Vision is a superb sensor for motor control, and its evolution in animals had much to do with the survival advantages that resulted from it. J. J. Gibson's observation, "We see in order to move, and we move in order to see" captures this succinctly. Autonomously driven robots and cars need sensors for controlling locomotion, and vision and vision-like sensors (e.g., sonar, laser range finders) are obvious choices.

Note that a complete 3-D reconstruction of the external environment, though helpful, is not absolutely necessary. To see this, consider the task of driving a car on a freeway. The driver needs to

- Keep moving at a reasonable speed.
- Control the lateral position of the vehicle in its lane—make sure it stays in the middle and is oriented properly.
- Control the longitudinal position of the vehicle—keep a safe distance from the vehicle in front of it.

The information needed for lateral and longitudinal control is just a small part of that potentially obtainable from a complete 3-D reconstruction of the freeway environment.

This simplifies the task considerably. One can design feedback control laws using visual measurements, and, as far back as the 1980s, Ernest Dickmanns' group in Munich, Germany had demonstrated automated freeway driving using these principles. In 2004, 2005, and 2007, the Defense Advanced Research Projects Agency of the United States organized "grand challenge" races for robot vehicles, the first two in rugged outdoor terrain and the most recent in an urban street environment. No vehicles completed the 2004 race, but several were able to successfully complete the 2005 and 2007 races.

Self-driving cars are not the only examples of the use of visual sensing for motor control. Mobile robots have many present and future applications ranging from autonomous exploration of other planets, operating in hazardous environments, and, of course, the still-awaited household robot that would wash dishes, launder clothes, and vacuum the floor. Unstructured environments such as the home pose the greatest challenges, but potentially the biggest payoffs in settings such as elder care. Although laboratory demonstrations of hand-eye coordination tasks such as reaching, grasping, or insertion, have existed for quite some time, the home robot is still in the distant future.

Past and Future Progress

Computer vision is a field that, like many other areas of artificial intelligence, began in the 1960s in a phase of wildly irrational exuberance and optimism. By the 1970s, researchers had to confront the inevitable disappointment and to realize that the challenges were real and immune to quick fixes. Since then, computer vision has gradually assumed the character of other science-based engineering disciplines. Progress has resulted from geometric and statistical modeling, implementation of ideas and algorithms, accompanied by careful experimentation to determine what works and what does not. The steady advance of computing power, both in processor speed and storage, has helped, as has a healthy exchange of concepts and findings with psychologists and neuroscientists studying biological vision. This has resulted in a large number of successful applications, and progress in the field shows no signs of slowing down.

CONSCIOUSNESS

Twenty seconds ago, how did it feel in your right big toe? To answer this question, you probably direct your attention to that toe and become conscious of how it feels now. Then you guess that, 20 seconds ago, it probably felt the same. But, did you really have a conscious experience of that toe 20 seconds ago? Or did you have an unconscious experience that only became conscious after you attended? Or was there no toe experience conscious or unconscious before you attended? We are all so familiar with conscious experiences that we take them for granted. But even a simple question about the conscious feeling of a toe can raise perplexing issues. Indeed, consciousness is among the most controversial topics in science and philosophy, as discussed in this entry.

What Is Consciousness?

There is no widely accepted definition of *consciousness.* It is widely agreed, however, that consciousness is not synonymous with *mind,* because there appear to be many unconscious mental states and processes. Consider, for instance, the visual processes that underlie stereovision, which is our ability to see depth using both eyes. The processes involve sophisticated computations of small differences (called disparities) between the images at the left and right eyes, followed by computations of depth and shape from these disparities; we are conscious of the depth and shape, but not of the processes that compute disparities, depth, and shape. The auditory processes that underlie our ability to localize the position of a sound source require sophisticated computations involving differences in phase and intensity of the acoustic signals at the two ears; we are conscious of the location of the sound source, but not of the processes that compute this location. Such examples as these suggest that *most* mental states and processes are unconscious.

A mental state or process is conscious if there is something it is like to be in that state or engage in that process. For instance, what it is like to see a flat plate differs from what it is like to see a round cup, and both are conscious states. What it is like to hear a plane overhead differs from what it is like to hear a mosquito buzz your ear, and again both are conscious states. What it is like to consider a logical argument differs from what it is like to hesitate between pizza or sushi, and both are conscious processes. There is something it is like to see a ruby red grapefruit, endure a pounding headache, enjoy a promising idea, imagine the canals of Venice, feel elated or depressed, or dream that you are flying. Each is conscious or, as it is sometimes put, each has a *phenomenal character* with *phenomenal qualities,* that is, *qualia.*

It is helpful in the study of consciousness to classify conscious states at three levels of detail: boot, general, and specific. The *boot* level simply describes whether a person is conscious at all. Examples of a boot-level transition from the unconscious to the conscious include being awakened from a dreamless sleep, revived with smelling salts after a concussion, or brought up from general anesthesia. The *general* level describes a global quality of consciousness, such as being drowsy, alert, sober, drunk, in a dream, or under hypnosis. The *specific* level describes particular conscious experiences (particular qualia), such as the chirp of a sparrow, the smell of frying bacon, the feel of velvet, or the glisten of dew on a blade of grass.

Approaches to the Study of Consciousness

There are two broad approaches to the study of consciousness: philosophical and scientific. The two approaches interact profitably, but their methods are substantially different.

Philosophical approaches focus on conceptual issues raised by consciousness. These issues are primarily, though not exclusively, ontological and epistemological. The central *ontological* issue is the nature of consciousness and its place in the world. What is consciousness? How is it related to space, time, and matter? The central *epistemological* issue is how we can know whether something is conscious. I think I am conscious, and I believe you are as well. But how can I know for sure that you are conscious? And how do I know that I am conscious? How do I know that a rock is not conscious? These central issues spawn a variety of related issues and philosophical theories.

Scientific approaches construct theories that make specific empirical predictions, and test these predictions in controlled experiments. The theories address several key questions: Why, and how, are some mental states conscious or unconscious? How are the three levels of consciousness related to activity in the brain? These questions are studied from the perspectives of several fields, including cognitive neuroscience, computer science, and physics.

Scientific Approaches

What is the biological basis of consciousness? In 2005, the journal *Science* placed this question second in a list of the top 125 questions that are as yet unsolved. Most scientists who study consciousness are trying to answer this question. The reason for their confidence that there is a biological basis for consciousness is the large number of correlations between neural activity and conscious experience.

There is, for instance, in the occipital lobes of the brain a tight correlation between activity in the primary visual cortex (called area V1) and conscious visual experiences. If area V1 of the left hemisphere is destroyed, then conscious visual experience in the right half of the visual world is also destroyed; the person is blind in this half of the visual world. If smaller portions of V1 are destroyed, then conscious visual experiences in correspondingly smaller portions of the visual world are destroyed. Electrical stimulation of V1 is correlated with anomalous visual experiences.

Activity in visual cortical area V5 is correlated with the conscious experience of visual motion. If area V5 in the right hemisphere is damaged, then the conscious experience of motion in the left visual field is destroyed, a condition called hemi-akinetopsia. Activity in area V5 can be inhibited by appropriate magnetic fields generated by transcranial magnetic stimulation (TMS); this leads to temporary hemi-akinetopsia.

Most of the empirical work on consciousness involves careful study of such correlations, seeking to find, for a specific kind of conscious experience, a specific neural correlate of consciousness (NCC). An NCC for a specific kind of conscious experience is a minimal system within the brain whose activity is normally sufficient for the presence of that conscious experience.

Much of the theoretical work on consciousness involves proposing specific candidates for NCCs. Some proposals point to microscopic properties of individual neurons, such as coherent and incoherent quantum states in neuronal microtubules. Others point to certain brain areas, such as the claustrum, a thin layer of gray matter that lies below and parallel to the cortex. Still others point to patterns of neural activity that loop between the brain's cortex and a subcortical structure called the thalamus. The brain is a complex organ with many levels of organization, from the submicroscopic, to the synaptic, to the neuronal, to local neural networks, to more global interacting neural systems.

Theoretical work on NCCs tries to specify where in the brain a NCC is located and at what level of brain organization it operates. There is not yet consensus about location and level for any NCC.

Proposing candidates for the NCCs is only half of the theoretical enterprise for scientists studying consciousness. The other half is explaining why there are such correlations. If, for instance, an NCC is found for the conscious experience of the taste of dark chocolate, then the next step is to explain why the brain activity in the NCC is correlated with that taste. Does the brain activity *cause* the taste? If so, precisely how? Why does this brain activity cause the taste of chocolate but not, say, the smell of lemon? Why does this brain activity cause any conscious experience at all? There are not yet any scientific theories that try to answer such questions (this is sometimes called, for good reason, the *hard problem* of consciousness). The focus, for now, is on constructing descriptive theories of *what* the NCCs are, rather than explanatory theories of *how* the NCCs actually work.

Brain-Imaging Experiments

The empirical search for NCCs often employs brain-imaging technologies, such as electroencephalography (EEG) and functional magnetic resonance imaging (fMRI). EEG measurements of brain activity give excellent temporal resolution, on the order of 1 millisecond, but poor spatial resolution because each electrode reports the summed electrical activity of millions of neurons. fMRI measures brain activity indirectly, through changes in blood flow that are correlated with changes in brain activity; it provides better spatial resolution than EEG does, but poorer temporal resolution.

These techniques can be used, for instance, to search for NCCs associated with shifts in conscious experience during "binocular rivalry." Suppose one presents a homogeneous green field to the left eye and a homogeneous red field to the right eye. Subjects will report that they consciously experience the whole visual world as green for a few seconds, then they report that red starts to invade and eventually spreads until they consciously experience the whole visual world as red. The green and red experiences continue to alternate in an apparent competition for perceptual dominance, hence the name *binocular rivalry*. This is an ideal situation for studying the NCCs associated with a conscious shift in perceived color because the stimuli to the two eyes remain constant even at the moment that the conscious perception shifts. Thus, any brain activity correlated with the shift in conscious perception cannot be dismissed as resulting from a change in the visual stimuli.

Using fMRI, one can determine which brain areas have changes in activation that are temporally correlated with the subject's report of a perceptual shift. EEG can do the same job, but with an interesting twist. One can constantly flash the green stimulus at a certain temporal frequency, say seven flashes per second (7 hertz [Hz]), and at the same time flash the red stimulus at a different frequency, say 14 Hz. The neural systems that process the green stimulus will have activity at many different temporal frequencies, but they will have considerable activity at 7 Hz; similarly, the neural systems that process the red stimulus will have considerable activity at 14 Hz. Thus, this frequency serves as a tag, to let the experimenter know what color a particular neural subsystem is processing. When the subject reports a shift in perceived color, one can then look for brain areas in which there is, at the time of report, a shift in the frequency tag. These areas are candidates for the NCC of the shifts in color experience.

Philosophical Approaches

Is there a relationship between biology and consciousness? This is a key question asked by many philosophers who study consciousness. Notice that this question differs from the question asked by the journal *Science,* namely, What is the biological basis of consciousness? The *Science* question assumes that there is a biological basis of consciousness. The philosopher questions this assumption, and asks whether there is a biological basis of consciousness. Maybe consciousness arises not from biology, but from physics. Or perhaps consciousness and biology exist side by side, neither arising from the other. Or perhaps physics and biology arise from consciousness. There are many possibilities, and philosophers debate their relative merits using logical arguments, thought experiments, and appeals to the best current evidence from science.

One thought experiment that is widely discussed concerns the possibility of philosophical zombies: Is it possible that there could be a person who is atom-for-atom identical to you, who walks, talks and, in every way, behaves just as you would, but who is utterly without conscious experiences? If this zombie were pinched, it would wince and cry just as you would, yet it would experience no feelings of pain.

Some philosophers claim that such zombies are logically possible. This would mean that consciousness is not determined by the physical facts or functional properties of an organism because these facts and properties are shared by the original and its zombie. Instead, consciousness would be something extra beyond the physical and functional. It would also mean that consciousness could not be shaped by natural selection because natural selection can only select among options that make a functional difference to the organism's reproductive fitness; if zombies are possible, then consciousness makes no functional difference, and hence no functional difference in reproductive fitness.

Other philosophers claim that zombies are not logically possible. Once you have specified the physical facts and functional properties of an organism, then all the facts about consciousness are also fixed. Many philosophers in this camp are reductive functionalists, who claim that consciousness is *identical* to certain functional properties. In organisms, these functional properties are most likely properties of the nervous system, but other systems, perhaps sophisticated computers, having internal functional states, could be conscious. According to the reductive functionalist, these functional states do not *cause* consciousness, they *are* consciousness; in the same way, 12 does not cause a dozen, it is a dozen. The reductive functionalist is thus exempt from the duty of explaining how functional properties cause consciousness. Instead, this functionalist must give a principled account of why certain functional states are conscious and others are not. No such accounts are widely accepted yet.

Still other philosophers claim that we are all zombies, and that none of us has any conscious experiences. Our belief that we are conscious is an illusion, perhaps caused by certain computational processes in the brain that monitor the states of other brain processes. Few philosophers are willing to defend this view. Most admit that we are not infallible about our own conscious experiences, and that we can at times be wrong about what we think we are experiencing. But few are willing to make the stronger claim that we are so wrong that we are in fact zombies: If we are that wrong about conscious experiences, is there anything we can be reasonably sure about?

Historical Perspective

The modern philosophical study of consciousness is usually traced to the work of René Descartes (1596–1650), who proposed *substance dualism,* the doctrine that there are two kinds of substance in the universe: physical substance and mental substance. According to Descartes, each human being is a composite of both substances, and they interact in the brain at the pineal gland. Few professional philosophers or scientists now advocate substance dualism, although a version of it was defended by Karl Popper (1902–1994) and John Eccles (1903–1997) in their 1984 book, *The self and its brain.*

George Berkeley (1685–1753) proposed a version of *idealism,* the doctrine that only consciousness exists, and that what we call the physical world is really the contents of conscious experience. Idealism was developed further by Immanuel Kant (1724–1804) and Georg Hegel (1770–1831), and enjoyed substantial popularity in the late 19th century.

Critiques of idealism by Bertrand Russell (1872–1970) and G. E. Moore (1873–1958) contributed to a decline in its influence. In its place, the dominant view became physicalism, the doctrine that all that exists is the physical world and that consciousness is caused by, emerges from, or is a property of certain physical systems. This switch was particularly striking in the field of psychology. The classic 1890 book, *Principles of Psychology,* by William James (1842–1910) freely discusses consciousness and the hard problem of its relationship to brain activity. But the behaviorist psychology of William Thorndike (1874–1949) and B. F. Skinner (1904–1990) restricted itself to the physical vocabulary of stimulus and response and considered consciousness to be an unsuitable topic for scientific study. Behaviorism was superceded about 1960 by more cognitive approaches to psychology, and consciousness once again became a topic for active scientific study about 1990. Most of the current scientific and philosophical work on consciousness assumes that some version of physicalism is true, and takes seriously the hard problem of explaining how conscious experiences could arise in a purely physical world.

Future Research

Empirical investigation of the neural correlates of consciousness is currently the most active area of consciousness research. It promises to remain so, largely because of the complexity of the brain, with its billions of neurons and trillions of synapses, and because of the complexity and variety of conscious experiences.

This will continue to be complemented by theoretical work that tries to explain how neural activity can cause, or give rise to, conscious experiences. Progress on this problem has been remarkably slow, with no theory yet proposed that has the minimal explanatory power expected of a genuine scientific theory. Current theories are sketches, serving primarily to suggest directions where a genuine theory might be found: perhaps quantum states of microtubules, or perhaps looping patterns of neural activity between the thalamus and cortex, or perhaps the informational complexity of neural activity. This promises to be an active area of research, with big new ideas needed for its solution.

The precise relationship between consciousness and attention is controversial and promises to be an active area of research. Are they in fact identical? If not, can there be attention without conscious experience, or conscious experience without attention? Is attending to your right big toe identical to having a conscious experience of that toe, or do you have a conscious experience of that toe even when you are not attending?

Also controversial is the relationship between the self and conscious experience. Does consciousness require a self? Can there be conscious experiences without an experiencer? Can there be an experience of the smell of garlic without a self that experiences that smell? If a self is required for consciousness, why is this the case and what is the nature of the self?

As these examples indicate, research into consciousness is highly multidisciplinary, spanning philosophy, neuroscience, cognitive science, computer science, and physics. The insights that emerge will transform our understanding of human consciousness, and therefore of human nature and its place in the world.

CONSCIOUSNESS: DISORDERS

As far as we know, a living being without a brain cannot have conscious experiences. But are certain parts of the brain more critical for conscious awareness than others? More specifically, how might disorders of perceptual consciousness after damage to the human brain inform the scientific world about relationships between neural systems and conscious perceptual awareness? In many cases, the loss of awareness is accompanied by indications that "invisible" information is nevertheless still being processed by the visual cortex. Studies of neuropsychological disorders of perceptual consciousness have shown that the primary visual cortex is neither necessary nor sufficient to account for perceptual awareness. This entry describes blindsight, unilateral visual neglect, Bálint's syndrome, visual agnosia, and further issues relating to consciousness disorders.

Blindsight

Blindsight refers to the unconscious detection of features that are not consciously perceived because of damage to the primary visual cortex. It was first reported in 1977 by Larry Weiskrantz. He collected evidence from a man who had undergone neurosurgery to remove a tumor from his primary visual cortex. The surgical procedure left the patient blind in the visual field opposite the affected hemisphere (contralateral). The primary visual cortex is the cortical entry point for most of the visual information received from the eye. It is located at the back of the brain with the right primary cortex receiving visual information from the left visual field (to the left side of fixation) and the left primary cortex receiving visual information from the right visual field (to the right side of fixation). The patient Weiskrantz studied lost his right primary visual cortex and saw nothing to the left of where he was currently looking, although, if the visual scene remained stable, he was able to compensate for his visual loss by moving his eyes. Thus, to probe his remaining visual abilities, he was tested by presenting stimuli briefly before he had time to move his eyes, thereby moving the stimulus into his good visual field.

Weiskrantz showed that after a light was briefly flashed in the patient's bad visual field, he was able to move his eyes to its previous location, or point at it much more accurately than if he had been guessing. Yet guessing is exactly what he reported he was doing; consciously, he saw nothing. Further testing revealed that he could discriminate the orientation of simple lines as well as the direction of moving dots above chance levels, although again, he denied seeing anything. Weiskrantz called this condition blindsight. At first, questions were raised, attributing the results, for example, to light scatter into good areas of the visual field, remaining pockets of the cortex, or undetected eye movements. However, in most patients, these alternative accounts have been ruled out.

Accepting that blindsight is a genuine phenomenon, what implications follow for the neural basis of consciousness? Does blindsight mean that the primary visual cortex is necessary for perceptual awareness of visual information? Other pathways for visual information to the cortex are known (e.g., superior colliculus to the frontal eye field; pulvinar and its connections to the posterior visual association cortex), but the fact that blindsight results from lesions of the primary visual cortex suggests that these other pathways are (at least initially) insufficient to support conscious visual awareness. One interesting question is whether other visual pathways can be trained to mediate conscious experience. Some patients with primary cortex lesions have shown spontaneous recovery of conscious vision, even after years of blindness, and monkeys, after full ablation of the primary visual cortex, have been trained to show improvements in visual discrimination. In a recent review, Tony Ro and Robert Rafal suggest that this evidence, at least in part, reflects learned access to visual awareness through pathways from the superior colliculus to cortical areas. Animals with lesions of both the visual cortex and the superior colliculus do not regain vision after training. These findings imply that visual awareness is at least partly a learnable skill. Normally, the salient information coming from the primary cortex dominates conscious visual experience, but, when that is removed, information normally used for other purposes (e.g., the planning of eye movements) can eventually create conscious experiences. One question that remains unanswered is the degree to which regained conscious experience is similar to normal conscious experience.

Blindsight has also been studied to address more cognitive questions, such as whether selective attention can influence unconscious processes. Some argue that attention and consciousness are so closely related that they may be the same thing. For instance, ignoring an item in a visual scene is an active process, but there is continued awareness that that item still exists and can become the focus of attention on demand. But if selective attention could also affect unconscious perception in blindsight, consciousness and attention would be separable processes. In a study by Robert Kentridge, a patient's attention was drawn to a particular location in his blind field (by an arrow in his seeing field pointing to a blind field location). The patient was faster to correctly guess the orientation of an unseen line when the cue pointed to the location of the line than when it pointed elsewhere. Thus, attention facilitated his response to an unconscious stimulus, ruling out the hypothesis equating attention with consciousness

Unilateral Visual Neglect

Blindsight patients see nothing in the area corresponding to the damaged area of the cortex, but they still understand that that area of space exists. A quite different type of problem, known as unilateral neglect, occurs when damage includes the parietal lobe (usually in the right hemisphere). In these cases, it is as if the left side of the world no longer exists, either because it is not adequately represented in an internal spatial framework or because it is no longer attended. Neglect patients ignore objects in the left visual field, even a $20 bill waved in front of them! They may leave the food on the left side of their plate or shave only the left side of their faces. They draw only half of an object (e.g. a clock, a tree, or a house). Neglect can affect other sense modalities besides vision. One woman hopped around on one leg even though her other leg worked fine. When asked why, she said, "How else can I get around?" Although blindsight shows that the primary visual cortex is necessary for conscious experience (at least in the early stages of blindness), unilateral neglect shows that it is not sufficient to support conscious perceptual experience.

As in blindsight, several studies have shown that undetected visual information presented in the neglected field can influence behavior. For instance, studies have shown that stimuli presented in the "bad" field on one trial (e.g., a drawing of a baseball bat) will prime (speed up) responses to a related stimulus presented subsequently in the good field (e.g., the word *sport* compared with *banana*). Jon Driver and his colleagues have shown that the organization of stimuli placed in the bad field can affect how a pattern is perceived in the good field. For example, "unseen" cues to depth can influence the perceived depth on the good side. Failure to detect stimuli in these cases means that the patient reports seeing nothing there at all.

A straightforward account of unilateral neglect is that attention can no longer move to the side of space opposite the damage. But the straightforward explanation runs into difficulty. For instance, when asked to copy the drawing of a plant with two flowers (one on the left and one on the right) planted in a single pot, a patient with left neglect drew the right half of the picture, leaving out half the pot and the left branch completely, as he would if neglecting the left side of space. But when the experimenter removed the pot and the shared stem by cutting off the bottom part of the picture, the patient drew the right side of each flower. In other words, he neglected the left side of each separate object, not the left side of space. If you move a picture behind a slit so that attention and vision are focused on a single narrow area of space, patients still neglect the left side of the object, although it is distinguished from the right only by being visible at a different time. So the brain converts time into space and then neglects the left side of the reconstructed image! To do this the brain must first "see" the whole object so that the brain can then suppress its left side.

There are some other exceptions to the claim that all stimuli presented on the neglected side are undetected. With other colleagues, Lynn Robertson showed that a unique feature, like a red circle in an array of many green and blue items, can be relatively easy to detect on the "neglected" side, whereas combinations of two features, such as a red circle among green circles and red triangles (i.e., a unique conjunction of features) is not. These findings are consistent with a theory of attention that Anne Treisman proposed in the late 1970s (feature integration theory). She suggested that unique features could be detected without attention or awareness of the spatial locations of those features, but conjunctions of two or more features required focused attention to their locations. For example, when looking for one's blue car in a parking lot, detecting that there is something blue in the visual scene does not require knowing where the blue is located, but identifying it as a blue car does. The data from patients with unilateral neglect demonstrate that the intact primary visual cortex is sufficient to support the perception of unique features, but that focused attention, controlled by the damaged hemisphere, is needed when these features must be bound together.

Is there a conflict here with the priming effects described earlier? Wouldn't the (unconscious) perception of a baseball bat require the integration of lines, curves, and angles? Perhaps the integration of different dimensions such as color and shape requires spatial awareness but the integration of curves, lines, and angles to form an object does not? If so, are there spatial maps below the level of awareness that support some types of integration but not others, and why are these not sufficient for conscious access of their content? Results from patients with spatial awareness deficits suggest that such maps exist, but research is needed to understand their nature and what neural mechanisms can be engaged to access them for consciousness.

Bálint's Syndrome

Unlike unilateral neglect, which results from damage to one side of the brain, Bálint's syndrome is caused by parietal damage to both sides. This syndrome is rare, and the experimental literature is generally limited to single case studies. Nevertheless, findings are generally consistent. Patients with Bálint's syndrome are functionally blind in both visual fields. When the syndrome is severe, patients left on their own will bump into walls and objects in the room, or ignore a fork at the side of a plate. They are unable to navigate from one room to another within their own homes or to do anything that requires accurate spatial information in the external world. When tested on spatial discriminations, they are unable to locate an object, whether through reaching, pointing, or verbally reporting. This is not a loss of the meaning of spatial terms because the patients can still locate touches on their own bodies.

Patients with Bálint's syndrome are not completely blind. They can see a single object, which may or may not be the object at which they are looking, but they act as if other objects are not present. Another puzzling fact is that the one object they see is usually seen as a whole, regardless of whether it is complex or simple, large or small. The famous Russian neuropsychologist Alexander Luria drew two circles side by side on a sheet of paper and asked a patient with Bálint's syndrome to tell him what he saw. The patient reported seeing one circle but could not see the other, even when prompted. Luria then showed the same two circles connected by a line and asked the same question. The patient now reported seeing "spectacles." Connecting the two circles changed his perception from one circle to one pair of eyeglasses.

Although it was originally thought that the same area of the parietal lobe was critical in producing unilateral neglect and Bálint's syndrome (the only difference being a lesion in one versus two hemispheres), reviews of the literature suggest that different areas of the parietal lobe are involved. Unilateral visual neglect is most often associated with parietal areas (supermarginal gyrus) that are somewhat in front of those associated with Bálint's syndrome (angular gyrus). This anatomical distinction is accompanied by differences in visual experience. Although patients with unilateral neglect miss parts of objects on the neglected side, patients with Bálint's syndrome perceive a whole object but lose its spatial relationship to other objects. Also, patients with unilateral neglect usually report the location of objects accurately once they detect them, but those with Bálint's syndrome cannot. Both syndromes disrupt spatial awareness, but in different ways.

A disruption of spatial awareness means that spatial attention is also disrupted in both syndromes. It follows that feature integration should be deficient, and single-feature pop-out should remain relatively intact, and research has confirmed this prediction. The Bálint's patient that Robertson and Treisman studied also made many "binding" errors. For example, if they showed him a red X and a blue T, even for as long as 10 seconds, he frequently reported seeing either a red T or a blue X. However, again evidence indicates that the deficits may be primarily in conscious experience. Studies using priming measures demonstrated that the locations of unique features were processed preconsciously, although they remained inaccessible to perceptual experience. M. S. Kim and Robertson instructed a Bálint's patient to make a speeded response whenever an arrow appeared at the center of the screen where he was looking. Unbeknownst to the patient, a feature display appeared simultaneously in the periphery. When the arrow pointed to the unique feature, response times were faster than when it pointed to one of the other items in the display.

Visual Agnosia

Whereas the visual pathways through the dorsal areas of the human cortex, including the parietal lobe, appear to deal primarily with spatial representation, the pathways through ventral areas, including the temporal lobes, seem more involved with object perception. Lesions in the occipital and temporal lobes can produce striking deficits in awareness and recognition of objects. These deficits are known as agnosia. Patients with agnosia are not blind—they see the visual features of the objects present but they are unable to make sense of them or to recognize what they see. One such patient with lesions in both temporal lobes was studied by David Milner and Melvin Goodale. When they showed her a paper card and asked her what it was, she was unable to say that it was a card or to see which way it was oriented. Yet when they presented a slit, like in a mailbox, and asked her to post the card, she immediately rotated it to the correct angle to pass through the slit. Her hands seemed to "know" something that her mind did not. The neurologist Rafal filmed another patient with visual agnosia who was unable to recognize objects. When the patient was shown a picture of a clarinet, he hesitated in naming it, suggested it was a "pencil," but meanwhile his fingers began to play an imaginary clarinet. These are cases where a patient seems both to see something and not to see it—to know something and not to know it at the same time.

Are these fragmentations of knowledge just some peculiarity of damaged brains, or do normal people show any comparable separation between knowledge for conscious perception and knowledge for action? Goodale showed that some visual illusions that affect conscious perception of objects might have no concomitant effect on motor interactions. For example, an illusion that induces conscious perception of increased size has no effect on the size of the gap between observers' fingers when they pick up the object. As in the patients, the brain areas that control grasping seem to use different information from those that determine what is consciously seen.

Further Issues

Neuropsychological disorders of spatial awareness are also relevant to philosophical debates. Immanuel Kant argued that there could be no intuition about the external world without the cognitive constructs of space and time. The research discussed in this short essay demonstrates that spatial concepts can disappear, yet simple features can still be perceived. The impact of the loss of space on the control of spatial attention also has implications for understanding object perception. Conscious representations normally bind features into integrated wholes, but without spatial attention, the binding can be lost, and only the features are correctly perceived, supporting a particular role for spatial attention in perceptual awareness.

Damage to higher levels of the ventral visual pathway yields new puzzles about consciousness. We think of ourselves as unitary identities with single organized minds. We either see the clarinet or we don't. Yet, evidence from both patient and healthy populations casts doubt on this unitary notion of individual cognition. The metaphor of an organization seems to fit much better with these dissociations between parts knowing and other parts not knowing particular things. Like the CIA, the brain seems to have information floating around in different offices and different files, not all of it accessible to every subsystem or usable for every purpose. Shapes can be used to shape one's fingers, while being verbally described inaccurately—or the reverse. The information that becomes conscious may be the information that makes a coherent organized story about what is happening, bringing together selected relevant facts from many different specialized subsystems, but leaving the detailed evidence for those conclusions and the detailed implementation of the selected actions to unconscious processors.

CONSTANCY

An important function of perceptual systems is to accurately determine *object properties*—physical properties of objects that remain constant. For example, an object's shape, size, and reflectance (fraction of light and spectral distribution of light reflected from the object) typically remain constant and so are considered properties of the object. Examples of object properties (with the object properties *italicized*) are a *brown* cat, a *six-foot-tall* person, a *rectangular* door. *Perceptual constancy* refers to the perception of these object properties as remaining constant even when things such as illumination, distance, and viewing angle cause changes in the stimulation these objects present to the receptors. For example, as a rectangular door swings open, the image it casts on the retina changes from rectangular, when the door is viewed straight on, to a family of trapezoidal shapes, as the door is viewed at different angles.

Perception of the door as remaining rectangular even as viewing angle changes is an example of shape constancy. The ability to perceive properties of objects as unchanging in the face of changing stimulation is an important adaptive property of perception, because it is important for organisms to be aware of the stable properties of the environment. The world would be a confusing and difficult place to cope with if we perceived everything as constantly changing. The person or animal that perceives a charging lion as small when it is in the distance, and as becoming large only when it is upon them, is not likely to survive to perceive another lion! This entry describes perceptual constancy by describing examples of constancy in vision, touch, and olfaction.

Size Constancy

Size constancy occurs when an object's perceived size remains constant even though the object is viewed from different distances. For example, as a person walks away from an observer, the size of the person's image on the retina gets smaller, but the person don't appear to shrink as he walks away, except perhaps at extreme distance. A 6-foot-tall person is judged to be about 6-feet tall when viewed at a distance of 3 feet and when viewed from 12 feet, even though image on the observer's retina is only a quarter as large at 12 feet.

One explanation for size constancy is a "taking-into-account" mechanism that proposes that the perceptual system takes distance into account. The idea of a link between size constancy and distance perception has led to the proposal that size constancy is based on a mechanism called size-distance scaling that operates according to the equation $S = K (R \times D)$, where S is the object's perceived size, K is a constant, R is the size of the retinal image, and D is the perceived distance of the object.

According to the size-distance equation, as a person walks away from an observer, the size of the person's image on the observer's retina, R, gets smaller, but the observer's perception of the person's distance, D, gets larger. Because these two changes balance each other, the net result is that size perception remains constant. This explanation for size constancy is also called the size-distance invariance hypothesis.

A classic experiment by Albert Holway and Edwin Boring investigated the effect of perceived distance on size perception by having observers adjust a comparison stimulus to match the sizes of test stimuli presented at different distances, and by manipulating observers' ability to perceive the distances of the test stimuli. When observers were able to perceive distance accurately, they adjusted the size of the comparison stimulus to correspond to the physical size of the test stimulus, no matter what the distance. In other words, they accurately perceived the sizes of stimuli presented at different distances. However, when information for distance was eliminated, so it became more difficult to accurately perceive the distances of the test stimuli, estimates of the sizes of the test stimuli became less accurate. The conclusion from this experiment and others like it is that size constancy is most likely to occur when distance can be accurately perceived.

Another source of information that can result in accurate size perception independent of the size of the retinal image is relative size—comparing one object to a familiar object with known size. For example, seeing a person standing next to the door to a room will usually (unless the door is atypically small or large) provide information about the person's height. A related example, which also involves comparison to the surroundings, occurs as a person walks away from an observer inside a room. If the person is 6-feet tall and the room has 12-foot high ceilings, the person's height relative to the height of the ceiling remains a constant fraction of the height of the ceiling (6/12 = 0.5 in this example), no matter where the person is in the room. (See Table 1 for a summary of conditions that are involved in size constancy, as well as for the other types of constancy described in this entry.)

Shape Constancy

Shape constancy occurs when perceived shape remains constant as viewing angle changes, as in the example of the door viewed from different angles. Robert Thouless called this constancy of shape perception "phenomenal regression to the real object." The explanation for shape constancy is similar to that for size constancy—observers consider the object's slant. This idea is supported by the results of experiments that show that eliminating information for slant makes it more difficult to accurately judge an object's physical shape.

Lightness Constancy

Lightness constancy occurs when the perceived lightness of a surface (where lightness varies along the dimension, white, gray, black) remains constant as the intensity of illumination is changed. For example, a black Labrador retriever appears black inside a room and still appears black when it is outside in sunshine, even though far more light is reflected from its coat when in sunshine.

When lightness constancy occurs, the perception of lightness is determined not by the illumination hitting an object, but by the object's reflectance. Objects that look black reflect about 5% of the light. Objects that look gray reflect about 10 to 70% of the light (depending on the shade of gray),

Table 1 Perception and Stimulus Conditions for Different Types of Constancy

What remains constant	*What is varied*	*Change in receptor stimulation*
Size	Distance	Image on retina gets smaller as distance increases
Shape	Slant/viewing angle	Image on retina changes shape as object is viewed from different angles
Lightness	Intensity of illumination	Stimulation of receptors increases as illumination increases
Color	Spectral distribution of illumination	Ratio of activation of different cone receptors changes when spectral distribution of light changes
Roughness	Speed of scanning with the fingers	More texture is scanned per unit time as scanning speed increases
Olfactory intensity	Magnitude of sniffing	More molecules of odorant stimulate olfactory receptors as sniff magnitude increases

and objects that look white reflect 80 to 95% of the light. Thus, when lightness constancy occurs, our perception of an object's lightness is related not to the *amount* of light that is reflected from the object, which can change depending on the illumination, but on the *percentage* of light reflected from the object, which remains the same no matter what the illumination.

One explanation for lightness constancy is that when illumination changes, the ratio of the amount of light reflected from neighboring objects in a scene remains constant. For example, if the print on the pages of a book reflects about 5% of the illumination and the white paper of the page reflects 90%, then if the illumination is relatively dim, as occurs inside a room (say 1,000 for the purposes of this example), then the print reflects 50 units of light and the white page 900. However, when the illumination is high, as occurs when in bright outdoor illumination (for example, when illumination is 100,000), then the print reflects 5,000 units of light and the white page reflects 90,000 units. Note that the black print reflects more light in the bright illumination than the white paper reflects in dim illumination, yet the print still looks black. This constancy of lightness perception can be attributed to the fact that the ratio of light reflected from the print and paper remains constant at 5/90 = 0.55, no matter what the illumination.

Another mechanism that plays a role in lightness constancy is the observer's awareness of the conditions of illumination. For example, lightness constancy breaks down when an object is illuminated by a hidden light source. In a situation such as this, a piece of black paper (that reflects 5% of the light) can appear light gray or white if it is the only object visible and is illuminated by a hidden source. When this occurs, the hidden illumination is causing an erroneous perception of a change in object property—normally black paper is perceived as white.

Experiments have also shown that the perception of lightness can be influenced by the interpretation of how light is falling on a three-dimensional object. For example, if light appears to be illuminating one side of a building and the other side is shaded, observers can account for the illumination conditions and so avoid perceiving the more intensely illuminated side of the building as having a different object property (being constructed with lighter colored bricks, for example) than the shaded surface is.

Color Constancy

Color constancy occurs when the perceived color of an object (where color includes perceptions such as blue, green, yellow, orange, red) remains constant even when the spectral distribution of light is changed. For example, a green sweater continues to appear green when illuminated by an old-fashioned light bulb that has a yellowish hue because it is relatively rich in long-wavelengths, and appears green when viewed in daylight, which has an even distribution of wavelengths across the spectrum. The wavelengths actually reflected from the sweater depend on both the reflectance curve of the sweater—green objects typically reflect more light in the middle of the spectrum—and the wavelength distribution of the light illuminating the sweater, but when color constancy occurs perception is determined primarily by the object's reflectance curve.

As for lightness constancy, color constancy has been shown to be affected by the availability of information indicating the nature of the illumination, and color constancy is most robust in environments or displays that contain a number of objects with a range of different spectral reflections, and when the illumination contains a wide range of wavelengths, as normally occurs under normal indoor or outdoor illumination. An example of a breakdown in color constancy is the distorted colors perceived when objects are viewed under lights such as sodium-vapor lights that emit only a narrow band of wavelengths.

Color constancy is enhanced by a process called selective adaptation. For example, when objects are illuminated by a light bulb that emits light with relatively more long wavelengths (so the bulb looks yellowish), the long wavelength illumination adapts or decreases the responses of retinal receptors that are sensitive to long wavelengths. This decreased sensitivity to long-wavelength light acts to prevent objects illuminated by this light from taking on a yellowish hue.

Another mechanism of color constancy is memory color—the effect of memory for the color of familiar objects on color perception. Research has shown that perception of the colors of familiar objects such as a red stop sign or a green tree, are richer and more saturated than the colors of unfamiliar objects that reflect the same wavelengths.

Roughness Constancy

Moving the fingers over a textured surface such as sandpaper results in the perception of roughness. Roughness constancy occurs when the roughness of a surface perceived by scanning the fingertips across a surface remains constant even when the speed of scanning is varied. Experiments in which roughness is estimated for different scanning speeds show that roughness for coarse textures (but not for fine textures) is relatively unaffected by the relative speed of motion between a surface and the hand or fingers. This occurs even though high scanning speeds result in more units of texture being sampled per unit of time, and faster firing rates of neurons that fire to textures. The exact mechanism responsible for roughness constancy is not clear, but two possibilities are that even when the speed of scanning changes, the relative amount of skin deformation may remain the same for a particular roughness. It is also likely that observers are aware of moving the hand at different speeds, and so can account for the speed of movement.

Odor Intensity

Constancy of odor intensity occurs when the magnitude of an olfactory stimulus is judged to remain the same whether the odorant is sniffed gently or vigorously. This was demonstrated by Robert and Martha Teghtsoonian and coworkers, who first showed that when subjects are presented with different concentrations of odorants, they rate the higher concentration as smelling stronger. This result is consistent with the idea that perceived odor is a function of the concentration of odorant molecules that are available to the receptors. However, constancy was then demonstrated by instructing half of the subjects to sniff a particular concentration weakly and half to sniff it strongly. When subjects did this, the strength of sniffing had no effect on their estimates of odor intensity. Thus, for a given odorant concentration, subjects produced the same estimate for weak sniffs and for strong sniffs. This occurred even though more odorant was delivered to the receptors for the strong sniffs compared with the weak sniffs and suggests that subjects are taking sniff intensity into account.

The ability to take sniff intensity into account is adaptive because it increases the chances that subjects will be able to accurately sense the concentration of an odorant, without being misled by different sniff intensities that they might use in different situations. They can also regulate sniff intensity to avoid excessive intake of hazardous odors. By sniffing strongly to detect weak odorants and weakly to sample strong, possibly toxic, odorants (which might pose a hazard if sniffed too vigorously), they can still tell that one odorant is weak and the other is strong.

Degree of Constancy

Constancy is not always complete. For all of the examples described, changes in perception of object properties can occur in response to changes in receptor stimulation. For example, changing the illumination on a piece of paper that looks white in bright illumination might cause it to look slightly grayer. However, the change in perception is generally less than would be expected from the magnitude of the change in receptor stimulation, an effect called *partial constancy*. Even though constancy can be "partial," it still serves an important adaptive purpose, by keeping our perception of object properties relatively constant and preventing our perceptual world of shapes, sizes, lightness, colors, and textures from changing every time the conditions of stimulation change.

CONTENT OF PERCEPTUAL EXPERIENCE

Suppose a subject recognizes George Washington on a dollar bill. It is an open question whether this is part of the subject's perceptual (in this case, visual) experience that the person depicted is George Washington, or whether all that is visually experienced are colors and shapes, with the judgment that it is George Washington occurring farther downstream (later in the perceptual system). According to *Thin* views about the contents of visual experience, these contents are limited to color, shape and illumination. According to *Rich* views, the contents of visual experience can involve more complex high-level features in addition to color, shape, and illumination, such as personal identity (George Washington), kinds (banana, truck), semantic properties (meanings of words), and causation. Rich views thus posit more informational richness in the contents of visual experience than do Thin views. If Rich views are correct, then even if some visual experiences are thin (such as the experience of looking out of an airplane window into a clear blue sky, with nothing else in your peripheral visual field), visual experiences *can* represent that someone is George Washington, or that an object is a truck, or that the ball's collision with the apple caused the apple to move. If Thin views are correct, in contrast, then visual experiences can represent only that there is a layout of colored shapes, variously illuminated, where some part may be moving.

The debate between Thin and Rich views affects the search for neural correlates of visual consciousness. Antecedently held assumptions about whether visual experience is Rich or Thin may influence what researchers are prepared to count as a neural correlate of visual consciousness. If contents are Thin, then the neural correlates are more likely to be limited to early visual areas, such as V1 or V5. If contents are Rich, then the neural correlates are more likely to involve later areas, such as the inferotemporal cortex and the fusiform face area.

The debate between Rich and Thin views interests psychologists because it is relevant to what the neural correlates of visual consciousness are, and on what cognitive processes are inputs to the underlying structures that give rise to visual consciousness. It is also relevant to the structure of disorders such as agnosia, in which subjects can see ordinary objects but cannot recognize them. If the Rich view is true, then agnosia may involve impoverished visual consciousness. If the Thin view is true, then agnosia may be a disorder downstream of visual consciousness, rather than a disorder involving visual consciousness itself. Finally, the debate is relevant to the cognitive structure of delusions such as Capgras syndrome, in which patients take a loved one to be an impostor. If a Rich view is true, so that visual experiences may represent such properties as "being an impostor," then Capgras syndrome may be a normal response to an abnormal experience, consisting in taking things to be the way they appear in the (abnormal) experience. If a Thin view is true, in contrast, whether or not the visual experience of Capgras sufferers is itself abnormal, the response to the experience almost certainly is abnormal. In that case, the disorder would consist of the abnormal response to evidence, perhaps in addition to an abnormal evidential base.

To philosophers, the debate between Rich and Thin views is of interest because of its impact on epistemological issues concerning the evidence provided by perception. If a Rich view is true, then there are likely to be top-down influences on visual consciousness by mental states preceding perception, such as emotion, mood, desire, and beliefs. If such influences are pervasive, then the idea that our perceptual inputs are unaffected by antecedent mental states is probably false. Although some top-down influences may help us perceive what we would otherwise be blind to (as when a radiologist sees a tumor on an X-ray), others may be epistemically pernicious (as it would if a depressive's expectation that everything will look gray influences her experience, so that indeed everything ends up looking gray).

The case of causation illustrates both the debate between Rich and Thin views, and the difficulty in settling it. Whereas a Rich view allows that visual experience can represent that the ball's movement causes the apple's movement, a Thin view will say that only succession of movements is represented in visual experience. In a series of experiments published in the 1960s, Albert Michotte showed adults a range of scenes that elicited causal descriptions. Many of these scenes consisted in "launching": an object A moves toward a stationary object B, makes contact with B, and immediately afterward B starts moving in the same direction as A was moving at the time of contact (see *Causality,* Figure 1). Through an extensive series of experiments involving a wide range of stimuli (including shadows, moving lights, marks on paper, and hefty objects), Michotte tried to isolate the parameters of motion that led adults to classify what they saw as causation. He discovered that even when A or B or both are lights or shadows, adults report that object A *launches* object B exactly when the separate motions of A and B are consistent with a single motion that is transferred from A to B. This led him to posit an "impression of causation" because subjects knew that shadows and lights cannot launch anything.

Though these results are suggestive, they do not conclusively favor Rich views over Thin ones. To get from Michotte's results to a Rich view, what's needed is a principle linking verbal reports to the contents of visual experience. That the verbal report mentions causation does not show that the visual experience represents causation, without some further principle indicating that the reports are reports of experiences, rather than reports of a mental state downstream of experience. For all Michotte's results show, visual experiences may represent the spatiotemporal parameters of motion that elicit causal reports, rather than representing causation itself. If so, then experiences in the launching condition when the stimuli are lights and shadows will be accurate, even though there is no causation. In contrast, if the experiences represent causation (and not just the parameters that elicit causal reports), such experiences would be inaccurate, whether or not subjects would go on to infer that A launched B.

The issue between Rich and Thin views arises for auditory as well as visual experience. We can often recognize who is speaking by their voices. Rich views allow that auditory experience can represent that Frank Sinatra is singing, whereas Thin views allow that it can only represent the sounds and their qualities. The judgment that the person singing is (or sounds like) Frank Sinatra must come downstream of auditory consciousness. Rich views allow that auditory experience can represent that a truck is going by, whereas Thin views allow that it can only represent a gradually fading groaning noise. Rich views allow that auditory experience represents that a string of sounds was a meaningful sentence, whereas according to Thin views it can only represent that a string of sounds.

Like visual experiences, auditory experiences represent the world outside the perceiver, and thus can be accurate or inaccurate. Relevant to this, auditory and visual experiences have spatial content: We hear sounds as coming from different directions, and we see things as having specific spatial locations. Whether a standard visual experience such as the one had when viewing a cube is accurate depends on whether the cube has the properties (including spatial properties) that the visual experience represents it as having. Whether standard auditory experiences such as the ones had when listening to a lecture are accurate depends on whether the lecturer made the noises that the subject auditorily experiences her as making. The exact accuracy conditions of the experiences thus depend on whether Rich or Thin views are true. For instance, suppose you are talking to an impostor on the telephone, but the disguised voice fools you and you wrongly take the impostor to be your spouse. There is clearly an error at the level of judgment, but is there an error at the level of auditory experience as well? If a Thin view is true, then your auditory experience may be correct in this case because it represents the tone of voice that the impostor actually has. In contrast, if a Rich view is true and your experience represents that the person you're hearing is your spouse, then your error will reach all the way down to the auditory experience itself.

CONTEXT EFFECTS IN PERCEPTION

When Groucho Marx observed, "Time flies like an arrow; fruit flies like a banana," he made two essential points about the effect of context on perception. The first point is that an isolated stimulus, such as the word *flies,* is ambiguous and must be interpreted in context. The second point is that this disambiguation process is normally so efficient and so accurate that we are unaware that it is occurring. On those rare occasions when context does not immediately resolve an ambiguity, we may be amused by our error.

Figure 1 illustrates the critical role that context plays in visual perception. The figure is intended to depict the view of a train engineer who must decide whether the obstacles on the track could derail the train. The engineer would likely judge that the first animal is tiny and poses no threat, but the second animal is huge and could cause a dangerous collision. The size judgments of the engineer must be based entirely on contextual information because the pictures of the two animals are identical. The converging tracks and the gradually shrinking railroad ties provide strong depth cues that indicate that the second animal is much further away than the first animal. Our visual system uses this distance information to rescale the animals' images so that we perceive their true physical sizes. If Figure 1 depicted a real three-dimensional scene, the contextual information provided by the depth cues would produce an accurate percept.

But Figure 1 is not a real scene; it is a composite photograph made by pasting two copies of one image onto an unrelated image. If we regard the figure this way, then the contextual information provided by the depth cues is misleading and the

Figure 1 Composite Image

Notes: This picture is a composite: The image of an animal was pasted twice onto an unrelated background. Although the animal images are identical, the top animal appears larger because the background causes it to appear further away.

differential size percept is an illusion. To see the animals as identical, we would need to isolate them from the background and see them as separated on the page, not as separated in depth. We are unable to do this because, like much of perceptual processing, this context effect is not subject to conscious control.

The size illusion in Figure 1, and our inability to overcome it, reveal the automatic and decisive role that context plays in our percepts. As the four examples in this entry illustrate, similar context effects pervade every aspect of perception, from such seemingly elemental percepts as surface lightness to such high-level processes as object recognition.

Lightness Constancy

In our everyday experience, surfaces have a constant lightness: A piece of white paper looks white whether we view it inside under dim illumination or outside in bright sunlight This perceptual constancy may give the impression that lightness is a property of the paper that can be measured directly from the light it reflects, independent of context. This impression is wrong, however, because it is relatively easy to create a situation in which a white piece of paper has a lower luminance (reflects less light) than a black piece of paper does. This can be achieved by casting a shadow over the white paper and directly illuminating the black paper, or by turning the white paper away from the light and turning the black paper toward the light. Even though these changes in illumination and surface orientation have a profound effect on the luminance of the paper, they have little effect on its perceived lightness. To achieve this constancy, our visual system uses several forms of contextual information to disentangle surface lightness from the other factors that affect luminance.

The processes that underlie lightness constancy may begin early in vision. Neurons in the eye measure the luminance levels within a small region on the retina. Each neuron responds when a spot of light illuminates the center of the region that it monitors. If the intensity of the spotlight is increased, the response of the neuron will increase, but if the area of the spotlight is increased, the response of the neuron will decrease. This is because each neuron compares the amount of light in a central region with the amount of light in the surrounding area and then generates a response that reflects the difference. Because the neurons calculate luminance differences, or contrast, their responses are largely unaffected by whether the region has a uniformly high luminance level or a uniformly low luminance level. This property makes the neurons less sensitive to the effects of illumination (i.e., whether the region is brightly lit or dimly lit) because illumination tends to be uniform over small regions. By responding most strongly to a patch of light only if it differs from its surround, these neurons use local context information to begin the recovery of surface lightness. Full lightness constancy involves more complex calculations that compare luminance levels over larger areas, but all of these calculations rely on contextual information.

Motion Detection

We are extremely sensitive to motion. Even a small motion in peripheral vision can immediately summon attention. It may seem unremarkable that a moving object would stand out in an otherwise stationary world, but the image of the world on our retina is far from stationary. Because of the movements of our bodies, our heads, and our eyes, the retinal image changes constantly and dramatically. To perceive an object as moving we must disentangle the retinal motion it produces from the retinal motions that we produce by our own movements.

The process of disentangling object motions from self-produced motions is possible because self-produced motions generate distinctive and characteristic retinal flow-fields: An eye movement to the right produces a full-field translation to the left; walking forward produces an expansion pattern that radiates outward. The visual system attributes these distinctive patterns to self-motion because it is unlikely that object motions would produce them. And when object motions do mimic these patterns, they can create an illusion of self-motion. For example, drivers sometimes experience illusory self-motion when waiting at a stoplight. When the other cars start to move forward, the motion they create in the driver's periphery can cause the illusion that the driver's car is rolling backward. In addition to the information provided by flow patterns, the visual system also receives information about self-movement from the vestibular system and from neurons that control and monitor eye and neck muscles. For example, when a motor signal is sent to the eye muscles to produce an eye movement, a copy of the signal is sent to the visual system. The visual system uses these extra-retinal signals to anticipate the retinal flow pattern that the self-motion will produce.

The process of disentangling object motion from self-motion likely involves neurons in the medial temporal (MT) area of the brain. Although this brain region is located several processing stages beyond the eye, many of its neurons have a similar type of center-surround organization as the eye's contrast sensitive neurons do. The neurons in area MT monitor a particular spatial location in the visual field and respond whenever a motion with a specific speed and direction occurs at that location. When the same motion is present in the surrounding area, however, the response of the neuron is suppressed. As a result of this surround suppression, these neurons respond weakly to the type of full-field motion produced by an eye movement. For many MT neurons, surround motion in the opposite direction produces an enhanced response, making these neurons especially sensitive to the motion gradients that arise when an object moves relative to its background. The local motion differences that are calculated in area MT are sent to neighboring brain regions that use more extensive contextual information, including extra-retinal signals, to fully segregate object-motions from self-motion. Only after analyzing the complete pattern of retinal motions and the extra-retinal signals can the visual system arrive at an unambiguous interpretation of a moving stimulus.

Object Recognition

Most people have had the frustrating experience of being unable to place a familiar face. This failure of face recognition seems to occur most frequently when we know someone from one context and then meet him or her in a different context. Context may play a similar role in the recognition of all objects, not just faces. Through experience, the visual system may learn that certain objects typically occur in certain locations in certain kinds of scenes. This knowledge can facilitate recognition, especially if the stimulus is ambiguous: On a desk, a small pink rectangle might be recognized as an eraser, but on a bathroom counter, the same stimulus might be recognized as a bar of soap. Because perceptual processes are largely subconscious, our perceptual knowledge of contextual associations may be independent of our conscious knowledge of these associations. Our perceptual system can exhibit knowledge that we do not know we know.

Object recognition may be facilitated by contextual information that pertains to a particular familiar location or to a general scene category. Our facility with this second type of contextual information allows us to interpret the sequence of unrelated images that we encounter when flipping through a magazine or surfing television channels. Within a fraction of a second, we can recognize whether an image depicts a city, a beach, a desert, or a kitchen. It might be assumed that we classify scenes based on the objects they contain, but recent research suggests that the opposite is true. When classifying an image as a cityscape, we do not first recognize buildings, cars, or street signs; instead, we simply detect the predominance of vertically oriented lines. Once a scene is classified as a cityscape, this contextual information may prime us to recognize buildings, cars, signs, and other objects that are likely to appear in this context.

The brain processes that underlie object recognition and scene categorization are not fully understood, and so the characterization of their interaction is still speculative. Unlike the previously described processes, which involved comparisons of similar information within a brain region, this context effect likely involves interactions between two brain regions that process different types of information: the parahippocampal area (PHA), which processes scene information, and the lateral occipital complex (LOC), which processes object information. For scene categorization to influence object recognition, the PHA would presumably relay the results of its processing to the LOC. These results would then bias processing in the LOC to favor objects associated with the scene category.

Phoneme Recognition

The Groucho Marx quote at the beginning of this entry demonstrated one role that context plays in speech perception: When a word has multiple meanings, we use context to select the meaning intended by the speaker. But context is involved at an even earlier level in speech perception because it allows us to recognize sounds as words. We perceive spoken words as a sequence of vowel and consonant sounds, that is, as a sequence of phonemes. Perceptually, each phoneme seems fixed, but acoustically, a phoneme can vary considerably depending on context. We hear the same /d/ sound in *die* and *due,* but the initial auditory signal of these words is different. This difference arises because of the flowing nature of speech production. As we articulate one phoneme, we are preparing to articulate the next, and the resulting co-articulation is reflected in the acoustical signal. The processes that underlie speech perception use contextual information to automatically and effortlessly compensate for the effect of co-articulation, resulting in a phonemic constancy similar to the lightness constancy described earlier.

In some situations, such as a noisy party or a crowded restaurant, the acoustical signal may be insufficient for reliable speech recognition. In these situations, we may rely heavily on lipreading to understand what is being said. But even when the speech signal is clear and we are not consciously paying attention to the speaker's mouth, visual context can influence phoneme perception. This automatic processing of facial movements explains why a dubbed movie can be particularly difficult to understand: We cannot ignore the visual context even when it is misleading.

Like the other aspects of perception described here, phoneme recognition is a topic of intensive research. Although this process is not completely understood, a full description will involve the integration of contextual information across time and across senses. Although it may seem paradoxical, we perceive phonemes as having stable properties that are independent of context precisely because we are so adept at interpreting them in context.

CONTRAST ENHANCEMENT AT BORDERS

Nineteenth-century visual scientists such as Michel-Eugène Chevreul, Ernst Mach, Hermann von Helmholtz, Ewald Hering, and Johannes Peter Müller discovered that simultaneously presented stimuli could affect each other's perceived contrast. For example, notice how each of the solid stripes in Figure 1 appears lighter on the left than on the right, even though each stripe has the same physical intensity across its width. This illusion is called "Mach bands," and it illustrates how the contrast of a stimulus is enhanced at its borders. This entry describes spatial and temporal contrast enhancement at borders.

Spatial Contrast Enhancement at Borders

Visual spatial contrast is the perceived difference in brightness or color between two or more locations in the visual scene. Perceived contrast is determined by the physical difference in intensity and color between two adjoining areas. Thus, contrast is not

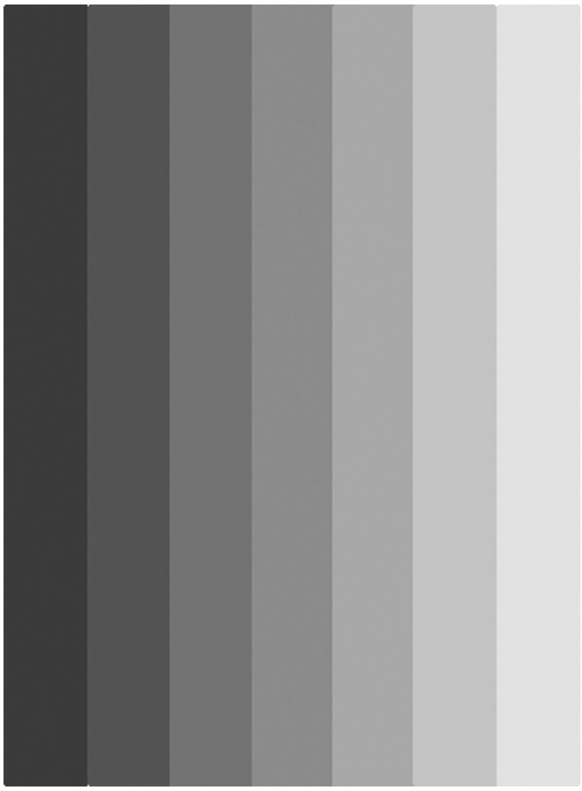

Figure 1 Mach Bands

Source: Chevreul, M. E. (1987).

Notes: This Mach band demonstration was originally designed by Chevreul in 1839. Notice how each vertical stripe appears to be lighter on the left than on the right. This illusory effect is caused by contrast enhancement at the borders.

a physical quantity but a perceptual comparison between two areas. The neural computation underlying the perception of contrast is partly carried out by lateral inhibition circuits in the visual system. Lateral inhibition is the process by which an excited neuron suppresses the activity of its neighbors across visual space. Lateral inhibition circuits are found in all levels of the visual system (such as in the bipolar and ganglion cells of the retina) as well as in other sensory systems. One perceptual consequence of lateral inhibition is that stimuli to both sides of a luminance border are differentially enhanced in an illusory fashion (as in Figure 1).

Another corollary of contrast enhancement at borders is that non-borders (such as the interiors of objects) are perceptually suppressed by the same lateral inhibition circuits that enhance the borders. Indeed, neurons in early visual areas are activated only by the borders (edges or corners) of stimuli, not by their interiors. The process is metabolically efficient in that it reduces the metabolic demand required to respond to the presentation of a stimulus. Only the neurons at the edges of surfaces require energy to respond, whereas the neurons in the interiors do not require as much energy (because they are quiescent). Thus, our visual system sees the edges of surfaces, and then uses this information to create the middles, through a process called filling-in. The neural circuits underlying filling-in have been localized to cortical visual areas beyond area V1 (such as areas V2 and V3).

Temporal Contrast Enhancement at Borders

Contrast is increased at their temporal borders (that is, their onsets and terminations) as well as at the spatial borders of stimuli, also because of lateral inhibition. And just as the interiors of spatial stimuli are suppressed when compared with their borders, so too are the temporal mid-lives of stimuli suppressed when compared with their onset and termination. The result is that the perceived contrast of a stimulus is highest just after it turns on and then again after it turns off. Visual masking (the effect in which the visibility of a target stimulus is reduced by a masking stimulus that does not overlap the target in space or time) occurs perceptually when the neural responses to the target onset or termination are inhibited.

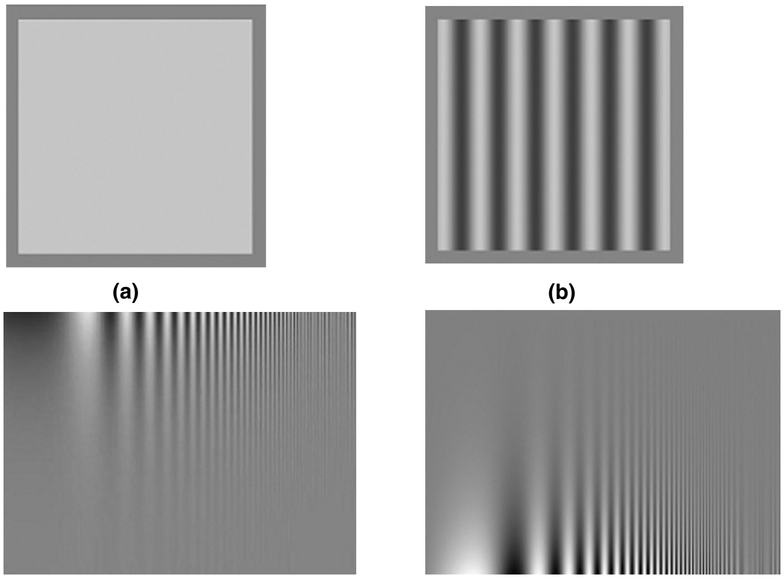
CONTRAST PERCEPTION

Sensitivity to light is common in the animal word. Even the one-celled euglena have eyespots that enable them to sense light. Only animals with eyes can sense differences in the light coming from different objects in their environment (*contrast*). Humans sense the intensity of light, but they are much more sensitive to contrast. What this means is that when intensities change slowly, as at sunset, we can tell that the intensity of light is changing, but we have a much better sense of differences in brightness between one object and another (*contrast perception*). Sensitivity to contrast makes it possible for us to see in detail what is around us and to do so over a huge range of intensities. This ability depends critically on the fact that different objects reflect light differently. Both the intensity and the spectrum (wavelengths) of light vary from one region of a scene to another. For example, in a scene with grass and a dark gray road, the grass will reflect more light and the light will be concentrated in the middle wavelengths; the road will reflect less light and it will have a broad spectrum of wavelengths. In this example, as in most real-world situations, both brightness contrast and color contrast are present. This entry focuses on brightness contrast perception.

There are several different measures of contrast, but they all indicate the *ratio* of light intensity in one location to the intensity in another. For scenes that are seen by reflected light, as most scenes are, the contrast remains constant as the light falling on the scene (illumination) changes. For example, going from bright daylight to dusk, the contrast (ratio) between the intensities of the grass and the road remains the same. Many visual systems, including ours, are designed to be sensitive to contrast.



(a) (b) (c) (d)

Figure 1 Spatial Patterns and Contrast Perception

Notes: (a) A uniform gray rectangle on a darker background. (b) A sine wave grating with the same contrast as the rectangle and background in 1(a). (c) A grating that decreases in stripe width from left to right and decreases in contrast from bottom to top. At normal reading distance, stripes of middle widths are visible higher in the image and thus at lower contrasts than are wide or narrow stripes. We see intermediate stripe widths better than we see wide or narrow stripe widths. The stripes that are seen best will vary with distance because the width in the retinal image determines visibility. An image like this was first created by Fergus Campbell and John Robson in 1964.

If a system were completely insensitive to absolute intensity, but sensitive to ratios of intensity, it would produce a constant response to a scene as the illumination on it changes. Our visual systems are not completely insensitive to absolute intensity, but they are much more sensitive to contrast. The process that brings about this difference is *light adaptation,* which has the effect of reducing sensitivity to light as the intensity increases and increasing sensitivity as the intensity decreases, while maintaining high sensitivity to contrast. Light adaptation does this by decreasing all the intensity signals in the visual system by the same fraction, leaving the ratios among the intensity signals (contrast) relatively unchanged.

Seeing Contrast Patterns

Any variation of intensity over space is referred to as a spatial pattern. Some patterns are much more visible than others are, and these variations in sensitivity provide evidence about the neural units and processes in the brain that bring about pattern vision. Differences in the visibility of patterns are often determined by measuring the *absolute contrast threshold,* the minimum contrast at which a pattern is seen. Low thresholds correspond to high sensitivity. Small patterns of stripes, called gratings (Figure 1b), have lower thresholds than do uniform surfaces (Figure 1a) and have frequently been used to study contrast sensitivity. There are two reasons for this. First, the visual system is sensitive to these patterns, which suggests that it has units tuned to such patterns, and second, gratings have properties that are useful in developing models of pattern vision.

We might guess that we would be most sensitive to the widest stripes, but we are actually most sensitive to stripes of intermediate width. This is illustrated in Figure 1(c). Many factors contribute to this variation in sensitivity, but the principal one is that the neurons in the brain that play the central role in the detection of patterns are most sensitive to gratings with intermediate stripe widths. These are called pattern vision units, even though higher-level units are also involved in pattern vision. For each of these neural units, there is a region of the retina (receptive field) such that light in that region will affect the response of the unit. The effect is either to increase the response of the unit (excitation) or to decrease its response (inhibition). The receptive fields of many cortical units are divided into striped regions that are alternately excitatory and inhibitory. The threshold for a particular pattern depends on how closely it matches the receptive fields of the detecting units. If the correspondence is close, the response will be large and less contrast will be needed to reach threshold. If the stripes of the pattern are made either wider or narrower, the response will be less. Evidence from single unit recording indicates that many neurons in animal brains have striped receptive fields (simple cells).

Seeing Differences in Contrast

Although much research on contrast perception has focused on absolute thresholds, the *contrast difference threshold* provides important insights into the process of contrast perception over the whole range of contrasts. To measure the difference threshold for contrast, a pattern is selected and set at the contrast at which the threshold is to be measured (base contrast). A small increase is added to the base contrast to produce a pattern of higher contrast. The two patterns are presented in random order and the observer indicates which pattern has the higher contrast. The added contrast is varied to determine the contrast difference threshold (minimum contrast difference that can be seen). As the base contrast increases from 0, the difference threshold at first decreases and then increases. In other words, we see differences in contrast best neither at absolute threshold nor at high contrast, but at an intermediate contrast. This result is interpreted as indicating that as the base contrast increases from 0, the response of contrast sensitive neurons in the perceptual system increases slowly, then rapidly, and then slowly. This has been confirmed by directly recording from V1 neurons in animals.

The Neural Code for Contrast Patterns

The evidence presented so far is consistent with the pattern vision units all having the same type of receptive field, differing only in their positions on the retina. However, there is both psychophysical and biological evidence for the existence of units tuned to different stripe widths and orientations. These units are in the visual cortex of the brain, not the eye, and they receive input from many

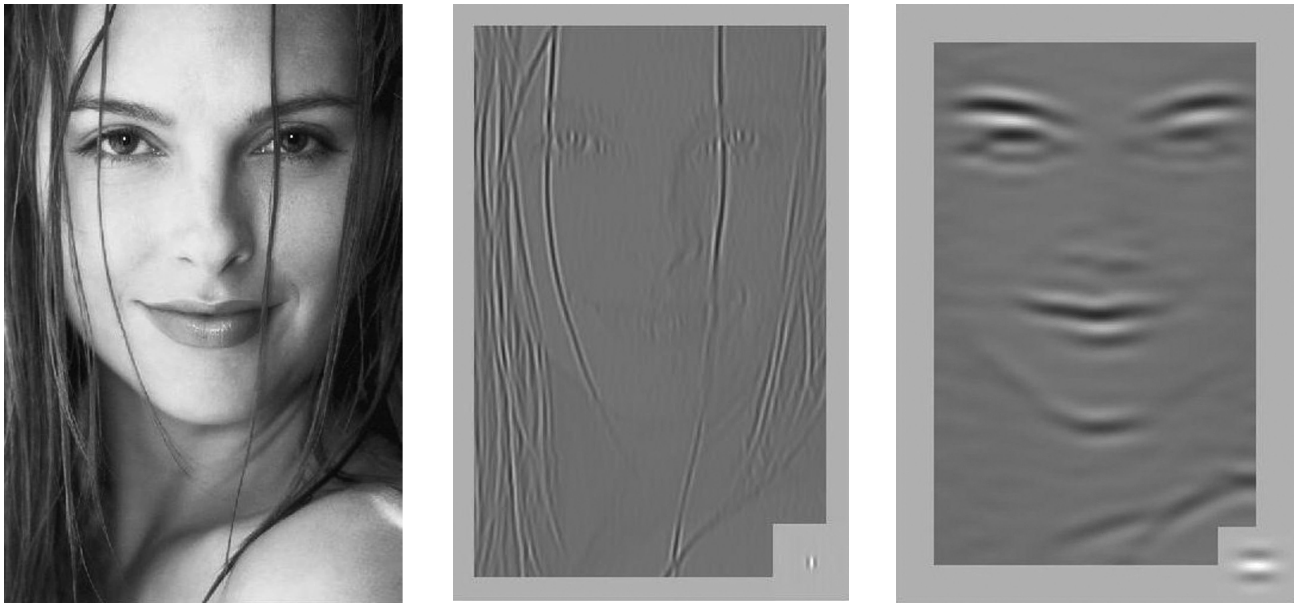


Figure 2 The Effect of Filtering a Natural Image

Bright regions correspond to excitation and dark regions to inhibition.

photoreceptors in the eye. Much of the psychophysical evidence comes from studies of *selective adaptation* and *masking* in human vision. If one pattern is viewed for several seconds before a second is presented, the first pattern will produce a decrease in sensitivity to the second (increase its threshold), but this happens only if the patterns are similar (selective adaptation). Likewise, when one pattern is superimposed on another, the sensitivity to that other pattern will decrease (masking) only if the patterns are similar in stripe width, orientation, and position. Models of contrast perception have been based on such evidence. A key assumption of these models is that a context pattern can affect the visibility of a test pattern only if the unit that detects the test pattern is either excited or inhibited by the context pattern. Thus, if a pattern is seen, but has no effect on the visibility of a second pattern, different neural units mediate the perception of the two patterns and the effects of the patterns are independent. If a pattern affects the visibility of the second pattern, the first pattern must influence the response of the units that detect the second pattern. Single unit recording has shown that neurons in area V1 of the cortex differ in the stripe widths and orientations, as well as the regions of the retina that they are most sensitive to.

Models of Contrast Perception

Current models of the contrast perception system assume an array of neurons with receptive fields tuned to different stripe widths, orientations, and positions. Each neuron sums excitation and inhibition over its receptive field and its response is an S-shaped function of this sum. Each small region of retina has a set of overlapping receptive fields tuned to different stripe widths and orientations. These arrays of receptive fields are repeated over the retina, but we do not know in detail what the sensitivities of these receptive fields are or how they are distributed. It would be sufficient for vision to have units tuned to a few stripe widths and orientations, and models often assume this, but single unit recording has found units tuned to

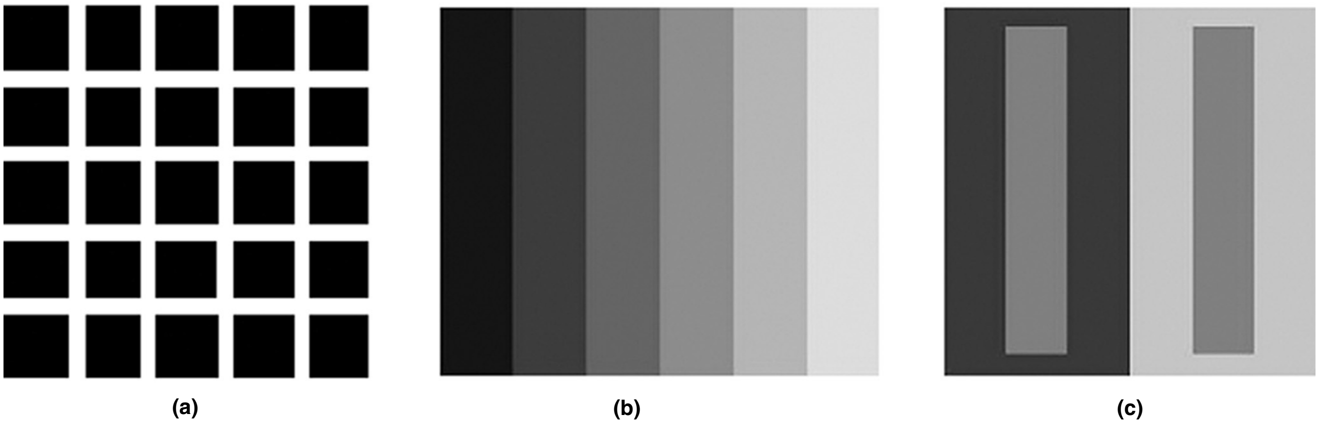

Figure 3 Three Contrast Illusions

Notes: (a) Hermann grid. The dark spots seen at the intersections of the white lines are not present in the stimulus. (b) Mach bands. Each step is uniform in intensity. That a bright line is seen to the right of each vertical edge and a dark line is to the left are created by the visual system. (c) Simultaneous brightness contrast. The two center rectangles are equal in intensity. The one on the left appears lighter. In each case, the region surrounding the region where the illusory percept appears is critical to producing the illusion. If you cover the surrounding regions, the illusion will disappear.

many spatial frequencies and orientations. The responses of these neurons together contain much of the information in the image, but the information is in a neural code. Imagine a set of neurons whose receptive fields lie in different places on the retina, but all respond to the same stripe width and orientation. The pattern of responses over this set of neurons may be thought of as a neural image that contains only those features of the retinal image that have the corresponding stripe width and orientation. Other sets of neurons have patterns of activation that represent features of other stripe widths and orientations. Thus, the image on the retina is represented by many different neural images, each containing part of the information needed to reconstruct the original image. For example, a set of horizontally oriented receptive fields with wide stripe widths produces a neural image like that in Figure 2(b). This is a blurry version of the original in Figure 2(a) emphasizing horizontal contours. The neural image produced by a set of vertical receptive fields with narrow stripe widths codes for fine detail that is vertically oriented (Figure 2c).

Two critical unanswered questions in contrast perception are these: What is the function of this multi-neural-image representation, and what role does it play in the generation of percepts? One function may be to represent the image in a way that minimizes the number of bits of information required to code natural images (a representationally efficient code). Although a huge variety of natural images are possible, natural images tend to have many properties in common. For example, in natural images, the contrasts at neighboring points tend to be similar, except at edges. Thus, natural images form only a relatively small subset of all possible images. Evidence indicates that the multi-neural-image code used by the visual system efficiently encodes natural images.

Consider what happens when the image of a complex scene lands on the retina. A set of neural images will be formed. Figures 2(b) and 2(c) represent two such images, but there would be many more. Contrast will vary over space in a different way in each of them. Objects are delineated by edges, so it is essential to find the edges in a scene. Where there is an edge between regions of different reflectance, there will be a change in contrast in those neural images with the same orientation as the edge. If such a change always indicated an edge, finding edges would be easy. However, differences in lighting, orientation of surfaces, shadows, and texture within a region will also produce changes in contrast. To perceive what is in the scene, the visual system has to disambiguate and interpret these changes in contrast. There are several models of how a multi-neural-image

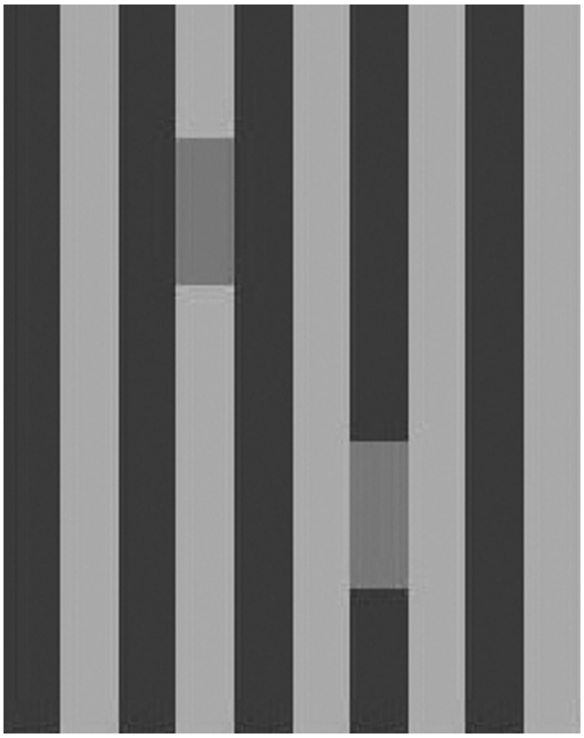

Figure 4 White's Illusion

Note: The rectangle in the dark stripe appears brighter than the rectangle in the bright stripe even though the first has intense regions on either side and the second has dark regions on either side.

representation might be used to do this. These analyze and combine the different neural images to extract edges, lines, bumps, and other elementary features in the scene.

Context Effects in Contrast Perception

The visibility and perceived contrast of a test pattern are greatly affected by other patterns that are near it in space and time; they need not be superimposed. These *context effects* present a challenge to models of contrast perception. The predominant effect of context patterns (*masking*) is to make the pattern harder to see or to reduce perceived contrast. Masking is thought to occur when the context patterns inhibit the unit that detects the test pattern. In some cases, context patterns make other patterns easier to see and higher in perceived contrast (*facilitation*). Low-contrast patterns that are similar to the test pattern often facilitate perception, whether they are superimposed over the pattern or adjacent to it. Facilitation is produced when the context pattern excites the unit that detects the test pattern. Masking and facilitation effects are complex and are not fully understood.

Illusions in Contrast Perception

An important fact about contrast perception is that our experience does not always correspond to the contrast pattern of the stimulus. Another way to say this is that there are many illusions in contrast perception. Three of the most familiar contrast illusions are the spots seen at the intersections of the Hermann grid, the dark and bright regions seen adjacent to edges (Mach bands), and the lower brightness of a region when it is surrounded by a region of high intensity (simultaneous brightness contrast). See Figure 3(a, b, c). There are many other contrast illusions. Models of these illusions are often based on units with concentric or striped receptive fields together with the assumption that the brightness at a point corresponds to the response of the receptive field centered at that point. This simple idea is central to explanations of these phenomena. For example, in Figure 3(c) imagine that there is a receptive field with an excitatory region centered on each of the center stripes and inhibitory regions on either side. Both receptive fields will be excited equally, but the one on the right will be inhibited more, and therefore this cell will respond less and we will perceive the center stripe on the right to be less bright. There are many contrast illusions that this simple model does not explain. White's illusion (Figure 4) is an example. Here the rectangle with more intense light on either side appears brighter. Some models combine the responses of many V1 type cells to explain these phenomena, but cognitive organizational processes at higher levels in the visual system explain the phenomena in other models. No current model describes all the phenomena of contrast perception.

COROLLARY DISCHARGE

Imagine an animal walking through a forest. As it moves, branches brush against its skin, twigs snap at its feet, and patterns of light and shade alternate across its eyes. In principle, the animal should be startled by these sensory events. The activation of its skin receptors could be interpreted as caused by a fly landing on its leg, and the sounds and shadows as meaning a predator is looming. Surprisingly, the animal is not startled by these sensory events; they are expected, partly because the animal has access to an internal report of its own movements called *corollary discharge.*

Each of an animal's movements is initiated by motor commands originating from movement areas of the brain that travel peripherally to activate the appropriate muscles. Neural copies of the movement commands are issued simultaneously and travel in the opposite direction, impinging on sensory brain areas. These corollary discharge signals inform the sensory areas of the upcoming movements and allow them to prepare for the sensory consequences of the movement. As a result, our animal in the forest is not surprised by the brush of the branch, the snap of the twig, or the change in shade. Were the animal at rest, or moving without the benefit of corollary discharge, the sensory events would be startling indeed.

As a theoretical concept, corollary discharge has a rich history. Behavioral and psychophysical evidence for corollary discharge has been around for more than a century, and direct physiological evidence has accrued within the past few decades. Corollary discharge circuits have been found, for example, that transiently inhibit a cricket's hearing while it chirps. Researchers now know corollary discharge to be ubiquitous. It is present in virtually every animal species and coordinates nearly every motor and sensory system. The most is known about corollary discharge circuits that interact with the senses of vision, audition, and somatosensation, as described in this entry.

Vision

Well-understood corollary systems reside in the visual and eye movement networks of vertebrates, particularly in primates. A common visuomotor behavior of the primate that requires corollary discharge is the saccade, a fast eye movement that occurs about 2 to 3 times per second as an animal scans a scene. Saccades are beneficial because they permit rapid relocation of the fovea, but are costly because each saccade results in two unfortunate consequences for the visual system: an intrasaccadic smearing of the image and a trans-saccadic displacement of the image across the retina. With each saccade, the world should appear as both blurry and jumpy because this is what the retina is actually reporting. Instead, the world appears focused and stable despite the retinal report because the visual system receives advance warning of each saccade in the form of a corollary discharge.

Corollary discharges of saccadic eye movements emerge from oculomotor structures that span virtually all levels of the nervous system and impinge on visual areas throughout the brain, early and late, subcortical and cortical. At their point of termination, the corollary discharges interact with recipient sensory areas to minimize the effects of the eye movement–induced sensory inputs. For the case of retinal blur, the corollary discharges participate in a mechanism known as saccadic suppression. Neurons participating in saccadic suppression are transiently inhibited by corollary discharges at the time of the saccade, thus reducing the amount of visual information they convey and ultimately the amount of blur that is perceived. As for the displacement problem, one putative compensatory mechanism involves neurons that shift their receptive fields before each eye movement. Instructed by corollary discharge, these neurons sample a new part of the visual field before the eyes begin to move. By sampling the same portion of space both before and after the eye movement, shifting receptive fields effectively seem to test whether the external world moves during the saccade. If the presaccadic and postsaccadic samples match, the world is judged as stable. The corollary discharge that shifts receptive fields, at least those of neurons in the frontal cortex, is known to arise from the midbrain superior colliculus.

Audition

Corollary discharges are also important for coordinating the vocal and auditory systems. One problem faced by many vocalizing animals is the effect their high intensity voices have on their hearing. This problem can be considerable for animals that vocalize at high decibel level. Such animals as the cricket generate high intensity sounds that should overwhelm their auditory circuits, rendering them temporarily deaf to independently incoming sounds. This scenario is avoided by auditory-vocal corollary discharge mechanisms analogous to saccadic suppression that enable tight coordination between auditory and vocal systems. With each vocalization, the corollary discharges exert an inhibitory influence on neurons of the auditory system. This prevents desensitization and ensures maximal attunement to external auditory events.

In humans, corollary discharge mechanisms involving speech production and auditory regions are thought to play a role in distinguishing self-generated speech sounds from other-generated speech sounds. Neurons in language areas of the temporal lobes are suppressed during self-generated speech, but remain fully responsive when others are talking. Interestingly, in schizophrenia, the auditory dampening effect is reduced, betraying a reduction in speech production/auditory coordination. An alteration in this coordination may result in internally generated events such as thoughts being experienced as having an external source. This may serve as a basis for certain aspects of the disease pathology such as auditory hallucinations and self-monitoring deficits.

Somatosensation

Movements of the body can result in sensory input (such as when an animal touches something) that is indistinguishable from the input caused by external agents (when something touches the animal). Corollary discharges from the skeletomotor system are critical for allowing the somatosensory system to tell the difference. They play a rather diverse role because they may amplify or suppress the responses of somatosensory neurons. The difference seems to depend on motor context. A rat exploring an object with its whiskers or a person reading Braille with her fingertips depends on corollary discharges that amplify the sensory information for detailed analysis. This contrasts with suppressive corollary discharges of the somatosensory system. These inputs, originating from premotor circuits, inhibit somatosensory neurons during voluntary movements. In effect, they provide a prediction of the sensory consequences of the movement. If the actual sensory feedback matches the predicted sensory feedback, the signals cancel and somatosensory input is not perceived. Unexpected sensory inputs, however, pass unhindered and result in a surprising somatosensory experience. An everyday example is the act of tickling. We cannot tickle ourselves because we cannot surprise ourselves. Our finger movements cause somatosensory inputs, but corollary discharges of our finger movements cancel them. If someone else moves their fingers across our skin, however, we experience the familiar “tickly” sensations at full force.

CORTICAL ORGANIZATION

When neuroscientists use the term *cortex,* they usually refer to the neocortex of mammals. This neocortex is part of the outer shell or bark of the forebrain that was thought to be a new structure that evolved with mammals. Now it is widely accepted that the neocortex of mammals is the same structure as the dorsal cortex of reptiles. However, the dorsal cortex is much smaller and simpler in laminar organization than the neocortex is. Thus, the neocortex is new, in the sense that all mammals have a more complexly laminated and functionally subdivided cortex than do reptiles. Although some use the term *isocortex* for *neocortex,* the term *neocortex* is almost universally used.

When we look at the human brain, most of what we see is the neocortex (color insert, Figure 38). It occupies the outer surface of the two cerebral hemispheres of the forebrain, just behind the olfactory bulb, above the piriform or olfactory cortex, and in front of the cerebellum and brainstem (color insert, Figure 38). All mammals have a neocortex. However, the structure is highly varied in size, structural differentiation, subdivisions of functional significance, and cellular and regional specializations across mammalian species. This variability is one of the reasons why the neocortex is such an important part of the brain; the neocortex has specialized features for the various needs of different species. Differences in cortical size (Figure 1) and organization largely account for the considerable differences in the abilities and behaviors of mice and men, or even monkeys and apes. But, as this entry describes, basic features of the neocortex are also shared by most present-day mammals because they were retained from an early mammalian ancestor.

Laminar Organization of the Neocortex

The laminar organization of the neocortex is similar in most mammals in that it is a thick structure that is divided from outer surface to inner white matter into a number of layers and sublayers. Traditionally, we count six layers (Figure 2; see also color insert, Figure 39), each with a specialized role in the functional organization of the cortex. This is in contrast to the dorsal cortex of reptiles where a thin row of neurons receives inputs from other parts of the brain and project to subcortical structures.

The middle layer of the neocortex, layer 4, is the main receiving layer. Neurons in this

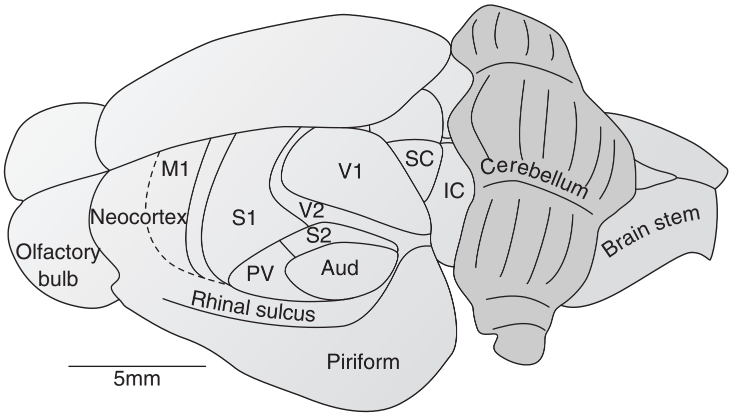

Figure 1 The Brain of a Hedgehog

Notes: The hedgehog is a mammal with a small brain. The neocortex forms the outer shell of the two cerebral hemispheres just behind the olfactory bulbs at the front of the brain (left), above the piriform or olfactory cortex below the rhinal sulcus, and in front of the more caudal superior colliculus (SC) and inferior colliculus (IC) of the midbrain, the cerebellum, and the brainstem. The neocortex is divided into a number of cortical areas including primary and secondary visual (V1 and V2) and somatosensory areas (S1 and S2), an auditory region (Aud), a parietal ventral somatosensory area (PV), and a primary motor area (M1).

layer are morphologically specialized to be activated by a small number of inputs. Thus, layer 4 neurons are small and star shaped in that short dendrites radiate out in all directions. These neurons, called granule cells because of their small size or stellate cells because of their star shape, are activated by a few axons from the thalamus, or a few axons from another cortical area. Thus, layer 4 neurons preserve the information from a few input neurons rather than integrate signals from a large number of inputs. Most of the neurons in other layers of the neocortex are pyramidal neurons, named for their pyramid shape with a long dendrite streaming from the apex toward the cortical surface. The apical dendrites typically extend into layer 1 where they are contacted by inputs with axons running parallel to the surface. Layer 4 neurons distribute information selectively to neurons above and below layer 4. Overall, small clusters of neurons in layer 4 connect with those neurons vertically aligned with them in layers above and beneath them. Neurons in other layers also tend to connect within a narrow vertical column of roughly 100 to 200 neurons. Adjacent clusters of layer 4 neurons connect in the same manner, so that the neocortex consists of arrays of narrow vertical columns of neurons extending across all layers that are directly or indirectly activated by the same small number of input neurons. Neurons above and below layer 4 are locally connected in ways that allow local circuits to derive different categories of information from the inputs, and send these different types of information to other subdivisions of the cortex as subcortical targets.

To briefly characterize the other layers of the cortex, from surface to white matter, the superficial layer 1 consists mainly of axons connecting with dendrites of cortical neurons in deeper layers. These axons largely come from brainstem neurons that are parts of modulating systems that connect with large numbers of cortical neurons, usually to enhance their responses to their dominant inputs. These modulating inputs play an important role in attention and learning. Layer 2, a narrow layer, consists of smaller neurons that make contacts with nearby neurons and the dendrites of neurons in lower layers. Layer 3 is a broader layer, especially in mammals with large brains and a lot of neocortex. Neurons in layer 3 analyze information received from layer 4 neurons, and project to other areas of the cortex. Different sublayers of layer 3 may project to different cortical areas, and they may send different types of information to these areas. Thus, the cortex has the capacity to send information to other subdivisions of the cortex, where it is processed further (serial processing). This reiteration or reprocessing is what gives the cortex its great computational capacity because simple processing steps repeated over and over can lead to sophisticated results. In addition, the same or somewhat different types of information can be

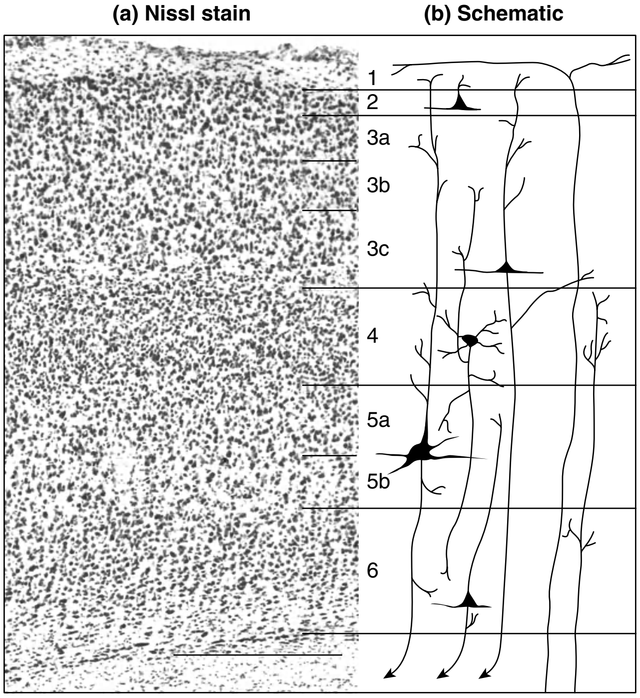

Figure 2 The Laminar Organization of the Cortex

Notes: (a) A thin section through the thickness of the cortex from the surface above to the fibers (axons that connect the cortex to other regions of the cortex and the brain) below. The Nissl stained section through V1 of a squirrel shows the locations of small, individual neurons as dark dots. Layers (1–6) are distinguished by differences in the arrangements, sizes, and shapes of neurons. (b.) A drawing of enlarged neurons (for visibility) and their local connections illustrates how vertical arrays of neurons are densely interconnected. Neurons have large cell bodies and thin dendrites and axons. Axons entering the cortex and terminating in layers 6, 4, and 1 are shown on the far right side in (b). See also color insert, figure 39.

sent from one cortical area to several others, so that information is processed in parallel streams. Thus, the cortex is characterized by both serial and parallel processing. The serial steps add processing power, and the parallel channels add processing speed.

Although most of the local connections within the cortex are vertically arranged across layers (Figure 2; see also color insert, Figure 39), some of the connections within layer 3 are horizontal and cross the vertical arrays of interconnected neurons. These horizontal connections are most dense over short distances, and few extend farther than a few millimeters. Although these horizontal connections are sparse and have weak effects, they are important in forming the complex response properties of layer 3 neurons so that these neurons are sensitive to the ongoing activities of nearby vertical columns of neurons. This is the start of a broader integration of information across larger groups of neurons in the cortex. Layer 3 neurons may also have inputs from smaller neurons in the thalamus. These inputs over their axons likely have weak but important modulating effects.

Most of layer 5 neurons are large pyramidal neurons with apical dendrites that extend up into and through layer 3. Thus, they sum much of the synaptic information of the sublayers of layer 3. These neurons project to various subcortical structures including the nuclei of the thalamus, the basal ganglia, the superior and inferior colliculi of the midbrain, and even the lower brainstem and spinal cord. For some cortical areas, a few such neurons may project to another cortical area as well. These projections help regulate ongoing behavior, influence sensory processing in other structures, and provide a further distribution of information by activating neurons in the thalamus that project back to the cortex.

The deepest layer, layer 6, has a mixed population of pyramidal and spindle-shaped cells that receive projections from upper layers of the cortex, especially layer 4, and even a small amount of thalamic input via branches of axons terminating in layer 4. These neurons, in turn, project back to the thalamic nucleus or cortical area that provides the activating input to the cortical field. Thus, layer 6 provides the important function of sending feedback to the neurons that provided the dominant activating input from the same region of the cortex. Feedback is important in modulating and adjusting the inputs to cortical neurons.

Thus, the neocortex of mammals has a laminar organization where neurons are specialized for receiving and distributing information to different targets. Species vary in the distinctness of the layers and sublayers in cell types and other features. Rather indistinct, poorly laminated layers likely reflect the primitive mammalian condition, whereas various types of morphological specialization of layers reflect more recently acquired specializations of layers as they became modified for various tasks. Most of the connectivity between neurons in the cortex is columnar, and vertical rows of neurons united by these vertical connections form a functional unit that is sometimes referred to as a mini-column. Larger collections of such vertical arrays may form functionally distinct groups of neurons called macro-columns or modules that are of two or more types within a cortical field, and variable across the cortex and across species. Variability in the types of cortical columns across cortical areas and across species provides another way in which the cortex has been modified to subserve the specific needs of different species.

Organization of the Cortex at the Local Circuit Level

The basic computations mediated by the cortex depend on the interaction of nearby neurons within layers and modules, the local circuits, as well as on the features of laminar and vertical organization. All layers of the cortex are composed of two fundamentally different types of neurons. The pyramidal neurons that project to other cortical areas or parts of the brain, and most of the layer 4 neurons discussed so far, excite other neurons and release excitatory neurotransmitters. The excitatory neurotransmitters depolarize the membrane potential of contacted neurons and thereby increase the probability that these neurons will have action potentials that stimulate other neurons. These excitatory pyramidal cells and excitatory spiny stellate and granule cells constitute roughly 80% of cortical neurons. Across all layers, the other 20% of neurons are non-spiny stellate cells and other interneurons that release an inhibitory neurotransmitter when they are excited. This transmitter hyperpolarizes synaptically contacted neurons so that they are less likely to produce action potentials (neuronal spikes). Inhibitory neurons have short axons and therefore act locally to reduce the firing rates (the production of action potentials) of pyramidal and spiny stellate neurons. Because external and intrinsic excitatory inputs tend to terminate on both excitatory and inhibitory neurons, the initial effect is excitation of excitatory neurons followed by inhibition from the inhibitory neurons. The inhibitory neurons tend to dampen the effects of persisting sources of excitation while having little effect on sudden changes in excitation. Thus, change in stimulus conditions is well detected by the cortical circuits, but less computation is devoted to persistent conditions. In addition, the inhibitory inputs often contribute to other types of computation based on temporal and spatial differences in the activations of excitatory and inhibitory neurons.

Plasticity of Local Circuits of Cortical Neurons

Another organizational feature of the cortex that makes it such a biologically useful organ is that the functions of circuits are adjustable rather than fixed. The synaptic contacts on individual neurons can be made stronger or weaker so that the activating inputs become more or less likely to cause the neuron to fire (produce action potentials) and send information to other neurons. This plasticity is possible because neurons have two types of receptors in their membranes for the excitatory neurotransmitter, glutamate. One type of receptor, the non-N-methyl-D-aspartate (non-NMDA) receptor is an excitatory channel that tends to generate neuronal spikes. If the NMDA receptor is activated when the non-NMDA receptors are activated, the activation of NMDA receptors results in internal changes in the neurons that strengthen the effectiveness of the non-NMDA synapses that were just activated. Thus, the neuron becomes more responsive to some of its inputs. This adjustment, called long-term potentiation or LTP, strengthens synapses for as long as weeks of time. Other patterns of synaptic activity weaken synapses, making some inputs less effective, a change called long-term depression or LTD. As a result, the functions of local circuits of cortical neurons are constantly adjusted so that they respond to inputs more or less forcefully. In sensory areas of the cortex, such adjustments are responsible for changes in a neuron's responsiveness to sensory stimuli. Such changes in neuron responsiveness may result in a type of performance improvement, called perceptual learning, where improvements in simple perceptual tasks follow practice.

Areas and Organs of the Cortex

The cortex is divided into a number of areas that have different functions (e.g., color insert Figure 38 and Figure 1). These areas were called the organs of the brain by an early investigator, Korbinian Brodmann, because different cortical areas are specialized for different functions, just as the heart, kidney, and liver have different functions. Although all areas of the cortex process information in basically the same way, areas differ in the inputs they receive and the brain structures they target. For example, all or nearly all mammals have a primary visual area of the cortex called V1 (visual area 1) or area 17, the 17th area described by Brodmann. V1 is distinguished from other cortical areas by having visual inputs relayed from the eye to a part of the thalamus (another part of the brain) and then to V1. As a result, neurons in V1 are activated by visual stimuli, and they participate in an initial analysis of the visual scene. The outputs of V1 go to the superior colliculus, a midbrain structure that instructs motor centers for eye movements so that the eyes are directed at objects of probable interest, such as changes in the visual scene. V1 also sends outputs to other, nearby visual areas, given various names or numbers, that process visual information further. After several such steps, the processing results in perception and the use of visual information to guide motor behavior, such as reaching for an object. Other types of sensory inputs access other cortical areas, where sensory information is analyzed in a number of steps across a sequence of sensory areas for taste, touch, or hearing. Other cortical areas combine information from areas devoted to one sense or another, to further influence perception and guide motor behavior. Still other cortical areas are involved in comparing ongoing events with past events, retaining information in short-term memory, determining the emotional significance of stimuli and events, and motivating behavior. A number of these areas access areas of the motor or sensorimotor cortex, where outputs to brainstem and spinal cord neurons that project to muscles produce movements.

Species of mammals vary in their number of cortical areas. Because areas need to be of a certain minimal size to perform their functions, mammals with small brains have few cortical areas. The least shrew, one of the smallest mammals, may have the fewest areas, on the order of 10 or so, but most small mammals have 20 to 30 areas. Macaque monkeys appear to have 80 or more, and some estimate that humans have more than 200 areas. The great advantage of having more cortical areas is that more steps are possible in the area-to-area processing sequence, leading to more sophisticated processing and more parallel processing sequences, resulting in more types of processed information. Most small-brained mammals have five or more somatosensory areas, three to five visual areas, and two to three auditory areas. Some mammals depend on the motor capacities of their somatosensory areas for cortical movement control, and placental mammals have at least two areas specialized for motor functions.

Cortical areas have been traditionally identified by differences in laminar structure as viewed in thin sections cut from the brain. Primary sensory areas, for example, are specialized for receiving sensory information from the thalamus, so that the receiving layer, layer 4, is packed with small neurons and is well developed. Motor areas have a poorly developed layer 4, and layer 4 may even be missing. Instead, motor areas have large neurons in layer 5 that project to the brainstem and spinal cord. These neurons send information a long distance via long axons, so their cell bodies in the motor cortex need to be large. Areas differ in many other ways, and the neurons within them specialize for their functional roles by expressing different proteins, receptors, and neural transmitters. But many adjoining cortical areas look much alike, and they are difficult to identify in brain sections. In addition, the same area—the primary visual cortex, for example—may look more distinct in some mammals than others because the area may be more or less specialized for its functional role.

As areas depend on differences in connections with other parts of the brain for their differing functions, areas can also be identified by their patterns of connections, which can be revealed by a number of experimental techniques. Sensory projections from the eye, ear, and skin maintain their relative spatial orders as they relay from early processing stations, brainstem nuclei, to the cortical primary sensory areas. The primary somatosensory area, S1, for example, occupies a middle portion of the cortex where it extends from the midline of the brain where the two cerebral hemispheres meet to near the lateral edge. Each hemisphere receives sensory inputs from the skin of mainly the opposite side of the body. Inputs from the toes activate neurons near the midline, whereas those from the lips activate neurons near the lateral margins of S1. Overall, the contralateral skin activates neurons from toes to lower trunk, to upper trunk, to fingers to chin, lips, and tongue in a mediolateral sequence across the cortex. Thus, S1 is said to represent the contralateral body surface. The size of the representation of different body parts varies across species as body parts vary in sensory receptor densities. Thus, humans have large representations of the fingers, which are densely packed with sensory receptors, whereas rats have a large representation of the sensory receptors of the whiskers of the upper face, which are activated when they whisk to detect objects in the dark.

Visual areas and auditory areas also represent arrays of sensory visual or auditory receptors in systematic patterns. In V1, vision of the lower, contralateral visual quadrant (upper section) is represented in anterior or medial V1, and the upper quadrant is represented in posterior or lateral V1. Humans, with a central fovea in the retina that is packed with receptors, devote a large area of V1 to these central receptors, but V1 of rats and mice is less specialized for central vision. The auditory cortex of echolocating bats is specialized for high-frequency hearing in ranges that humans cannot perceive. Thus, sensory areas vary across species in the ways they represent sensory receptors.

Cortical Modules

Areas are at least sometimes and possibly often or always divided into smaller functional divisions called cortical columns or modules. For example, the somatosensory cortex, S1, of primates, receives two types of information from the skin. One type, the slowly adapting (SA) input, is from neuron afferents that respond with neuronal spikes throughout a brief period of maintained skin touch, but the other type, rapidly adapting (RA) afferent input, responds only at the onset and offset of the touch. Remarkably, the two types of inputs are kept separate as they are relayed over two brainstem nuclei all the way to the cortex, where SA and RA inputs activate small, alternating patches of layer 4 neurons. As the information in each patch is processed in neurons in a column of cells above and below the layer 4 patches, the cortex is said to have columns of neurons that process either SA or RA information. The SA information from any skin location—the tip of the thumb, for example—is processed next to the RA information from the same skin location, resulting in two interdigitated representations of the skin of the contralateral body from toes to tongue. As another example, the primary visual cortex of humans and most primates has alternating narrow bands of layer 4 neurons that are activated by either the right or left eye. In turn, neurons in these bands activate vertical bands of the cortex, the so-called ocular dominance columns that selectively process information from the right or left eye. Other such separations of cortical areas into alternations of two or three types of processing columns or modules have been demonstrated in other cortical areas. In this way, a single cortical area can function as two or three. These types of modules within any area vary across species, so this is another way that cortical organization can vary to produce functional differences between species.

Little Cortex in Some Mammals

The neocortex emerged as a new type of structure in early mammals that differed from the thin dorsal cortex of reptiles by being a thick, laminated organ divided into areas differing in inputs and outputs. In each area, narrow, vertical arrays of 100 to 200 neurons process information from a small number of inputs, and send this information to similar vertical arrays of neurons in other cortical areas where the processing steps are repeated. This reiteration of a 100–200 neuron-processing step allows complex computations to result from the summation of a series of simple computations. Thus, the cortex can be a powerful processing organ.

The cortex is also a flexible processing organ in that it varies in organization and size as mammals have evolved and adapted to different environmental niches. Large brains with large amounts of neocortex provide a computational advantage, especially as large amounts of the cortex are likely to be subdivided into large numbers of cortical areas. The cortex specializes for the needs of different mammals by varying in how it is subdivided into areas, how areas disproportionately represent sensory inputs or motor functions, how areas are divided into modules of neurons with different functions, how areas are differentiated into layers and types of neurons, and how areas connect with other areas and nuclei. This potential for functional variability has allowed species of mammals to become different in behavior and mental capacities. In humans, and at least a number of other mammals, the neocortex, with its great information processing and information storing capacity, somehow mediates consciousness.

If the neocortex is so useful, why do some mammals have little of it? The simple answer is that large brains with large amounts of cortex take a long time to make and become fully functional. Thus, mammals with a lot of neocortex grow up slowly, and take a long time to reproduce. They cannot have short life spans. Small mammals with small brains and little neocortex (Figure 1), may have rather limited computational abilities, but they can reproduce early and often in their relatively short lives. Large brains are also metabolically costly to maintain. Mammals with large amounts of neocortex need to eat a lot of highly nutritious food. The different sizes and organizations of the neocortex, in conjunction with the rest of the brain, largely determine if you behave as a human or a mouse. Humans have large brains with a massive amount of neocortex (color insert, Figure 38). This cortex mediates complex abilities that allow humans to live a long time, protect their offspring while they develop, and obtain high-grade food that meets the metabolic demands of the large brain.

CORTICAL REORGANIZATION FOLLOWING DAMAGE

In humans, the cortex is a large part of the brain that is so extensive that it covers most other parts. This cortex receives inputs over brainstem and thalamic relays from the sensory receptors in the eyes, skin, ears, and other parts of the body. This information is further processed to create a model of the external world that usefully directs our behavior via the outputs of a number of motor and motor-related cortical areas. Although cortical size and organization vary greatly across the various mammalian species, all have primary sensory areas, the subdivisions of the cortex at the start of the cortical processing systems that relay to variable numbers of additional sensory, multisensory, evaluative, motivating, motor, and memory related cortical areas and subcortical structures. When damage to the nervous system impairs the functions of some part or parts of the cortex, usually the person or animal is unable to perform all of the sensorimotor, or other functions. Impairments could result from direct damage to the cortex itself, such as that following a stroke, or after damage at any level of the incoming sensory relays, such as after spinal cord damage, so that cortical areas are deprived of some of the sensory information they use to do their job.

Clinical studies of patients with damage to the nervous system have shown that impairments vary with the parts of the nervous system that are damaged, and that the impairments can be severe or mild, depending partly on the extent of the damage. But, these studies also show that considerable recoveries of lost abilities can occur, and mild impairments can completely disappear after weeks to months of time. Furthermore, some behavioral therapies seem to potentiate these spontaneous recoveries. Why do such recoveries happen, and what can be done to maximize the return of functions?

To help answer these questions one needs to know what is happening to the brain during the recovery periods. The general assumption is that the damaged nervous system is, to some extent, repairing itself. To see if this is happening, and how, it is useful to consider the results of simple, controlled experiments on animals. In cases of human stroke, the damage often involves a number of cortical areas, and the extent of the damage and the areas impaired can be highly variable across individuals. Likewise, when sensory and motor losses occur as the result of accidental spinal cord damage, many systems may be impaired, and the types and extents of damage are variable. This entry considers the results of two types of experiments. In one type, there is no direct damage to the cortex itself. Instead, a sensory loss is created by damaging a peripheral sensory nerve or another part of a sensory pathway that leads to the cortex. Thus, part of the sensory input that is used by a primary sensory area and subsequent cortical processing areas is missing. The sensory and motor impairments that follow such damage usually diminish over time, but why? The second type of experiment is one where part of a cortical area is directly damaged. If behavioral improvements follow the initial impairments after such lesions of the cortex, do they depend on compensations based on other parts of the nervous system, or on internal alterations within the damaged areas? The results of controlled experiments of both types indicate that both the loss of activating inputs and direct damage to parts of cortical areas are followed by a sequence of changes in the internal organization of the affected cortical areas, and these structural and functional reorganizations are, at least partly, responsible for some of the recoveries that do occur.

Consequence of Sensory Loss

Sensory areas of the cortex are a good place to determine the consequence of a loss of inputs because their internal organizations can be reliably determined, both before and after a sensory loss. Sensory pathways from the peripheral receptors to the cortical areas maintain topographic organizations that reflect the spatial arrangement of receptors on the receptor sheet. Thus, the afferents from touch receptors in the skin of the hind limb, trunk, forelimb, and face project to a nuclear complex in the lower brainstem in a sequence. This somatotopic order is maintained in the projection from this brainstem nuclear complex to the ventroposterior nucleus of the contralateral thalamus, which in turn projects in the same sequence of body parts to the primary somatosensory cortex (area 3b). In humans and other primates, this means that the most medial part of the somatosensory cortex is activated by touching the foot and hind limb, a more lateral part by the hand and forelimb, and a most lateral part by the face and tongue (Figure 1). The primary area of somatosensory cortex is thus said to “represent” the contralateral body surface from toes to tongue in a mediolateral sequence. Within a lateral part representing the hand, the digits 1 through 5 are presented in a sequence, next to the pads of the palm. The representation of the hand, and other parts of the body, is remarkably consistent across individuals of the same species. This organization can be revealed in several ways, most usually by recording from neurons throughout the area with microelectrodes and determining where on the body light touch activates neurons at each recording site. This is called mapping the somatosensory cortex. The organization of the map can be determined in great detail, so any changes in the map produced by a sensory loss can be detected by a mapping experiment after the recovery period.

Because of its experimental advantages, the somatosensory cortex has been the most investigated cortical area for the consequences of sensory loss. One of the first of this type of investigation was to cut a sensory nerve to the thumb side of the hand in monkeys. This produced a loss of tactile inputs from the thumb, digit 2, part of digit 3, and the adjoining palm. Immediately after such a sensory loss, the part of the contralateral somatosensory cortex that is normally activated by the missing inputs failed to respond to touch on the denervated skin or on any other part of the hand or body. However, within weeks of post-lesion recovery, the deactivated part of the hand representation became responsive to the preserved inputs from the hand, mainly

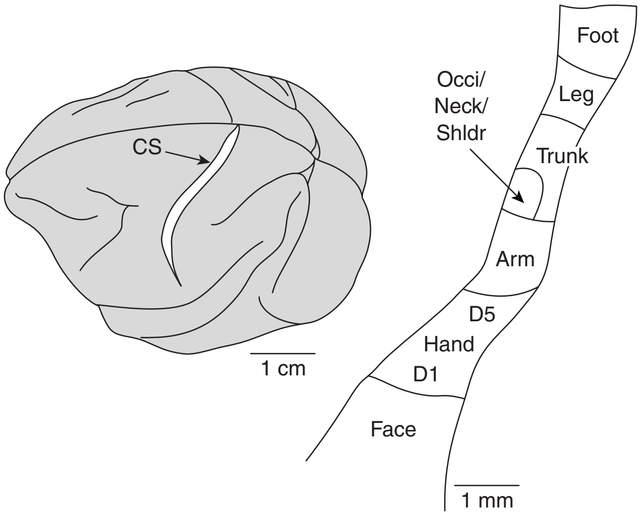

Figure 1 The Brain of a Macaque Monkey Showing the Location of the Central Sulcus (CS), in Which Most of the Primary Somatosensory Cortex (Area 3b) Is Hidden

Notes: The way touch receptors on the body surface are represented from medial to lateral in the brain is shown on the right. The motor cortex is in front (to the left) of the somatosensory cortex, and it contains a similar representation, but one of body movements.

those from the back of the digits and hand. Thus, deactivated portions of the cortex did not remain deactivated because preserved inputs took over by expanding into the cortex that originally responded to the damaged inputs, thereby activating neurons that would otherwise be unresponsive to sensory inputs. Other experiments with different types of sensory loss also produced cortical reorganization. The key result was that neurons throughout even large extents of deactivated cortex recovered responsiveness to touch, but on parts of the body surface with remaining inputs. This process became functionally significant when a few scattered inputs from the hand remained. Normally, these few intact inputs would activate few cortical neurons, or even none if the inputs were too sparse, but during weeks of recovery, these inputs come to activate large numbers of neurons throughout the deprived zone of the cortex. With this recovery of cortical activity evoked by touch on the hand, the ability to use the hand in tactile discrimination and the sensory control of motor behavior returned. The important lesson here is that a few preserved sensory inputs can do a lot. But how do they become more powerful in activating the cortex? What happens during the recovery period?

Related experiments in which anatomical pathways were studied during the recovery period indicated that the connectional anatomy of the mature brain is not fixed. Instead, new connections can form, and this plasticity is the basis of the functional recovery. Most of the new connections are those formed by the growth of the terminal branches of the preserved axon arbors into the nearby or adjacent territories of axon arbors that were lost or totally deactivated by the damage to the sensory system. If neurons no longer have a source of activation, active axon branches grow toward these silent neurons until they contact and become capable of activating them. This growth, with the formation of new connections occurs at both subcortical and cortical levels of the sensory systems. Synaptic contacts with nearby axons predominate and occur most rapidly, but more distant connections are possible during long recovery times of months. However, the shorter new connections are likely to be the most useful because they are concerned with similar body parts and thereby have more potential for substituting for lost connections. Longer new connections may lead to misperception rather than compensation. For example, a touch on the face may be also felt on the hand when the deactivated hand cortex is reactivated by inputs from the face. Nevertheless, the experiments show that new connections do form in the parts of the brain that have become unresponsive and nonfunctional, and these new connections are capable of restoring high levels of neural activity. Most importantly, restored levels of neural activity in the cortex and elsewhere can result in the return of lost functions.

Such growth patterns and reactivations are not limited to the somatosensory system. Extensive cortical reactivation and reorganization has been demonstrated after sensory loss in the auditory and visual cortex. Presumably, they occur in all cortical areas, sensory or not, because deactivations following brain lesions are followed by reactivations based on the growth of axon arbors of active neurons so that they replace and compensate for the arbors of inactive neurons. Further evidence for this comes from studies where a portion of the primary motor cortex has been removed.

Consequence of Removal of the Motor Cortex

The primary motor cortex of monkeys is another part of the cortex that has proven useful in studies designed to determine if brain changes accompany behavioral recoveries after damage.

The motor cortex of primates lies in the most posterior portion of the frontal lobe, just in front of areas 3a (for proprioception) and 3b (for touch) of the somatosensory cortex. Although the primary motor cortex receives sensory inputs from somatosensory areas of the cortex, it is not practical to determine the somatotopic organization of the motor cortex by recording from neurons throughout the field to determine their receptive fields. Instead, the motor cortex is “mapped” by using microelectrodes to electrically stimulate (activate) neurons in rows of sites across the field. Typically, short bursts of electrical pulses of the right amplitude will evoke a movement of some part of the contralateral body. The movement may be a gross one, possibly involving movements of fingers, the wrist, elbow, and even the shoulder, but the stimulating current can be lowered until only a small, simple movement remains, such as the twitch of a single finger. When the electrode is moved to another nearby site, and the process repeated, a different small movement is usually obtained. By stimulating sites throughout the primary motor cortex, an overall movement map is obtained. This is possible because a major output of the primary motor cortex is to neurons of the contralateral brainstem and spinal cord where these neurons directly or indirectly activate the muscles that produce movements. The overall movement map resembles the sensory map in the somatosensory cortex (area 3b) in that in both areas the hind limb and foot are represented medially in the motor cortex, the trunk more laterally, the forelimb and hand still more laterally, and the face and tongue most laterally. In the motor cortex, however, we have a map of evoked movements and in area 3b, we have a map of sources of sensory activation. Perhaps as a result, the maps differ in detail. The sensory map in area 3b is systematic such that digits are represented in order with the hand portion of the field, but the motor map does not have this detailed order at a fine grain level of representing movements. There is a hand representation where movements of fingers are evoked, but similar finger movements can be evoked from several, nonadjacent sites, and sites evoking wrist or even elbow movements might be mixed in. Thus, a lesion of part of the hand representation in the motor cortex would remove a mixture of sites related to various hand and forelimb movements, but leave a mixture of such sites in the preserved hand cortex.

As one might expect, even an incomplete lesion of the hand representation in the motor cortex of monkeys impairs skilled hand use. Although crude movements of the hand remain immediately after the lesion, the monkeys have difficulties in picking up small pieces of food or in retrieving them from shallow holes. However, during the weeks to months of post-lesion recovery, the monkeys improve on these tasks, eventually recovering most of their abilities to make skillful finger movements. This recovery is accompanied by a change in the organization of the motor cortex. When electrically stimulated, the remaining hand cortex has changed its organization so that more sites evoke finger movements, compared with wrist or elbow movements. The motor map has been altered in the effectiveness of its output so that more of the remaining cortical hand region is devoted to finger movements. This is at least partly the result of changes in the distribution of the termination of axon arbors of the preserved cortical neurons as they grew into the territories of spinal cord motor neurons that were deprived of many of their activating inputs by the cortical lesion.

These results from lesions of the motor cortex are not likely to be unique to the motor cortex. Lesions of any portion of the cortex will disrupt the functions of the damaged region of cortex and remove outputs to other areas of the cortex and to subcortical structures. These portions of the brain, now deprived of their activating inputs, will not function normally, and impairments in abilities will follow as processing in a network of cortical areas and subcortical nuclei has been disrupted. In addition, neurons in cortical areas and subcortical nuclei that projected to the lesioned cortex will be damaged as they lose their axon terminals that were in the lesion site. Thus, damage to a part of any cortical area is likely to be followed by a sequence of repairs and reorganization, both within partly damaged fields and within fields projecting to the damaged cortex or receiving inputs from the damaged cortex (cortical areas generally both receive inputs and send projections to other cortical areas). Likewise, subcortical thalamic nuclei and other structures with inputs and projections altered by a cortical lesion would reorganize. These reorganizations would be based on the formation of new connections, and reactivated neurons would contribute to behavioral recoveries.

Current research is focused on the use of neurochemical treatments that could enhance the new growth of connections after brain damage or sensory loss, and possibly improve recoveries. In addition, considerable evidence indicates that post-lesion training and experience can improve recoveries by influencing the formation and selection of synapses in damaged systems, thereby promoting the formation of more useful neural circuits. Further research has the potential of revealing those treatments and procedures that are most effective in promoting recoveries.

CROSS-MODAL TRANSFER

Can a person born blind, upon gaining sight, differentiate between a sphere and a cube using vision alone? In other words, can knowledge previously learned by touch be used to inform vision? This question, first posed by William Molyneux in the late 17th century, concerns cross-modal (across senses) transfer, when information gathered in one sensory modality (e.g., touch) transfers to knowledge in another sensory modality (e.g., vision). Cross-modal (CM) transfer results from stimulus characteristics that are related across the senses. For example, an object with a rough texture has a property (roughness) that is readily picked up by touch, but that can be detected by vision as well, as a visually uneven surface. For this reason, CM transfer is sometimes referred to as intermodal (between senses) equivalence.

Though there may be CM transfers across all senses, most research focuses on transfer between vision and touch, with some research on transfer between vision and audition. This entry describes methods of testing CM transfer, transfer between vision and touch, and transfer between hearing and vision.

Methods

To test CM transfer, adults are asked to recognize by sight (or touch or sound) an object they previously experienced in a different modality. Another method involves training subjects on a task with one modality, then asking them to perform an analogous task in another modality. Performance on the second task is compared with that of subjects who had no training on the first task. Faster learning or better performance of the first group is attributed to CM transfer.

A method typically used with infants involves familiarizing them with a stimulus in one modality until they are habituated to it (no longer show interest), then presenting the same object in another modality paired with a new object. Infants show evidence of cross-modal transfer if they explore the new object longer, as they have already learned about the familiar object in the first modality.

Transfer Between Vision and Touch

Although adults can transfer information from touch to vision and from vision to touch, there are situations in which they do not succeed, or are less accurate. For example, after holding an apple with closed eyes, an adult may be able to identify it when shown a visual array of differently shaped objects. Experimental factors that affect performance include length of exposure, object complexity, and stimulus properties (e.g., length versus shape). Another crucial factor is the degree to which vision and touch can derive the same information about a stimulus, known as perceptual equivalence, which depends on how strongly the stimulus characteristics are related across the senses. For example, if touch and vision were equally accurate at picking up an object's roughness, then roughness would be perceptually equivalent for touch and vision.

Shape

Overall, adults can visually recognize a shape (e.g., a cylinder or a prism) they previously felt and can identify by touch a shape they just saw. However, there is often an asymmetry, such that they are better at CM transfer from touch to vision than from vision to touch. Similarly, newborns can visually recognize a shape they previously felt, at least when they explored it with their right hands, but often fail to transfer the same shape information from vision to touch with either hand throughout the first year of life. The opposite asymmetry is found occasionally during development and depends on how different the test shapes are from one another, as well as the length of time subjects explore the objects.

Texture

Adults and children are generally accurate at transferring information about whether a texture is rough or smooth from vision to touch, as well as from touch to vision. Newborns also show evidence of transfer of texture information between vision and touch. At 1 month of age (the youngest age tested), infants can transfer information about softness and hardness from oral exploration to vision.

Despite the evidence of CM transfer of texture in both directions, when the stimuli tested possess a low degree of perceptual equivalence, an asymmetry emerges at all ages in favor of transfer from vision to touch.

Asymmetry in CM transfer could result because different properties of objects are easily picked up by vision and touch. Because vision is arguably better suited than touch to extract shape information, it might be easier to recognize a previously felt shape by sight than it is to recognize a previously seen shape by touch. Although touch is arguably better at picking up texture information, there is generally not an asymmetry in CM transfer of texture. The different patterns of asymmetry may reflect stronger perceptual equivalence across vision and touch for texture than for shape.

Although CM transfer improves with age, individual differences in CM transfer are apparent from infancy and continue throughout development; infants who display greater CM transfer in infancy also do so later in childhood.

At-risk infants (e.g., premature infants) are worse at CM transfer than are full-term infants, even when they have the same general sensory functioning. At-risk monkeys (e.g., low birth weight) also show poorer performance on CM transfer tasks. Further, monkeys raised in the dark later fail to show CM transfer to the previously deprived modality (i.e., vision), even when sensory limitations are accounted for. Thus, although CM transfer is present at birth before visual experience, its later refinement depends on visual input. Molyneux's blind man would be only partially successful.

Transfer Between Hearing and Vision

Adults are fairly accurate at transferring information between vision and audition, though transfer abilities/asymmetries differ based on the stimulus properties tested. Adults transfer information about intensity between audition and vision in both directions, but for rhythm and complex auditory patterns, they only show evidence of transfer from vision to audition: they are better at discriminating auditory patterns (e.g., Morse code) after training on an analogous visual task but do not transfer auditory training to the visual task. However, with simpler rhythms, 4- to 5-year-old children show transfer in both directions, but 4-month-old infants only show transfer of rhythm from audition to vision. Newborns can transfer intensity from vision to audition (the only direction tested): They respond less to a loud sound after being exposed to a bright light.

Despite the difficulties in making conclusions from diverse lines of research, evidence indicates that some cross-modal transfer exists at birth. Thus, cross-modal transfer may be a fundamental property of our sensory systems, one that contributes to our rich understanding of the world around us.

CULTURAL EFFECTS ON VISUAL PERCEPTION

Mainstream psychology has generally assumed that psychological processes are universal and that the main role of psychology is to investigate these universal aspects of human beings. Visual perception, attention, and even visual illusion have, therefore, been understood mainly through the underlying optical mechanisms and characteristics of visual information hardwired in the human brain and shared by human beings in general.

During the last couple of decades, however, increasing numbers of cross-cultural studies have empirically reexamined this theoretical assumption and advocated an alternative view of human psychology in which culture and human psychological processes are considered to mutually influence one another. This entry reports some recent attempts to reexamine the so-called universal systems of visual perception and discusses the possibility of cultural influences on perception as evidenced by cultural variations in optical illusion, in color perception, in visual attention, and in brain functioning that governs visual attention.

Cultural Effects on Visual Illusion

In the literature of psychology, optical illusion is often used as evidence of human universals in perception. One of the most famous optical illusions is the Müller-Lyer illusion (see Figure 1), in which people perceive that a line segment ending in inward-pointing arrows is longer than a horizontal line segment ending in outward-pointing arrows. This seemingly universal phenomenon, however, has been tested cross-culturally, and the results indicate cultural variations in the magnitude of illusion. For example, Murray Islanders in Melanesia and members of the Toda tribe in India showed significantly smaller errors than do their British counterparts in judging the relative lengths of the lines. Similarly, extensive cross-cultural studies of 17 societies—including a variety of African agricultural and hunter-gatherer cultures, an Australian Aboriginal foraging culture, a tribe of Filipino horticulturalists, and midwesterners in the United States—show that the degree of illusion is much stronger among U.S. residents. Furthermore, children in some cultures (e.g., hunter-gatherers from the Kalahari Desert) were completely immune to the Müller-Lyer illusion. The findings suggest that individuals who grew up in certain visual environments are not vulnerable to the Müller-Lyer illusion.

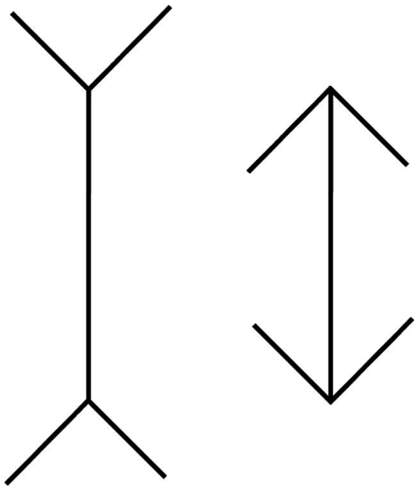

Figure 1 Müller-Lyer Illusion

Source: General Social Survey, National Opinion Research Center (2000).

Various studies have proposed hypotheses to examine the main causes of cultural variations in susceptibility to this illusion. The carpentered environment hypothesis, for example, suggests that people developmentally acquire perceptions of a three-dimensional world in accordance with their experiences with the surrounding environment. In Western industrialized societies, individuals' depth of field is founded on the structure of rooms, houses, and furniture consisting of vertical and horizontal lines with corners in a variety of angles. People in these societies associate acute angles with nearby objects (such as the corner of a rug), and obtuse angles with somewhat more distant views (such as the intersection of two walls and a floor). Once they acquire this specific perceptual pattern in the three-dimensional world, they apply the same rules even when they observe the visual representation in the two-dimensional field. The Western perspective in art is a good example. In Western perspective, objects close to the viewer are drawn larger and are characterized by acute angles, and objects farther from the viewer are drawn smaller and feature obtuse angles. For this reason, Westerners perceive a line ending in inward-facing arrows to be farther away (and therefore actually longer) than it appears. However, in cultures where structures are built using less angular shapes, people have fewer opportunities to interpret the relationships between lines and angles in their perceptual world. The carpentered environment hypothesis thus helps explain why people from some cultures are less susceptible to the Müller-Lyer illusion than Westerners.

Drawings using Western perspective have been used to study cultural variations in depth-of-field perception. For example, one study examined how children and illiterate adult laborers from an African Bantu tribe interpreted the image of a large hunter aiming a spear in the direction of two animals, an elephant and an antelope (see Figure 2). The elephant was closer to the hunter from a non-Western two-dimensional point of view, but because it was drawn smaller than the antelope and the hunter, it would be farther away according to Western perspective. The antelope was farther away from the hunter in the two-dimensional view, but because of its size, it would be considered closer to the hunter in Western perspective. Therefore, although Westerners would be expected to perceive that the hunter was aiming at the large prey, the Bantus perceived the same image without the depth of the field, and for this reason they reported that the hunter was aiming at the smaller prey, which they believed to be closer to the hunter.

The causes of cultural variations in the effects of optical illusions need to be studied further. Current findings, however, suggest that humans' susceptibility to optical illusion may depend heavily on their visual experiences in the environment and on culturally shared interpretations of visual information.

Cultural Effects on Color Perception

Colors accentuate our daily life. But do all people perceive color in exactly the same way? Color is an excellent stimulus for use in scientific investigation because although the spectrum is physically defined, color perception entails psychological processes. One line of research provides evidence that supports the universality of color perception. A cross-cultural study of 98 societies suggests that 11 colors (red, orange, yellow, green, blue, purple, pink, brown, gray, black, and white) are universally recognized, even in the absence of color terms corresponding to these colors. For example, although the Dani people of Irian Jaya on the island of New Guinea had only two color terms (dark and light), they were able to quickly distinguish among the basic colors.

Moreover, researchers who investigate the relationships between colors and color terms advocate an evolutionary account of the development of color terms. That is, the appearance of color terms is predictable according to the number of color terms in a language. If the language has only two color terms, these always turn out to be black (dark) and white (light). However, if the language has three color terms, the third term will correspond to the red end of the spectrum. The fourth and fifth color terms will be green and yellow (or yellow and then green), the sixth color will be blue, and the seventh color will be brown. The last color terms to appear will be purple, pink, orange, and gray, not necessarily in that order.

New findings challenge the idea that color perception is universal among humans, however. For example, the Dani performed relatively poorly in tasks requiring them to remember the basic colors; their retention rate was much lower compared with that of English speakers. Another study investigated color perceptions of Berinmo speakers in East Sepik, Papua New Guinea, whose language contains five basic color terms. The Berinmo's language distinguishes between *nol* (a kind of bluish green) and *wor* (a kind of yellowish green) but not between blue and green. In this study, English and Berinmo speakers were asked to view and remember color chips representing colors spanning either the blue-green boundary or the nol-wor boundary. The Berinmo speakers' performance of the color retention task was better with regard to colors on the nol-wor boundary. The English speakers did better at remembering colors on the blue-green boundary. These findings suggest that linguistic color terms do affect the ability to remember specific colors.

Does language play a role in facilitating or inhibiting our perceptual processes? A study of Russian and English speakers examined whether the existence of a language category influences color perception. Russian has two independent color terms to represent blue: light blue (*goluboy*) and dark blue (*siniy*), whereas English speakers usually distinguish these colors by adding adjectives (light or dark) to the base term *blue*. English and Russian speakers were presented with a variety of blue color chips that were slightly different from each other in hue and saturation, and the task was to discriminate which one corresponded to the target chip. For example, a blue chip was presented as a target stimulus; subsequently, two alternative blue chips were presented, and the participants were asked to select which of the alternatives was identical to the target chip. Russian speakers were quicker to discriminate between two colors when they fell into different categories (goluboy and siniy) than when they were from the same color category. However, these differences did not provide the same advantages for English speakers. This experiment demonstrated that categories in a language affect participants' performance in simple perceptual color tasks. This line of research suggests that culturally shared ways of naming colors may influence speed of color perception.

The issue of universality versus cultural variability in color perception is still controversial. One position holds that language and cultural conventions do not affect color perception; the other maintains that color perception is subject to arbitrary, culturally defined color terms. It has recently been suggested that both positions are partially true. The color terms used in a given culture do influence retention, learning, and ongoing processes of color discrimination. But there is still about 75% overlap in how cultures draw boundaries around color terms. For example, the boundaries of the color terms used by the Berinmo speakers mentioned earlier are similar to those of the five color terms used by Himba speakers in Namibia, although the ecologies and economies of the two groups diverge significantly. Thus, there seem to be universal constraints regarding categorization of colors.

Cultural Effects on Visual Attention

Another line of research has examined whether culture can affect attentional processes. Research on perception and cognition indicates that there are systematic cultural variations in attention between people in East Asian societies (e.g., China, Korea, and Japan) and Western societies (e.g., Canada and the United States). East Asians, who holistically attend to the entire field and relationships between objects, are more context sensitive than Westerners, who analytically focus on salient objects and can easily separate target objects from the context.

A research group used the rod and frame test to compare the levels of context sensitivity of U.S. and Chinese participants. This task used a device consisting of a square frame box of a certain depth, with a rod situated at one end of the box. The participant sat at the other end of the device with his or her chin on a chin-rest, observing the rod through the box. The participants were asked to manipulate the position of the rod until they subjectively thought the rod was perfectly vertical. The experimenter then manipulated the angle of the frame box, and the participant tried again to position the rod vertically. When the angle of the frame was vertical, the frame could serve as a reference point for the position of the rod. When the frame was tilted, however, the judgment of participants who could not ignore the frame would be hindered. The Chinese participants made more errors than the U.S. participants did, suggesting that the Chinese were more sensitive to contextual information and therefore more influenced by the angle of the frame. U.S. participants were able to detach the task from the influence of the angled frame, which suggests that they were relatively immune to the contextual cue.

Are there cultural differences in how attention affects memory for objects in scenes? In an object recognition task, U.S. citizens and Japanese were presented with pictures of wild animals in natural settings. The same participants were then shown pictures of the original animals, as well as new animals, and asked to identify which animals they had seen previously. In this part of the study, the combination of animals and backgrounds was manipulated: Half of the original animals were presented with their original backgrounds, and the rest with completely new backgrounds. Although the task was to identify the animals, the results indicated that, compared with those from the United States, Japanese participants were less able to recognize previously seen animals—especially when they saw them against the novel backgrounds. These results suggest that the Japanese encoded the background information in the images they saw in first part of the study and had more difficulty detaching the target animal from the context.

What are the underlying mechanisms of cultural variation in patterns of attention? And to what extent do sociocultural factors influence our patterns of attention? Recent findings in psychophysiology and neuroscience provide evidence that culture deeply influences attention. Results of an eye-tracking study indicated that East Asians were more likely than were Westerners to allocate their attention to the surrounding information. When given the aforementioned animal recognition task, Chinese participants made more saccadic (rapid nonfocused) eye movements to the background scenes than did those from the United States, even though the task was to evaluate the target objects. These results suggest that context-oriented attention is deeply internalized among East Asians, and for this reason, they cannot help referring to contextual information even when they do not have to. These findings are further supported by a study that measured brain activations during a similar object versus background task. In this study, magnetic resonance imaging revealed that when identifying objects and their locations, more brain regions relating to object information processing were activated in U.S. participants than in Chinese participants. Another cross-cultural study measured activity in the brain area that processes object recognition. There were no identifiable differences between Singaporean college students and their U.S. counterparts; however, Singaporeans 60 years of age and older showed less activity in that brain area than did U.S. residents in the same age group. These results suggest that even the neural circuitry for attending visual scenes is affected by culturally influenced information processing over the long term.

What are the causes of this systematic cultural variation? Researchers in general maintain that people internalize a specific pattern of attention through their experiences of living in a given cultural environment. Some researchers maintain that exposure to culturally biased visual representations such as paintings, drawings, and even photographs facilitate the internalization of a specific pattern of attention. For example, East Asian painting masterpieces were found to be more context rich than are their Western counterparts. Furthermore, when asked to draw scenic images, contemporary members of East Asian cultures were more likely than Westerners were to draw context-rich images. Other studies suggest that East Asian cultures emphasize a sense of interdependence, whereas Western cultures emphasize a sense of independence regarding interpersonal relationships and reasoning styles. Such cultural values may encourage culturally adaptive patterns of attention—for example, making Westerners more likely to see independent objects in the scenes and Easterners more apt to see relationships and contexts that surround the objects. In sum, these findings support the notion that cognitive experiences in the real world influence the processes of our visual systems.

Implications of Research on Culture and Perception

Current research provides evidence of cultural influences on perception. These effects have a variety of implications for social, cultural, and personality psychology, as well as for cognitive psychology. The reasons are threefold. First, the cross-cultural examination of human perception allows us to examine in what ways, and to what extent, our perception is flexibly structured and influenced by systems associated with sociocultural experiences. Some researchers maintain that basic visual processing exists independently of socioculturally shared beliefs. Their findings suggest that the physical and structural systems of visual perception are sufficient for understanding human perception. However, under the rubric of "new look psychology," which emphasizes influences of beliefs and values on visual perception, researchers maintain that our perceptions, even perceptions of so-called neutral stimuli, are fully influenced by our knowledge structures, which in turn are based on our experiences. The underlying processes have not been fully investigated, however, and further research is necessary.

Second, social and cultural psychologists who have identified cultural variation in social cognition—such as causal attribution, self-perception, judgment, inference, and categorization—have long awaited more objective measurements than previously existing quasi-experimental and quasi-survey data collection, which was based mainly on participants' self-reports. Current technological advances allow cross-cultural researchers to scrutinize underlying processes of these variations in human behaviors.

Finally, the theoretical frameworks of perception research do not sufficiently account for the functions of emotions, motivation, and psychological states. Since the emergence of new look psychology, however, substantial numbers of studies have suggested that such factors play an important role in perceptual processes. Again, the findings of cultural influence on perception mutually accelerate further investigation into the complexity of human perception.

CUTANEOUS PERCEPTION

The skin, far from being just a passive wrapping for the body, provides a wealth of capabilities that combine to allow for extraordinarily complex patterns of perceptual experience. Although cutaneous perception might be taken for granted by most persons, for individuals with visual or auditory disabilities, their impression of the world can depend heavily on their senses of touch. Cutaneous perception results from combinations of responses from skin receptors, evoked by mechanical and thermal stimuli, and, occasionally, chemical and painful events. Historically, there has been some question about the structures and mechanisms that mediate these percepts, partially because it is so difficult to isolate the suspect components, and because some sites (such as the cornea of the eye) are sensitive to touch, temperature, and pain, yet do not possess specialized structures. Nevertheless, converging data from anatomy, physiology, and experiments using "psychological dissection" have led to strong contemporary models of underlying structural-functional relationships.

Mechanical stimuli include static pressure, movement—such as stroking and vibration—and even skin stretch. Thermal stimuli can result from warming or cooling shifts in skin temperature, with extremes that produce pain. Even chemical stimuli, such as pain-relieving salves, generate numerous sensations, including cooling from menthol and heating and irritation from capsaicin. And electricity, the great nonspecific stimulus, can evoke similar perceptual experiences, bypassing receptors to activate nerve fibers directly, mimicking sensations produced by normal ("adequate") stimulation of the skin. To complicate matters further, these qualities can combine to evoke complex illusory percepts—for example, cold pressure stimuli can feel wet (like touching mercury), and the perception of movement can be produced by a rapid sequence of touches.

Cutaneous perception can result from passive contact with static or moving point-like ("punctate") stimuli, such as a mosquito lighting on our arms, or extended 2-dimensional surfaces, such as sandpaper, the tines of a comb, or even dense vibrotactile displays like the Optacon, a machine that blind people use to read print. Similarly, we are sensitive to changing stimuli, such as the warming of a coffee cup, and are aware, through the whole body's surface, when the ambient room temperature drops several degrees. More complex percepts can be evoked from active exploration of simple or multidimensional stimuli, as when we try to identify a Braille character, determine a tomato's ripeness, or assemble a wristwatch. Sensitivities to stimuli vary across the body, leading to different perceived qualities. This situation holds because the structures that subserve tactile experience, the cutaneous receptors, differ in type and density from one site to another. For example, the elbow has recently been empirically shown to be a more sensitive site for thermal stimuli (as mothers, testing their babies' bathwater, have always known) than other areas of the arm.

The skin has two broad divisions—glabrous (smooth) skin, such as the fingertips, and hairy skin, which covers most of the human body. Distinctions between these two skin types include the presence or absence of hairs and the intricate labyrinthine fingerprints. Most research studies of the skin and its capabilities have concentrated on glabrous sites, particularly the fingers and hands. From these experiments, physiological models of cutaneous perception that relate particular characteristics of tactile experience, such as roughness or stretch, have been proposed (Joel Greenspan and Sandy Bolanowski provide a detailed history and description). Because of differences in the receptor populations between the skin types, these models based on glabrous skin should be extrapolated to areas such as the limbs or trunk, only with great caution. This entry discusses cutaneous perception in relation to intensity, space, and time and describes real and virtual tactile surfaces and environments.

Cutaneous Perception and Intensity

Research has shown that tactile perception of simple points, or "asperities," can be extraordinarily acute—we can feel (and localize) 1 micrometer "bumps" on an otherwise smooth surface with our fingertips. Our experience of feeling imperfections along the surface of an automobile or piece of furniture attests to this ability. Place that bump into motion by vibrating it, and our sensitivity can improve a great deal, under certain conditions. Vibrating an area on the fingertip the size of a pencil eraser at a frequency of about 250 hertz (Hz) can be felt at signal amplitudes of much less than a micrometer. The fingertips, sometimes characterized as the "retina" of the skin, are the most sensitive to vibration. Move that stimulator to the palm of the hand, the wrist, forearm, or chest, and sensitivity drops by a factor of as much as 100. One of the underlying mechanisms for this sensitivity gradient is the reduction in the number of receptors and changes in receptor types. For example, Roland Johansson and Åke Vallbo report that there are more than 130 Meissner's corpuscles per square centimeter (cm^2) in the skin of the index fingertip, whereas at the base of the thumb, there are fewer than 30/cm^2, and they don't seem to exist at all in hairy skin.

The maximum intensity that can be felt depends on a number of stimulus conditions, including site, frequency, contactor size, and age. Usually pain or tissue damage defines the upper limit, but a usable dynamic range between just noticing a stimulus and a comfortably "loud" level can be as much as 10,000:1. Despite this large range, if we wanted to use tactile signals—say, in a cardiac emergency code indicating a range of importance from "Check your blood pressure" to "Call 911!"—cognitive limitations restrict the number of useful intensity levels to three or four, even though we can discriminate many more differences when directly compared. Roger Cholewiak consulted on this kind of problem in the development of an implanted cardiac monitor, the AngelMed Guardian, in which subcutaneous tactile feedback is used to warn the user of the severity of an identified condition. Finally, Joseph Stevens and his colleagues have quantified changes over body loci that occur with aging. These are generally attributed to the reduction in number and "health" of the most sensitive touch structures in elderly persons.

Cutaneous Perception and Space

Of the spatial modalities, touch falls between vision and audition in its acuity, being less precise than vision but more precise than hearing. It is not difficult to locate an insect on the arm because it bends hairs while it walks about. Generally, the ability to localize vibrations on the 2 square meters (m^2) of the skin can be quite good, as long as they can be felt. This ability has been tested empirically with both active and passive presentations of stimuli. Active exploration mimics the typical way we use our skin in everyday life ("haptics"). Passive stimulus presentations, however, allow the researcher to control the signal more precisely, but at the expense of losing the richness of kinesthetic and motor feedback that enhances "everyday" spatial percepts. In the same way that sensitivity to a stimulus varies over the body, so does our ability to localize an event: Touch the fingertip lightly with a pencil point and it will be felt every time; on the back of the hand it will be felt often, but not always, whereas on the chest a light touch might be missed at many loci. A sidelight of this demonstration is to attend to the "coolness" of the tip. On the back of the hand most touched points will be felt as neutral, but occasionally, "cold spots" will brightly announce their presence. These demonstrate that the distribution of cutaneous receptors is neither dense nor uniform. There is an interaction between this punctate sensitivity and perceived intensity: The skin's sensitivity to warmth (as well as to higher-frequency vibrations) depends on the area of stimulation. Specifically, the larger the region warmed or the size of the contactor, the "louder" the sensation, a characteristic called *spatial summation.*

The ability to distinguish whether one or two points have been touched depends on how far apart they are, increasing from about a millimeter on the fingertip to several centimeters on less-sensitive areas such as the abdomen or thigh. Interestingly, there are certain "anchor points" near which localization is better. Although the limb joints serve this function, the midline of the body—front and back of the trunk—have recently been shown by Roger Cholewiak and his colleagues to anchor near-precise localizations. Finally, as Stevens and his colleagues have shown, spatial acuity deteriorates with age, as do many perceptual functions.

A one-dimensional stimulus such as a vibrating point might be employed for a kind of tactile Morse code, or to signal the presence of an event, but the temporal characteristics of the skin limit transmission rates for complex streams. More useful information can be communicated to a person with two-dimensional displays, such as Braille cells, incorporating spatial information. Experienced Braille readers can read at 60 words per minute (wpm), although 300 wpm rates have been reported. (Visual rates range from 250 to 400–600 wpm.) What limits the processing of tactile patterns? One important factor is *masking,* in which stimuli preceding or following a pattern degrade its processing. This degradation can take the form of changes in sensitivity, or in the ability to recognize the pattern. In the latter case, depending on the relative shapes and the timing between patterns, features can be dropped, added, or distorted. For example, a "P" might be perceived as an "F," or an "H" felt as an "A," as James Craig's extensive work has shown. These interactions typically occur when presentations occur within 200 milliseconds (ms) of one another, regardless of whether they are static or scanned across the finger. Another type of spatial interaction, reviewed by Lynette Jones and Susan Lederman, is related to patterns "drawn" on the skin's surface (*graphesthesia*), and the position of the body part in space. Here, identification of similarly shaped letters (such as b, d, p, q) drawn on the hand, arm, thigh, or forehead can depend on the limb's orientation and "point of view" (egocentric vs. allocentric) taken by the viewer. These data suggest that mobile body sites should be used for tactile displays only with caution. The torso has been chosen to present tactile information about the environment for navigation in cases of sensory disability, or for displays for situation awareness (such as Angus Rupert's aircraft Tactile Situation Awareness System) to augment overloaded "major" senses.

Cutaneous Perception and Time

Regarding temporal acuity, the skin again takes the middle ground, this time being more acute than vision but less acute than audition. Tests of temporal order indicate that there is some parity among these modalities (the chemical senses usually being considered far slower), so that regardless of the stimulus, a separation of about 20 ms is required to identify the order of two events (brief clicks, flashes of light, or taps on the skin). We are also able to detect gaps in prolonged single-frequency vibration or vibrotactile "noise" (where many frequencies are combined), but again, depending on a number of factors, such as age and stimulus intensity, gaps shorter than 250 ms are difficult for observers to appreciate.

Like vision and audition, tactile perception is limited to a narrow range of temporal variation (frequencies). Whereas the other mechanical sense, audition, has a useful frequency range from 20 Hz to about 20 kilohertz (KHz), that of the skin is more limited, from about 20 to 300 Hz. There are instances of low frequency sensitivity, say to swaying of a tall building, but those experiences are often ephemeral and the sensations confused with internal body functions. And, like vision and audition, a tactile stimulus has to stay on for some minimal time before the richness of its qualities can emerge. A pressure pulse (a "touch") can be felt if it is as brief as 2 ms, and increases in perceived intensity with duration, a phenomenon described as *temporal summation.* But not only do stimuli briefer than about 200 ms have to be presented at higher intensities even to be felt, for durations far below than this, vibration will not feel periodic (nor will sound have tonal quality—the "atonal" interval). However, because the more-sensitive skin receptors tend to respond best to transients, even more durative stimuli (either pressure or vibration) won't necessarily be appreciated as being proportionally stronger and might lead to the sensory phenomenon known as adaptation. That is, like the constant pressure of the clothes on our body, prolonged vibration leads to a reduction in apparent intensity.

So, the changes in the several perceptual qualities associated with temporal summation lead to a recommended upper limit for vibrotactile bursts of about 200 ms, beyond which sensation magnitude can fall. There is a similar range of thermal sensitivity (our "physiological zero") that occurs over a limited span of ambient temperatures where we may feel neither warm nor cool, given enough time to adapt. All our sensory systems are tuned to respond to changes, considering constant stimuli less informative: Sitting still provides little information about our clothes, but move the arm and we can become aware of the fabric around our sleeve, if we pay attention. Given these limitations, a vibrotactile Morse code could result in communication with relatively slow transmission rates (Hong Tan and Nat Durlach showed that at most, about 20 wpm can be achieved tactually, the amateur level for acoustic Morse).

Interestingly, when trying to determine whether one or two points have touched the skin, introducing a difference in time can make the task trivial. Even when identifying the orientation of two-dimensional gratings (similar to the tines on a comb), if the fingertip can stroke the surface rather than have it passively touched, the array becomes a spatiotemporal display and the groove orientation becomes immediately obvious. Research has shown that grid orientation tasks clearly show the influences of aging on the ability to distinguish texture, as long as stimuli are passively presented. However, allow the finger to stroke the surface and there is no difference between a 10-year-old and an octogenarian.

Because movement is a change in location over time (spatiotemporal), it has a number of perceptible qualities in those domains, such as direction, distance, and velocity. Greg Essick has shown that movement can be generated on the skin in a variety of ways (such as a brush dragged across the skin or a series of taps on individual vibrators), and that we are good at identifying its direction, unless the movement is very fast. Our perception of extent and "straightness" also depend on velocity: If the sequence is too fast, perceived extent may be foreshortened, but if it is too slow, the path may wander. With appropriate controls, illusory motion (akin to vision's "Phi") can be observed with only two tactile stimuli, such as vibrations at locations separated by 10 cm and 100 ms. A different illusory experience, described by Frank Geldard, is evoked by a sequence of, say, five taps at one site, followed by a sixth at a second site about 10 centimeters (cm) away, with inter-tap intervals of about 50 ms. In this case (sensory saltation), the series will be felt evenly distributed between the two sites. In all of these, the sensations of movement can generate tactile "vectors" within virtual environments for communication systems and appear to have correlates in the central nervous system.

Tactile Surfaces and Environments: Real and Virtual

Because of the interest in applying tactile displays to enhance virtual environments, as well as for sensory substitution and augmentation, it has become important to study the ability of the skin to appreciate physical dimensions of real-world surfaces and structures. As children, we would lay paper on the ground and create patterns with crayons, the tip rising and falling with the underlying surface. This texture was transmitted to cutaneous receptors via the crayon's vibration, and the surface roughness perceived through two primary sources. The vibrotactile information, spatial variation over time, conveys something about a surface's features, but alone does not provide enough information to form the percept of a texture (e.g., a vibrating cell phone does not feel like sandpaper). Adding proprioceptive feedback—information from muscles and joints—gives egocentric knowledge of the relative locations of each body part. The combined information from vibrotactile and proprioceptive sources underlies tactile perception of texture. Additional information, such as from vision, can form an even stronger percept.

Combinations of these spatial and temporal qualities in tactile exploration can make us aware of a number of physical surface qualities, including stiffness, force, and friction. To assess the ripeness of a pear, it's often helpful to squeeze the fruit and feel its stiffness. Stiffness—the force exerted by a surface proportional to the distance it is compressed or stretched—can be perceived because of the mechanical stimuli (static pressure and movement) and the proprioceptive feedback of the joints. Force is a bit more difficult to distinguish from other characteristics because the static pressure sensed by the cutaneous receptors is supplemented by skin stretch and displacement. Some attributes of a surface, such as friction, might be appreciated using vision, but the skin often provides information that would be otherwise imperceptible, such as the stickiness of flypaper. Although vision helps to guide the extremities, haptic information ultimately provides information about the complex forces (e.g., weight and friction) and compliancy of surfaces, as Steven Cholewiak, Hong Tan, and David Ebert have shown. These qualities, as well as texture, are important for appreciating surfaces in everyday and virtual realities.

There is particular interest in using cutaneous perception and haptics to enhance skill learning in many virtual environments such as telesurgery. Telesurgery, performed using a human-controlled robot, relies on surgeons' abilities to map their movements with controllers to the three-dimensional locations of the robot's appendages. It requires long and tedious practice proficiency. Any features that could make the surgery more "life-like" can potentially smooth the transition. By providing haptic force and cutaneous feedback (e.g., texture, pressure, temperature, stiffness), learning time may be reduced and the procedure taught to a wider array of individuals, who may have avoided the technology because of its perceptual sterility.

CUTANEOUS PERCEPTION: PHYSIOLOGY

A major challenge in neurobiology is to understand how the brain constructs mental images of the world around us. The mental images that arise from the sense of touch are based on continuously changing patterns of electrical activity called action potentials that are evoked in the nerves that innervate the skin, muscles, and joints. The dynamic patterns of action potentials that come from the skin are the basis of cutaneous perception. These patterns are sent to the central nervous system via two main nuclei located in the brain stem and thalamus. Once the information reaches the cortex, it is systematically transformed through several processing stages into an alternate transformed pattern that is matched against previously stored patterns to evoke mental images of objects and surfaces in contact with the skin. The challenge facing neurobiologists is to understand the anatomical pathways and neural circuits that transform the patterns from the initial pattern into the representation that underlies memory, in other words, the challenge is to understand the neural code(s) that underlie behavior.

When exploring and manipulating an object with our hands, we readily appreciate many qualities or features of the object. These features include characteristics such as its size and shape, the texture of the surface, its weight, and dynamic properties, such as whether it is stationary or is moving in our hand. Many studies have shown that our ability to discriminate and identify objects is based on a rapid pattern recognition mechanism. For example, common everyday objects are recognized (typically in less than 3 seconds) without visual input at accuracy rates greater than 96%. In those experiments, subjects typically report that they identified the object using two to three features, such as its size and texture. In addition to be being highly accurate and rapid, the cutaneous system is also extremely sensitive with young adults being capable of detecting vibrations with amplitudes as low as 100 angstroms.

Discovering the neural code(s) that underlie cutaneous perception has been difficult for a number of reasons. First, the sense of touch is composed of multiple sub-modalities with individual features being coded by different afferent types. Somehow, these features are processed and integrated in the cortex to produce a single unified percept of objects. Second, in contrast to vision and audition, the cutaneous receptors are imbedded in a deformable sensory sheet (i.e., the hand) that dynamically changes as the hand moves around in space. Thus, the pattern matching is a dynamic process. Third, sensory inputs play a dual role and are important for both sensation and action. The sensory inputs provide information about the world, and the inputs related to action play important roles in motor control. Fourth, cutaneous perception is tightly linked to higher cognitive functions such as selective attention and drive what aspects of the inputs are given privileged access to perception.

To illustrate the role and complexity of the sensory processing from the hand, imagine what happens during the simple act of grasping and tossing a tennis ball. During the grasping phase, the fingers must spread apart to surround the ball and the hand moves to surround and enclose the ball. After contact, sensory afferents send their outputs to the cortex where they are transformed and matched against stored memories of tennis balls. The sensory inputs also play an important role during manipulation and ensure that the proper grip force is used to prevent the ball from being dropped. Finally, to toss the ball, the motor system must be activated in a way that is highly coordinated with the sensory inputs to allow the ball to be released at just the right time. How this simple task is performed in the nervous system is not known.

This entry first discusses how information related to cutaneous perception is initially encoded in the peripheral afferent nerves that innervate the hand to produce a primary neural representation of the cutaneous inputs. Then the entry discusses the anatomical pathways that carry the information to the cortex and how and where cutaneous information is processed in the cortex.

Primary Afferent Representation

Perception from the hand begins with 13 different types of afferent fibers that innervate the hand. Four of these afferent types respond to mechanical stimuli and provide information about cutaneous inputs. The other 9 afferents provide information about pain (2), temperature (2), itch (1), and hand position (4) and will not be discussed further. Two of the mechanoreceptive afferent types lie close to epidermis and densely innervate the skin, and two afferent types lie deep in the dermis and have much lower innervation densities, which are defined as the number of afferent fibers per square centimeter of skin. One mechanoreceptor is called the slowly adapting type 1 (SA1) afferents. Individual SA1 afferents end in a neurite complex called the Merkel cells, which are specialized epidermal cells located at the tips of the epidermal ridges and enfold the branches of the axon terminal of the SA1 afferents (see color insert, Figure 7). There are about 100 SA1 afferents per square centimeter (cm^2) on the distal finger pads, and the innervation density declines rapidly as you move proximally along the arm toward the body. Sensory neurons and their afferent fibers are characterized by which stimuli cause changes in their firing rates. For the cutaneous receptors, one characteristic is a property called the receptive field (RF), which is defined as the area of skin that causes a change in the firing rate of the afferent fiber. The region on the skin where stimuli cause increases (or decreases) in firing rate are called excitatory (or inhibitory) regions. The RF sizes of SA1 afferent fibers are typically about 2 to 3 millimeters (mm) in diameter and contain one or more central "hot" spots or zones within their RF of high sensitivity. SA1 afferents, like all of the cutaneous afferent fibers, have purely excitatory RFs. The acuity threshold of SA1 afferents, which is defined as the minimum distance that these afferents are able to discriminate one point indented into the skin from two points, is about 1.0 mm. This threshold is nearly identical to the perceptual threshold of human spatial acuity on the finger pad, which demonstrates that these afferents are responsible for two-point discrimination. The SA1 afferents adapt slowly (which is why they are called slowly adapting) to a constant indentation with the baseline firing rate increasing with increasing intensity of the stimulus (probe indented deeper into the skin).

The SA1 system, which consists of the SA1 afferents and their central projections, is the spatial system in touch. When a two-dimensional (2-D) pattern such as an embossed letter of the alphabet is indented into the skin, activity is evoked in the afferents that have part of their RF below the letter while other SA1 afferents remain silent. Because the SA1 afferents densely innervate the skin, the neural activity evoked across the population of afferent fibers is in the same spatial form as the pattern (Figure 1). That is, an isomorphic (i.e., in the same form) neural representation of the 2-D pattern with each afferent fiber acts like a single pixel in the neural image. This peripheral neural image is sent to the brain by the SA1 afferents.

Practically everything that we know about the functional roles of the afferent fibers comes from studies that combine psychophysical measurements in humans with neurophysiological recordings from nonhuman primates. A series of studies showed that the SA1 afferents are not only responsible for spatial acuity and 2-D form but also are responsible for coding features related to texture perception. Those studies show that the perception of roughness (and smoothness) is based on the spatial variation in firing rates among the population of SA1 afferents. Thus, surfaces that cause every other afferent fiber to fire vigorously show high spatial variation in firing and are perceived as feeling rough, whereas surfaces that evoke similar firing rates across the SA1 afferent population are perceived as feeling smooth. Thus, the SA1 system is the spatial system and plays the analogous role in cutaneous perception that the parvocellular system plays in vision.

The second mechanoreceptive afferent type is called the rapidly adapting (RA) afferents. These afferents also branch as they approach the skin with their individual branches embedded in anatomical structures called Meissner's corpuscles (see color insert, Figure 7). Meissner's corpuscles are composed of stacks of laminar disks that are tethered between the sweat ducts and primary ridges of the dermal papillae. Like the SA1 afferents, RA afferents innervate the skin densely (about 150 afferents/square centimeter [cm^2]). However, there are significant differences between these afferent types. RA afferents respond only to the onset and offset of a probe indented into the skin and hence adapt rapidly to the stimulus. These afferents do not respond during the period when the probe is statically indented into the skin. The RF sizes of RA afferents are larger than SA1 afferents (3–6 mm in diameter rather than 2–3 mm) and show uniform sensitivity to an indented probe placed inside the RF. RA afferents show poor spatial acuity and are unable to resolve gaps in gratings spaced more than 3 mm apart.

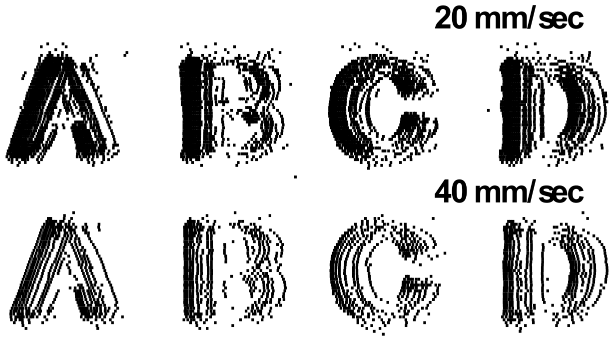

Figure 1 Spatial Event Plot for a Typical SA1 Afferent to Embossed Letters (ABCD) Scanned Across the RF at Two Different Velocities

Note: This plot represents the spatial pattern of input that is sent to the cortex from the population of SA1 afferent fibers.

The RA afferents are highly sensitive to dynamic events such as moving stimuli across the skin and to low-frequency vibrations (below about 60 hertz [Hz]). RA afferents play an important role in grasping by signaling when objects begin to slip in our hands. The working hypothesis is that the RA system, which includes the RA afferent fibers and all of their central projections, is the tactile motion system and is analogous to the magnocellular system in vision.

The third mechanoreceptive afferent type is the Pacinian afferent (PC). This class of afferents is also rapidly adapting, but in contrast to the other SA1 and RA afferents, these afferents do not branch as they approach the skin; instead, they end in the deeper layers of the dermis in a large anatomical structure consisting of concentric layers of fluid filled sacs known as the Pacinian corpuscle (color insert, Figure 7). The multiple layers of the Pacinian corpuscle act as a mechanical filter for low frequency vibrations and cause these afferent types to be extremely sensitive to high frequency vibrations (100–300 Hz). Studies show that PCs can detect indentations as small as 1 nanometer (nm) applied directly to the corpuscle or 10 nm when applied to the skin surface. Because of their extreme sensitivity, the receptive field boundaries for PC afferents are nearly impossible to define.

PCs play the dominant role in coding temporal information that is transmitted from the working end of tools to the hand during tool use. PCs are the temporal system in touch.

The fourth afferent type is the slowly adapting type II (SA2) afferents. These afferents have not been found in nonhuman primates and rodents, and as such, fewer studies have been devoted to understanding their functional role in perception. They are located deep in the dermis. Historically, it was thought that the receptor ending for these fibers was a structure called the Ruffini's corpuscle (color insert, Figure 7); however, recent studies have questioned whether the Ruffini's corpuscles exist in the hand. Thus, the precise receptor ending for the SA2 afferents is at present not known. Neurophysiological studies in humans show that these afferents have large RF sizes spanning about 1 centimeter (cm) of skin and respond with a slowly adapting response to stretching of the skin in tuned directions. The working hypothesis for these afferents is that as the hand is moved to different positions, the pattern of skin stretch on the back of the hand changes in a systematic way. These stretch patterns are encoded in the SA2 afferent population. As such, the population response of the SA2 afferents is thought to code for hand conformation.

Ascending Pathways

The outputs of the peripheral afferent fibers related to cutaneous perception ascend in a fiber tract called the dorsal-column medial lemniscal pathway and synapse on neurons in the dorsal-column nuclei (DCN), which is located in the brainstem (Figure 2). Outputs from the DCN neurons send their projections to neurons located in the contralateral hemisphere in a group of neurons called the ventroposterior complex (VPC) of the thalamus. Little is known about how the neurons in these intermediate stages process information in the primate. However, neurons in the ventroposterior lateral nucleus (VPL), which are the neurons in the VPC that receive cutaneous inputs from the hand, have small receptive fields that are similar in diameter to the RFs of the peripheral SA1 and RA afferents. This suggests that information is minimally processed at these subcortical stages.

Cortical Processing of Tactile Information

From the thalamus, neurons in VPL project in two directions (Figure 2). The main dense projection is to the primary somatosensory cortex (SI), which is composed of four separate areas that are given the names 3a, 3b, 1, and 2. The other projection, which is much smaller, projects directly to the second somatosensory cortex (SII). The small projection to the SII cortex is not well understood, but one hypothesis is that it is the pathway responsible for processing vibratory information because many of the neurons in this pathway have PC-like responses.

Area 3a is located deep in the central sulcus (CS). It receives its inputs from a particular part of VPL that contains neurons that respond best to arm position and movement. Consequently, area 3a is thought to be involved in coding information about body position and movement, which is also called proprioception or the sixth sense. Little is known about how information is coded in area 3a; however, it is becoming a region of interest as a possible cortical location where stimulating electrodes could be placed in humans with prosthetic arms to provide artificial feedback of proprioceptive input.

Area 3b has been studied extensively. It is located in the posterior bank of the central sulcus, and neurons in area 3b respond exclusively to cutaneous inputs. The RFs of neurons in area 3b are large, confined to a single finger pad, and highly elaborate. In contrast to the RFs of the peripheral afferents, the RF of 3b neurons are composed of an excitatory region surrounded by one or more regions of inhibition. Stimuli placed in the excitatory part of the RF cause the neuron to increase its firing rate, whereas stimuli placed in the inhibitory part cause a decrease in firing rate. The receptive field structures that are observed in 3b are similar to the RFs that have been described of simple cells in the primary visual cortex. As in the visual system, these RFs are feature selective and selectivity responsive to spatial features such as the orientation of bars indented into the skin. The minimum angle that can be discriminated by the population response of area 3b neurons is about 20 degrees, which is identical to psychophysical thresholds of orientation discrimination of humans—suggesting that

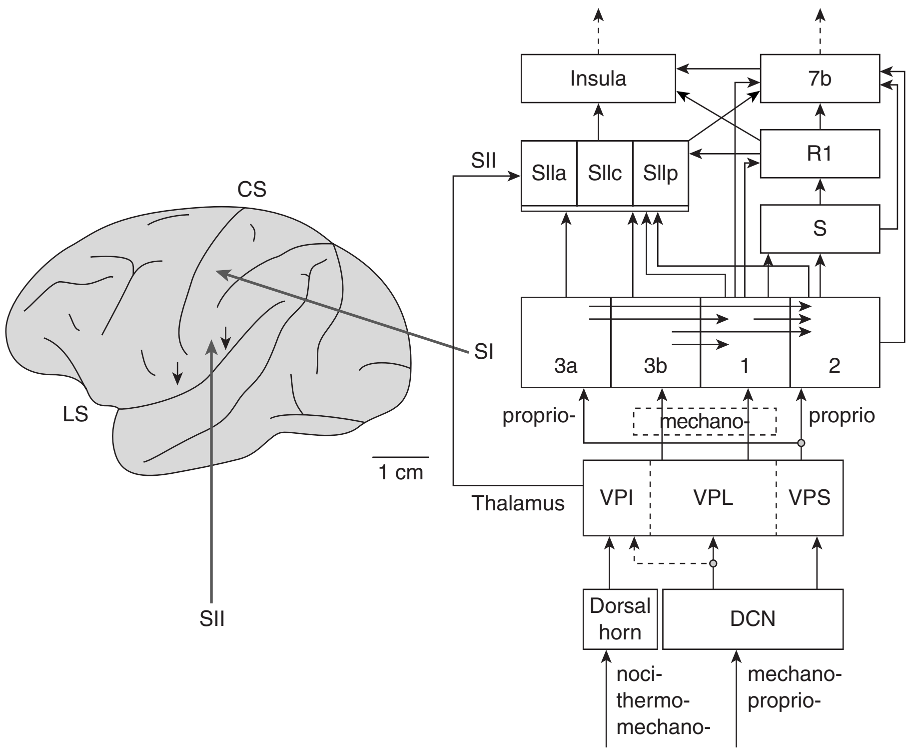

Figure 2 Block Diagram Showing the Flow of Information Through the Somatosensory System

Notes: Outputs from the peripheral afferents related to cutaneous inputs first synapse on neurons in the dorsal column nuclei (DCN). These neurons send their main projections to the ventroposterior lateral nucleus of the thalamus (VPL), which in turn projects to the four areas of the SI cortex and has a minor projection to the SII cortex. The four areas of SI then project to SII and to areas 5, retroinsular (Ri), and 7b. SI is located in the postcentral gyrus of the central sulcus (CS). SII is located in the upper bank of the lateral sulcus (LS). VPI and VPS stand for ventroposterior inferior and superior.

orientation discrimination occurs in area 3b. Discriminating features such as orientation is the first initial step in the transformation of spatial information into the central representation that underlies form processing. These findings suggest that mechanisms underlying form processing in vision and touch are similar and that area 3b is part of the SA1 system for coding spatial form and texture.

Area 1 receives both direct inputs from the thalamus and indirect inputs from area 3b (Figure 2). Like area 3b, area 1 neurons have RFs consisting of excitatory and inhibitory subregions, and area 1 neurons also show orientation-tuned responses. However, several lines of study suggest that it lies further along the processing pathway for form and motion. First, the RFs of area 1 neurons are larger, more complex than 3b neurons, and typically span multiple fingers. This is important because it suggests that area 1 performs further computations on the inputs from area 3b. Furthermore, many area 1 neurons are highly sensitive to stimulus motion. A working hypothesis is that area 1 neurons code for shapes moving across multiple digits.

The RF of area 2 neurons are different from the other parts of SI. They are much larger and typically respond to both proprioceptive and mechanoreceptive inputs. Animals that have area 2 ablated are unable to discriminate large shapes, and neurophysiological and imaging studies suggest that neurons in area 2 respond selectively to objects that differ in three-dimensional (3-D) shape. The working hypothesis for this area is that it is where the initial representations of features related to the 3-D size and shape of objects is generated and plays an important role in processing sensory input for action.

Beyond Primary Somatosensory Cortex

The four areas of the SI cortex project in two directions. One projection is to areas 5, Ri, and 7b (Figure 2). This projection is the action pathway and is important for processing sensory inputs for coding where the body is in immediate personnel space, to directing attention, and to guiding the hand to targets in space.

The other projection is from SI to SII (Figure 2). Animals that have SII ablated are unable to recognize the shape of objects, which means that this projection lies along the pathway underlying tactile object recognition. Many studies now support the idea that SII is composed of multiple areas—SIIa, SIIc, and SIIp in nonhuman primates (Figure 2), and parietal operculum 1 (OP1), OP2, OP3, and OP4 in humans. The different areas in SII respond differently to tactile stimuli. Specifically, the anterior and posterior parts of SII (SIIa and SIIp) respond well to both cutaneous and proprioceptive inputs (such as neurons in area 2). These areas flank a central area of SII (SIIc) that contains neurons that respond mainly to cutaneous inputs. SII neurons have much larger and more elaborate RF than SI neurons do, and many of the neurons (about 30%) show selective responses to oriented bars indented in the skin. SII neurons typically have receptive fields that span multiple pads on the fingers with some pads having orientation-tuned responses and others pads being driven by the stimulus but not being tuned. The diverse set of RF structures that are observed in the SII cortex suggests that this area of the cortex is most likely coding features of large objects that span multiple fingers and is important for processing and integrating information related to the representation of 3-D shapes.

Processing of Touch Beyond SII Cortex

The processing of tactile information beyond SII is poorly understood; however, other areas of the cortex have been shown to be important for processing information about form and vibration. Of particular importance are studies by Ranulfo Romo and his colleagues who have systematically mapped the neural pathways that underlie the decision process in animals trained to discriminate whether vibrations of different frequency presented in sequence were the same or different. Further, neural imaging and studies using transcranial magnetic stimulation, or TMS, in humans suggest that other areas of the cortex play important roles in processing tactile form and texture. Candidate areas include the anterior parts of the intraparietal cortex (IPA), supramarginal gyrus, right intraparietal sulcus (pIPS), and possibly visual areas. How the information is processed in these areas is not known.

The mechanisms of form processing are not understood, but a growing body of evidence suggests that it involves a number of processing stages. The process begins with the activation of the four cutaneous afferents that innervate the glabrous skin of the hand. In the periphery, each of the four types of afferents is responsible for encoding different local features, but in the cortex, the segregation of function appears to be distributed across different hierarchal processing stages with the higher stages responding to more global aspects of the inputs and being influenced by the cognitive state of the animal. About 90% of the neurons in SII are affected by the animal's focus of attention. Beyond SII, the tactile representations are merged with inputs from the other senses to produce a central representation that can be matched to stored memories. Where this matching process occurs is not known.

D

DECISION MAKING, PERCEPTUAL

One can define *perceptual decision making* (PDM) as a categorical choice based on sensory information. For example, did you just hear an airplane flying by or was it a helicopter? PDM can be contrasted with economic, emotional, reward-based, or value-based decision making, in which the decision is driven by the desirability of an option. For example, you see two identical-looking boxes in front of you. From past experience, you know that you are less likely to find candy when opening the right box. You therefore choose the left box. Because perceptual decisions can only be studied when the choice is reported by the subject, studies of PDM usually also involve a verbal report or triggering an action (pushing a button, for example).

Perceptual decisions can be classified based on their complexity. The simplest type of perceptual decision is deciding whether a stimulus has been present or not (stimulus detection). "Did you perceive a flash of light?" would be an example. More complex perceptual decisions involve making a choice between two categories (binary choice). Examples would be "Did you see a cat or a dog?," "Was the second tone louder or softer than the first one?," or "Did you feel a touch on your left or on your right arm?" Even more complex perceptual decisions involve choices between multiple categories (for example, "In which of the four cardinal directions was the object moving?").

The goal of studying PDM is to understand how humans and animals process sensory information for categorizing stimuli and triggering appropriate actions. This involves understanding the choice behavior itself as well as the neural mechanisms leading to this choice behavior. Traditionally, PDM has been studied primarily by psychophysicists and (mathematical) psychologists, but more recently, it has also become a popular area of research in neuroscience. Interdisciplinary approaches that combine behavioral and physiological experimental techniques with mathematical modeling are aimed at understanding the mathematical algorithms underlying PDM (the "recipes" for how to come up with an appropriate choice) as well as their neural implementation (how these computations are performed by the brain).

This entry first summarizes behavioral aspects of PDM, continues with a discussion of neural correlates, and finishes with a review of theoretical concepts.

Behavioral Findings

Accuracy Effects

For a stimulus to be perceived, its intensity needs to exceed a critical level. Thus, it is usually observed that stimuli with intensities well below some critical level are never detected, stimuli with intensities well above this critical level are always detected, and stimuli with intensities close to this critical level are sometimes detected and sometimes missed. The probability of detecting a stimulus as a function of the stimulus intensity is referred to as the *psychometric function.* The stimulus intensity at which the stimulus is detected with a probability of 0.5 (half of the time) is typically referred to as the *perceptual threshold*. When the stimulus is only presented for a very short amount of time (typically less than 100 milliseconds), the intensity threshold changes systematically with presentation time (Bloch's law: higher threshold for shorter presentation time).

The idea behind why the same stimulus can sometimes be detected and sometimes be missed is that the internal representation of the stimulus is noisy and therefore fluctuates across stimulus presentations. It is assumed that the strength of this internal representation has to exceed a decision criterion or threshold for the stimulus to be detected. Note that this decision threshold, linked to neural activity, is different from the perceptual threshold, linked to stimulus intensity, mentioned earlier. For example, we might present a visual stimulus with an intensity slightly above the perceptual threshold multiple times. Note that the stimulus intensity always exceeds the perceptual threshold. Nonetheless, the stimulus will sometimes be detected (seen) and will sometimes be missed (not seen). This is because the neural activity constituting the internal representation of the stimulus fluctuates from presentation to presentation. Sometimes it exceeds the decision threshold and sometimes it does not. This concept has been formalized in *signal detection theory*.

Choices between two possible categories (e.g., "Was the object moving to the left or to the right?") are more accurate when the stimulus is less ambiguous. This is usually the case when the stimulus is of high quality, meaning that it provides a lot of information about its contents and the noise level is low. Experts refer to this situation as a high signal-to-noise ratio (SNR). A clear, focused image would be an example. When a comparison between two stimuli is required (e.g., "Was the second tone louder or softer than the first one?"), subjects are more accurate the more different the two stimuli are with respect to the relevant dimension or attribute (in this example, the sound pressure level). Furthermore, this difference typically has to be a certain fraction of the base value to achieve a particular level of accuracy. For example, when presenting a 1-kilohertz (kHz) tone and asking by how much the frequency of a second tone has to be increased to be able to detect an increase in pitch, you will probably come up with a "just noticeable difference" (JND) of approximately 5 hertz (Hz). When presenting a 4-kHz tone and asking the same question, you will probably come up with a JND of approximately 20 Hz. The ratio between the JND and the base value (in this example, 5 Hz/1,000 Hz = 20 Hz/4,000 Hz = 0.005) is referred to as the Weber fraction and, according to Weber's law (Weber-Fechner law), remains constant over a wide range of base values.

Response Time Effects

In free response paradigms, subjects are allowed to respond whenever they are ready. For example, you are watching a movie of an animal wandering through the bushes. You can watch the movie for as long as you want to. You are told to say "cat" when you see a cat and "dog" when you see a dog. In experimental situations in which subjects are presented with a random mixture of trials with varying difficulty (or signal strength), one usually observes that both accuracy and response time (RT) vary systematically with task difficulty (high SNR = low difficulty = high accuracy = fast responses; low SNR = high difficulty = low accuracy = slow responses).

Another characteristic phenomenon is observed when additional instructions to emphasize either accuracy or speed are given: When subjects are instructed to emphasize accuracy, they tend to make more accurate choices, but responses are also slower. Thus, the increase in accuracy comes at the cost of having to spend additional time on making the decisions. When subjects are instructed to emphasize speed, they tend to make faster but less accurate choices. Thus, the increase in speed comes at the cost of reduced accuracy. This phenomenon is referred to as *speed-accuracy tradeoff*. These RT effects are captured by sequential sampling models of PDM.

It has further been observed that RT varies systematically with the number of available choice options (Hick's law). RT is approximately proportional to the logarithm of the number of choices (i.e., RT increases by a certain amount every time the number of options is doubled).

Neural Correlates

Neural correlates of PDM have been studied in humans using non-invasive techniques (such as electroencephalography [EEG], magnetoencephalography [MEG], or metabolic measures of brain activity like positron emission tomography [PET] or, in particular, functional magnetic resonance imaging [fMRI]) as well as in animal models using invasive techniques (extracellular recordings of action potentials from single or multiple neurons). Whereas fMRI provides an idea about which brain areas are active during PDM, the animal recordings, because of their much higher temporal resolution, provide additional insight into how the decision unfolds over time. Overall, these studies suggest that decision-related neural activity, depending on the PDM task, can be observed in various brain areas, including the prefrontal cortex, parietal association cortex, and premotor cortex. These results suggest that the brain uses a continuous flow of information strategy rather than strict sequential processing: Perceptual decisions are not first made by some abstract PDM module, independent of how the choice is reported, and then an appropriate action is requested once the decision has been finalized. Instead, when the decision maker has a choice between several possible known actions, the decision unfolds as a competition between simultaneous action plans. Neural activity can be measured in motor planning areas well before the choice is actually made, and a transient simultaneous activation of neurons coding for different possible actions can be observed.

The time course of neural activity recorded from the parietal cortex of monkeys performing a visual PDM task (stimulus discrimination) with goal-directed eye movements as the means of reporting the choice seems consistent with sequential sampling models: initially, if the animal does not show a choice bias, the firing rates of pools of neurons coding for the different possible actions are approximately identical. The firing rates then ramp up or down with the slope of the ramp being a systematic function of the stimulus strength. Sensory evidence in favor of a particular action leads to an increase in the firing rate of the associated neurons, evidence against a particular action to a decrease. Immediately before an action is triggered, the neurons coding for the chosen action exhibit a stereotyped activity level, consistent with the idea that a decision threshold has been reached.

Theoretical Approaches

Signal Detection Theory

When a stimulus with an intensity that is close to the perceptual threshold is presented, it is sometimes perceived and sometimes missed. A breakthrough theoretical formalization of this phenomenon was signal detection theory (SDT) in the 1960s. The basic idea behind SDT is that the internal representation of a sensory stimulus is noisy and therefore fluctuates across stimulus presentations. SDT assumes that the internal representation of a sensory signal follows one particular distribution in the absence of the stimulus (noise only distribution) and another distribution in the presence of the stimulus (signal and noise distribution). It is further assumed that the stimulus is detected if the strength of the internal representation exceeds a decision criterion. Because of the variability of the internal representation, the same stimulus can sometimes cause a neural activation that does not exceed the decision criterion (stimulus is missed) and sometimes an activation that exceeds the criterion (stimulus is detected). Likewise, this concept also explains why noise can cause an observer to detect a stimulus when no physical stimulus is actually presented (the neural activation might still exceed the decision threshold).

SDT can explain why perceptual decisions are more accurate when the signal is stronger. A higher SNR is equivalent to less overlap between the two distributions of internal signals that need to be discriminated. It is therefore easier to place a decision threshold in such a way that the largest part of one distribution is on one side of the criterion and the largest part of the other distribution is on the other side of the criterion.

Sequential Sampling Models

SDT cannot explain any of the RT phenomena because time is not part of the SDT formalism. This is where sequential sampling models of PDM come into play. The basic idea behind sequential sampling models is that, in the presence of uncertainty or noise, a decision maker can benefit from sampling multiple times from the noisy distribution of internal values (neural activity) representing the stimulus. The SNR, and therefore the accuracy of the decision, can be improved by integrating or accumulating the evidence obtained from these samples. But when should one stop sampling? The sequential sampling models ("accumulator," "integrator," or "drift-diffusion" models) usually assume that a decision is made when the accumulated evidence exceeds a certain decision criterion. Mathematically, these models are closely related to the Sequential Probability Ratio Test (SPRT), which was developed during World War II. In this framework, choosing between different categories can be thought of as a race to threshold between multiple integrators, each being associated with a particular choice option.

Sequential sampling models can explain several of the experimental observations mentioned earlier. Because the integrators accumulate both signal and noise, with the signal driving the appropriate integrator closer to the correct decision boundary and noise driving any integrator closer to any decision boundary, the higher the SNR is, the more accurate decisions are. (Accumulating noise means that the actual state of the integrator is unpredictable, but the variance of the state of the integrator constantly increases. It is therefore increasingly likely that one of the decision thresholds is crossed, just by chance; which one is unpredictable, and this phenomenon therefore interferes with making a correct decision.) Decisions are also faster when the signal is stronger because the decision criterion is reached earlier (because of a steeper slope; when trials with varying difficulty [signal strength] are presented in random order, it is assumed that the decision maker is unable to make systematic adjustments to the decision threshold based on difficulty). Sequential sampling models can also explain the speed-accuracy tradeoff. When the decision criterion is moved further away from the starting point of the accumulation (the height of the decision boundary is increased in response to an emphasis on accuracy instruction), the accumulation of noise makes it less likely that a decision threshold will be crossed and therefor the decisions will be more accurate, but the signal has to be sampled for a longer duration until the decision threshold is crossed, leading to slower decisions.

DEPTH PERCEPTION IN PICTURES/FILM

Depth perception in general can be understood as a reconstructive process that interprets the retinal image in our eye such that a three-dimensional (3-D) object arises in our mind. Pictures and films can also provide vivid impressions of depth. This pictorial depth differs in nature. It is a constructive process of its own and presents an additional level of difficulty. Normal vision allows us to glean information about an object's shape and color as well as about such things as its spatial relations, its mass, and its potential danger. Normal vision typically reconstructs the real-world object which gives rise to the retinal image with admirable precision. This is possible because our visual system is able to resolve the many ambiguities present in the retinal image. Pictorial depth is both more confined and broader than normal depth. Figure 1 illustrates the nature of the (re)constructive processes in pictorial viewing compared with normal viewing. In normal viewing, a large number of 3-D objects would qualify as permissible reconstructions that could be made on the basis of one given retinal image. This is the case for the canvas. Pictorial depth is processed in addition.

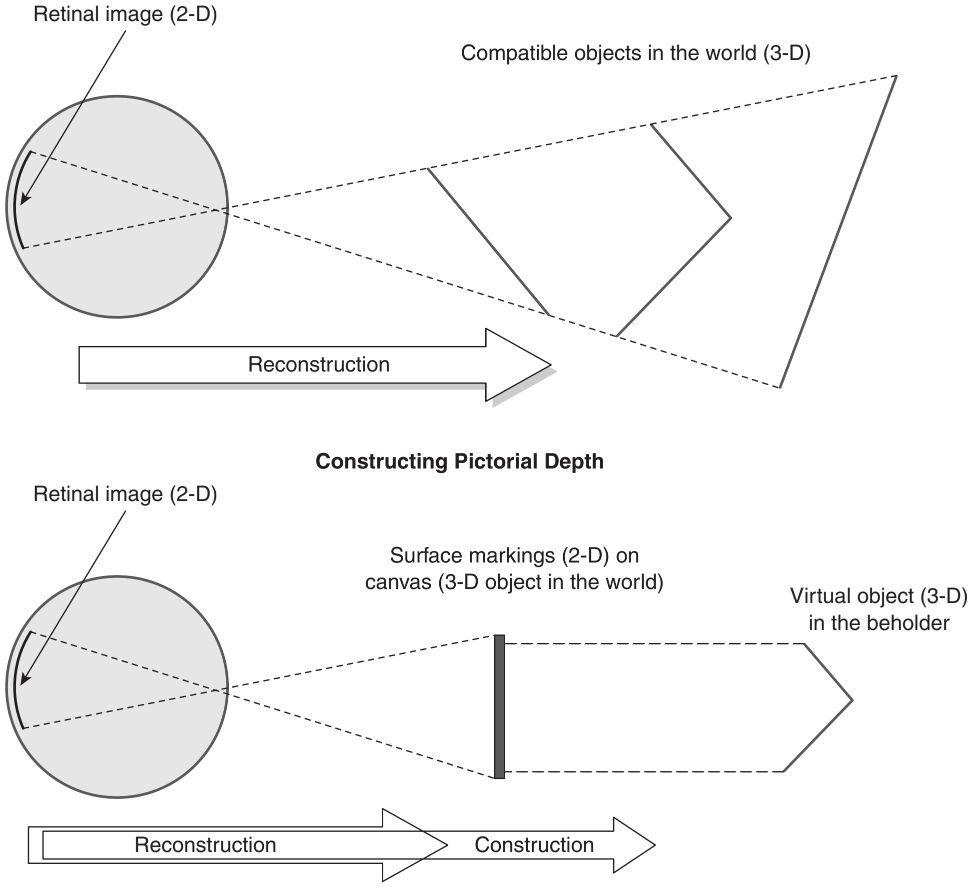

Figure 1 Reconstructing Physical Depth and the Two-Layered Process of Constructing Pictorial Depth

To date, perceptual psychologists have not been able to agree about just how the mind solves this so-called underspecification problem and singles out the one reconstruction that ends up in our awareness. The reconstruction is close to the actual 3-D object that we see, most of the time. The great physiologist Hermann von Helmholtz has argued that the visual system acts like a problem solver and uses unconscious inferences and depth cues to solve the underspecification problem. This entry describes the dual nature of pictures, the limitations of pictorial depth, and violations of spatial construction rules in frozen and dynamic renditions.

The Dual Nature of Pictures

Pictures add a new layer to the problem. To illustrate this additional layer, consider the portrait painting of Mona Lisa (or any other portrait). Assume that your vantage point is right in front of the painting and that Mona Lisa is looking straight at you. If a real person had been in her place, one side step by the observer would evade the gaze. Not so the painted portrait. You can walk several yards to either side and still, Mona Lisa is looking straight at you. Her gaze appears to follow you around, no matter where you are. This eerie quality of pictures illustrates the fundamental difference between pictorial space and normal space. Now we can take a closer look at the dual nature of picture perception, at the two layers that are both involved. On the one hand, a picture is a real-world object. It is a flat piece of canvas placed at a certain position and orientation in real space. On the other hand, the content of the picture, *Mona Lisa,* is there as well. However, she seems to obey different laws than the canvas itself does. Although the canvas does change its orientation toward us as we take a step to the side (the first layer), Mona Lisa is unmoved and does not change her orientation toward us (the second layer). The two layers of (re)construction that are present in every picture (with the exception of abstract paintings, monochromes, etc.) are at the heart of our understanding of depth in pictures.

One attempt to understand the second layer of picture perception is to conceive of paintings and photographs as seen with a disembodied eye. Although the canvas itself is seen with the normal eye, the entire content of the picture is seen as if our eye were put right in front of the canvas and remained there. Alternatively, one could think of the second layer as the content of the picture being yoked to the observer. The difference between still and moving pictures, in comparison, is rather trivial. The picture can be treated as a frozen frame of a movie. The lack of motion makes the reconstruction of the depicted object a little harder, but the process is in principle the same.

As helpful as it may be to separate the two layers of picture perception, one should not take them to be two consecutive steps. If one does, many mysteries arise, such as the mystery of the slanted picture surface. For instance, if we slant our portrait painting with respect to the observer's line of sight, the image on the retina becomes distorted. Inferring the would-be 3-D object from the painted surface is hard to begin with, and arriving at the spatial layout of the virtual object in the painting by way of the retinal image should be close to impossible when the image surface is slanted with respect to the observer. The mystery is that such a devastating effect of image slant does not occur. Its absence has long preoccupied artists, philosophers, and psychologists alike. As Maurice Pirenne has shown, the perceived aspect ratio, depth, and size of the painted object is amazingly robust. However, this robustness disappears thoroughly when we add just one layer of depiction and look at a photograph of the picture taken at an angle. Now the slanted portrait looks distorted compared with a portrait whose canvas surface was orthogonal to the camera axis.

The Limitations of Pictorial Depth

When comparing depth cues in pictures (content layer) with depth cues provided by 3-D objects, pictures are deficient in that they do not contain stereoscopic information, that is, the differences between the two views from the two eyes. The cues to actual depth provided by the degree of disparity between the two retinal images are exploited with exquisite accuracy for objects that are within our reach, and less well for objects beyond our immediate action space. In pictures, this information specifies the distance of the canvas from the observer (layer one) rather than the distance(s) specified by the content of the picture (layer two). Because the two differ, this results in conflict and renders the pictorial depth cues less powerful. It helps if we remove the disparity and regard pictures with just one eye or if we use a synopter, which duplicates the image and sends two identical views to both eyes. Gallery visitors in the 19th century were encouraged to use such devices to perceive the "true" depth in paintings. Note that viewing with one eye accomplishes the same effect by eliminating any possibility of disparity. Although this may seem paradoxical, removing the mere possibility of disparity does increase the impression of depth.

In analogy, with special viewing devices, stereo photographs can be presented to observers such that retinal disparity is reintroduced—this time artificially congruent with pictorial depth as evoked by perspective and other pictorial cues, with striking results. Typically, however, the lack of stereo information, the limited resolution of photographs, and the viewpoint independence limit pictures and distinguish them from natural viewing. In near space the extraction of depth information from pictures is ultimately limited compared with that from an actual scene. And even if we do all we can to cure that situation, such as in virtual reality displays, near space appears to be compressed in comparison. Notwithstanding this limitation, the visual system's ability to extract depth from pictures is quite remarkable. But rather than expanding on the subtler deficiencies of pictures to specify depth when the intention is to approximate normal viewing, let us now focus on the blatant opportunities to play with depth that open when the artist's intention is no longer focused on veridicality. Pictures, still or moving, can deliberately violate the laws of natural viewing and play on the visual system's inclination to construct world-like objects even if the pictorial cues are inconsistent or violate the laws of geometry or physics.

Violations of Spatial Construction Rules in Frozen Renditions

The liberty of the artist to play with pictorial depth falls into two categories. First, the artist could merely challenge our past experience. For instance, if the artist were to paint a distorted perspective rendition of a house, its sides may no longer look parallel and the roof may be bent in strange ways. Although we have never seen such a house, it could in principle exist. Our mind constructs spatial relations that are highly unusual but in principle possible. The artist has merely violated conventional wisdom but not natural law. Even size violations may depict a possible world. Imagine a photomontage with a giant seemingly touching a dwarf. Merely shrinking a pictorial object on an empty canvas will remove it farther back in virtual space; shrinking it while perspective and occlusion cues indicate its proximity will turn the object into a dwarf. The second category, violations of natural law, is less benign. For instance, objects that are clearly too heavy to float could rest in mid-air. If such a picture is produced, the visual system attempts to reconcile the depiction with natural law. The objects are typically not seen to hover above the ground but they appear withdrawn into space toward a position where they should have been had they touched the ground. The visual system proceeds as if undisturbed by the compromise that it just produced. Yet more extreme examples are so-called impossible figures, such as the famous *Waterfall* by Maurits Escher where the water continuously flows downhill but still ends up back at the top. Although the waterfall merely violates global depth relations and thereby creates the illusion of a perpetual mobile, the impossible triangle (see Figure 2), called Penrose triangle, which is attributed to Oscar Reutersvärd, appears to violate the laws of geometry and of space itself. Note that three-dimensional objects have been designed that do appear as Penrose triangles, but they work only if a stationary observer views the object from one specific vantage point, whereas the pictured Penrose triangle implies an object that could be viewed from any vantage point; such an object cannot, however, exist in reality. The power of such pictorial art is tremendous. It reveals significant aspects of the perceptual process proper, and a fundamental category of perception—space itself—is being questioned when viewing an impossible object. Spatial relations can no longer be judged, let alone in a quantitative fashion. At the same time, we could make estimates about the object's general shape (a triangle) and maybe even its size. The normal process of gleaning metric information and (re)constructing a world object is still engaged. All the counterfactual aspects of the Penrose figure do not suffice to halt the constructive perceptual process. After all, the markings on the page could be seen as a two-dimensional design. Instead, a triangle is constructed and accompanied by an emotion of awe or the feeling of being tricked.

Violations of Construction Rules in Dynamic Renditions

Moving images open another realm of possible violations of space and time. One could even say that the defining feature of movies consists in violations of normal viewing. The alter ego of the movie can levitate, walk backward without looking in that direction, fly, or shrink to fit into a keyhole. These abilities redefine space and time internally for the observer. Teleportation becomes possible and the narrative time-line can move forward or backward. Given that the constraints of normal space and time perception can be and are typically violated in motion pictures, quantitative models of space and time perception in pictures appear impossible. Both normal perception and its filmic violation must rely on a small set of common principles of depth perception. Some are almost never violated, such as occlusion relationships, but others are regularly violated, such as the laws of

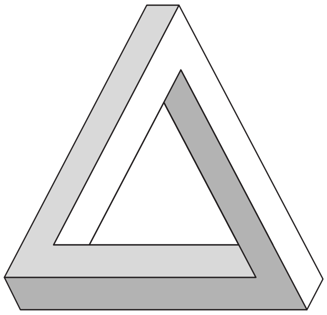

Figure 2 Impossible Figure: Penrose Triangle

perspective transformation and the apparent foreshortening of objects when different viewpoints are assumed. Here the visual system is rather tolerant, as we can see because it often fails to distinguish between the mere magnification caused by zooming-in and the more complex enlargement caused by a camera approach. The zoom has no equivalent optical transformation in natural viewing.

When it comes to optical specification of the external world, strange places can be conjured where, for example, people walk on surfaces that specify a liquid state, objects fall up instead of down, and debris assembles itself into objects. The visual system nonetheless attempts to assign specific depth values to these events and sort them into the preexisting categories of causality. In the fantasy of the virtual world to which their existence is limited, the spatial assignments cannot be verified and remain inconsequential for action. Interestingly, despite artistic freedom and the possibilities of special effects studios, the conventions of virtual space that have established themselves bear witness of a rather restrained use of the potential for violating the rules of normal viewing.

In sum, depth perception in pictures and film reveals the propensity of the visual system to construct a consistent 3-D space on the basis of optical information even if it defies the laws of physics or geometry. With regard to the limitations of pictures and movies in comparison with natural viewing, depth information from pictures is surprisingly robust.

DIGITAL IMAGING

In 1969, the *Apollo 11* astronauts landed on the moon, the Woodstock Festival attracted nearly 500,000 concertgoers, and George Smith and Willard Boyle invented the first charge coupled device (CCD). Although greeted with less fanfare than the other events of 1969, the CCD gave rise to *digital imaging*—the process of capturing and representing an image in a format readable by a computer. By replacing the traditional film with an electronic CCD sensor, digital imaging revolutionized photography ranging from the Hubble telescope in outer space to the cell phone in your pocket. This entry describes the capture, storage, and manipulation of digital images.

Formation

The CCD sensor is the "film" of a digital camera. It consists of a two-dimensional array of photoelectric elements that become electrically charged when exposed to light. Because the amount of charge is proportional to the light's intensity, the CCD's electrical pattern is a faithful representation of the light pattern striking the sensor. Although exquisitely sensitive to light intensity, a CCD element does not differentiate light wavelength (color). To record a color image, a color filter array (CFA) is overlaid on the CCD (see Figure 1; see also color insert, Figure 22). With a CFA, each CCD element records a limited range of wavelengths, corresponding to red, green, or blue.

The pattern of electrical charge on the CCD is transferred to the camera memory, where it is represented as an array of picture elements or pixels. A six mega-pixel digital camera, for example, corresponds to a CCD sensor with 6 million elements and a digital image with 6 million pixels. Associated with each pixel is a number between 0 and 255, where 0 corresponds to the minimum charge and 255 to the maximum charge, yielding 256 distinct intensity values. In a full resolution color image, each pixel is assigned three numbers, one for the intensity of red, one for green, and one for blue. But as noted previously, the color filter array limits each sensor element to one color and so initially each pixel represents either red, green, or blue (RGB). For a full resolution RGB color image, the camera must interpolate across neighboring pixels to fill in the missing color values (Figure 1; see also color insert, Figure 22). These three values are sufficient to give rise to tens of millions of colors. For example, red is given by the RGB triple [255,0,0], green by [0,255,0], blue by [0,0,255], yellow by [255,255,0], a dark red by [128,0,0], black by [0,0,0], and white by [255,255,255].

Three values are sufficient to represent millions of colors because a digital camera encodes wavelength in a way that is similar to the human eye. The three filters in the CFA are analogous to the three cones in the eye that selectively absorb light in either the red, green, or blue range of the color spectrum. A digital camera and the human eye invite other comparisons. For example, in the center of the visual field (the fovea), the human eye has an estimated spatial resolution equivalent to tens of millions of pixels, and a dynamic range equivalent to several thousand distinct intensity values. A dynamic range equivalent to millions of intensity values is possible for the human eye because the eye can dynamically adjust its lightness sensitivity range. Similar effects can be achieved digitally through high dynamic range (HDR) imaging in which multiple images photographed at different exposures are combined.

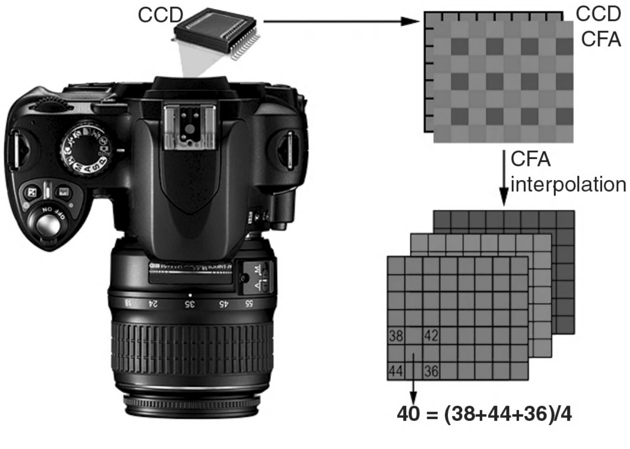

Figure 1 Color Filter Array (CFA) Overlaid onto a Charge Coupled Device (CCD) Sensor

Notes: Each CCD element records a limited range of wavelengths, corresponding to either red (gray), green (light gray), or blue (dark gray). A full three-channel RGB color image is created by interpolating the missing color pixels by, for example, averaging the recorded values. See also color insert Figure 22.

Format

A digital image in the camera and computer memory can be stored in many different formats. The most basic format, raw file, stores the pixel values directly recorded by the CCD before CFA interpolation. This format affords efficient storage because only one number is stored for each pixel, but it requires any subsequent photo editing software to perform the CFA interpolation. The remaining image formats fall into one of two categories: non-lossy and lossy. Non-lossy formats such as TIFF, PNG, and BMP, store the full RGB digital image without any loss of information. The benefit of these formats is that they permit high-quality reproductions, but with the drawback that they require significant amounts of memory for storage. The lossy GIF image format achieves compression by limiting the total number of colors in the image from tens of millions to, typically, a few hundred. The image format JPEG, perhaps the most popular lossy format, achieves compression by removing some color and high spatial frequency information (i.e., image details). These lossy image formats reduce the disk space required to store an image, but at the cost of degrading the quality of the image.

Quality

Camera manufacturers typically tout the number of pixels as the single measure of image quality. Many factors, however, contribute to the final quality of a digital image, including the camera lens, the CCD sensor, the CFA filter, and the image compression level. Low-quality lenses can lead to chromatic aberrations where the color channels are misaligned relative to one another. Lenses may also produce geometric distortions that cause straight lines to appear curved. Low-quality CCD sensors can lead to high levels of noise or graininess in the image. Low-quality CFA filters and interpolation can lead to poor color reproduction. And high levels of lossy compression can lead to significant loss of color and details. These degradations can range from the slightly to highly visible and can be particularly problematic when enlarging a digital image for printing.

In high-end digital cameras, these artifacts have been largely eliminated with results that rival those of the best traditional film cameras. In low- to mid-range digital cameras, today's six- to eight-megapixel cameras (millions of pixels) are of sufficient resolution for most consumer needs (for example, at a high resolution of 300 dots per inch [dpi], a six-megapixel digital image can be printed to a size of 8 × 10 inches).

Digital Image Processing

Before the digital revolution, the enhancement and manipulation of images required talented artists and technicians to spend long hours in the darkroom. With the advent of digital imaging, such alterations are now only a few computer mouse clicks away.

Some basic image manipulations involve systematically remapping pixel values using a lookup table (LUT). This remapping is represented graphically in Figure 2, which shows how a LUT can be used to alter the brightness of an image. The horizontal axis of the LUT corresponds to the original intensity value (in the range 0 to 255), and the vertical axis corresponds to the remapped intensity value (also in the range 0 to 255). By sliding the LUT down, for example, all pixel values between 0 and 80 are mapped to 0, and the remaining pixel values between 81 and 255 are linearly mapped into the range 1 to 175 (resulting in a darkening of the image—see Figure 2b). Functionally, consider a single pixel whose value is in the range 0 to 255. Find this value on the horizontal axis and draw a line straight up to intersect the LUT. Now draw a straight line leftward to the vertical axis to determine the new value for the pixel. This process is effectively repeated for each pixel to uniformly change the appearance of an image. Also shown in Figure 2(b) is the intensity histogram after the brightness adjustment. The horizontal axis of the histogram corresponds to the intensity value, in the range 0 to 255, and the vertical axis corresponds to the number of pixels that have the specified gray value. Darkening corresponds to a leftward shift of the histogram. Similar to darkening, brightening is achieved by shifting the LUT upward, which corresponds to a rightward shift of the histogram (Figure 2c).

As shown in Figure 2(c), image contrast can be increased by increasing the slope of the LUT. Similarly, the contrast can be decreased by decreasing the slope of the LUT. Note that both brightness and contrast enhancement can saturate pixels, where a range of values is collapsed to a single value. As a result, these operations are not reversible because once the values are mapped en masse to 0 or 255, their original values are lost. This saturation can be seen in the histogram where there is an increase in the number of pixels in the bin at 0 (black) and at 255 (white) corresponding to all of the pixels that were mapped to these values. To increase contrast while avoiding saturation, an image can be auto-scaled by adjusting the LUT such that the smallest pixel value in the image is mapped to 0 and the largest pixel value is mapped to 255.

Image contrast can also be increased or decreased through a nonlinear LUT. Shown in Figure 2(d) is the result of one such contrast enhancement, gamma correction, where each pixel value, divided by 255, is raised to the power 2, and then re-multiplied by 255 (the scaling by 255 is so that the pixel values of the gamma corrected image remain in the range 0 to 255). Varying amounts of gamma correction are often automatically applied by digital cameras and in computer monitors used to view digital images. Unlike brightness and contrast enhancement, gamma correction does not saturate any pixels. Lastly, shown in Figure 2(e) is the result of quantizing a digital image to only two gray values (also known as thresholding). The corresponding LUT

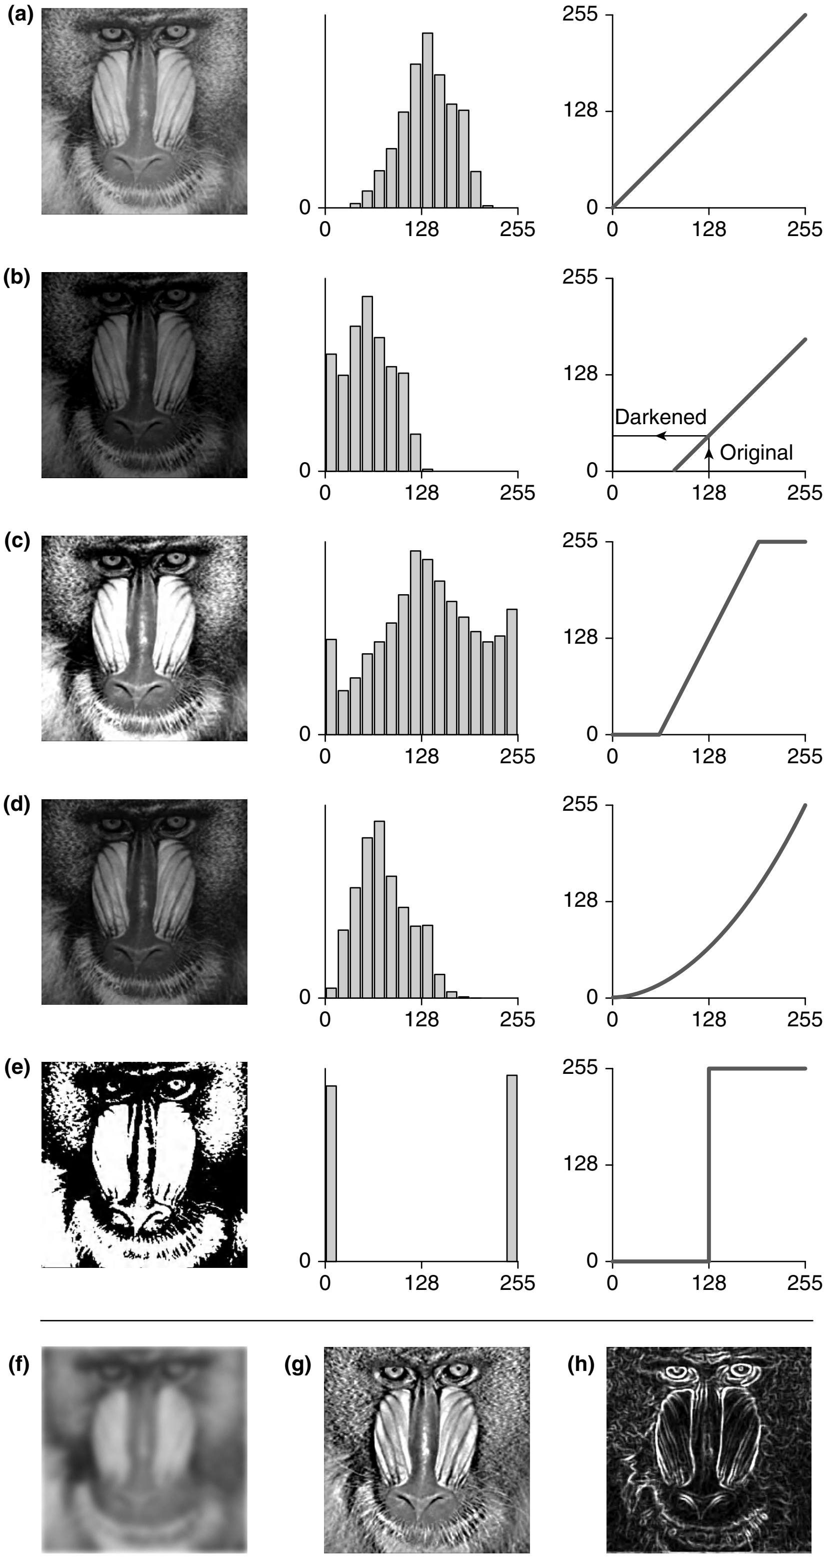

Figure 2 Basic Image Manipulations

Notes: Shown is (a) an original grayscale image that has been: (b) darkened, (c) contrast enhanced, (d) gamma corrected, (e) quantized (thresholded), (f) blurred, (g) sharpened, and (h) edge extracted. Shown in the second column of panels (a)–(e) is the corresponding intensity histogram, and in the third column is the lookup table (LUT) that embodies the transformation.

is a step function that uniformly collapses a range of intensity values to a single value.

In addition to basic intensity manipulations, digital filtering can remove or enhance information in an image. Shown in Figure 2(f) is an image that has been blurred to remove image details. Shown in Figure 2(g) is an image that has been sharpened to enhance image details. And shown in Figure 2(h) is the result of filtering that isolates edges. Each of these filtering operations involves adjusting pixel values based on the values of neighboring pixels. An image is blurred by replacing each pixel value by the average of its neighboring pixel values—the larger the neighborhood, the greater the blurring. An image is sharpened by replacing each pixel with the difference between itself and its neighboring pixels. And, an image's edges are enhanced by replacing each pixel with a combination of horizontal and vertical differences in pixel values.

Many photo-editing software packages perform these LUT and filter operations, along with many more sophisticated manipulations: red-eye can be removed from flash photographs, objects or people can be added or removed from an image, several images can be stitched together to create a wide-angle mosaic, and much more.

Implications

Advances in digital and computer technology have revolutionized photography in ways that could not have been imagined when the CCD was first invented. These advances have had an exciting impact on science, medicine, and art. These advances have also had the problematic consequence that they make it easy to doctor images in ways that are difficult to detect. Doctored images are appearing with a growing frequency and sophistication in tabloid magazines, fashion magazines, mainstream media outlets, scientific journals, political campaigns, courts of law, and our e-mail in-boxes. As a result, our trust in photography has been diminished. This in turn has given rise to the field of digital forensics and the development of techniques to authenticate digital images. In the coming years, digital and computer technology will continue to develop, and the field of digital forensics will try to help us regain our trust in photography. Although it is impossible to imagine precisely how these fields will develop, digital imaging has forever changed our relationship with visual imagery.

DIRECT PERCEPTION

When we open our eyes, it seems to us that we are aware of ordinary objects and events such as tomatoes, elephants, and bouncing balls. *Direct perception* means that we are indeed aware of such environmental objects, without mediating representations or inference processes. Yet this appears to present a paradox, for we are not in physical contact with environmental objects, but only with the light that arrives at our receptors, the neural signals it elicits, or resulting sensory states. The problem of perception is how it is possible to be aware of environmental objects and events when we are only in immediate contact with such intervening states.

There are three general responses to the paradox. The *phenomenalist* concedes that we are only aware of sensory phenomena, not environmental objects. When we look at a tomato, we have sensory impressions of roundness and redness, but we do not perceive the tomato itself. For all we can tell, we could be living in the virtual world of *The*

Matrix, with an illusory tomato induced by electrical stimulation of our brains.

The *indirect realist* goes a step further, arguing that the perceiver can at least make inferences about environmental objects based on sensory states. When we look at a tomato, we construct a mental representation of it; we are directly aware of this internal representation, and indirectly perceive the tomato.

The *direct realist* is willing to go all the way, holding that the perceiver is directly aware of environmental objects, not just their mental proxies. When we look at the apocryphal tomato, we are in perceptual contact with and have access to the tomato itself, without mediating inferences or representations. The challenge for the direct view is to articulate a theory of perception that can sustain this claim.

The position one takes on this philosophical question has practical consequences for psychology and cognitive science. Most researchers have adhered to an indirect view, ranging from the constructivist theories of the 1950s through 1960s, in which perception is an internal construction based on impoverished cues and rules of inference; to the computational approach of the 1970s through 1980s, in which perception is the computation of an internal representation based on insufficient input and prior assumptions; and the Bayesian framework of the 1990s through the early 2000s, in which perception is statistical inference based on ambiguous image data and prior knowledge of probabilities.

Yet, during the last century, prevailing opinion among philosophers of mind has shifted from indirect theories to some version of direct perception. This entry briefly presents several of the arguments for and against direct perception and introduces the main scientific theory that aims to sustain a direct view, the ecological approach developed by James J. Gibson and his followers.

Problems for the Indirect View

Arguments for direct perception often begin with a concern that the indirect view is insupportable, easily sliding into phenomenalism and even skepticism. On the indirect view, perception consists of getting a representation of the world into the observer's head; the direct realist's concern is that this doesn't really solve the problem of perception.

Representationalism

Traditionally, the indirect view has claimed that the perceiver is aware of an external object in virtue of being aware of something else, such as an internal mental or brain state. These intervening states may be representations, mental images, sensory impressions, sense-data, neural signals, or retinal images. However, this view commits what is called the *representationalist fallacy.* The claim that the perceiver is aware of an internal state confuses the *object of awareness* (the actual tomato) with the *vehicle of awareness* (the intervening state). In particular, to say that the perceiver is aware of an internal representation sets up a logical regress, implying an inner perceiver (homunculus) who must create an inner representation of the representation. The traditional version of the indirect view is thus confused.

The regress can be avoided by claiming that awareness of an external object is *constituted* by having an internal representation of it; the perceiver is not aware of the representation itself, but of what it represents (its content). Thus, one perceives the tomato (the object of awareness) in virtue of *possessing* an internal representation of it (the vehicle of awareness). This move satisfies some philosophers that perception is direct in the traditional sense, yet on this view, the perceiver experiences the content of a representation rather than the living tomato. The representation must somehow be derived from the visual input by a process that establishes its content. This leads to a skeptical argument known as Hume's problem.

Hume's Problem

Hume's problem, posed by David Hume, also called the semantic problem or grounding problem, is the problem of how internal representations get connected to the world. If perceptual awareness consists of having representations, how does the perceptual system determine the environmental entities to which they correspond? Without some independent, extrasensory access to the world, there appears to be no way to establish which internal states indicate which environmental properties, or which representations stand for tomatoes and which for elephants. The perceiver is trapped in a closed universe of sensory phenomena or uninterpretable representations.

The indirect solution is *inference to the best explanation:* The perceptual system infers a representation of the world that best accounts for the order in sensory input. For example, a particular sequence of gray blobs with an extended protuberance may be best explained by the presence of an elephant, rather than a tomato. However, as Hermann von Helmholtz understood by the mid-19th century, this inference process presumes that the perceptual system already possesses knowledge about (1) the structure of the world, including the sorts of entities that exist and predicates to describe them, and (2) how the world structures sensory input, such as a theory of image formation and transduction.

The trouble is that such prior knowledge must somehow be acquired, again in an extrasensory manner. As Gibson observed, knowledge of the world cannot be explained by supposing that knowledge of the world already exists. A common response is that prior knowledge has evolved via natural selection or learning, but as pointed out by Michael Turvey and Robert Shaw, this seems to require an organism that already has a working perceptual system—including the requisite prior knowledge—as a precondition. The indirect position thus appears to be circular.

Inference

There is a further problem with treating perception as a process of inference. Inference is a logical relation that holds between conscious mental states (beliefs, thoughts, statements) corresponding to premises and conclusions. But as we have just seen, if we are to avoid the representationalist fallacy, perception cannot be based on conscious awareness of internal states.

If the perceptual process is unconscious, then whatever else it may be it cannot be inferential; the same goes for related terms such as *hypothesis, clue, evidence,* and *assumption.* The notion of perception as *unconscious inference,* originally suggested by Helmholtz, is thus inconsistent. Computational theories seek to avoid this objection by treating perception as a process of computation over representations, but this leaves Hume's problem unresolved.

Obstacles for the Direct View

These objections to indirect perception tend to drive theorists either to outright phenomenalism or some form of direct perception. But the direct view is not without its own obstacles.

The Argument From Illusion or Hallucination

Direct perception seems to imply that perception is veridical, that is, that the world is as it appears to be. Yet in cases of visual illusions and hallucinations, the world is *not* actually as it appears to be. According to the argument from illusion or hallucination, such cases undermine the claim that perception is direct:

1. Assume it is possible to experience illusions or hallucinations that are subjectively indistinguishable from cases of veridical perception. For example, we may have an alcohol-fueled experience of a dancing pink elephant that seems compellingly real.
2. In such cases, we are aware of *something,* but it is not a normal physical object. Hence, we are aware of a *nonnormal* object, such as a dancing pink sense-datum or an elephantine representation.
3. If we are aware of sense-data in cases of hallucination, and we cannot distinguish them from veridical cases, this implies we are aware of sense-data in veridical perception as well. Therefore, perception is not direct. As Hippolyte Taine famously remarked, veridical perception is merely hallucination that happens to be true.

The argument gets its force from the parsimony of admitting only one kind of object of awareness, nonnormal sense-data. The *disjunctivist* response (named after the logical *or* relation) denies that there is only one kind of object of awareness, rejecting step 3: It is logically possible that we are aware of nonnormal objects in cases of hallucination, while being aware of normal objects in cases of perception. Hence, we are aware of a normal *or* nonnormal object, although this is less parsimonious.

One might go further and deny step 2, arguing that when we hallucinate a dancing pink elephant, we are not aware of any *object* at all, normal or nonnormal. We are merely having a subjective experience that arises from some neural activity in our visual systems. If we can account for hallucinatory experiences in this manner and avoid introducing a spooky class of nonnormal objects, this approach appears more parsimonious. Although an observer may not be able to tell "from inside" whether a subjective experience of an elephant is veridical or hallucinatory, "from outside" the former involves awareness of a normal environmental object whereas the latter does not.

The Argument From Underspecification

Another argument against direct perception holds that perception is underdetermined by the available information. The stimulation at the receptors is said to be inherently impoverished or ambiguous, insufficient to uniquely specify environmental objects and events. A tomato is a three-dimensional spherical object, but its retinal image is just a two-dimensional circular form; working backward, this image could correspond to a flat disk or various ellipsoidal objects stretched along the line of sight (as illustrated by Adelbert Ames' famous distorted room).

To solve this "inverse optics" problem, the perceiver must somehow "go beyond the information given," inferring or computing a representation of a spherical tomato based on prior knowledge or assumptions. Perception is consequently indirect. However, if we accept that all stimulation is ambiguous, it is not clear how a working perceptual system (with the requisite prior knowledge) could evolve in the first place, returning us to Hume's problem.

Gibson's Ecological Realism

Gibson sought to dissolve these paradoxes by reformulating the problem of perception to sustain an ecological version of direct realism. Instead of treating perception as a process of getting a representation of the world into the perceiver's head, he considered it to be a *relation* between the perceiver and its environment that puts the perceiver in epistemic (knowing) contact with aspects of the environment that are relevant to its way of life.

The starting point for the ecological approach is Gibson's principle of *animal-environment mutuality*. Because a species and its ecological niche co-evolve, the perceiver is adapted to regularities of its niche that support successful perceiving and acting. In particular, perceptual systems have evolved to detect patterns of stimulation (optical, acoustical, mechanical, chemical) that uniquely specify behaviorally relevant aspects of the environment (*affordances*). The frog's visual system, for example, is tuned to the motions of small black specks that specify edible prey and large expanding patches that specify looming threats. Because such information is specific, not equivocal, perceptual systems can evolve by adapting to the available stimulation without prior knowledge, putting organisms in direct contact with the affordances of their niche and guiding effective action. This offers a means to resolve Hume's problem.

Gibson thus rejected the argument from underspecification. Information, in Gibson's sense, is a complex spatiotemporal pattern of stimulation that is lawfully structured by the environment and is specific to environmental features, under ecological constraints. The perceptual system need not "know" or "assume" these constraints explicitly, merely adapt to the informational regularities they guarantee. Within the frog's niche, for example, moving black specks overwhelmingly correspond to edible insects (although there may be an occasional blowing bit of bark), so adapting to this motion pattern promotes successful action and survival. Research has shown that there is sufficient information available to a moving observer to specify many (but not all!) aspects of environmental layout, objects, events, their relation to the perceiver, and what they afford for action.

Direct perception does not mean there is no perceptual process or mechanism, only that the process is based on specific information and hence non-inferential. In Gibson's view, perceptual systems are active attentional systems with ascending and descending neural pathways that seek and "resonate" to information. These systems become tuned to available information through evolution and learning and come to embody an implicit mapping from patterns of stimulation to behaviorally relevant environmental features. When information is detected, the perceiver is put in direct contact with its environment: The object of awareness is the environmental situation and the vehicle of awareness is the resonating perceptual system.

Optic Flow and the Control of Locomotion

A primary example of such information is the *optic flow field*. When an observer moves through the environment, a radial pattern of motion is produced at the eye, much like the outward expanding motion on the screen of a driving video game. The focus of expansion specifies the observer's direction of travel, the rate of expansion specifies the time-to-contact with objects, and velocity gradients specify the layout of surfaces.

Species ranging from insects to primates possess neural pathways that are selective for such complex flow patterns. Research by David Lee, William H. Warren, and others has shown that optic flow (along with other information) is used to control locomotion, including balance, braking, steering, and landing and escape responses. Many behaving animals thus appear to be connected to their environments by the optic flow field.

Invariants and 3-D Shape

How we perceive three-dimensional (3-D) shape with a two-dimensional (2-D) retina is often considered a classic example of underdetermined perception. But Gibson argued that such constant properties as surface shape are specified by constant spatiotemporal patterns of stimulation, which he called *higher-order invariants*. Recent work by Jan Koenderink, James Todd, and others has begun to bear out this claim: Higher-order patterns of texture, shading, optic flow, and binocular disparity indeed specify the 3-D shape of a smooth surface. However, this information is not sufficient to determine Euclidean shape (absolute depth, slant, curvature) as researchers have typically assumed, but rather qualitative surface shape (hills, dales, ridges, valleys, and plains). These qualitative features are perceived more accurately and reliably, and are theoretically sufficient to identify objects and guide actions like grasping.

An important implication of this research is that whether we consider perception to be veridical depends on the properties we assume are perceived. Perception can be accurate and direct only insofar as the property is specified by information.

The definition with which we began can now be refined. In Gibson's view, direct perception means that the perceiver is in epistemic contact with behaviorally meaningful aspects of its environment by virtue of detecting specific information, without mediating representations, inference processes, or prior knowledge.

DYSLEXIA

Dyslexia is marked by unusually slow reading development in children who are otherwise normally developing. Although most children learn to read with little conscious effort, children with dyslexia lag well behind their peers in acquiring this fundamental skill. These children fail to learn to read adequately despite normal hearing, cognitive, neurological, and emotional abilities. The disorder is not uncommon, with an estimated 5 to 15% of all children having significant difficulties in learning to read. Despite early reports, there is no sex link, with an equal preponderance in boys and girls. The term *dyslexia* is occasionally also used to refer to individuals with reading disturbances following stroke, although the more common term in that case is *alexia,* which is not discussed in this entry.

Diagnosis of dyslexia usually precludes general sensory impairments such as severe loss of hearing or vision, or a broader cognitive deficit. Affected individuals show slow laborious reading marked by errors in single word identification and poor text comprehension. In addition, they tend to show poor generalization, such that they have difficulty reading unfamiliar words or nonsense words, indicating that they have failed to learn consistencies in the relationship between spelling and sound.

There is a relatively broad consensus that dyslexia stems from a deficit in processing phonology, or the basic sounds of words. Phonological abilities seem to play an important role in successful reading development because they are an inherent part of reading: Recognizing a word involves translating orthography (a word's visual form) into a phonological code (the sounds that the word is composed of). Thus, the phonological deficit hypothesis of dyslexia holds that affected individuals have difficulty learning to read because of a deficit in how they process phonological information. This does not necessarily imply a perceptual deficit, as is discussed further in this entry.

Consistent with this, affected individuals have difficulty with *phonological awareness.* Measures of this include *rhyme awareness* (judging whether two words rhyme or producing words that rhyme with a sample word); *phoneme blending* (assembling a set of phonemes into a single word); *phoneme counting/tapping* (counting or tapping a finger to indicate distinct phonemes in a word); and *phoneme deletion/elision* (repeating a word after removing one or more of its constituent sounds). Importantly, phonological awareness relates to processing spoken words, and performing such tasks does not hinge on the ability to read words. Listeners must understand that auditory words are not wholes, but instead can be broken down into constituent sounds.

Phonological awareness allows the beginning reader to analyze spoken words into phonemes, which can in turn be associated with orthography. It also allows the beginning reader to make analogies among similar sounding words, which typically share similar spellings, allowing beginning readers to learn new words quickly. Phonological difficulties in dyslexia are thus hypothesized to make it more difficult to process or identify the similarities and differences among sounds, ultimately making learning to read more arduous. Some of the earliest evidence supporting this view comes from the finding that phonological skills in pre-reading children are highly predictive of later reading achievement. Thus, preliterate children with phonological difficulties tend to develop reading deficits later on. Furthermore, phonological deficits tend to persist into adulthood, even in cases where reading difficulties have been effectively remediated.

One challenge to the phonological deficit view is that, despite widespread findings of poor phonological abilities in dyslexia, it has been difficult to identify what specific aspects of phonology are affected, and what their root cause might be. The opacity of the underlying deficits in dyslexia may result from the nature of the tasks used to measure them. These tasks are typically metalinguistic, requiring individuals to provide overt judgments about phonology. For instance, although rhyme awareness early on is a good predictor of eventual reading success, by ages 8 or 9, rhyme awareness becomes too easy to adequately differentiate good and poor readers. Metalinguistic tasks are also influenced by nonverbal processes such as attention and working memory. Thus, although children with dyslexia have poor phonological awareness, performance on these tasks may be constrained by age, reading skill, and other compensatory strategies that might obscure the cognitive bases of an underlying phonological deficit.

One approach to better refining our understanding of this deficit comes from studies of speech perception. Typically developing children and adults exhibit categorical perception of phonemes (especially consonants), marked by stronger between-category than within-category discrimination and non-monotonic categorization curves along equally spaced acoustic continua. For instance, it is possible to manipulate the sound "d" in a way that causes listeners to perceive it as "t," by modifying a single acoustic parameter called voice onset time (VOT). Typically, VOTs 30 milliseconds (ms) or greater are perceived as "t," and VOTs less than this are perceived as "d." Interestingly, listeners are poorer at discriminating two exemplars within a category (e.g., 10 vs. 20 ms VOT) than two exemplars from different categories (e.g., 20 vs. 30 ms VOT), even when the magnitude of this acoustic difference is the same in both cases.

In contrast, children with dyslexia have shown weaker between-category discrimination and less reliable categorization of sounds at endpoints or midpoints. Likewise, these children show atypical event-related potentials (ERPs) in response to auditory speech sounds. Importantly, these measures can be obtained for unattended stimuli, suggesting that effects are not caused by differences in attention, short-term memory, or motivation in children with dyslexia versus controls.

There remains considerable disagreement concerning perceptual deficits in dyslexia. Some studies have failed to observe such deficits, and others have only observed them in subsets of dyslexic children. Thus, it remains an open question whether speech perception difficulties can adequately account for the phonological awareness deficits and ultimately reading deficits in dyslexia.

Equally contentious is whether perceptual deficits in dyslexia are speech-specific, or caused by a more general auditory processing impairment. One theory holds that these children have a rapid temporal processing (RTP) difficulty such that they cannot process rapidly changing sensory information. This deficit would lead to difficulty perceiving the types of acoustic features that are important to phoneme recognition (especially consonants). However, this theory also holds that this deficit is domain-general such that affected individuals also have difficulty with nonspeech stimuli involving rapid temporal cues (e.g., temporal order judgment, gap detection).

Finally, two alternative theories of dyslexia bear some mention here. The first is the magnocellular deficit theory, which suggests that individuals with dyslexia have a low-level visual deficit that impairs how affected individuals process visual words. Consistent with this, some studies have reported reading-impaired children have difficulties with visual contrast detection and other types of tasks linked with the magnocellular visual channel (this is the neural pathway associated with resolving coarse object detail and motion and that contrasts with the parvocellular pathway used for resolving fine detail and color). The second theory is the cerebellar deficit hypothesis, which suggests dyslexic children have abnormal cerebellar function that affects the development of automatization in speech-related function, which in turn leads to reading delay.

ECHOLOCATION

Echolocation is an active perceptual system, used by some animals to localize and identify objects in complete darkness. The active component of echolocation is the animal's production of sounds that reflect from objects in the environment, and perception arises from listening to the features of these echoes. Echolocation has been documented in bats, marine mammals, some species of nocturnal birds, and in blind or blindfolded humans to a limited extent. This entry describes echolocation signals, perception by echolocation, and neural mechanisms for echo processing.

Consider an echolocating bat hunting insects in the night sky. Light levels are low, and the bat need not rely at all on its vision. Obstacles are present, but the bat dodges branches and telephone wires with ease. As the animal flies, it produces vocalizations that are in the ultrasonic range, from 20 kilohertz (kHz), the upper frequency limit of the human ear, up to 200 kHz in some species. These high-frequency signals are well suited to return echoes from small objects, such as insects, because the wavelengths of the signals are short with respect to the reflecting surfaces.

During each attack on a prey item, the bat relies on changing echo features to guide its movement. Imagine an insect located off to the right of the bat's midline when first detected. The bat computes the horizontal and vertical positions of the insect from differences in the perceived arrival time, intensity, and spectrum of echoes at the two ears. After determining the two-dimensional position of the insect, the bat aims its head at the prey, produces sonar vocalizations, receives new acoustic snapshots of the target, and redirects its flight path. Also essential to the bat's successful pursuit of prey is the estimation of target distance. The bat determines target distance from the time delay between its sonar vocalizations and the returning echoes. It uses the three-dimensional (3-D) information about target location to guide the features of its sonar vocalizations and to position itself to grasp the insect with its wing or tail membrane.

Echolocation Signals

The signal types used by different bat species vary greatly, but all contain some frequency modulated (FM) components, whose frequency varies over the duration of the signal. FM signals are well suited to carry information about the 3-D position of objects because each frequency in the broadband signal activates different populations of frequency-tuned neurons, whose onset responses can collectively mark echo arrival time at the bat's ears. Constant frequency (CF) components are sometimes combined with FM components, and these tonal sounds are well suited to carry information about target movement through Doppler shifts in the returning echoes. A Doppler shift is a change in sound frequency that is proportional to the relative velocity of the source (in this case, the sonar target) relative to the listener (in this case, the bat). If the bat approaches the target, the echo frequency increases, noted as a positive Doppler shift. Evidence indicates that bat species using both FM and CF signals show individual variation in signal structure that may facilitate identification of self-produced echoes. One echolocating bat species, *Rosettus aegyptiacus,* produces clicks with the tongue. The most widely studied echolocating marine mammal, the bottlenose dolphin (*Tursiops truncates*), produces brief clicks, typically less than 50 microseconds in duration, with spectral energy from 20 kHz to well over 150 kHz. The temporal and spectral characteristics of the dolphin clicks depend on the acoustic environment in which sounds are produced.

Perception by Echolocation

Detection of objects by echolocation depends on the strength of returning echoes. Large objects, such as trees, buildings, and the ground reflect strong echoes and can be detected at distances greater than 10 meters. Small insect prey can be detected by bats at distances of 3 to 5 meters. Once an animal using echolocation detects a target, it relies on interaural time and amplitude differences, spectrum, and arrival time of the echoes to localize the object in 3-D space. Laboratory studies of target tracking along the horizontal axis in bats suggest an accuracy of about 1 degree. Accuracy of vertical localization in bats is approximately 3 degrees. Behavioral studies of distance discrimination in bats using FM echolocation calls report thresholds of about 1 centimeter (cm), corresponding to a difference in arrival time of approximately 60 microseconds. In marine mammals, behavioral experiments show that the dolphin's horizontal angular discrimination depends on sound frequency; for pure tones, horizontal discrimination is 3.6 degrees at 6 kHz, 2.1 degrees at 20 kHz, and 3.8 degrees at 100 kHz. Localization accuracy in dolphins improves with broadband click stimuli, with thresholds in both the horizontal and vertical planes of less than 1 degree. Along the distance axis, dolphins can discriminate target range differences of approximately 1 cm, similar to that of the bat.

Many bat species that use CF echolocation sounds are specialized to detect and process frequency and amplitude modulations in returning echoes that are produced by the moving wings of flying insect prey. The CF signal components are relatively long in duration (up to 100 milliseconds), sufficient to encode echo changes that occur from the movement of a fluttering insect over one or more wing-beat cycles. For example, the greater horseshoe bat (*Rhinolophus ferrumequinum*) can discriminate frequency modulations in the returning echo of approximately 30 hertz (Hz) (less than 0.5% of the bat's 83 kHz CF signal component).

In addition, this species can discriminate fluttering insects with different echo signatures. Several bat species that use CF signals for echolocation adjust the frequency of sonar transmissions to offset Doppler shifts in the returning echoes, the magnitude of which depends on the bat's flight velocity. These adjustments in the frequency of the CF echolocation calls, referred to as Doppler shift compensation, allow the bat to isolate small amplitude and frequency modulations in sonar echoes that are produced by fluttering insects.

More complex aspects of perception by echolocation have been examined in some bat species. Free-flying bats can discriminate between small objects differing in shape and texture. 3-D target recognition of fluttering insects viewed from novel perspectives has been reported in the greater horseshoe bat.

Dolphins can use echolocation to discriminate between objects made of different materials and shapes. Target dimensions and materials influence the intensity, spectrum, and temporal characteristics of the returning echoes, providing a number of potential cues for complex target discrimination by dolphins.

Neural Mechanisms for Echo Processing

Decades of research have revealed specializations for the processing of sonar echoes in the auditory system of bats. In dolphins, studies of neural processing have been limited, but early work documents brain responses to sounds in the ultrasonic range of marine mammal echolocation calls.

Some bat species using CF echolocation calls show specializations in the peripheral (inner ear) and central (brain) auditory systems for processing echoes in the CF range of their echolocation sounds. The greater horseshoe bat, for example, adjusts the frequency of its sonar vocalizations to receive echoes at a reference frequency of approximately 83 kHz. Its auditory system shows a large proportion of neurons devoted to processing this reference frequency, and an expanded representation of 83 kHz can be traced to mechanical specializations of this bat's inner ear.

Other specializations in the bat central auditory system for processing echolocation signals that may play a role in the perception of target distance. In several bat species, researchers have identified neurons in the midbrain, thalamus, and cortex that respond selectively to pairs of FM sounds, separated by a particular delay. The pairs of FM sounds simulate the bat's sonar vocalizations and the returning echoes, and the time delay separating the two signals corresponds to a particular target distance. The pulse-echo delay that elicits the largest facilitated response is topographically organized in some bat species that use CF signal components. Most delay-tuned neurons in the bat auditory system respond in the range of 2 to 40 milliseconds, corresponding to target distances of approximately 34 to 680 cm. These best delays represent a biologically relevant range for localizing prey items using echolocation.

ECOLOGICAL APPROACH

Ecological psychology, as it applies to the domains of perception and perceptual development, refers to the perspective developed during a 30-year period by J. J. Gibson and Eleanor J. Gibson, and elaborated during the past two decades by their students and colleagues. The impetus for this approach grew largely from J. J. Gibson's work early in his career on several practical problems, such as how individuals control their movement when driving a car or landing a plane. These investigations led him to conclude that traditional theories of perception, and their supporting evidence mostly gathered in laboratory conditions, did not apply well to more everyday circumstances of perceiving. This entry describes major concepts in ecological optics, perceptual learning and development, and philosophical implications of ecological realism.

The adjective *ecological* in ecological psychology refers to two distinguishing characteristics of Gibson's approach to perception that sets it apart from more traditional theories.

1. Traditional theories of visual perception begin their analysis with consideration of patterns of stimulation on the sensory receptors (i.e., the retina), and the ensuing patterns of neural firing to sites in the brain. The starting point for an ecological approach to perception is an analysis of the environment within which a species has evolved (i.e., its *econiche*). The environment for terrestrial organisms is filled with *substances* of a wide-ranging variety, from soils and grasses to bodies of animals and water. In the case of visual perception, these substances can be perceived because of the way light from a radiant source (e.g., the sun) interacts with their *surface* properties (e.g., orientation to light source, texture, pigmentation). The resulting array of reflected light that has been structured by such surface properties fills the *medium* (the air), and this array of structured light surrounding the individual (*ambient optic array*) can function as potential *information* for perceiving. The study of how light in the medium is structured by surfaces is referred to as *ecological optics*. J. J. Gibson proposed that psychologists begin to consider higher-order structure in the ambient optic array of information for perceiving.

2. Traditional theories of visual perception take as their primary focus a stationary perceiver positioned at a fixed observation point. In contrast, the ecological approach takes as its primary focus the *dynamic perceiver-environment relationship*. What is dynamic about the perceiver-environment relationship? On the one hand, environmental conditions are not static, but change over various units of time (e.g., seconds, hours, days, seasons) requiring perceivers to keep abreast of conditions. On the other hand—and significantly—perceiving involves ongoing, exploratory actions of the individual (the functioning of *perceptual systems*) in the detection of stimulus information. Just as it is far easier to identify an object through active touch (manipulating the object in one's hand) than passively grasping it, perceiving through vision is facilitated by actions of the individual, such as moving the head and body in relation to objects and to the overall environmental layout.

Why do actions of the body contribute to detection of stimulus information? They produce perceived changes in the ambient optic array, and in so doing reveal that which does not change, what is invariant in the array of reflected light. (An invariant is a set of relationships among structures that do not change across transformations of those structures over time.) Invariance in the ambient array is posited to be specific to stable and persisting features of the environment. For example, if a perceiver walks around a table, certain relationships, such as the adjacent order of corners and edges, will remain invariant across successive views, displaying the specific rigid structure of this object. Actions of the various perceptual systems play an essential role in revealing invariants in the ambient array over time. Concurrently, the perceived changes in the ambient array that are generated by the perceiver's actions provide information for self-movement.

Major Concepts in Ecological Optics

Texture Gradients

Early work in ecological optics emphasized the perception of filled space rather than abstract space. J. J. Gibson proposed that "space" could not be perceived in the absence of perceiving a continuous background surface and that the topic of "space" perception would be more accurate if called "ground" perception. The texture of the ground (e.g., dirt and clumps of grass) projects a regular pattern of decreasing image size, and increasing density, from observer to horizon. This regular change is an example of a *texture gradient*. The texture gradients of surfaces, especially the ground stretching to the horizon, became the basis of reformulating numerous classical problems, two of which are distance perception and size perception. The perception of the texture gradient of a surface from observer to horizon establishes a scale of perceivable distance for a given height of the observer's eyes. The topic of size perception often is stated in a way that features the problem of *size constancy*. This asks, How is it possible to see an object as having a constant size with changes of viewing distance when the image size changes with distance? Gibson criticized this way of stating the problem of size constancy in its failure to acknowledge that in terrestrial environments most objects rest on *textured* ground surfaces. The same object, seen at different distances on the ground, covers (occludes) the same number of texture units regardless of distance, illustrated in Figure 1(a). Likewise, when there is a horizon line present in the field of view, it will intersect equally sized objects at the same height even when the objects are located at different distances (Figure 1b). In short, relations in the field of view (i.e., object/ground surface texture, object/horizon) serve as perceptual information for object size constancy. Because these relations remain the same under changes of viewing distance, they are invariants.

Optic Flow

As a perceiver moves forward, an optic flow of structured light from reflecting surfaces is generated, appearing to stream past the perceiver. This experience of self-motion through vision—*visual kinesthesis*—explains the commonplace illusion of feeling that you are moving when actually movement is occurring in your surround (an adjacent car in a line of traffic).

Self-generated optic flow radiates outward from a stationary point in the optic array, and this point of outflow (center of expansion) specifies where one is heading (Figure 1c). As a result, perceivers can control their direction of movement by maintaining

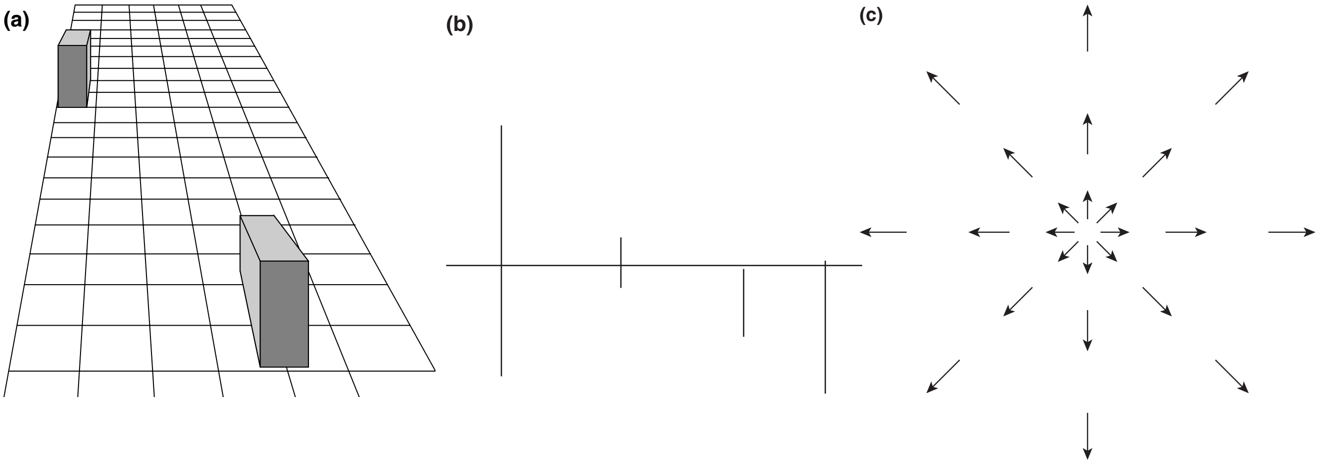

Figure 1 Perceptual Information for Depth and Size

Notes: (a) Object size—ground texture invariant: Objects of equal size occlude equal units of ground surface texture, even when they are positioned at different relative distances from the perceiver. (b) Horizon—object height invariant: The horizon line appears to intersect equally-sized objects in the same proportion, even when they are positioned at different relative distances from the perceiver. The two vertical lines on the left are depicted as twice the eye height of the observer. The two at the right are depicted as nearly the same eye height as the observer. (c) Optic flow showing the focus of expansion during approach to a flat surface.

the center of outflow on the target of interest. For example, a predator in pursuit of a prey must keep the prey at the focus of expansion of optical outflow. If the solid angle of the target changes (smaller or larger) in the optical flow field, this change is information for the predator that it is losing or gaining ground on the prey. In the case of a stationary target and a moving perceiver (or inversely a moving object relative to a stationary perceiver, as in the case of a thrown baseball), *time to contact* is specified by rate of flow. In general, time-to-contact (dubbed *tau* by David N. Lee) for a constant velocity of approach is given by the ratio of a changing quantity to its speed of change. An object in the world separated from an observer by a gap of 10 meters, traveling at 10 meters per second, will arrive in one second. This suggests that to perceive that time of arrival, an observer would need to know an object's distance and velocity as elements of a computation. However, the image of the gap on a retina, divided by the velocity of gap closure, yields the same time—without the need for separate estimates of distance and size. Lee proposed that this quantity is detected by animal nervous systems as a unit and is widely used in the control of timing.

Note that in each of these cases, perceiving is based on the *detection* of relevant higher-order information in the optic array *over time* rather than the mental calculation of separate variables, such as distance of the target and speed of movement. In this respect, self-motion and time-to-contact, like relative size constancy, is specified by information available to be *perceived* in the ambient optic array. During the past three decades, optic flow has been the subject of a great deal of research and discussion.

Occluding Edges

When a perceiver moves laterally with respect to two objects positioned one behind the other, the surface of the farther object will be gradually revealed (surface accretion) at the visible edge of the closer one. If the perceiver then reverses direction, the surface of the farther object will be concealed (surface deletion) at the occluding edge. These *reversible occlusion effects* serve as information for two perceptual phenomena: (1) the *relative distance* of two surfaces in the line of sight, and (2) the apparent *persistence* of objects that are presently not in view.

Relative Distance

A surface that is revealed or concealed at an occluding edge is experienced as being located farther away from the perceiver. In traditional theories, object occlusion is a pictorial cue for relative distance, but as a static cue (in the absence of movement), it is unreliable.

The earliest research pointing to the significance of occluding edge effects for moving perceivers was Eleanor Gibson's classic research using the *visual cliff* apparatus. Figure 2 shows a diagram of a visual cliff emphasizing the occluding edge.

A crawling baby at the edge of a visual cliff causes perceivable accretion and deletion of the lower surface at the edge of the upper surface with her movements. In this way, information for depth at an edge is available to be perceived by even newly crawling babies, and as Gibson found, they avoid venturing forth under such circumstances. This outcome contradicts what would be expected from a traditional empiricist view, which assumes that distance, not being presented in the retina, would require considerable learning. Likewise, it would be wrong to attribute this outcome to innate knowledge, as evidence with non-crawling babies has shown. Moreover, positing an innate "cognitive module," as is currently fashionable, merely begs the question of what is perceived. The individual discovers occlusion at an edge and its functional significance with exploration.

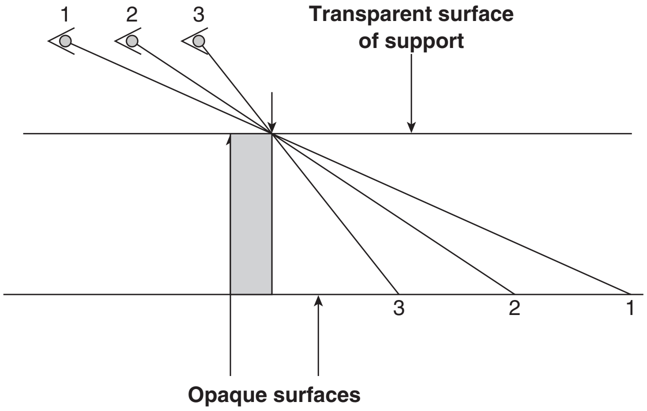

Figure 2 Occlusion Effects and the Visual Cliff

Notes: At position 1, the lower surface can be seen to the right of the numeral 1, but everything to the left is occluded. At position 2, the lower texture between 1 and 2 is revealed. At position 3, only the area to the left of the 3 is hidden. Moving from position 1 to 3, then, reveals texture (accretion) and from 3 to 1 hides texture (deletion). Thus, reversible transition of accretion or deletion of texture specifies depth at an edge.

Object Persistence

In the process of turning our heads and moving our bodies, some objects go out of sight, as others come into view. Curiously, objects that are no longer immediately visible are experienced as still being "there" (object persistence). They are not experienced as having gone out of existence, but rather as having gone out of sight. But how can this be? How is it that an object not immediately in sight can be experienced as persisting? If we bear in mind that perceiving is a process occurring over time, when surface information gradually goes out of sight at an occluding edge with perceiver movement, it can be brought back into sight by reversing the movement. This *reversible transition* at an occluding edge specifies the *persistence* of the object even when it is temporarily hidden (out of sight).

This effect has been demonstrated in a variety of ways. For example, if very young infants observe a moving object that gradually is occluded at the edge of a stationary object (it appears to go behind the latter), they will *anticipate* the reappearance of the moving object at the occluding surface's opposite edge. (Anticipation is gauged by indications of their surprise when it does *not* reappear.) From an ecological perspective, the infant's anticipation of the reappearance of an object that presently is out of sight indicates an awareness of the persistence of the hidden object. To generalize from this, it would seem that perceptual awareness of persisting objects and even places that are presently out of sight (such as the town over the next hill) is grounded in reversible occlusion effects. From this point of view, perceiving is an act of cognition.

Affordances

A number of perception researchers over the years have noted that some perceived characteristics of the environment appear to be meaningful (e.g., the cliff-edge affords falling-off, a surface at knee height appears to be a place to sit). It seems difficult, however, to reconcile apparent meaning in perception with the standard formulation of the stimulus for vision being some physical parameter of light. Light, considered as a physical stimulus, cannot carry a psychological quality such as meaning. But perhaps from the point of view of ecological optics, it can.

J. J. Gibson proposed a new concept, *affordances,* to refer to the perceived functional significance of environmental features, and he tied affordances to properties of the environment taken relative to an individual. For example, if a surface of support is roughly knee-high, it will be perceived as affording "sitting-on." Note, however, that because knee-height can vary across individuals, what might afford sitting-on for a tall person would not readily do so for a short person. This seemingly trivial fact has important implications for theory. An affordance points to a domain of properties that is not "in" the environment considered apart from an individual nor are these intra-psychic properties "in" the individual considered apart from the environment. *Affordances are relational properties.* Like optic flow and reversible occlusion, affordances arise from dynamic perceiver-environment relations.

Experimental work during recent decades has provided evidence for this supposition. For example, William Warren investigated individuals' judgments of whether a surface of support afforded stepping-up-on. He found that individuals' judgments were based on the ratio of step riser height to their leg length. Significantly, because this value is scaled relative to the body, rather than being a property of the environment independent of the perceiver, it is constant (invariant) across individuals of varying heights.

Subsequent research has examined numerous other affordances, including whether a surface affords sitting-on, whether an aperture can be passed through, whether an object is graspable as well as whether it is within reach, whether a barrier can be stepped over, and whether a task is perceived to require the participation of another person in addition to oneself. Each of these affordances is scaled relative to an individual; hence, they are not properties of the environment strictly speaking, but properties of a person-environment system.

An affordance approach to environmental properties underscores the significance of the body as a frame of reference in perception and cognition. The recent burst of activity on embodiment in cognitive and social psychology can be partially traced to J. J. Gibson's groundbreaking work on affordances, although much of this work fails to adopt the relational perspective of affordances.

Perceptual Learning and Development

The research programs of J. J. and Eleanor Gibson ran along complementary but parallel tracks. In one of their few collaborations, they proposed that growing perceptual awareness of new environmental properties over time (perceptual learning) is largely a process of discovery (perceptual differentiation) rather than of associative learning. As noted earlier, the ambient optic array is filled with light that has been structured by reflecting distal surfaces. This ecological fact indicates that a rich array of potential information is available to be perceived by individuals, and at any given moment, a perceiver is extracting only a limited portion from what is available. All of the concepts discussed in this entry refer to examples of higher-order information that are available to be perceived and that individuals become attuned to with exploration. Over time, a perceiver's awareness of properties of the environment becomes ever richer and extended with continuing opportunities to detect distinguishing relational and higher-order information specifying features, objects, and events.

Eleanor Gibson and her students have pursued these ideas through innovative developmental research, including investigations of rigid and nonrigid motion, traversability of surfaces, intermodal perception (e.g., detecting common invariants across different perceptual systems), perception of surface properties relevant to locomotion (e.g., slopes), reaching and grasping, and the use of tools. Much of this work has served as an impetus for psychology's recent wholesale reassessment of the perceptual world of infants.

Philosophical Implications: Ecological Realism

The ecological approach is unique among perceptual theories in its claim that the environment is perceived directly (*direct realism*). This view holds that our everyday impression that the environment, in most cases, is as it appears to be, is warranted. Historically, it has been pejoratively referred to as "naïve" realism. Why is that?

Traditional approaches to visual perception uniformly claim that what we experience when we perceive the environment is not the environment itself, but a mental construction of it (a view called *indirect realism*). The basis for this seemingly counter-intuitive position rests in its initial assumptions. As we have seen, traditional approaches take it for granted that the stimuli for vision are initially projected on a two-dimensional picture plane.

These stimuli are inherently equivocal (ambiguous) because as projections on a two-dimensional plane, they do *not* uniquely specify their sources in the environment. And yet it is our impression that we experience with considerable certainty a three-dimensional world around us. Hence, it must be the case—according to traditional views—that perceiving involves some intervening processes that interpret this two-dimensional display of equivocal stimuli, resulting in a "best guess" as to what the current environmental conditions truly are. The product of such processes is posited to be a mental image or a mental representation of the environment. Consequently, each individual is assumed to experience the environment as a private, intrapsychic mental construction. This assumption has created philosophical problems for centuries. Psychologists who operate from one of the traditional theories have either ignored these problems or dismissed them as being irrelevant to the research enterprise.

As we have seen, from an ecological perspective, perceiving is a dynamic process of detecting information in the stimulus array that univocally specifies features of the environmental layout. To review, the structured light of the ambient optic array carries information specific to environmental objects and events. Critically, actions of the individual introduce perceivable changes in the ambient optic array, thereby revealing non-change (invariant structure) in the context of change. Because these higher-order invariants are specific to particular stable and persisting features of the environment, they function as information for direct perception of those features. Reciprocally, change generated by the perceiver's actions specifies the self as a source of agency (intention).

This is not to say the perceiving is always free of error—under special circumstances the perceivable structure in the light can mislead, as in the case of an apparently bent stick in water. Nor is this to deny that sometimes individuals are forced to engage in guesswork when there is insufficient or equivocal information (e.g., conditions of fog, inadequate illumination), or under conditions of artificial constraints imposed in research laboratories. Moreover, all of us rely to a great extent on second-hand descriptions (e.g., reportage) or representations (e.g., photographs) of the actual state of things. This second-hand information is accurate only to the degree that it faithfully carries information about its sources. Information in the ambient array affords us the opportunity to perceive the environment directly and to look for ourselves.

EFFORT: PERCEPTION OF

Perception of effort, also known as perceived exertion or sense of effort, refers to the conscious sensation of how hard, heavy, and strenuous a physical task is. This perception depends mainly on feelings of effort in the active limbs, and the sensation of heavy breathing (a type of dyspnea). Several authors think that somatic sensations such as muscle pain, thermal discomfort, and chest pain also contribute to perceived exertion. However, it has been demonstrated that people can differentiate perception of effort from these somatic sensations experienced during exercise (e.g., muscle pain). This entry describes the history, measurement methods, physiological and psychosocial determinants, neurophysiology, effort and other perceptions, and relevance and practical applications of perception of effort.

History and Measurement Methods

The sense of effort, including perception of force and weight, has been studied by psychologists and physiologists since the mid-to-late 19th century. However, the construct of perceived exertion was introduced in the early 1960s by Gunnar Borg, a Swedish psychophysicist with an interest in exercise. Borg also developed the two most common instruments used to measure perception of effort: the rating of perceived exertion (RPE) scale and the category-ratio (CR-10) scale. Both scales are based on the principle that most people share meanings of "no exertion" and "maximal exertion" based on similar experiences with physical activity, and careful selection of verbal expressions of effort to obtain category scales with interval or ratio properties.

The RPE scale measures the intensity of perceived exertion on a 15-point category scale representing equal intervals and ranging from 6 ("no exertion at all") to 20 ("maximal exertion"). Seven of the 13 intermediate points are anchored to verbal expressions of effort such as "very light," "somewhat hard," and "heavy." The CR-10 scale can be used to rate not only perception of effort, but also the intensity of other sensations such as pain. This scale ranges from 0 (no perception) to 10 (the strongest perception ever experienced) with various verbal anchors (e.g., "weak" and "moderate"). Subjects can give ratings higher than 10 (e.g., 13) if they perceive an intensity stronger than the one they have ever experienced. With proper familiarization and standardized instructions, both instruments have good reliability and validity. The latter has been demonstrated by significant correlations between RPE and objective measures of physiological strain (e.g., heart rate and blood lactate concentration) during exercise with incremental workloads.

Although the RPE scale and the CR-10 scale are the most widely used, other instruments have been developed to rate perception of effort. These methods include visual analog scales and pictorial scales portraying people exercising at different intensity levels. Classical psychophysical methods such as magnitude estimation, weight discrimination, and force-matching have also been used to quantify perceived exertion.

Physiological and Psychosocial Determinants

The workload at which somebody is exercising (e.g., running speed, resistance on the stationary bike, or amount of weight lifted) is an important factor determining perception of effort. Indeed, perceived exertion increases as workload increases. However, across individuals, there is a poor relationship between absolute workload and perception of effort. This is because perceived exertion accurately reflects relative exercise intensity, which depends on two factors: absolute workload and individual exercise capacity (i.e., physical fitness). For example, the same running speed of 12 kilometers per hour (km/h) can be perceived as "very hard" by an unfit middle-age man or as "very light" by an endurance athlete. However, both subjects would perceive a similar effort when running at 80% of their maximum endurance running capacity. Because physical fitness is affected primarily by physical training and health status, these two factors are important determinants of perceived exertion. Another important determinant of perceived exertion is the duration of the exercise bout. Perception of effort is known to increase significantly over time during prolonged exercise at a fixed workload. This phenomenon is an essential feature of fatigue during physical tasks. Nutritional (e.g., caffeine and muscle glycogen) and environmental factors (e.g., altitude and ambient temperature) are among many other physiological factors affecting perceived exertion.

Like other subjective feelings, perception of effort or its rating can be affected by psychological factors. These include personality, mood, somatic perception, locus of control, and self-efficacy. The presence and gender of another person during exercise testing can also influence RPE, but the effects of other social factors are poorly understood at present. Both psychological and social factors seem to affect perception of effort at low-to-moderate exercise intensities rather than during high-intensity exercise.

Neurophysiology

The neurophysiology of perceived exertion has not been extensively investigated, and its exact mechanisms are still being debated. One point of view is that perception of effort results from the complex integration of different afferent sensory inputs to the brain including those underlying proprioception, pain, and thermal discomfort. This proposal is supported by the significant correlations between RPE and several indicators of physiological strain measured during exercise (e.g., heart rate and blood lactate concentration). However, these high correlations may not be indicative of a cause-and-effect relationship. Indeed, because RPE increases as workload increases, any physiological variable that increases with workload could be related to RPE. Importantly, perception of effort is not affected by interventions (e.g., epidural anesthesia and lung transplantation) that block afferent feedback from receptors sensing the physiological conditions of skeletal muscles and internal organs.

An alternative explanation is that perception of effort reflects the magnitude of the central motor commands sent from the brain to the active muscles, including the respiratory muscles. This is achieved by forwarding neural signals, termed *corollary discharges,* from motor to sensory areas of the cerebral cortex. This view is supported by several experimental studies in which peripheral neuromuscular function is reduced using, for example, partial curarization or muscle fatigue. In these experimental conditions, higher perception of effort is thought to reflect the increased central neural drive necessary to exercise at the same workload with weaker muscles.

Experimental studies using hypnotic suggestion, dissociative cognitive strategies, imagery, psychoactive drugs, and mental fatigue suggest that cognitive factors are also important for perception of effort. Some of these experimental manipulations have also been used to locate the cortical areas associated with RPE using positron emission tomography. These areas include the anterior cingulate cortex, insular cortex, thalamus, and supplementary motor area.

Effort and Other Perceptions

Perception of effort interacts with other sensory information (e.g., proprioception and optical information) to produce other perceptions. For example, experimentally induced muscle weakness influences the perception of static limb position because more effort is required to hold the limb against gravity. When the limb is not held against gravity (no effort required), muscle weakness does not influence judgments of static limb position.

Experimental manipulations of effort also affect perception of distance. For example, wearing a heavy backpack significantly increases subjective judgments of distance to various targets. Interestingly, in this and other experiments, higher effort was anticipated. Therefore, effort does not need to be exerted to affect perception of distance.

Relevance and Practical Applications

Perceived exertion is a common phenomenon in daily life (e.g., climbing a flight of stairs or lifting a heavy object). Therefore, this perception plays an important role in regulating our physical activity behaviors. These behaviors range from choosing the pace during endurance competitions to adopting a sedentary lifestyle. It has also been proposed that primary disturbances in the sense of effort may underlie some of the symptoms characteristic of chronic fatigue syndrome and schizophrenia.

From an applied perspective, RPE is widely used as an adjunct to physiological and clinical measures (e.g., electrocardiogram) during maximal exercise tests. It can also be used to predict exercise capacity from responses to submaximal exercise tests. Because it accurately reflects relative exercise intensity, perception of effort is useful to prescribe and monitor exercise intensity in individuals participating in endurance and team sports, cardiac rehabilitation programs, and fitness training. The RPE scale has also been applied to evaluate work demands in a variety of occupations involving significant physical effort.

ELECTRONIC NOSE

Across a wide range of applications there is a need to rapidly detect, identify, and quantify complex volatile mixtures. Food manufacturers need to monitor the quality of incoming raw products and evaluate the perceptual properties of their products; environmental agencies seek to regulate the emission of malodors from waste treatment and other industrial plants. Humans readily accomplish these tasks through the sense of smell. Could an instrument be developed to mimic these capabilities? This entry describes the technology of electronic noses, discusses the challenges associated with mimicking human olfaction, and reviews past and current application areas of electronic noses.

Definition

Electronic noses (or e-noses for short) are scientific instruments that detect, recognize, and quantify volatile chemicals in a manner that is loosely reminiscent of the sense of smell. The concept of an e-nose dates back to a 1982 article by Krishna Persaud and George Dodd, which showed that fine discrimination between odorants is possible without highly selective sensors. Instead, and much like the human nose, e-noses rely on cross-selective sensors; that is, sensors that respond to many different odorants, though the strength of the response varies with each odorant. To discriminate odorants, e-noses (and human noses as well) use an array of sensors with different cross-selectivities. In this way, the response pattern across sensors becomes a fingerprint for each particular odorant. In addition to chemical sensors, e-noses require a pattern-recognition system and an odor-delivery system.

Chemical sensors consist of two elements: a sensing layer and a transducer. The sensing layer is made of a material whose properties change when odorant molecules are adsorbed on its surface; as an example, the sensing material may change its electrical resistance or its mass. In turn, the transducer converts these changes into an output signal; as an example, a transducer may convert mass changes in the sensing layer into frequency changes of an output signal, which then can be easily recorded with a computer. Sensing materials for e-noses can be inorganic (metal oxides are typical), organic (e.g., conducting polymers), and biological (e.g., proteins). Typical transducers for e-noses are based on conductivity or mass changes, though other transduction principles can be used as well (e.g., capacitive, calorimetric, optical, field effect), sometimes simultaneously.

Most e-noses operate under two basic forms of odor delivery: static headspace and dynamic headspace. In static headspace analysis, a sample is placed inside a closed container along with the sensor array, and the headspace above the sample is allowed to equilibrate before recording the sensor array response. In the dynamic headspace method, an effluent (e.g., filtered room air) flows through the sample continuously, carrying odorant molecules to the sensor array located in a separate chamber. Several techniques (e.g., preconcentration, separation) can also be used to condition odorant samples before they are delivered to the sensors.

Once an odorant sample has been delivered to the sensor array and the corresponding response has been recorded, the signals are analyzed with a pattern-recognition system. Depending on the application, the goal of the analysis may be to classify the sample into one of several potential categories (e.g., fresh vs. spoiled milk), predict a set of properties for the sample (e.g., concentration, quality), or find samples that are similar (e.g., clustering).

Mimicking Human Olfaction

The term *electronic nose* suggests that the instrument could be used to predict the perceptual properties of an odorant. Prediction of perceived intensity is straightforward because both chemical sensors and olfactory receptors have monotonic concentration-response curves. However, prediction of qualitative descriptors is more challenging, unless the problem is constrained to specific applications (e.g., rating the freshness of particular foods). Unlike vision and hearing, in which the properties of rods/cones and hair cells can be explained in terms of light wavelengths and sound frequencies, respectively, the primary dimensions of olfaction are still unknown. Findings by Linda Buck and Richard Axel, which led to the 2004 Nobel Prize in Physiology or Medicine, indicate that olfaction has a large number of dimensions (about 350 olfactory receptors in humans). However, the precise odorant properties detected by each olfactory receptor are yet unknown, which makes it difficult to develop chemical sensors with response properties similar to those of olfactory receptors. In addition, olfactory stimuli can contain many individual chemicals (e.g., more than 800 different volatile compounds in coffee), and the perception of odor mixtures is poorly understood. Finally, current chemical sensors have detection thresholds that are several orders of magnitude higher than those in the olfactory system.

Applications and Outlook

E-noses represent a trade-off between high-end analytical instruments, such as mass spectrometers or gas chromatographs, and sensory analysis with human panels. Like analytical instruments, e-noses can provide objective results; like human panels, e-noses provide an overall response (a gestalt), rather than a fine analysis of a smell into its individual constituents. Early commercial e-noses were marketed as general-purpose instruments that could be calibrated to any application by “retraining” their pattern-recognition model on the odorants of interest. Experience has shown that this is not possible with current chemical sensors. As a result, current commercial efforts are moving toward application-specific chemical sensor systems. In the food and beverage industry, e-noses can be used to inspect raw ingredients (e.g., olive oil quality), monitor production processes (e.g., fermentation and roasting), and estimate the shelf life of products (e.g., fish spoilage), to name a few scenarios. E-noses also have application in environmental problems, where they could be used to monitor emissions (e.g., waste disposal sites) and indoor air quality (e.g., ventilation systems in hospitals). Finally, e-noses have shown potential for the rapid diagnosis of disease by analyzing odors from skin (e.g., yellow fever), breath (e.g., diabetes), sweat (e.g., diphtheria), as well as odors from waste products and excretions. Thus, although e-nose systems are yet unable to describe a Marqués de Murrieta 1989 Ygay Rioja wine as having “intense black fruit and vanilla aromas with a lovely scent of something surprising like toasted coconut,” a variety of applications can benefit from specialized e-noses that can rapidly recognize and quantify volatile compounds.

ELECTRORECEPTION

Electroreception is the sensory ability of some species of animals to detect weak, naturally occurring electrostatic fields in their environment. It is found in the most ancient lineages of fishes and survives today in about 10% of all vertebrate species—all of which are aquatic. Electroreception was lost in evolution when vertebrates crawled onto land, so we humans can only imagine the perception of an electrical world with this sixth sense. For reasons unknown to biologists, electroreception was also lost among the ancestors of the modern fishes only to reappear in two separate lineages of ray-finned, or teleost fishes. The sense also appeared independently with the evolution of the monotreme mammals such as the platypus and echidna. All electroreceptive species possess sensitive electroreceptor organs in their skin that can detect electric fields as weak as a fraction of a microvolt per centimeter. These electroreceptors exhibit a low-resistance pathway for current to flow from the external environment to a sensory epithelium containing cells with voltage-sensitive ion channels in their membranes. As these sensory cells are depolarized, they activate nerve fibers to send action potentials to the brain. The oldest lineages of fishes with electroreceptors have ampullary organs that can sense direct current (DC) fields. This allows them to detect and capture prey in the dark or in murky water. The more recently evolved teleosts with electroreceptors have tuberous organs that can sense alternating current (AC) fields, an ability that is useful for social communication and for active object-location if it is combined with discharges from an electric organ. Terrestrial animals have no use for electroreception because the high resistance of the air prevents the flow of electric current.

Only a few investigations have searched for electroreception among invertebrates, although a few studies report on electric sensitivity of crayfish and worms, but the behavioral thresholds are so high (more than 3 volts per centimeter (V/cm) in the worm *Caenorhabditis elegans*) that it is doubtful that natural fields would ever activate them. For comparison, sharks and rays, which have the most sensitive ampullary receptors, have thresholds as low as 0.02 microvolts per centimeter, the equivalent of an electric field set up between one pole of a 1.5 volt battery in San Francisco Bay and the other pole connected to the ocean near Los Angeles.

Even though humans lack electroreceptors, we can perceive strong electric currents from batteries, static generators, and other sources if we make direct contact with them or establish indirect contact through a conducting medium such as water. The perception is unpleasant because electric currents stimulate sensory and motor nerve fibers indiscriminately, producing a tingling sensation at threshold levels, and painful sensations and muscle twitch at higher levels. Human thresholds are in the 1 milliamp current range, which translates into electric fields of 0.1 to 1 Volts/cm in freshwater. Our threshold for sensing an electric field in air is more than 4 kilovolts per centimeter (kV/cm), a perception that originates with the mechanical displacement of charged dermal hairs in electric fields. This entry describes the discovery, perception, and functions of electroreception, as well as the evolution and anatomy of electroreceptors.

Discovery

Electroreceptor organs were first identified physiologically in the early 1960s from weakly electric fish by the U.S. neuroscientist Theodore H. Bullock and colleagues and by French scientists Thomas Szabo and A. Fessard. The existence of electroreceptors had been anticipated in the late 1950s by Hans W. Lissmann from Cambridge University who was the first to discover continuous “weak” electric discharges from an electric organ—the tail of the African fish, *Gymnarchus niloticus*. By 1958, he had demonstrated the reason for the discharge by showing that these fish could detect the presence of glass and metal rods or other conducting or nonconducting objects at distances of 10 centimeters or more, even in the absence of visual, mechanical, or chemical cues. Lissmann postulated that they were sensing the distortions of their own electric organ discharges as electrical shadows on their skin. Lissmann correctly guessed that there were dermal electroreceptors in these fish. He called their behavior “electrolocation” after the well-known ability of bats to echolocate objects by detecting returning ultrasonic echoes from their calls.

In the 1960s, Dutch scientists Sven Dijkgraaf and Adranius Kalmijn established that sharks and rays, which have dermal sense organs called ampullae of Lorenzini, could sense weak electric currents from their prey organisms such as flatfishes even when they were buried under sand. Dijkgraaf and Kalmijn showed that the ampullae of Lorenzini were essential to this behavior, which was entirely based on electrosensory cues, and that prey have weak DC electric fields surrounding their gills, gut, and skin wounds that gave away their presence to the sharks. When given a choice between a prey fish covered with plastic wrap and a pair of wire electrodes connected to a prey fish in another tank, the shark preferred to dig up the wires. Kalmijn and colleagues called this ability "passive electrolocation" in contrast to the "active electrolocation" ability of *Gymnarchus niloticus* discovered by Lissmann.

Evolution and Anatomy of Electroreceptors

Electroreception first appears in crainates among lampreys that have epidermal "end-bud" organs innervated by the lateral line nerve. The end-bud receptors are sensitive to weak, low-frequency (DC to 50 hertz [Hz]) electric fields. Among the earliest jawed vertebrates we see the first ampullary electroreceptors embedded in the skin or at the base of a long conducting canal leading from the skin surface to a specialized patch of modified sensory epithelial cells in the case of ampullae of Lorenzini. The sensory epithelial cells resemble hair cells of the lateral line or inner ear, and the nerve fibers connecting them to the brain travel in the same nerve bundles with the lateral line nerves. The cells lining the ampullary canals are packed tightly to make a high resistance insulator around the low-resistance canal lumen, which is composed of a salty gelatinous matrix. Like an insulated wire, this arrangement is ideal for conducting electric currents to the sensory cell membranes. All vertebrate electroreceptors follow this basic design.

Electroreception is shared by all of the primitive aquatic vertebrates, including some aquatic amphibians, but it was lost in the amniotes as they made the transition to a terrestrial existence. In those monotreme mammals in which the sense reappears, electroreception is derived from modified mucous glands on the bill or snout. These mucous glands have low-resistance canals leading from water to bare nerve endings of the trigeminal nerve. Electroreception is absent in most modern fishes (including bowfins, gars, and teleost fishes) except that it appears in two independently evolved lineages of teleosts, first as ampullary receptors among catfishes and independently among notopterid knifefishes of Africa. Remarkably, tuberous or AC sensitive electroreceptors also appear in both of these lineages as subgroups of electric fishes. These are the South American gymnotiform fishes, related to the electric eel, and the unrelated mormyroid or elephant-snouted fishes from Africa. Members of both groups use their tuberous organs for active electrolocation of objects and for electrical communication. There are sufficient anatomical and physiological differences between teleost electroreceptors and the ancient ampullae of Lorenzini so that biologists conclude they were derived secondarily. The molecular basis for electrosensory transduction is unknown for electroreceptors.

Functions of Electroreception

Ampullary electroreceptors are used for passive electrolocation of the DC electric fields from prey organisms, predators, or conspecifics. The ability to sense other animals gave these fishes a decided advantage in navigating in the dark or in turbid water. Tuberous electroreceptors, which are found only in the two independent lineages of teleosts already mentioned, are used for sensing the AC electric fields from electric organs, either in the context of active electrolocation of objects, or for social communication. Electric communication signals from electric organs can be quite elaborate and varied. A rich repertoire of electric signals is used for signaling threats, submission, alarm, and courtship, and some of these fish have electric signals for sex, species, and individual recognition.

Perception

Because humans lack electroreception and the words to describe it, we can only imagine what this sense must be like for other animals. For those with true electroreceptors, the sensation is probably nothing like the unpleasant feeling we associate with electric shocks. To understand what an animal perceives, we can only do behavioral tests, make physiological recordings, and examine behavior of animals with sensory deficits, and even so we will never experience what the animal feels. We imagine that electroreception must resemble the touch because both modalities have receptors distributed over the body surface and both have sensory maps of the body surface in the brain. However, electroreception is also like the thermal sense because electric currents flow in vague and diffuse pathways and never create sharp boundaries. But there are also similarities between electroreception and hearing because both modalities are encoded by frequency-tuned receptor cells resembling hair cells and both use time encoding to represent time varying stimulus waveforms. Electroreception is also similar to vision because multiple receptor types are distributed over the skin surface as in the retina, and in both modalities, there are local regions where receptors are extremely dense, creating a fovea of acute spatial resolution. Whether electroreception is perceived more like we perceive touch or hot or cold or hearing or seeing is unimportant to the scientists who strive to describe the sensory experience in terms of physical attributes of the stimulus, electrophysiological properties of sensory afferents, or central neurons, or the behavioral performance during natural behavior and trained discrimination. An animal's perception will remain unknown to us. Nevertheless, the widespread appearance of electroreception among aquatic vertebrates and the multiple cases of its evolution suggest that this sense, although foreign, is an extremely important part of the evolutionary history of our vertebrate lineage.

EMBODIED PERCEPTION

Embodied perception refers to a conglomerate of theoretical claims postulating that the body, its movements, and the interaction with the environment fundamentally shape people's perception of the world. All these claims have in common that they criticize "disembodied" notions of perception that are characteristic of the information-processing approach. Conceived during the cognitive revolution that made the computer the main model for the mind, the information-processing approach postulates that the function of perception is to encode and classify physical stimuli to form mental representations. These representations are then used in further cognitive (symbolic) processing. However, different strands of embodied perception take issue with the information-processing approach for different reasons. As yet, there is no set of core assumptions that every embodied perception researcher would subscribe to. This entry describes four influential notions of embodied perception by classifying them in terms of their core assumptions.

Focus on Interaction With the Environment

An influential approach to embodied perception has its roots in ecological psychology and the work of J. J. and Eleanor Gibson. At the core of (neo)-Gibsonian versions of embodied perception is the idea that observer and environment are so tightly coupled that a meaningful explanation of perception must focus on their interaction. Perception does not happen in the mind or brain alone. Accordingly, this approach rejects the assumption of the information-processing approach that unconscious inferences create a stable mental representation of the stimuli that appear in the outside world.

Instead, it is postulated that to understand perception one needs to investigate how the relation between observer and environment enables *direct perception.* This term refers to the claim that information emerges in a dynamic spatiotemporal relationship between observer and environment, characterized by perceptual invariants—properties of the environment that remain constant as the observer moves. For example, an observer can directly perceive how large an object is from the dynamic pattern of information that the movement generates as the observer is approaching the object (optic flow). Similarly, if one is passively moved (e.g., riding a train), one can directly perceive the distance of different objects (e.g., trees along the tracks and distant hills) based on how quickly they pass by.

The ecological approach is radically embodied because it implies that perception cannot exist independently of an observer who moves through the environment. The key concept of affordance provides a further illustration of this idea: Affordances are conceived of as action possibilities that objects in the environment provide for the moving observer. Importantly, the relation between an actor's capabilities and physical properties of objects determines what is afforded, rather than the objects alone. For example, for adults, a chair affords sitting, whereas for an infant it may afford drawing himself or herself up to standing position.

The notion of direct perception has had a major impact on new developments in artificial intelligence, and especially, robotics. Earlier attempts at building intelligent machines relied on the assumption that a central processor stores input and performs logical operations that lead to a meaningful output. Embodied, interactionist thinking in robotics led to the construction of robotic agents that avoid central planners. Instead, they rely on direct links between input (perception) and actions. These links define which action is appropriate given a particular input. Conflicts between different possible actions are not solved through explicit selection of a behavior by a central controller. Rather, they are solved implicitly by organizing the different perception-action links in a hierarchical manner so that certain behaviors are prioritized over others. Despite the lack of a central controller, robots with such a subsumption architecture evolve complex, intelligent behavior in real-time through interaction with a rich environment. An illustration of this is Herbert, an MIT robot from the 1980s. Herbert was able to collect empty cans without stored long-term plans or a model of the world, relying just on a small set of behaviors such as object avoidance and locomotion.

The direct perception approach to embodiment shares with other embodiment theories a focus on the real-time character of perception, and on the emergence of adaptive behavior through close interaction with the environment. However, the outright rejection of mental representations and their neural correlates is a contentious issue. For instance, the philosopher Andy Clark, one of the main proponents of embodied perception, has argued that there must be room for at least action-centered representations and partial models of the world. The rejection of any central, integrated processing is incompatible with evidence that the brain integrates multiple sources of information and ignores the existence of internal models that provide links between perception and action in real time.

Focus on Evolution and Body Morphology

Arguments for another biologically inspired take on embodied perception come from evolutionary approaches stressing the fact that brain and body have evolved together over time to maximize the chances for survival in particular environmental niches. This fact, it is argued, has been neglected by the information-processing approach to perception where evolutionary considerations and evolved anatomical constraints have only played a marginal role.

Evolutionary approaches to embodied perception often focus on the relation between body morphology and perceptual abilities in different species. It is thought that ecology can provide important clues to how evolutionary constraints have shaped sensory systems. For instance, predators' eyes tend to be closer together and more to the front to provide the accurate binocular vision that is important for locating prey. In contrast, animals that are more likely to be preyed on have the eyes farther apart and more on the sides to produce the wide field of vision needed to spot predators.

In addition to considering the relation between body morphology and the senses, evolutionarily inspired embodiment approaches also address the relation between body morphology and neural control. For example, if a ferret's brain is rewired so that retinal projections reach the auditory cortex, the auditory cortex contains a map of visual space and its cells have properties typical of cells in a normal primary visual cortex. This suggests that the patterns of maps in sensory cortices are not hardwired, but emerge as a consequence of the patterning inherent in the sensory input (are plastic).

Evolutionary takes on embodied perception have an increasing impact on robotics and have led to the development of "evolutionary robotics." Whereas early work in this area focused on central control processes and ignored body morphology, recent studies have addressed how evolving mechanical "bodies" constrain behavior and vice versa. Using known genetic principles of reproduction, computer simulations of evolutionary processes across multiple generations have shown that simple organic units group to form stable bodies. These exhibit rather complex behaviors in response to particular environmental conditions, for example, pushing blocks out of the way. In such scenarios, genes do not explicitly code for the body structure of the evolving agents. Rather, the interaction between genes and environment determines which anatomical structures and which behaviors provide the best chances of survival.

The evolutionary take on embodied perception is close in spirit to interactionist strands of embodiment described earlier because the interaction between organism and environment is regarded as crucial. However, evolutionary approaches consider much larger time scales than are considered in ecological psychology, thus adding a historical perspective on emergent properties that arise through the interaction between organisms and the environment.

Focus on Proprioception

The label of *embodiment* is also increasingly found in more traditional perception research that is not committed to strong interactionist or evolutionary notions of embodiment. Here, embodiment reflects the view that the body is a special object of perception. Accordingly, proponents of this view maintain that perception critically depends on sensory information about one's body, especially proprioception.

The most radical version of this claim is that proprioceptive information about body movements and touch provides an inner perspective through which all other sensory information, especially visual and auditory information, appears to the observer. This inner body perspective is thought to be at the core of all perceptual experiences. Less radical versions focus less on this experiential aspect and more on specific empirical questions. Both have in common that they argue that the body senses have been undervalued in perception research.

Closely related is a renewed interest in multimodal integration. Research in this field suggests that the body can constrain perception via associations between body senses and distal senses such as vision and audition. Examples for such links include differences in perceptual ability in the area immediately surrounding one's body (near space) compared with the area outside of one's reaching space (far space), and increased perceptual efficiency in areas that are close to one's body parts. A related discussion addresses whether there are specialized processes and brain systems for the visual processing of the human body structure. For example, the extrastriate body area (EBA) that contains neurons responding to bodies may selectively filter out body-like visual configurations and pass them on to higher brain systems. Alternatively, people may map others' visually perceived bodies onto their own multimodal body schema assumed to reside in the inferior parietal cortex.

Focus on Intentional Action

Another take on embodiment comes from accounts of perception capitalizing on intentional action and the action repertoire of the perceiver. These accounts go back to William James's ideomotor theory that explains voluntary action as driven by perceptual images. Researchers criticize the neglect of intentional action in perception research. In line with interactionist notions of embodiment, perception is conceived of as serving action rather than providing an image of the world. However, the notion of internal representation is not rejected. Rather, internal representations are assumed to play a central role in controlling actions.

The basic functional claim of this approach is that actions are coded by their perceptual consequences. This creates a common representational space for performed and perceived actions (common coding). For instance, when a person claps his or her hands, this will produce a particular sound. When another person perceives this sound, this will activate a representation of the corresponding clapping action. The more similar the sounds that both persons produce when clapping, the higher this activation will be.

Support for the assumption of such perception-action links has been provided by the finding of mirror neurons in monkeys and an analogous mirror system in the human brain. The same motor areas of the brain are activated when individuals perform an action and when they perceive somebody perform a similar action. The more one is an expert at performing a particular action, the more responsive motor areas in the brain are to perceiving this action. For instance, primary motor areas are active in pianists when they hear piano tones but not in novices. Both the functional principle of common coding and the neural evidence for a mirror system define a brand of embodiment that stresses that the ability to perform intentional actions fundamentally shapes people's perception of each other's actions.

EMOTIONAL INFLUENCES ON PERCEPTION

The effect of emotion on perception has been a topic of interest through much of the history of psychological thought. The notion that what we see is influenced by our internal emotional and motivational states is appealing to those inclined to view aspects of the mind as interconnected even at the earliest information-processing stages. Although accumulated evidence demonstrates that emotion affects the result of perceptual processing—that is, perceptual awareness—questions remain debated and unresolved regarding the precise processing stages at which emotion exerts its influence.

In the 1940s and 1950s, pioneering work by Jerome Bruner and colleagues inspired what became known as the "New Look" movement, a loosely knit effort among psychologists to reveal contributions of emotion, knowledge, personality, and motivation to perception. In one of their classic studies, children were asked to adjust the size of a patch of light so that it matched the size of either various nearby coins or size-matched cardboard disks. The children's errors were greater when estimating the sizes of coins than cardboard disks, a pattern particularly evident among the poorer than more wealthy children. The researchers concluded that perception is influenced by the value accorded to aspects of the environment, and they made the rallying argument that motivational factors need to be considered to understand perception in the real world. Two ideas that emerged from this movement were those of *perceptual defense* and *perceptual vigilance,* which referred to the peculiar manner in which people appeared to exhibit, respectively, impaired or enhanced perception of taboo or emotional stimuli (for example, worse or better recognition of such stimuli, relative to neutral stimuli, in noisy displays). Notably, such ideas—proposed before the maturation of information-processing approaches to perception, which involved differentiation and identification of interacting perceptual stages—seemed to contain within them an insurmountable paradox: How could emotional stimuli gain distinctive perceptual status when the act of prioritizing them necessitated that their emotional significance had already been perceived?

Modern research has at least partly resolved this dilemma, demonstrating that perceptual awareness reflects the output of many processing stages, with contributions from neural regions distributed throughout the brain. Thus, there are many opportunities for the emotional significance of sensory information to be registered before awareness. The amygdala, a neural structure heavily implicated in emotional processing, appears to receive some sensory inputs that bypass cortical areas associated with attention and awareness—which may explain findings that it responds even to emotional stimuli that people can't report. Furthermore, while this structure receives input from multiple brain areas, it also projects back reciprocally even to early neural processing regions—in the case of vision, as far back as the primary visual cortex. Such feedback connections may be important mechanisms underlying the enhanced activity, as revealed through neuroimaging, in vision-related brain areas in response to emotional, relative to non-emotional, stimuli. For example, emotionally expressive faces have been found to elicit more vigorous activity in a face-selective region of the temporal lobe (i.e., the fusiform face area, or FFA) than do neutral faces, and they have also been found to elicit increased amplitude of event-related potential (ERP) components as early as the P1 component, which peaks a mere 100-ms after stimulus onset. This entry describes the enhanced perception of emotional stimuli, effects of emotion on early perceptual processing, subliminal effects of emotional stimuli, questions about the function of preferential attention to emotional stimuli, and the influence of emotional states.

Enhanced Perception of Emotional Stimuli

Although early research emerging from the New Look movement gave consideration to both enhanced and impaired perception of emotional stimuli, recent work has tended to focus more on the former than the latter. Such work has found that people often are able to perceive emotional stimuli under conditions that would typically render non-emotional stimuli imperceptible. For example, when people search for two targets within a rapidly streaming sequence of stimuli, they often detect the first target at the expense of the second target, an effect known as the *attentional blink;* however, among neurally intact individuals, this effect is diminished when the second target is an emotional word. In other words, the emotional words seem to break through the attentional blink (patients with bilateral amygdala damage, however, show no such benefit for emotional words). Similarly, emotional stimuli tend to predominate over non-emotional stimuli and are perceived more readily during experimental manipulations in which separate inputs to the left and right eyes compete for awareness (e.g., binocular rivalry). Enhanced perception of emotional stimuli is not limited to the visual domain; for example, several experiments have employed "dichotic listening" tasks, in which people attend to auditory information presented to one ear while ignoring auditory information presented to the other ear. Although people often report being unaware of most information presented in the unattended channel, they do tend to notice particularly salient, emotionally meaningful words such as the sound of their own names.

Effects of Emotion on Early Perceptual Processing

In addition to neural evidence, behavioral evidence also suggests that effects of emotion on perception may occur early in the stream of processing. For example, one study found that presentation of an emotional face enhanced *contrast sensitivity* for subsequent targets. This term refers to the threshold of contrast at which people are able to disambiguate a stimulus from the background, and it typically is assumed to be an index of early vision. Although previous research has shown that contrast sensitivity tends to be enhanced via shifts of attention, evidence has also been found suggesting the effects of an emotional stimulus presentation and the effects of spatial attention on contrast sensitivity are additive, raising the possibility that emotion and attention might affect perception somewhat independently of each other. Although speculative, such possibilities converge with findings emerging from the neuroimaging literature: Although the impact of emotion on activity in visual areas can look similar to the impact of attention, some have suggested that the effects might possibly originate from and be instantiated via different neural pathways.

"Subliminal" Effects of Emotional Stimuli

Emotional stimuli tend to attract attention and engage some level of perceptual processing even when participants cannot report them because of laboratory-based manipulations. For example, in one study, high-contrast masks were presented to one eye and intact and scrambled versions of an erotic picture were presented to the other eye—a manipulation that, because of interocular suppression, leads the masks to dominate and obscure awareness of the pictures. Nevertheless, even though people could not report the presence of an erotic picture, they preferentially attended to its location, as revealed through higher target discrimination accuracy when a subsequent target appeared at the same location as the erotic picture rather than at the location of its scrambled counterpart. In the auditory domain, even when emotionally relevant words escape awareness in dichotic listening tasks, evidence suggests that they are perceptually processed at some level; for example, words that had previously been paired with electric shock—and that thus have some emotional significance—have been found to elicit indices of electrophysiological arousal, even when presented in the unattended stream and when participants report not having been aware of them.

Enhanced Perception as a Function of Preferential Attention to Emotional Stimuli?

Despite behavioral and neural evidence consistent with early effects of emotion on perception, the view that earliest stages of perceptual processing are open to the influence of emotion has been strongly challenged. Indeed, although the emotionality of a stimulus is reflected by activity in early sensory cortices, such findings provide relatively little insight into questions regarding where in the flow of information-processing emotion first exerts its influence. This is because it is difficult to determine whether such effects reflect modulation by emotion at initial processing stages or, instead, reflect "feedback" modulation instantiated via reciprocal projections from areas involved in higher-order processing. Indeed, notions that emotion (or any mechanism outside of a narrowly defined perceptual module) can affect early stages of perception are controversial. Although few would deny that the end product of perception can be colored by emotion, visual perception researchers such as Zenon Pylyshyn have argued forcefully that early stages of perceptual analysis—thought to extract and compute three-dimensional structure in the environment, among other visual tasks—must proceed beyond the influence of higher-order knowledge, expectations, or factors such as emotion and motivation; in other words, they must be cognitively impenetrable. According to this view, effects of emotion on visual processing could stem from effects on attentional allocation (which determines what receives perceptual processing in the first place) and on perceptual judgments and interpretations (which also contribute to our conscious experience), but most aspects of early visual computations lie beyond emotion's bounds. Even early appearing neural signals such as emotion-induced enhancements of the P1 ERP component resemble those that emerge simply as a function of attending versus ignoring a visual stimulus; thus, it could be that emotion influences perception solely through its impact on attention.

Many demonstrations of emotional influences on perception *can* be attributed to effects on attentional allocation. Emotional stimuli often seem to capture attention reflexively, and many of the manipulations that render non-emotional stimuli—but not emotional stimuli—imperceptible involve direct manipulations of attention. For example, the attentional blink described earlier is thought to render targets unreportable by presenting targets closer together in time than can be accommodated by the time it takes to make multiple attentional selections. Also consistent with the notion that emotional stimuli grab attentional resources that support perceptual awareness, the presence of emotional stimuli can actually impair perception of neighboring information: when people monitor a rapid stream of items for a single target, they often fail to detect the target when it is preceded by a particularly emotional distractor.

Influence of Emotional States

Although some research endeavors have focused on the role of emotional stimuli, others have focused on how emotional states influence perceptual processing in general. For example, experiments stemming from what is known as the *broaden-and-build* hypothesis—which suggests that positive emotion widens the scope of attention—have found that inductions of positive mood tend to bias participants to attend to "global" aspects of visual information rather than to "local" aspects: participants who underwent a positive mood induction showed an increased bias to make matching judgments based on global, rather than local, aspects of stimuli in which the local and global aspects contained conflicting information (e.g., where an assemblage of small squares (local) are arranged to form a larger triangle (global)). Such evidence that emotional states influence perception suggests an important bridge between perception research and clinical psychology, the latter of which focuses heavily on individual differences in chronic emotional states.

EVENT PERCEPTION

Event perception is the ability to recognize specific events, to recognize objects in events, and to perceive properties of those objects such as their shape and their weight as well as the specific ways that those objects move. The following is an illustration of event perception: A woman sets out for a walk in the park on a breezy fall day. She is able to see that she is walking and see the world go by as she walks. She can see the trees blowing in the breeze and falling leaves swirling about in the air. Squirrels can be seen leaping among the branches. She sees other people walking or jogging through the park. She sees a child swinging on a swing and another playing hopscotch while a third runs by while bouncing a ball. She sees an elderly man who is lifting a bag that she can see is heavy, so she offers the old man some assistance. All of these acts of perception entail event perception. This entry discusses the beginnings and significance of event perception, auditory and haptic event perception, the problem of information, event segmentation, and mirror neurons and motor theory.

Beginnings and Significance of Event Perception

The study of event perception was begun in 1950 by Gunnar Johannson, who, in his dissertation, actually started two closely related areas of investigation: event perception and structure-from-motion (or SFM). SFM is about seeing objects in events. One can see the rigid three-dimensional (3-D) shape of an object (is it a ball or an egg, a round can or a flat flask?) from seeing the motion of only a few random points on the object's surface. Johansson introduced a technique for isolating patterns of motion as visual information about events and objects in events. He distributed bright dots or patches on the surfaces of moving objects such as a person and filmed them in the dark so that only the dots showed up in the film appearing against a dark black background. When such movies are freeze-framed, so that only any single image from the movie can be seen, it just looks like a random distribution of dots. Without the motion, no three-dimensional structure can be seen. However, as soon as the movie is set in motion, it becomes obvious that it is a person walking.

At the first International Conference on Event Perception in 1981, one could witness about 200 of the leading perception scientists at the time gasp as they listened to Johansson and observed one of his now classic *point-light person* demonstrations. An unmoving arrangement of random dots suddenly moved and instantly could be seen to be a person sitting cross-legged and getting up out of a chair. The scientists likely gasped for two reasons. First, the informative power of patterns of motion was obvious. In such displays, you can see that it's a person and what he or she is doing. You can identify whether the person is male or female, how old the person is, whether the person is fatigued, whether the person is carrying a weight and if so, how much. You might be able to recognize a person's emotional state or who the person is. Established perceptual theory described information in static images formed when light was reflected from the entire surface of an object. But here there were just a few random dots in motion and not much, if anything at all, was gained perceptually by turning on the lights! It was all in the motion.

The second reason they gasped is because of what this implied about the role of time in perception and experience. Perceptual scientists were used to thinking about the information presented to the nerves in the retina on the back of the eye by a single momentary static image that was then processed by the brain to derive a perception of objects in the world. Event perception meant that the information as well as the thing seen were both distributed over significant lengths of time. The perception of a bouncing ball in a point-light display requires the time for the ball to fall, hit the ground, and rebound to provide enough spatial-temporal structure to enable one to recognize the event. This takes seconds, not milliseconds. Scientists still do not well understand how the brain might work with this kind of spatial-temporal information.

Auditory Event Perception

Event perception involves sensory modalities in addition to vision like audition (that is, hearing) or haptics (that is, touch and kinesthesis). We can recognize events from the sounds they make. One can recognize a bouncing glass bottle that has been dropped and distinguish it from a plastic one or one made of glass that shatters. One can tell from the sound of the water being poured into a glass when the glass has become full! Of course, one of the most puzzling feats of acoustic event perception is the ability to hear what someone is saying, that is, speech perception. The production of speech is an event involving movements of the vocal bands, the tongue, the lips, and the teeth of the speaker. Speech perception is like the visual perception of point-light people in that one can recognize, for instance, familiar people or the gender of a person or their emotional state from their speech as well as from what a person is saying.

Historically, the information in sound for speech perception has been analyzed by trying to make it as much like static snapshots as possible. The stream of sound has been analyzed into extremely brief elementary sounds such as letters and phonemes. The problem with this is that the phonemes change radically in the context of a continuous stream of speech where a given phoneme is preceded and followed by other phonemes. They interact in the production (acoustically, the "t" at the beginning of "titter" is entirely different from the "t's" in the middle of the word), but this does not seem to hinder one's ability to perceive what is being said. This problem is called *co-articulation.* The implication is that a more time-extended aspect of the sound patterns of speech may actually carry the information.

Haptic Event Perception

Objects, both animate (a cat versus a hamster) or inanimate (a potato masher versus a whisk), can be recognized by touch or haptic perception (with eyes and ears closed). This is a form of event perception. The reason is that people cannot readily recognize things just pressed into the passive palm and fingers of their hand. If they are allowed to manipulate an object in the hand actively, then recognition is rapid and accurate. The spatial-temporal structure generated as the hands interact with the surface textures and surface compliances (rigid, elastic, plastic) and surface shapes of objects yields information about those objects. Speech can be recognized haptically. Some people who are both blind and deaf can perceive what a person is saying by placing their open hands over the bottom of the speaker's face covering the lips and the jaw with a thumb on the throat touching the voice box or larynx. This is called the Tadoma method.

The Problem of Information

What is the information that allows one to recognize events? What is it about the spatial-temporal pattern of moving dots in a point-light people display or a structure-from-motion display that allows one to recognize the event or the object? Attempts to answer these questions can be categorized into two types: one analyzes kinematics and the other analyzes dynamics. *Kinematics* is the motions in events. Kinematic properties include time or frequency, position and its change over time, velocity and acceleration and their changes over time, and so on. Kinematics is lengths and times. *Dynamics* is about mass and the force or energy required to move it. *Dynamics* is concerned with the causes of motion. It entails the Newtonian laws of motion that generate the specific forms of events: pendulums, projectile motion, bouncing balls, and yes, walking people.

Johansson's approach was kinematic and he called it perceptual vector analysis. He analyzed the relative and common motions of the dots in the display. His point was that we really see motions in these ways. So, for instance, if you have a dot moving horizontally along the bottom of (an invisible) square and another dot moving at the same time vertically along the right edge of that square so that the two dots met at the bottom right corner and then reach the bottom left corner and the top right corner, respectively, at the same time (that is, the two dots are moving in phase), then what a person sees is not the motions as they have been described so far. Instead, what one sees is the two dots moving directly toward one another (as they approach the bottom right corner) and then directly away from one another (as they move to the bottom left and top right, respectively), and the line along which they are perceived to move itself moves diagonally across the square (that is, from the bottom right to the top left). The perceived motion of the dots toward and away from one another along the line is *relative motion* and the diagonal motion of the entire "line" is *common motion.* The discovery of this principle was important because it meant that one does not see the motion of the dot on the foot of a point-light walker as a hopping motion along the ground, but instead, as a pendular motion relative to the dot on the hip while the whole person moves over the ground. Johansson was a Gestaltist, and this analysis was characteristic of Gestalt. This kind of analysis was elaborated into an entire field of research on structure-from-motion (SFM)

James Todd performed a study using the kinematic approach in which he concluded that the approach could not be used to solve the problem. He set out to investigate how observers distinguish and recognize two different human gaits, namely, walking and running. Todd recorded the actual human motions in each case and then made stick figure animations of legs walking and running. He analyzed each into motion functions for each joint, and then he mixed the joint motions to try to determine which was the most important for making the whole gait look like either walking or running. The result was that none of them did. As he increasingly mixed the motions at different joints, the resulting gaits simply became more ambiguous. Basically, his approach was to perturb the motions in an event in an effort to discover what it was about the motions that made them recognizable as what they were. At the end of his study, Todd concluded that the space of possible motions was much too vast to be able to investigate in this way.

Subsequently, researchers in biomechanics revealed that walking and running are distinguished dynamically. Walking consists of upright pendulums and an inverted pendulum. The leg with the foot on the ground (the stance leg) is an inverted pendulum (like an old fashion metronome). The other leg (the swing leg) is a coupled set of upright pendulums. Two legged robots have been built that walk in this way with no motors down a slight slope, and they move and look just like a human walking. Running consists of a bouncing ball or pogo stick dynamic (elastic rebound and projectile motion). Running robots have been built using these dynamics and again, they look alive.

In a dynamic approach, events are characterized by the underlying dynamics (physical laws) that generate the specific forms of motion characteristic of a given recognizable type of event. In this approach, events are recognized like objects, namely, by their shapes. Object shapes are spatial. Event shapes are spatial-temporal. Each point moves along a 3-D path of specific shape and as it does so, the velocity of motion varies in a specific way. The result is what has been referred to as a trajectory form. A specific dynamic generates a specific trajectory form. Geoffrey Bingham has shown that human observers can discriminate among a variety of different trajectory forms and are able to use them to recognize different events. Furthermore, they were able to do this reliably when they saw the events from different perspectives.

Gravitationally governed events, such as a walking person or a bouncing ball, that have been inverted in a point-light display are difficult to see and to recognize. Thomas Shipley has shown that this is not simply because we are not used to seeing a person upside down, but instead because the motions have been perturbed with respect to the gravitation frame of reference. Shipley made point-light displays of a person walking on his hands (that is, inverted but consistent with the gravitational constraints on the motion). Observers had no difficulty seeing and recognizing this event.

So, both the study of the phase relations among moving points (that is, the timing of relative motions) and dynamically generated trajectory forms provides some insight into the visual information that allows people to recognize events. However, it remains difficult to discover what it is, for instance, about the walking motions of men and women that enables people to recognize the gender of point-light walkers. Nikolaus Troje used a kinematic approach to provide some understanding of this. He used an advanced correlational method (principal component analysis or PCA) to analyze the motions in point-light displays that were identified by observers as being male or female walking. In this way, he isolated properties that he could vary to turn a point-light display into either male or female walking. He was able to manipulate the motion to make it look one way or the other. This analysis, however, did not reveal what generates the specific recognizable forms of motion.

Dynamical analysis has revealed some of the information that allows us to see how big things in events are. Motions governed by gravity yield timing that covaries with spatial scale. For instance, the period of a pendulum's swing is a function of its length. The legs of animals, including humans, are essentially pendulums. So, the timing of their motions provides information about their scale, and human observers have been shown to be sensitive to this information.

Event Segmentation

Events are continuous in time and some events, especially those involving human actions, are so complex that they are composed of both a hierarchy and a series of simpler events. This was true of the walk in the park described earlier or, for instance, the act of cooking a meal. A meal might involve multiple dishes to be prepared, and the preparation of each dish involves a series of tasks, each of which involves subtasks such as reaching to grasp, stirring, peeling, or dicing. The whole business runs continuously in time potentially against a background of other distinct, but similarly continuous complex events (such as kids doing their homework at the kitchen table). Thus, perception of the event requires that it be segmented both from its background and into its various component parts. Barbara Tversky and Jeff Sacks have addressed this problem by showing observers movies of complex events and asking them to indicate where the simpler component events start and stop. Tversky and Sacks find that observers are consistent in their segmentation of the events. Their theory is that observers have mental representations of events that are used to predict what should happen in the immediate future and that these predictions are continually compared with what actually happens. When one event ends and another begins, the predictions momentarily become less accurate because, until the appropriate event representation can be identified, the course of motion cannot be anticipated. The idea is that observers use error rates in their predictions to determine boundaries between events. Many aspects of the theory have not yet been tested, but it's all fairly new.

Mirror Neurons and Motor Theory

Finally and more recently, there has been much excitement generated among researchers by the discovery of mirror neurons. These are neurons found in monkey brains that light up when the monkey sees the goal-directed movement of either its own or another monkey's hand reaching for something. This has led to a body of research pursuing the idea that the perception of biological motion (that is, point-light walkers rather than bouncing balls) is special. This theory is reminiscent of a motor theory of speech perception that was developed at Haskins Laboratories in the 1970s. The idea is that these events are seen in terms of the perceiver's own motor system. A limitation of this theory is that it cannot explain how events other than biological motions are perceived.

EVOKED POTENTIAL: AUDITION

Auditory evoked potentials (AEPs) represent synchronous neural activity in the brain in response to a sound changing—for example, in frequency or level—and that can be recorded from electrodes attached to the scalp. AEPs can be used to detect hearing loss in newborns and infants; they are exquisitely sensitive at the millisecond (ms) level to changes in conduction time in axons and temporal processing in neurons. This high time resolution allows the tracking of maturational changes in the brain, the documentation of short-term auditory learning, and the diagnosis of disorders related to temporal processing in general.

AEPs comprise activity from neural generators in the auditory nerve, the fiber tracts in the brain stem, and the pyramidal cells in the auditory cortex. Table 1 provides an overview of type, origin, and use of the response components. This entry discusses compound action potentials and compound synaptic potentials, the auditory brain stem response, obligatory cortical evoked potentials, and auditory memory.

Compound Action Potentials and Compound Synaptic Potentials

The neural activity underlying AEPs, typically evoked by clicks or short tone pips, consists either of compound action potentials, that is, composed of firings occurring at the same time, in nerve tracts that make up the auditory brain stem response (ABR), or of simultaneously occurring postsynaptic potentials in cortical cell dendrites that make up the cortically generated evoked potentials. Action potentials are of much shorter duration (about 1 ms) than synaptic potentials (about 15 ms) and because the extracellularly recorded activity is biphasic, action potentials can cancel each other for small time differences whereas postsynaptic potentials typically are much less sensitive to this. In both cases, the amplitude of the AEP components is proportional to the number of synchronously activated nerve fibers (in case of the ABR) or number of synchronously activated synapses on cortical pyramidal cell dendrites. AEPs can only be detected if the generating elements (nerve fibers, dendrites) are spatially aligned and currents therein flow in the same direction.

The Auditory Brain Stem Response

The ABR is a short latency subset of the AEPs. It is a multi-peaked response that alternates between vertex positive and negative voltages starting with a positive peak termed *wave I,* followed with 1-ms interval by further positive peaks II and III, and then by an often double-peaked wave IV/V. Waves I and II originate from the extracranial and intracranial part of the auditory nerve, respectively, wave III from the first auditory nucleus in the brain stem, and wave IV/V from the tract of the lateral lemniscus on its way to the auditory midbrain. The ABR threshold matches that of behavioral measures. The amplitude at the scalp is small (about 0.1 mV). The latency difference between waves I and V represents the brain stem conduction time, including synaptic delays and nerve conduction.

Table 1 Auditory Evoked Potentials: Type, Origin, and Use

Name	*Response latency*	*Origin*	*Generator*	*Use*
Auditory Brainstem Response (ABR)	1–10 ms	Auditory nerve and nerve tracts in the brainstem	Synchronized action potentials	• Newborn hearing screening • Disorders affecting nerve conduction
Middle Latency Response (MLR)	18–50 ms	Primary auditory cortex on Heschl's Gyrus	Synchronized post-synaptic potentials in pyramidal cell dendrites	• Cortical maturation • Frequency-place map changes • Learning
Long Latency Obligatory AEPs	5250 ms	Association cortex on the Planum Temporale		
Mismatch Negativity (MMN)	150–300 ms	Superficial layers in primary auditory cortex		• Pre-attentional sound, melody and phoneme discrimination

This latency difference is a sensitive indicator of auditory brain stem maturation in the first year of life and of the presence of tumors pressing on the auditory nerve or brain stem, diseases such as multiple sclerosis that slow nerve conduction, and auditory neuropathy. Immaturity and the listed disorders all increase the brain stem conduction time or make waves beyond wave I undetectable or, as in auditory neuropathy, do not show any wave in the ABR. The ABR is unaffected by sleep and light sedation or anesthesia and is therefore of prime interest in newborn hearing screening.

Obligatory Cortical Evoked Potentials

An oscillatory complex with period of about 25 ms is found in the latency range of 15 to 50 ms and is called the middle latency response. When the stimulus is presented with intervals around 25 ms (about 40 hertz [Hz]), a steady-state response mimicking a 40-Hz sine wave results. The middle latency response is composed of activity entering and leaving the primary auditory cortical areas situated on Heschl's gyrus.

A slower oscillation with a period of about 100 ms reflects activity in secondary cortical areas situated on the planum temporale. This oscillation is characterized by a positive (P)–negative (N) P1–N1–P2–N2 sequence with approximate latencies of 50, 100, 150, and 220 ms. Although the amplitude of these components is affected by sleep, sedation, and attention, they are always present in normal hearing adults. The dependence on attention makes these responses not suited for threshold estimation. The P2 component is the first to mature (about 2 years of age) whereas the N1 component matures to well into the late teens. The N1–P2 complex increases in amplitude as a result of learning an auditory task on a time scale of a few hours.

Auditory Memory

When a sequence of tone pips with frequency of 1 kilohertz (kHz) and presented at a rate of about 1 per second is randomly interrupted by a tone pip with different frequency (say, 1,100 Hz, called the oddball), the obligatory response to the oddball is different from that to the frequent stimulus just preceding the oddball. The difference between the response to the frequent and oddball stimuli represents a dominant negative wave peaking about 150 ms latency. This is called the mismatch negativity (MMN). It does not require attention and is used to objectivate the ability of the person to detect acoustical differences such as frequency, duration, and level, but also phonemic and melodic differences. When the interval between the tone pips becomes larger, the size of the MMN decreases and altogether disappears around a 10-second interval between the stimuli. This has been equated with the length of the auditory memory span.

The cortically generated AEPs are complementary to imaging methods such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) that reflect local energy requirements resulting from neural activity. The AEPs have an exquisite temporal resolution and reflect the degree of neural synchrony in the activated neural population. PET and fMRI only depend on the number of activated neurons in the population not on the synchrony of their activity. In contrast, the spatial resolution of active neural populations is better for the imaging methods, especially fMRI.

EVOKED POTENTIAL: VISION

A *visual evoked potential* (VEP) refers to a systematic change in the electrical activity of someone's brain in response to a change in what the person is viewing. It is revealed by averaging over many trials the raw electrical activity, the electroencephalogram (EEG), recorded from 2 to 256 electrodes at standard positions on the person's head from each individual trial. For example, if a person is looking at a set of lines with one eye and at an oppositely oriented set of lines with the other eye, and then one set of lines changes to be identical to the other, the EEG from electrodes on the back of the head changes in a typical way over about 400 milliseconds (ms): a VEP (color insert, Figure 23a). The VEP is an event-related potential (ERP), because it is linked to a specific stimulus event—in this case, a visual stimulus. VEPs are used for clinical purposes, such as for locating problems to particular parts of the visual system, and for research. This entry describes VEPs, their advantages and disadvantages, and their clinical and research uses.

From the EEG to the VEP

In 1929, the German psychiatrist and neurologist Hans Berger placed an electrode on a person's scalp, recording the first EEG. He discovered that when the person closed his or her eyes, the EEG altered reliably even on a single trial, anticipating the VEP. In 1939, Pauline Davis reported that a unique, reproducible deflection of EEG activity could be evoked by an auditory stimulus. This was the first evoked potential, visible on a single trial. In 1960, Bill Cobb and George Dawson recorded the first, unambiguous VEP, averaged over many trials.

The fluctuations in electrical activity of a VEP depend on the location of the electrodes and on the sort of visual change. The VEP in the color insert, Figure 32(a), shows its first major component as a positive wave around 100 ms after the change, the P100 or P1. After that is a negative wave around 175 ms (N175, N2).

The amplitude of any VEP, peak-to-trough, is around 10 microvolts (μV), much below the spontaneous brain electrical activity of about 100 μV, so to see a VEP one needs to repeat the visual change about 100 times and average the EEG. This reveals the VEP, time-locked to the change, whereas the other activity, not time-locked, is averaged out (color insert, Figure 23a).

No one is sure what generates VEPs, but for many researchers, the most convincing theory is that VEPs arise from postsynaptic potentials (PSPs) over the dendritic trees and cell bodies of neurons. What is certain is that VEPs are not from action potentials, which are too brief. In any individual neuron, PSPs create a *dipole,* a gradient of electrical activity from positive (e.g., cell body for excitatory PSPs) to negative (dendrites). When a huge number of neighboring neurons are parallel to each other and have the same dipole for more than a few milliseconds, this can be recorded from an electrode on the scalp. The P100, therefore, represents simultaneous dipoles from one set of neurons; the N175 represents simultaneous dipoles either from a different set of neurons at a different angle or direction to the electrode or from inhibitory PSPs in the same neurons.

A crude measure of where in the brain a VEP's dipoles (its sources) are located is which electrodes show it most clearly (see color insert, Figure 23b). More precise measures try to reconstruct the dipoles that gave rise to the voltages in electrodes scattered over the scalp. In theory, any distribution of electrode voltages can be produced by an infinite number of one or more dipoles. In practice, constraints on the number of dipoles (e.g., fewer rather than more) and on their location (e.g., in grey matter rather than in white), yield solutions having a spatial resolution below 10 cubic millimeters (mm^3). One such approach is illustrated in Figure 23(c) in the color insert.

Advantages and Disadvantages

VEPs have at least three advantages over other methods of measuring electrical activity in the brain. First, VEPs are inexpensive to obtain, much cheaper than functional magnetic resonance imaging (fMRI) or magnetoencephalography (MEG). Second, VEPs are noninvasive. This differs from techniques such as positron emission tomography (PET) (requiring observers to ingest radioactive material) and local field potentials (requiring observers to have electrodes inserted into their brains). Third, VEPs have temporal resolution in the millisecond range. This is about 1,000 times better than PET and fMRI. VEPs' only disadvantage is their poorer spatial resolution (about three times coarser than PET and fMRI).

Clinical Uses

A corneal electrode and brief (< 1 ms) flashes of a homogeneous field, *flash stimulation,* yields the electroretinogram (ERG). This indicates rod or cone function in the *a*-wave at about 20 ms and bipolar function in the *b*-wave at about 50 ms. A pattern such as a checkerboard, with the black squares turning white and the white squares turning black at 2 Hz, gives *pattern (reversal) stimulation.* This evokes the pattern electroretinogram (PERG), from the retinal ganglion cells.

Scalp electrodes over the occipital lobe with flash and pattern stimulation yield the *flash VEP* and the *pattern (reversal) VEP* respectively. These assess the entire visual pathway up to V1, with pattern VEPs being more sensitive. The finest pattern VEP is correlated with visual acuity. Characteristics of pattern VEPs are well established in ophthalmology and neurology where diagnostic uses include finding lesions that block transmission along the visual pathway, revealing pathway misrouting (e.g., in albinism), and identifying malingering (people falsely claiming to be blind).

A typical VEP to pattern reversal has a N75, a P100, and a more variable N135 (N2). To pattern onset stimulation, many display a P90 (C1), an N120 (C2), and a P200 (C3). Amplitude of components varies by more than a factor of two among people.

Research Uses

Just about every aspect of visual perception has been researched using VEPs. All that is required is some visual event that can be specified with millisecond accuracy. Manfred Fahle and Michael Bach recently reviewed the wide range of research topics, which include the effects of visual attention, visual memory, and type of visual stimulus. With its high temporal resolution and its reasonable spatial resolution, VEPs offer an invaluable perspective on brain activity associated with visual perception.

EVOLUTIONARY APPROACH

Perception is a universal phenomenon. It functions primarily as a means of allowing an organism to process changes in its external environment. Thus, perception has substantial survival value and can be observed in all living species. Its prevalence leads to questions about its origins and about how perceptual mechanisms have evolved. These questions require a firm understanding of evolution, particularly the main processes of innovation and constraint, and their interrelationship.

Evolution is considered as change in the inherited traits (particular characteristics) of a population of organisms from one generation to the next. These changes are caused by a combination of three main processes: variation (differences between genotypes underlying the traits, caused by, for example, mutation), reproduction (heritable traits are propagated between generations), and selection (individuals with advantageous traits are more likely to reproduce). In the 150 years since Charles Darwin published *The Origin of the Species,* scientists have gained an understanding of a great number of biological phenomena that could not have been achieved without a firm knowledge of the mechanisms of evolution. Perception is one of these.

Perception using an evolutionary approach allows us to search for the causal explanations of the adaptations that are seen in modern-day organisms. All traits have both mechanical and evolutionary causes, and a complete explanation of perception requires an understanding of both of these, as described in this entry.

Questions About Evolution

A complete understanding of an organismic trait such as perception requires answers to four main questions. For example, the question "Why does a pigeon see five colors?" can mean four different things, some times referred to as *Tinbergen's four whys* after the pioneering ethologist Niko Tinbergen. The different meanings of "Why?" originate from different levels of explanation. The first "why" examines the function of a trait, asking, for example "How does the eye work?" This is a question of (proximate) causation, studied mainly by (neuro-) physiologists. The second question is about the survival value of a trait; for instance, why is visual perception useful? The third question asks how an ability arises during an individual's development (ontogeny) given some early experiences and the genetic makeup. And finally, it is important to know how a particular behavior evolved, how it came into existence. This requires inference about the behavior of ancestral species, examining how and why this behavior changed over generations.

In the animal kingdom, there is not one brain, one sense, one problem, and one solution. At every level of organization, variation prevails. Of great value to understanding how novel features emerge is the study of the relationships between individual development and phenotypic change during evolution (the new science of Evo-Devo). The inescapable difficulty is tracking the process of innovation and variation (resulting in the evolution of new traits) on the one hand, and stabilization and conservatism (resulting in traits remaining stable across time) on the other. Why have many solutions to the same problem evolved in some cases, but in other cases only one? Why did some structures not disappear despite their obvious malfunction (e.g., the appendix)? Why are the receptor cells in the retina facing backward in vertebrates but not in invertebrates?

Answers to these questions demand a rigorous evolutionary and comparative approach. In a nutshell, the evolutionary paradigm holds that the result of natural selection is the generation of adaptive organic structures that are sustained as the result of two factors: correspondence to external circumstances and coherence between the components of the system. The latter follows the principle of organization and is particularly important for such complex organs as the eye, in which many elements must work together. Therefore, explaining how animals solve the sorts of problems they face in their natural habitats cannot be achieved by applying a purely functional (and sometimes anthropomorphic) approach.

Some people think that perceptual faculties (e.g., perceiving color) are the result of selective forces exerted by specific environmental circumstances (e.g., discriminating between flowers, or between ripe and immature fruits). However, evolution is seldom as straightforward as this. The adequate metaphor is to view evolution as a "tinkerer," building innovations by modifying existing structures, rather than by designing them from scratch. A famous example is the transformation of jaws into the three ear bones (the hammer, anvil, and stirrup). Understanding the main classes of evolutionary processes—innovation and constraint—and their interrelationship, requires a firm understanding of evolution and the adoption of a systemic viewpoint.

An important question asks how major changes evolve and how new features originate. First, we can ask what the genetic and developmental bases of such changes are. Second, we can ask what role natural selection plays in their evolution. For instance, we may ask whether each step, from the slightest initial alteration of a feature to the full complexity of form displayed by later descendants, could have been guided by selection. A major problem here is to understand what functional advantage there can be in an organ that is not completely developed. The evolution of the eye is a good example of this. Darwin himself was skeptical about whether natural selection could explain a stepwise progression to a fully functional vertebrate eye. In particular, one must question how such a complex organ could have evolved if its proper function depends on the mutually adjusted forms of each of its components (e.g., lens, cornea, retina, blood vessels).

The Evolution of the Eye

Organisms have exploited light for perceptual information through the evolution of photoreceptors and, ultimately, eyes. However, only a handful of eye types exist. One reason for this is that the physics of light constrains photodetection; the other is the result of the constraints of evolution.

Visual perception was well established by the time there is any fossil record of life on Earth. Most basic eye types arose in a brief time during the Cambrian period, around 530 million years ago. As soon as organisms became more mobile and predation became a common way of life, more efficient eyes developed, and they developed rapidly. Computer simulations have revealed that the evolution from a patch of shadowed photosensitive tissue to an eye resembling that of a fish could take as little as half a million years.

Only about a third of the animal phyla have no specialized organ for detecting light, a third have light-sensitive organs, and the rest possess eyes. Image-forming eyes appeared in 6 of the 33 extant metazoan phyla (Cnidaria, Mollusca, Annelida, Onychophora, Arthropoda, and Chordata); these six contribute to about 96% of the known species alive today. This simple calculation shows that the evolution of eyes (and thus visual perception) contributes significantly to survival.

It is thought that the eye has evolved independently about 40 different times. However, there is much structural similarity between different eyes—for example, there are few types of photoreceptor. Photoreceptors might predate eyes and might have evolved from a single common root; however, it is also feasible that, because of structural constraints, they represent the only possible solutions. Furthermore, the photopigment rhodopsin appears in all animals, and the master control gene (Pax6), which causes eye development in the embryo, is amazingly similar in all vertebrates and invertebrates (that have been investigated so far). This apparently suggests that all eyes have a common ancestry. However, we do not know if the master control gene originally evolved to control the development of an eye with spatial vision, or a directional photoreceptor, or perhaps just the simplest form of light sensitivity. Furthermore, despite the discovery of profound homologies (similarity by common descent) in the regulatory genomes of a diverse set of organisms, other levels of homology in the evolution of the eye must be considered. It is likely that the photopigment molecule originated a long time ago in a common ancestor to all animals. Photoreceptor cells then evolved independently a handful of times and spatial vision (real eyes), numerous times, all within the physical constraints of the preexisting structure.

Ecology and Evolution

We can see the impact of the environment on the evolution of the eye by looking at animal species that are alive today. Different visual abilities can be observed even within a species. New world primates exhibit an unusual variation in color vision, all the males have dichromatic vision, but the females can either be dichromats or trichromats. This difference is thought to be maintained by selective forces that act differently on the two morphs. Trichromats are better at finding ripe fruit, whereas dichromats are better at detecting objects with red-green camouflage (such as insects). Natural selection plays a key role in maintaining this polymorphism.

Eyes have also become redundant as a result of changes in selective forces. Cave animals are ideal subjects for the study of evolutionary change, and are particularly important for perception. Examining how an animal that lives in complete darkness has adapted from its surface living ancestor can reveal much about the key factors that play a role in the evolution of perception. Mexican cavefish (tetra) have evolved in multiple isolated populations. Interestingly, the impact of the change in environment has revealed similar traits in the different populations. The darkness of the caves leads to limitations in food, space, and reproduction; these have led to a specific suite of perceptual adaptations in the cavefish. They have evolved increased chemical senses and specialized sensory organs that respond to mechanical input such as tension, pressure, or displacement (mechanoreception). However, the cavefish still have small, nonfunctioning eyes. The eyes have not entirely disappeared, so it is likely that they no longer hinder the animal and thus there is no evolutionary pressure to reduce them further.

Interestingly, the auditory and olfactory systems have remained largely unchanged in the cave dwelling populations. The consequence of living in caves has had different effects on the perceptual abilities that can be seen in the surface dwelling populations. Those senses that still work in a cave environment (olfaction) remain the same; however, those that are no longer useful (eyes) regress, and novel perceptual mechanisms (mechanoreception) appear.

Origin of Perception

A major task for evolutionary biologists is to track the origins of traits. When one thinks of perception, it tends to be in terms of the visual; humans (and other primates) are highly visual animals. However, this level of sophistication is not available to single-cell organisms. For a population of organisms to survive, the individuals within that population must be able to recognize a suitable living environment (and avoid poor environments), recognize food items, and recognize mates. For an organism to fulfill these tasks, it must have the ability to survey the world outside its own body and respond to the information that it receives. That is, the organism must be able to perceive its surroundings (in some way) and act upon them.

If the evolutionary pressure to perceive is so great, then we would expect that even single-celled organisms should be able to perceive at a very basic level. One does not normally think of bacteria or protoctista as having sensory perception or even possessing behavior for that matter. However, they possess a rich repertoire of responses (changes in the metabolism of the cell, changes in movement direction, production of molecules that are perceived by neighboring organisms), which suggests that the basic mechanisms to perceive our environment evolved when most organisms were but single cells. By using surface receptor molecules, single-cell organisms are able to distinguish between a wide range of different molecules. Study of these very simple organisms and their perceptual mechanisms can provide essential evidence for uncovering how perception evolved in its earliest forms. Further, it elucidates the basic "systemic" principle of closing the loop from perception to action and again to (new) perception.

Processing

There are two possible ways of processing sensory information. Senses can be processed in parallel, with information from different senses being transmitted along separate lines. They can also be processed centrally, in which case a neuron's receptive field (the area on the receptor surface that influences firing of the neuron) is modified by synapses in the central nervous system (CNS) and processed together in the sensory cortex, resulting in interaction across senses. The parallel organization is quite different and would result in a representative system for each sense organ (eyes, ears, nose, etc.), which allows the possibility that an animal would live in several different sense worlds simultaneously. Reptiles possess this processing system. For example, snakes use different senses separately when hunting. The snake uses visual perception to track and intercept the prey, once struck, it uses only its sense of smell to locate the prey (it is particularly interesting that boas and pythons do this even when the prey is held in their coils). Then the snake searches for the prey's head (they swallow food head first), and for this, only the sense of touch is used.

This example reveals how an organism can successfully use a number of separate systems to hunt and feed. However, an entirely centralized system (as can be seen in mammals) is able to combine the information received from the sense organs and their associated brain areas. It thus generates a multimodal representation of the world; this evolutionary breakthrough allows much greater possibilities for cognitive representation and behavioral flexibility

From Perception to Cognition

The primary function of the brain is to compute dynamic, predictive models of the environment. Across the animal kingdom, organisms are able to rapidly evaluate their current situation and respond appropriately to it. This suggests that the perceptual constructions of the external world provide meaning or functional significance to objects and situations. As humans, we perceive an object as having a particular shape or color, and we perceive it as a dog, or a tree (or whatever it is). Being able to identify objects as members of known categories allows the organism to respond to them in appropriate ways. Categorization can thus be seen as the end point of perception and the groundwork of cognition. Without the ability to perceptually classify items into known categories, it would be difficult to behave appropriately toward the enormous variety of new objects that are encountered daily. Classification allows a reduction of the vast amount of information that is perceived and takes advantage of the fact that objects within the same category share many properties and behaviors.

The evolutionary pressures to minimize processing requirements have led to several different solutions, ranging from selective attention to feature learning and abstraction. These abilities have been studied in a wide range of organisms, with such success that leading researchers in the field have suggested that evidence of categorization has been observed in every level of the animal kingdom in which it has been adequately sought. Pigeons, for example, are able to categorize pictures of both complex natural scenes and human-made stimuli. The underlying cognitive mechanisms include memorization of pictures, feature learning and prototype formation. All of these are based on the animal detecting the presence or absence of physical features. However, evidence indicates that animals are able to do more than this; they can classify stimuli based on abstract relational information.

"Sameness" is a good example of a relational concept. A very basic test of this would present an animal with a red circle, and then subsequently with a green circle and a blue square. If animals are able to categorize based on choice of the same shape, they should select the green circle because it is the same shape as the sample stimulus. However, it appears that access to knowledge about the relations between stimuli is easier for some species than for others. For example, primates, corvids, and dolphins can extract abstract rules more readily than the pigeon can; however, in many cases, pigeons are able to do this, but they have difficulty and are only successful if the experimenter makes it impossible for them to use any consistent visual cues or rote learning of specific stimulus arrays. This difference does not necessarily reflect a vast gap in cognitive and perceptual abilities, but suggests that the abstract rules are less salient to the pigeon than to (say) corvids. This is likely to be related to complexity of social structure. Further evidence that supports this idea can be seen in lemurs. Different species have different levels of ability to infer relations between objects; this appears to be related to differences in their social structure, with the social species being more readily able to perform at high levels on these tasks than are their solitary counterparts. To be able to judge complex relations between stimuli is the end point of perception and the start of cognition.

Cognition, which includes learning and memory, has evolved as a means of guiding behavior. However, the path from perception to action isn't necessarily long and indirect. We now know that the perceptual and the motor system are strongly interlinked from very early stages of processing. The mirror neurons in the premotor cortex F5 and the anterior intraparietal (AIP) area, which respond both when an organism carries out an action and when it observes another organism carrying out the same action, have both sensory and motor properties. They contribute to the sensory-motor transformations that are necessary to select and locate objects and implement the movements required to act on these objects. The AIP-F5 circuits categorize objects by possible actions that can be made upon them; for example, a cup can be picked up by the handle or by the main body. Upon perceiving an object (such as the cup), these neurons immediately code a given set of possible actions. Thus, they respond selectively to the objects by their affordances (action possibilities) and the potential motor acts that can be conducted on them. Most evidence for the presence of these neurons has been found in primates (macaque monkeys and humans). However, neurons with this mirror function have recently been discovered in songbirds. What is currently unclear is whether they are a very old and widespread phenomenon or the result of convergent evolution of perception-action processes.

EVOLUTIONARY APPROACH: PERCEPTUAL ADAPTATIONS

Anyone with the slightest knowledge of cameras who considers the anatomy of the eye can understand that its purpose is to gather light and focus it on the retina. The eye is the "poster child" for evolution of the human body by natural selection. Yet the implications of evolution for perception are often overlooked. The various senses evolved to serve the survival and reproduction of organisms. This entry discusses how attention to these functions helps us understand perception.

What Is Perception For?

Because philosophy was such an important part of the history of perception, it is often said that the purpose of perception is to gain knowledge. But long before there were philosophers, people had to move about in space without bumping into things, decide what is edible, swallow food without choking, and find their way home. Thus, perception is first of all for action. For example, we are much better at moving about in space and avoiding objects than we are at estimating our distance from those objects.

We could avoid collision with objects by estimating our distance from them and our speed of approach. Instead, we do something much simpler: Because the image on the retina grows at a rapidly increasing rate as we approach an object at a constant speed, we are able to avoid collision by stopping when the rate of expansion reaches a threshold. This simple method is used by pilots landing a helicopter, pelicans diving for fish, and babies blinking at looming objects.

Perception and Fitness

An evolutionary approach leads us to consider the energy requirements of perception. We note that more than half of the human brain is devoted to perception, and the brain consumes about 25% of our metabolic resources. Thus, perception must make a great contribution to our fitness; otherwise, we would spend that energy on some other resource, such as muscles. Humans are properly considered perceptual generalists, in that our senses respond to many kinds of information. Nevertheless, we devote metabolic resources to those sources of information that are most useful to us, and ignore others. Thus, we do not respond to ultraviolet light and are relatively poor at echolocation, which is judging objects and their distances by sounds reflected from those objects. Similarly, sessile animals (those that don't move), such as sponges, lack eyes altogether. A remarkable example of this principle involves sexual dimorphism, where with at least one animal, the insect stylops, the winged male has eyes, but the parasitic female is sightless.

Sensory Ecology

Consideration of the sources of energy available in the world enables us to understand what the senses were designed to do. Vision, for example, responds to electromagnetic energy, which is abundant in the daytime, travels extremely fast in a straight line, and is little affected by air. Still, we use only a small part of the electromagnetic spectrum. Wavelengths longer or shorter than the visible range travel through objects, and so would be less useful. In addition, shorter wavelengths tend to be filtered out by the atmosphere, so there is not much available to be used. Further, shorter wavelengths, such as ultraviolet, X-rays, and gamma rays, tend to be damaging to tissue. So it is not surprising that the eye contains pigments that filter out near-visible ultraviolet rays, which we could otherwise see.

Sound waves travel through air, water, and solids. Because sound travels in the dark, and goes around corners, it is useful at night when there is little light. Further, the relatively slow speed of sound waves makes it possible for us to locate sounds by their time of arrival at the two ears.

Perhaps more than any other sense, audition demonstrates the physical principles that shape the senses. Larger animals such as elephants are capable of producing low frequencies (infrasound), which travel over long distances. By contrast, small insects can only produce high frequencies, which do not travel as far. Whereas the production of sound is limited by physical principles and may be incidental to size of the organism, the reception of sound is necessarily an adaptation; that is, it is the product of selection. The elephant's ability to hear extremely low frequencies (infrasound) permits it to communicate over long distances. By contrast, tiny insects respond to high frequencies that only travel the short distances of significance to them.

The Case of Pain

Pain provides a particularly good example of how evolution selects mechanisms that serve our survival and reproduction, regardless of other consequences. Although we might think life would be better without pain, those rare cases of individuals lacking pain show otherwise. F. C. was a young woman who was born without any pain sensitivity. As a child, she received third-degree burns from kneeling on a hot radiator while looking out the window. She bit her tongue so often that it became deformed, and she eventually bit the end off. But these were not the most serious problem. Her joints deteriorated because she failed to make normal postural adjustments, and this eventually led to a massive infection that took her life at age 29. Fortunately for us, natural selection has given us many sensations that are pleasurable, so that we seek them out. But pleasure and pain both serve our fitness.

Sensory Adaptation Is an Evolutionary Adaptation

The term *adaptation* has two separate meanings that are both highly significant in the present context. An evolutionary adaptation is a mechanism crafted by natural selection to solve problems posed by the environment encountered by ancestral populations during their evolution. So far, this entry has considered the senses as adaptations. One of those mechanisms is sensory adaptation. Sensory adaptation allows us to tune out stimuli that do not provide us with new information needed to cope with the environment. This is the property of adaptation that is generally used to define adaptation in textbooks. But this overlooks that adaptation makes us more sensitive to the changes that do occur.

One of the ways that adaptation makes us more sensitive to changes is by range shifting. You have no doubt had occasion to go into a darkened building such as a movie theatre from bright daylight, and noticed that you had trouble seeing in the reduced light. Then you adapted to the darkness and could see clearly about you. Later when you left the theater, you were temporarily blinded by the light outside. At any one time, our eye responds to only about a two log unit (100 to 1) range of light. By contrast, the range of intensities that our eye is capable of responding to is about 15 log units, or a thousand trillion to 1. Because we are most sensitive to changes in intensity near the level to which we are adapted, range shifting permits us to place our greatest sensitivity to changes where it is most needed. Similar shifts, albeit less dramatic, occur in the other senses. For example, our range of thermal adaptation is only a few degrees because temperatures outside of that narrow range are life threatening.

Other consequences of adaptation include an increase in response to certain other stimuli after adaptation. In the example of thermal adaptation just given, after adaptation to warmth, a previously neutral stimulus will seem cool (as well as pleasant), aiding us in maintaining optimal body temperature. Sensory adaptation should be seen as one of a number of mechanisms that serve the fitness of organisms to the environment.

Modularity of Perception

The senses evolved to deal with specific problems, such as identifying predators and judging where they are looking and where they are going. These particular questions would be expected to lead to the development of a number of specific mechanisms, rather than to a single general-purpose mechanism. Thus, the brain should consist of a number of specialized “organs” corresponding to these tasks, just as we have lungs for breathing and a stomach for digestion. Modularity of perception, then, is to be expected from an evolutionary perspective. Many examples of modularity are seen in perception. The distinction between rod and cone vision is familiar, as are their specializations for different light conditions. Rods are more widely distributed in the retina, thus permitting peripheral vision. They respond more to movement than the cone system, and function in lower light conditions. Cones serve color vision and are more densely arrayed in the center of the retina, permitting better acuity. In addition, two separate processing streams in the cortex serve different sets of functions that have been summarized as “what” (for identifying objects) versus “where” (for locating objects or carrying out actions involving objects). Further, the visual areas of the brain also tend to be segregated into regions that serve special purposes such as perceiving motion, faces, and the like. The auditory structures of the brain are also organized into two separate “what” and “where” systems. Injury or stroke can leave a person with the ability to localize sounds but unable to recognize them, or vice versa.

The many examples of perceptual adaptations indicate that an evolutionary approach to perception leads us to appreciate the organism in its environment and its need to use the available sources of information toward its survival and reproduction.

EXPERIENCE-DEPENDENT PLASTICITY

Experience-dependent plasticity refers to changes in the anatomical or functional organization of the nervous system as a consequence of sensory input or motor output. This can be at the anatomical level of how different neurons project from one area to the next (e.g., how neurons from the eye send their axons to the brain). Alternatively, the gross anatomical projections themselves may not change; rather, the individual synapses are refined, or pruned, so that only restricted recipient neurons are contacted. Finally, there can be instances where functional changes occur in the absence of anatomical changes. In this case, certain synapses are strengthened, whereas other synapses are weakened, with the result that neurons that used to respond to a particular sensory input now respond to a different sensory input (e.g., from touching the index finger to touching the thumb).

Plasticity occurs under a number of different conditions, such as development, neuronal injury, or experience. For example, the amputation of a finger will result in a reorganization of the primary somatosensory cortex so that neurons that used to respond to the amputated finger come to represent the adjacent, intact finger. A second example is following massive injury to a particular sensory structure, such as the eyes leading to blindness or to the cochlea leading to deafness. In these cases, evidence indicates that the parts of the brain that usually represent the missing sensation come to respond to a different sensation, such as visual areas responding to auditory stimuli in blind individuals and auditory areas responding to visual input in deaf individuals.

Plasticity strongly depends on the stimulus history of the individual. This can be the result of experience during development or in adulthood well after all developmental processes have been completed. This entry provides a brief description of both developmental and adult plasticity, providing examples of these plastic changes in different sensory systems.

Normal Organization of Primary Cortical Areas

Experience-dependent plasticity has been described in both cortical and subcortical areas of the nervous system. Although subcortical plasticity is known to occur in many contexts, it remains unclear whether the reorganization of the cerebral cortex is a reflection of the reorganization of subcortical areas, the subcortical reorganization is directed by the cerebral cortex, or some combination of the two. This entry concentrates on the plastic changes in the cerebral cortex and will not address the topic of subcortical plasticity.

In all mammals, distinct cortical areas process the initial inputs to the cerebral cortex for a specific sensory modality. Thus, auditory, visual, and tactile stimuli are processed initially in the primary auditory, visual, and somatosensory cortex, respectively. The bulk of the early work was conducted in these primary areas because they have an orderly and predictable functional organization. For example, there is a "map" of the contralateral body surface in the primary somatosensory cortex, such that neurons that respond to touching the big toe are next to neurons that respond to touching the second toe and neurons that respond to the foot are next to those that response to the ankle. A similar organization is seen in the primary visual cortex, where neurons that respond to one region of space are adjacent to neurons that respond to adjacent regions of space, creating a map of visual space. The auditory cortex is organized somewhat differently, with neurons responding best to a particular tone frequency (pitch) forming a band across the cortex, and neurons that respond best to higher tone frequencies are organized as bands progressively farther from the lower frequency bands. Thus, in the auditory cortex, each frequency is represented by a strip of neurons.

Developmental Experience-Dependent Plasticity

Stimulus-driven activity critically influences the development of sensory systems. If the nervous system does not receive normal sensory input during a defined time in development, termed the critical period, then it will not develop normally. A wealth of knowledge has been gained by experiments exploring the basic principles of experience-dependent plasticity during development, prompted by the classical experiments of David Hubel and Torston Wiesel. The cerebral cortex shows much greater capacity for plasticity during development compared to adult plasticity, which is largely based on exuberance of axonal projections in young animals, which are normally pruned and eliminated in adults, but which allow for a greater range of inputs to the recipient neurons in young animals.

Visual Cortex

If stimulus-driven activity of one eye of a developing mammal is prevented, a condition known as monocular deprivation (MD), there is a dramatic change in the way that the visual cortex develops. Normally, the inputs to the visual cortex form ocular dominance (OD) columns, such that neurons are segregated into those that respond to one eye next to those that respond to the same region of space, but from the other eye. In MD animals, the axons that respond to stimulation of the patched eye are greatly retracted, allowing the axons from the open eye to make more synapses on the cortical neurons. When the patch is removed, the region of the cortex that responds to the eye that was patched is much smaller than is the region of the cortex that responds to the eye that was not patched (Figure 1). This organization persists through adulthood and cannot be reversed, and consequently, that eye is effectively blind, even though it is perfectly fine.

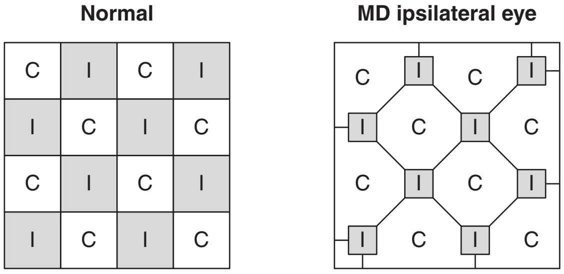

Figure 1 Change in Ocular Dominance Column Organization Following Monocular Deprivation

Note: The deprived eye (in this case, ipsilateral) has a much-reduced cortical territory compared with the intact eye.

Subsequent experiments in the past decades have further defined the critical period where this effect occurs. Similar types of experiments in older or younger cats or monkeys, or if the patching does not occur throughout the critical period, do not result in the same dramatic change. During normal development, experience-dependent activity shapes the anatomical structure of the inputs to the visual cortex as well as the functional connections.

Somatosensory Cortex

A second good example of developmental plasticity is in the representation of the whiskers in the rat somatosensory cortex. Rats are nocturnal animals that depend heavily on inputs from their whiskers to palpate their environment and use them to effectively "see" in the dark. Correspondingly, there is a large representation of the whiskers in the primary somatosensory cortex. Anatomically discrete structures in the cortex where neurons are closely packed are called barrels. A single barrel corresponds to each whisker on the snout on the opposite side, and the neurons in these barrels respond most strongly (although not exclusively) to the whisker corresponding to that barrel. This anatomical and functional structure can be modified during development by removing one or more whiskers. If this is done, the corresponding barrel does not form. If done after the critical period, which is a matter of days after birth, the barrel forms normally anatomically, but the neurons respond to the adjacent whiskers (the corresponding whisker is not there anymore). Thus, the experience of receiving inputs from one whisker establishes the anatomical structure of the barrel. There is plasticity in the responses of barrel neurons in adults, but the anatomical structure remains regardless of the stimulation history and experience.

Auditory Cortex

The auditory system also establishes critical periods during development, with the functional organization of the primary auditory cortex able to change as a function of passive exposure to different sounds during early development. For example, playing noise but not tones to rat pups results in neurons that respond to all frequencies instead of a select few. This must be done at a young age because the mother rat is exposed to the same sounds as the pups, yet the mother rat shows no change in the functional organization of the primary auditory cortex. Again, exposure of certain sounds during the early critical period can result in large-scale changes in the way that the auditory cortex responds.

These results have implications for individuals who are born deaf because there are critical periods of development for the ability to process and understand speech sounds. Speech is arguably the most important sensory stimulus that humans perceive, as without it, the ability to communicate with others is severely impaired. A device called the cochlear implant consists of a set of stimulating electrodes that can be inserted into the cochlea of a deaf individual to simulate some type of hearing. If the device is implanted within the first 4 to 5 years of life of someone born deaf, chances are good that near normal speech understanding will occur. However, if it is implanted later, the device is less effective. In contrast, if a person becomes deaf as an adult, there is no critical period in which the device will work better or worse depending on when it is implanted. In the case of speech perception, the developmental critical period almost certainly influences higher-order cortical areas, well beyond the primary auditory cortex and likely within language areas of the brain such as Wernicke's area.

Adult Experience-Dependent Plasticity

William James, one of the great early psychologists of the late 19th century, noted that adult animals and humans retained the ability to learn new behaviors and would improve on them with practice throughout life. Although this was well known by most people, he was the first to postulate that learning such new behaviors and skills was reflected in changes in the excitability of certain neural structures. This was ahead of his time because the neural structures underlying perception and skill acquisition were still decades away from being identified. The first measurements of such changes at the neuronal level were performed by Sir Charles Sherrington, who noted that electrically stimulating the motor areas of the brains of anesthetized monkeys changed the way that the motor cortex was functionally organized. For example, if he stimulated one location, the monkey's hand would twitch. If he stimulated a few millimeters away, the monkey's elbow would move. If he went back and stimulated the hand place again and again, he found that then stimulating the elbow place would make the monkey's hand move. Thus, by stimulating for several minutes, the elbow part of the motor cortex changed to be incorporated into the hand part. This was one of the first direct demonstrations that just stimulating, or changing the way that the neurons were activated, could cause the adult cerebral cortex to change.

Somatosensory Cortex

The initial modern experiments that investigated experience-dependent plasticity in the cerebral cortex were conducted in the primary somatosensory cortex in the 1980s and early 1990s. These experiments showed that the details of the topographic representation of the body surface, specifically the representation of the fingers in the primary somatosensory cortex of monkeys, could be altered in the adult by a number of different manipulations. For example, most neurons in these areas respond only to touching one finger, and only extremely rarely will they respond to touching the skin of two different (but always adjacent) fingers. However, surgically suturing the ring and middle fingers together for several weeks made neurons that normally responded to only one finger respond to both. This persisted even after the two fingers were again surgically separated, indicating that this was not caused by the sensory receptors growing across the suture line to the other finger. Similar results were shown for the "neurovascular island" transplant. This is a surgical technique to help people who have suffered severe nerve damage in the hand, usually the thumb. The skin, artery, vein, and nerve to a section of skin on the ring finger are transplanted to the damaged part of the thumb. This results in the patient being able to feel the thumb again and a corresponding reorganization of the hand representation in the cerebral cortex. The neurons that used to respond to the ring finger come to respond to stimulation of the thumb (the same skin); however, these neurons are adjacent to those that respond to the index finger, not the pinky as before.

Subsequent experiments verified that these experience-dependent forms of plasticity had functional consequences. These included a study where monkeys were trained to perform a frequency discrimination task to vibrations on a single finger. Over several weeks, the monkeys improved their performance, and the area in the cortex where neurons responded to touching the skin that was stimulated grew larger. In addition, how well the neurons responded to the particular frequencies was sharpened and was directly correlated with how well that particular monkey could perform the task. Thus, these experiments showed that repeating a tactile discrimination task (practice) resulted in both an improvement in performance over time and an expected change in the functional response properties of cortical neurons. These findings have since been extended over a large range of different preparations. For example, human imaging experiments have shown that people who play musical stringed instruments have a larger representation of the left hand in the primary somatosensory cortex compared with non-musicians.

Auditory Cortex

A similar result is seen in the auditory system. Monkeys that learn to discriminate between tones at particular frequencies have an expansion of neurons responding to those frequencies in their primary auditory cortex. In this case, the expansion of the trained frequencies was directly correlated with the ability of the individual monkey to perform the frequency discrimination. An important finding from these training experiments in the tactile and auditory cortex is that attention was required for the plastic changes to occur. The monkeys trained to perform the tactile discrimination task heard in the background the same tone frequencies as the other monkeys did, but had completely normal auditory cortical representations (but big changes in their somatosensory cortex). Similarly, the monkeys performing the auditory frequency discrimination task were also stimulated on their fingers exactly the same way as were the monkeys trained on the tactile discrimination task, but again it was irrelevant. These monkeys had completely normal representations of their hands in the somatosensory cortex (but big changes in their auditory cortex). Thus, passive stimulation in these contexts does not drive plastic changes in the cerebral cortex.

An experimental technique that results in cortical plasticity in the absence of overt attention is electrically stimulating a region in the brain that is known to release the neuromodulator acetylcholine throughout the cerebral cortex. Pairing stimulation of this structure with passive exposure to a single tone frequency results in an increase in the representation of that frequency, similar to that seen with behavioral training. Similarly, pairing stimulation with specific temporal sequences will result in an enhancement of the temporal processing ability of cortical neurons. These studies indicate that neuromodulators have a distinct role in the generation of cortical plasticity, with acetylcholine used in this example, but other neuromodulators such as norepinephrine and dopamine have also been implicated in other aspects of cortical plasticity.

Visual Cortex

Training-induced cortical plasticity is seen in the visual cortex as well and has the advantage that the parameters that are altered can give insights into the level that the plasticity is effective. For example, perceptual gains that are restricted to a single eye must be manifest in monocular regions of the nervous system, and not in binocular regions (areas beyond the primary visual cortex). Such training experiments have shown that plastic changes can occur as early as the primary visual cortex (V1), and these changes can be an expansion of the representation of the relevant stimulus features, as in the auditory cortex. Thus, across somatosensory, auditory, and visual cortical areas, the functional organization can be altered as a consequence of training at a particular sensory discrimination task. These changes are correlated with the ability to perform the particular task, and thus in the ability to perceive the stimuli, and it is likely that this experience-dependent plasticity is the underlying neuronal mechanism of skill acquisition with practice.

EXTRASENSORY PERCEPTION

Extrasensory perception (ESP) is the most common term for a number of related claims, such as clairvoyance (knowledge of events other than by the senses), telekinesis (affecting events other than by the body), and precognition (knowledge of events before they happen). Although such claims go back many centuries, the modern period began with the founding of the (British) Society for Psychical Research in 1882. The founders were prominent intellectuals who were motivated to find evidence for phenomena that materialism could not explain, including life after death. Thus, much of the work in this area has a quasi-religious motivation. This entry describes the phenomena attributed to extrasensory perception and the controversy surrounding these phenomena.

The history of this area is one of repeated claims based on some methodology, followed by failures to replicate. Among the prominent workers have been J. B. and Louisa Rhine, who conducted laboratory work with card guessing in the United States during the 1940s. In England, S. G. Soal performed similar studies about the same time. The methodological weaknesses in this research led to much controversy.

More recent research has included the Ganzfeld situation, in which an isolated individual attempts to send information about a target to the subject in a type of sensory isolation effected by putting half a Ping-Pong ball over each eye. Also, Robert Jahn conducted many studies in which subjects attempted to affect the output of random number generators. These two lines of work have produced large data sets that have been analyzed using meta-analysis, a method of considering many separate studies together. One problem with such research comes from what is called the law of truly large numbers. As Percy Diaconis and Fred Mosteller point out, when a sample becomes extremely large, extremely rare events tend to happen. In the present case, tiny effects caused by design flaws that would be inconsequential in ordinary research could be responsible for statistically significant results when the data set becomes extremely large. In the usual sorts of research, researchers study larger effects so that experimental design and methodology are not so critical.

These studies are only a small part of a large number that have been published over many years. The literature as a whole provides inconsistent evidence of paranormal effects, indicating the existence of a file-drawer problem: Investigators conduct a great many studies but publish mostly those that give positive results.

The judgment of the scientific community concerning the validity of the field of ESP may be seen in the 1988 report of the U.S. National Academy of Sciences that found no justification for the belief in parapsychological phenomena based on 130 years of research.

It is significant that the research in ESP has been conducted largely by people with no particular expertise in sensory processes and perception, the areas of research most closely related to the field. Thus, the typical studies have various flaws that would be avoided by those with relevant training. For example, researchers Russell Targ and Hal Puthoff employed a so-called soundproof room to isolate their subject, Uri Geller, who was famous for bending spoons and reproducing figures sketched by others. Targ and Puthoff were apparently unaware that the sound attenuating properties of such rooms are far from total and that it would be a simple matter to communicate by ordinary means through the walls. In fact, Geller's assistant was outside the room during the session, and evidently communicated to Geller what he should draw.

A particularly revealing example is given by the work on "digital color sensing" in the 1960s. It was claimed that people could detect the color of items in the dark using only their skin. Walter Makous, a visual scientist, recognized that the phenomenon, if true and if based on color, per se, would require unknown sensory capacities. Others had claimed that failures of the blindfold system must be responsible. But Makous was able to show that the temperature sensitivity of the skin was sufficient to detect differences in the heat that was reflected back to the skin by surfaces of different color. First, he showed that this was theoretically possible given the physics of the situation and the thermal sensitivity of the skin. Specifically, the longer wavelengths (the so-called warm colors, especially red) reflect more infrared energy, and thus feel warm. Shorter wavelengths (the so-called cool colors, especially blue) reflect less and thus feel cool. Then he did an experiment in which subjects discriminated between a front surface mirror and a black surface placed near the skin. These conditions maximize the differences possible when relying on the thermal sensitivity of the skin as the signal. The results were consistent with his calculations. His paper put a sudden and virtually complete end to this line of work. The paranormal community had little interest in understanding how the senses operate, only in the possibility of finding a phenomenon that could not be understood by ordinary science.

Researchers have questioned the findings of parapsychological research, both on the grounds of methodological problems and the failure to replicate, and philosopher C. D. Broad has noted that the proposed effects would violate the limiting principles of science. These principles are seldom discussed but nevertheless form the basis of all science: (a) that effects cannot precede causes, (b) the mind depends on the brain, (c) the world affects the mind only via the body, and (d) the mind affects the world only via the body. These are contradicted respectively by claims for (a) precognition, (b) seeing objects during out of body experiences that would be otherwise hidden from view, (c) extrasensory perception, and (d) telekinesis.

Although science is a highly interconnected enterprise in its institutional structure, methods, results, and theoretical considerations, the field of ESP stands apart. For example, ability to communicate by ESP has not been shown to be affected by distance, whereas ordinary physical signals decrease in intensity over distance, following the inverse square law. Nor is there any consistent relation between ESP and emotion. On the hypothesis that ESP would be more likely under great stress, some have looked for evidence of naturally occurring paranormal communication in wartime or natural disasters. Others have taken the opposite tack, supposing it would be better during relaxation, as in the Ganzfeld studies. Unlike normal science, the field of ESP shows a complete lack of progress. A discussion of the most recent studies reveals no newer principles or understanding than we had 50 or 100 years ago.

Given that positive results have been so hard to find, it may not be surprising that some of the apparently strongest evidence has been the result of fraud. George Price published two articles in which he proposed that many of the most famous results must be fraudulent and suggested how they may have been produced. Although the paper was assailed as speculation, and Price later even apologized for making unfounded accusations, further events showed his article to be remarkably prescient. For example, the work of Soal, in particular, was much later shown to have been the result of his altering the data. Walter J. Levy, Rhine's chosen successor in his lab, was caught altering data in a supposedly automated study of the ability of rats to predict pleasurable brain stimulation.

EYE: STRUCTURE AND OPTICS

The human eye is a simple, but extremely robust, optical instrument. It produces images of the visual world onto the retina with a quality that matches or exceeds the resolution of the neural circuitry. The eye is composed of only two positive lenses, the cornea and the crystalline lens, that produce real images of the world on the retina, initiating the visual process. Traditionally, the eye has been regarded as an equivalent of a camera, with the ocular optics acting as the lens and the retina as the film (or the sensor). Compared with artificial optical systems, often formed by many lenses to improve image quality, the eye is simple, but well adapted to the requirements of the visual system. Lenses form images of objects by bending the light. The refractive index is a measure of how much a lens material changes the direction of the light, from a value of 1 for air to a typical figure of 1.5 for glass. The eye has to form high-definition images of a large field of view for objects placed at different distances using transparent living tissue, instead of glass. Because of the nature of light and its own characteristics, the eye imposes the first physical limit to vision. Vision will be good if the images formed on the retina have sufficient quality. However, if the retinal images are blurred or fuzzy, the visual system will not function properly and vision will be poor. This entry describes the structure and optical properties of the eye.

Structure of the Eye

The eye in adult humans is approximately a sphere about 24 millimeters (mm) in diameter. Externally, it is covered by a resistant and flexible tissue called sclera, except in the anterior part where it turns to the transparent cornea that allows the light to pass into the eye. Within the sclera are two other layers: the choroid, which is a mesh of blood vessels to provide nutrients, and the retina, where the light is absorbed by the photoreceptors as the second step of the visual process. The eye can be moved by the action of six external muscles that permit fixation and the scanning of the visual environment.

The light reaching the eye is first transmitted and refracted by the cornea. This is a thin transparent layer free of blood vessels of about 12 mm in diameter with slightly more than 0.6 mm thickness in the central part. An aqueous tear film on the cornea ensures that the first optical surface is smooth to provide the best image quality. After the cornea, there is a small space, called the anterior chamber, that is filled with a water-like substance, the aqueous humor. In the posterior area of this space is the iris, a muscle with a central hole the size of which depends on the iris's contraction. The iris is a diaphragm with characteristic color, depending on the amount and distribution of pigments. The pupil is the variable opening in the center of the iris that limits the amount of light passing into the eye. The pupil size changes with the ambient light, from less than 2 mm in diameter in bright light to more than 8 mm in the dark. Other factors, such as emotions or certain drugs, also affect the size of the pupil. The pupil controls retinal illumination and limits the rays entering the eye to improve the images.

After the iris is the crystalline lens, which combines with the cornea to produce the images on the retina. To ensure transparency, similar to the cornea, the crystalline lens has no blood vessels, with the surrounding aqueous humor providing nutrients. With normal ageing, crystalline lenses tend to become less transparent, which diffuses light and degrades the retinal image. In advanced stages of this situation, a condition called cataracts, the lens is nearly opaque, leading to a low quality of vision. The standard, and successful, surgical procedure consists of replacing the cataractous lens with an artificial implant, called an intraocular lens, that restores the eye's ability to form clear images on the retina.

The cornea is a lens with fixed optical power, and the crystalline lens is an active optical element. It changes its shape, which modifies its optical power, and therefore the whole eye's power. This is the basis of the mechanism of accommodation that allows the eye to focus in the retina objects placed at different distances, from distant to near. The lens is suspended in a bag with a set of muscles attached, the ciliary muscles. The action of these muscles permits the lens to increase or decrease power. The ability to keep near objects in focus declines continuously with age. After 50 years old, the crystalline lens cannot change its shape anymore because of the modifications of its mechanical properties. This condition is called presbyopia and can be alleviated by using different optical tools, such as bifocal, progressive, or contact lenses.

After the light is finally refracted by the lens, it enters the area called the posterior chamber, which is filled with a transparent and viscous fluid, the vitreous humor. After passing through this area, the light reaches the retina, the thin layer of neural tissue covering the back of the eyeball that acts as a screen where images are formed and the light is converted in electrochemical signals. The human retina has a central area, the fovea, where photoreceptors are densely packed to provide the highest resolution. This area is used for demanding visual tasks, such as reading. The eyes continuously move to fixate the desired details into the fovea. The peripheral parts of the retina render lower resolution but are important for movement detection and to first locate objects in the visual field. The eye's optics produces retinal images that match the foveal requirements in spatial details but have better resolution than that required in the peripheral retina.

Optical Properties of the Eye

The eye as an optical instrument is composed of two lenses, the cornea and the crystalline lens, the pupil to limit the light entering the eye, and the retinal plane, which acts as a screen. The cornea is approximately a spherical section with a refractive index of 1.377. The largest difference in refractive index occurs from the air to the cornea (actually the tear film), so this accounts for most of the refractive power of the eye, over 70% on average. The rest of the optical power to bring the images into focus at the retina is provided by the lens. This is a biconvex lens with the anterior surface (the one closer to the cornea) and the posterior surface with radii of 10.2 mm and –6 mm respectively. The internal structure of the lens is layered (similar to an onion), which produces a nonhomogeneous refractive index, larger in the center than in the periphery, and with a mean value of 1.42.

An average eye with a distance from the cornea to the retina (called axial length) of 24.2 mm will image distant objects precisely in focus into the retina (see Figure 1). This ideal eye is called an emmetrope and has an optical power of about 60 diopters (a diopter is a unit of measurement of optical power given by the inverse of the focal length in meters). In a young emmetropic subject, near objects will be also in good focus because of accommodation. However, most eyes have neither the adequate optical properties nor the dimensions to achieve perfect focus; they are affected by optical refractive errors. In these cases, the images formed in the retina are blurred, typically imposing a lower limit to visual perception. Refractive errors are classified as myopia (or near-sightedness) when the images of distant objects are focused in front of the retina; hypermetropia (or far-sightedness) when the distant objects are focused behind the retina. Typically, myopic eyes are longer and hyperopic eyes are shorter than are those of an emmetropic eye. A visual deficit has an optical origin if vision is restored after adequate optical correction. Refractive errors are corrected by placing either negative or positive lenses in front of the eye, as eyeglasses or contact lenses. Another permanent alternative is re-shaping the cornea by laser refractive surgery. In every person, the eye is not rotationally symmetric as ideally described here. The optical surfaces are not exactly spherical in shape, and they are not perfectly aligned. A common manifestation of these facts is the presence of ocular astigmatism: the retinal images of a point source are two perpendicular lines. If astigmatism is severe, it can degrade image quality, compromising vision. The correction of astigmatism requires the use of cylindrical lenses or refractive surgery techniques.

Even eyes free of any refractive error, without defocus and astigmatism, do not produce perfect images. The retinal image of a point source is not another point, but an extended distribution of light (see Figure 1). This sets the minimum detail that can be imaged in the retina and then visual resolution. Details subtending less than 1 minute of visual angle (a letter detail of 0.1 mm for a reading distance 40 cm) are readily resolved by the eye and well discriminated in the fovea. This corresponds to the standard value of 20/20 (or 1 in decimal notation) visual acuity.

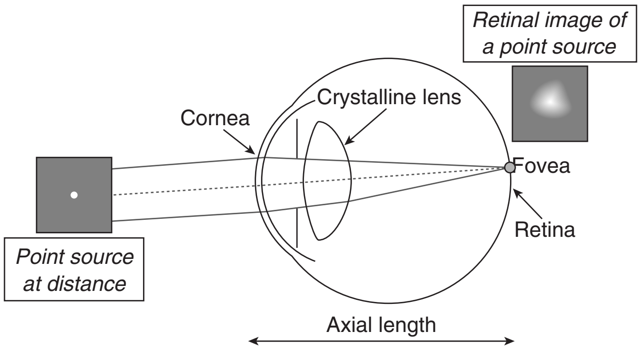

Figure 1 Diagram of the Optics of the Human Eye With Description of Main Components

Several factors are responsible for the degradation of the retinal images: diffraction of the light in the eye's pupil, optical aberration, and intraocular scattering. Diffraction blurs the images formed through instruments with limited apertures, such as the pupil, because of the wave nature of the light. The effect of diffraction in the eye is small and only noticeable with small pupils. It can be perceived as halos when seeing distant lights through a small pinhole aperture. Aberrations affect all optical instruments, particularly the eye. Light rays entering the eye at different parts of the pupil are not focused at the same retinal locations, causing an additional blur in the image. Two of the more important aberrations in the eye are spherical aberration and coma. An optical system is affected by the coma aberration when it forms images of a point source with a comet-like shape. The impact of ocular aberrations in image quality is more significant for larger pupil diameters. The aperture of the eye ranges from f/8 to f/2, which can be compared with values in a camera. The amount of aberration for a normal eye with about an f/4 aperture is approximately equivalent to less than 0.25 diopters of defocus, a small error typically not corrected when dealing with refractive errors.

In the normal young eye, the optical properties of the two ocular components are somehow tuned to produce an improved overall image quality. In particular, coma and spherical aberration are partially corrected in the eye, similar to an aplanatic artificial optical system. It is rather extraordinary to realize how the optics of the eye is optimized with the crystalline lens correcting the corneal spherical aberration and with the proper choice of shapes to reduce coma. During normal aging, this balance is partially disrupted leading to an increase of the eye's aberrations and a degradation of the retinal image quality.

An additional source of degradation of the retinal image is caused by the spectral content of the white light and the dispersive nature of the eye media. The optical power of the eye depends on the wavelength (color) of the light, so an eye perfectly focusing green light in the retina will be myopic for blue and hyperopic for red light. This is known as chromatic aberration and causes a colored blur in the retinal images, although with a limited impact on vision.

Despite all those optical imperfections, the eye represents an optimized design solution rendering a stable retinal image quality for a variety of geometrical configurations and meets the exquisite demands of the visual system.

EYE AND LIMB TRACKING

Most daily activities—whether at work, play, or home—involve eye and limb movements. Sometimes the association between the two is direct—for example, when we look at the handle of a coffee cup to reach out to grasp it. Sometimes the association is indirect, as in driving, where one looks at objects on the road while using the hands and feet to control the car. Probably the most studied aspect of this association is eye-hand coordination. As with most such topics, outside of the laboratory we usually take eye-hand coordination for granted unless we remark on the "good eye-hand coordination" of an athlete, or notice a problem that arises in an individual with neurological disease or damage. But how does eye-hand coordination work? Eye-hand coordination has both temporal aspects and spatial aspects. The brain needs to properly control the order and timing of eye and hand movements, and it needs to account for changes in eye position to use spatial vision to guide the hand. This entry reviews the basic aspects of eye-hand coordination and some associated clinical problems.

Behavioral Aspects

When we fix our vision on some point in space, the direction of the line from our eyes to that fixation point is known as our *gaze direction.* Our sense of sight provides highly detailed information about objects along this gaze direction. Therefore, when exploring novel environments, quickly moving, unexpected, or otherwise salient objects that we might want to evaluate in greater detail will tend to attract our gaze. However, when vision is used to guide the limbs for planned action, the nature of eye movement tends to be more structured. In this latter case, eye movement appears to be optimized to obtain information that allows for the most efficient movement of our limbs. For example, if we are making a peanut butter sandwich, we might direct our eyes to a knife so we can determine its location precisely enough to pick it up. Once the location of a given target (e.g., the knife) has been gathered, the eyes initiate a saccadic movement to the next target (e.g., peanut butter jar) at about 100 to 200 milliseconds (ms) before the limb actually reaches the first target. This is likely because visual information from this time period cannot be processed quickly enough to be of use in guiding a limb to the first target, but planning for the next target *can* begin. In some situations, however, gaze direction remains locked to a target until the instant the limb reaches it. This is most easily seen in pointing, where the eyes fixate on the pointing target until the pointing motion is complete. In addition to target location acquisition, our eyes are used to monitor complicated motor tasks and search for errors of movement that can be corrected. Thus, we may watch what our hands are doing as we attempt to spread peanut butter on bread or cut the resulting sandwich into equal halves.

These qualitative observations have been measured and quantified experimentally. For example, when subjects are asked to perform simple tasks that involve grasping and moving of single objects, it is found that their eyes tend to fixate only on locations that will become the targets of limb motion, or on objects that could become obstacles to such motion. When such tasks involve direct reaching to a target, it is found that gaze usually begins shifting to the target at about 100 to 200 ms after the target becomes visible, and the hand begins movement about 100 ms later. Typically, a subject's gaze will reach a visual target at a few hundred milliseconds (usually less than 500 ms) before the hand arrives. This is thought to be enough time for visual feedback (discussed further later in this entry) to aid in accurate reaching.

Although people tend to direct their gaze to reaching targets well before the hand comes near the target, this pattern sometimes occurs in reverse. In 'naturalistic' experiments, subjects occasionally will begin reaching for a target up to a full second before gaze is directed to it. Detailed visual information about a target can only be obtained when it is near where the observer is looking, so this begs the question of how the brain knows where to direct the reaching movement. One possibility is that target location information has been remembered from previous visual fixations. Two ways in which such remembered information could be represented in the brain are discussed in the next section.

The eye is not always used to guide limb motion. Sometimes it works the other way around. For example, when we look for our keys in near darkness, we might find them first with our hands by groping around on a table. To be sure that we have found our car keys instead of our house keys, we might then bring the keys toward our eyes and direct our gaze at them. In this case, gaze is directed based on knowledge of where our limbs are in personal space. Empirical experiments have shown that in such cases gaze shifts are fairly accurate, except for certain errors that appear to arise from a lack of subconscious knowledge of the complexity of the limb system.

Visuomotor Transformation

Any visual information that reaches our brain must do so through our eyes. If such information is to be used to generate behavior, then it must also pass through a transformation process. For example, if someone sees a button in his or her field of view, then the light reflecting off that object will fall on a small region of the person's retina. Before the person can press the button, the retinal location of its image must be converted into a temporal sequence of muscular contraction intensities that will bring the fingertip to it. At this point, we are discussing a purely visual *feedforward* process in which knowledge of the initial conditions (the target location, eye position, etc.) is used to determine all subsequent movements that will be made to reach it. The advantage of this mechanism is that it can be fast, but it must be carefully calibrated and it might make mistakes if those initial conditions have changed. Alternatively, the distance and direction between the retinal image of the effector (fingertip) and the retinal image of the object of interest (button), known as the retinal error, could be sampled by the brain at various times throughout the movement sequence. By using this dynamic information, the brain could provide online corrections to the effector movement. Such a process is known as visual *feedback* because the effector output at one instant in time becomes part of the brain's input at the next instant. The advantage of this mechanism is that it can be accurate, but it is relatively slow because the delay of sensory feedback in the brain is significant.

Although the precise extent to which visual feedforward and feedback processes are used to guide movement to a visual target is not fully understood, both processes are involved. In the case of feedforward, people placed in complete darkness and unable to see any of their own limbs can still point to a small, illuminated target with reasonable accuracy. Because no visual feedback information is available in this case, only visual feedforward and *nonvisual* feedback mechanisms can be acting. However, these other feedback mechanisms are known to be relatively slow compared with how quickly people can point, indicating that purely visual feedforward mechanisms can produce accurate pointing. In the case of visual feedback, it is known that removing visual information about the position of the limbs during reaching movements does reduce the accuracy of those movements, thus demonstrating the existence of these feedback mechanisms.

That visual feedforward mechanisms can be used in isolation to produce rapid and accurate reaching movements tells us that the brain must have an accurate internal knowledge about how the signals it sends to the effector muscles will affect their subsequent position. Computer modeling work has shown that the brain seems to account for the body's detailed geometry, including how the eyes are oriented in the head and how the head is oriented with respect to the body when transforming visual position information from the retina into arm movements (see Figure 1a).

The transformation from retinal position to arm movement is only one type of visual transformation made by the brain. As mentioned in the previous section, people can reach accurately to targets that are not currently fixated, or that are not even currently visible! That they can do so implies that the brain must be relying on a memory of the target location from previous fixations. It has been argued that before the brain can maintain a memory of a target location after a subsequent gaze shift, the brain must transform this location information into a stable frame of reference. For example, a person might remember where an object from a previous fixation is relative to his or her head. This head-centered information will not change with eye movement, so accurate reaches can be made based on it. However, evidence suggests that the brain does something less intuitive in at least some circumstances. In this alternate framework, the target location is remembered relative to the eye. During a shift of gaze, this location information is updated as the eye moves so that the brain "knows" where the reach target is relative to the eye at all times. Only when a limb movement to the target is required does this eye-centered representation of location go through the feedforward transformation process required to generate limb movement. This gaze-centered updating scheme is probably not the only mechanism for spatial memory and action—for example, the brain also stores the relative locations of objects and makes use of body-centered coordinates for some tasks—but it likely reflects a default mechanism for simple visuomotor tasks that provides a framework for other mechanisms.

Cortical Mechanisms

The path followed by visual information through the brain is complex, and the information itself is broken down and distributed across numerous neural circuits. To begin, signals from the retina flow along the optic nerve and undergo preprocessing in various subcortical structures before reaching the

Notes: (a) Some of the variables required by the brain to transform target location into a reaching plan. (b) Simplified flow of information in the feedforward transformation process. Visual information from the retina flows to the primary visual cortex, then to the parietal cortex where it is combined with information about the body and its current configuration from the somatosensory cortex. This information can then be used by frontal motor areas to generate movement of the appropriate effectors.

primary visual cortex in the occipital lobe (see Figure 1b). Leaving the occipital lobe (visual cortex), visual signals that flow to the parietal lobe are associated with direct action relating to environmental entities. In this area of the cortex, visual information is further separated and transformed into representations of the locations of possible targets for eye and effector (e.g., hand) movements. This is discussed further later in this entry. Information from the parietal cortex is then used by structures in the frontal cortex to generate movement plans that are finally conveyed to the brain stem structures that control the appropriate muscles.

Focusing on the parietal cortex, an area known as the parietal reach region (PRR), which encodes the locations of future reaching targets relative to the eye, has been identified in the monkey. Neuroimaging studies have identified a possible PRR analogue in the human parietal cortex as well. These studies indicate that the putative human PRR also encodes reach target locations in an eye-centered frame and that such location representations are continuously updated as the eyes move. Thus, the PRR might serve as the neural substrate for the eye-centered updating. Another area of the parietal cortex, known as the lateral intraparietal (LIP) area in monkeys and the parietal eye fields (PEF) in humans, encodes the locations of targets for future eye movements. As with the PRR, the PEF seems to maintain an eye-relative representation of target location, even when the target is lost from view and eye movements are made. In addition to representing target locations, neurons in monkey PRR and LIP respond to planned movements when no target location information is yet available. In particular, greater numbers of PRR neurons tend to respond when reach movements are planned, and greater numbers of LIP neurons respond when eye movements are planned, but both areas do show responses to both types of planned movement.

The eye-relative representations of the PRR and LIP/PEF may seem counter-intuitive given that the brain needs to know how to drive the muscles for reaching targets, but it has been argued by some that information about locations of visual objects stays in eye-relative form until it is needed for action. At that point, it must be converted into a form that is more closely associated with the effector limb. Neurons in the parietal cortex of monkeys have been found to represent a mixture of where a target's image falls on the retina and how the eyes are oriented in the head. More specifically, a given neuron will exhibit an elevated firing rate only when the image of a target falls on a small, isolated region of the retina specific to that neuron, with the intensity of this firing response being modulated by the position of the eye in the head. Neurons with this latter property are said to exhibit eye-position-modulated gain fields. Neurons with other gain field properties have also been found in the parietal cortex. These findings are particularly important because computer models show that such gain field neural responses could form the basis of the feedforward transformation between eye-relative representations of location and the kinds of body-centered signals needed to control the limbs. Moreover, both single-unit recordings in animals and brain imaging studies in humans have demonstrated that activity in these parietal regions are remapped during eye movements as predicted by the gaze-centered updating model of spatial memory.

Clinical Aspects

Eye-hand coordination involves vision, eye movements, and arm movements—which in turn involves much of the brain—so it can be negatively affected, either directly or indirectly, by many types of disease process or injury. In the simplest case, the eyes, optic nerves, or primary visual cortex could become damaged, resulting in blindness in all or part of an individual's normal field of view. Similarly, damage to the limbs, spinal cord, brain stem, or motor cortex could result in an inability to use some or all of the limbs. However, deficits in eye-limb coordination are not always so extensive. For example, strabismus is one of the most common visual disorders that children are born with. In this usually congenital condition, the eyes do not align properly so that the affected individual can look directly at an object with one eye only, and the other eye is directed at a slightly different location in space. When a person with normal vision looks at an object, the image made on the retina of one eye is in a slightly different location than it is on the retina of the other eye because of the physical separation between the two eyes. This *binocular disparity* is an important source of information that the brain uses to determine how far away nearby objects are. Depending on the severity of misalignment, strabismus usually results in a lack of ability to use this depth cue and thus reduces the accuracy of reaching movements in depth.

Many other disorders of eye-limb coordination are the result of damage to visual and motor areas of the brain. Take, for example, damage to the parietal cortices, which gives rise to deficits in eye-hand coordination that we can now understand given the physiological knowledge described earlier. Such damage can arise from strokes, traumatic brain injury, tumors, multiple sclerosis, and so on, but the nature and severity of the resulting deficits generally depends on the sizes and locations of lesions rather than on their ultimate cause. An easily understood example of such a deficit is known as optic ataxia. In this condition, patients with damage to certain regions of the parietal cortex have difficulty in reaching directly to visible targets, even though they can visually identify such objects with ease. The degree of impairment varies with lesion size and location, and is generally higher when objects are in the patient's peripheral vision. Optic ataxia sometimes occurs as part of a trio of deficits, known as Bálint's syndrome, that also includes ocular apraxia and simultagnosia. Patients with ocular apraxia have difficulty directing their gaze to objects of interest, whereas those with simultagnosia are thought to be able to perceive only one visual object at a time. It has recently been shown that some of the errors related to optic ataxia can be explained in terms of the gaze-centered spatial updating signals that have been observed in the parietal cortex. Thus, after the patient views an object, an eye movement can either improve or degrade his or her reaching performance, depending whether it shifts the internal image of the object into the good or the damaged part of the parietal cortex.

Because motor output is a complex process that relies on widespread neural circuits, damage of widely varying etiology to any number of brain regions can interfere with this process. Furthermore, although various behavioral aspects of eye-limb coordination have been studied, and some progress has been made in understanding how the brain maintains and transforms visual information into appropriate movements, much remains to be learned. For example, the gaze-centered updating model has allowed us to understand several aspects of how stored information from the eyes and hand remains aligned, but we do not yet know how the brain integrates these simple visuomotor mechanisms with more complex perceptual and cognitive processes.

EYE MOVEMENTS: BEHAVIORAL

Movements of the eyes are crucial for being able to see a clear and sharp image of the world. Understanding why this is the case requires considering some facts about vision. An optical image of the visual environment is formed on the retina of each eye, much like the image in a digital photographic camera. Because of properties of both the retinal receptors and the brain, the quality of human vision is inhomogeneous across space. Visual resolution is best in a small, central portion of the retina (the *fovea*), and falls steeply toward the periphery. Movements of the eyes are used to bring images of interesting objects to the fovea, where they can be seen with optimal clarity. Movements of the eye are also responsible for ensuring that the selected images do not leave the fovea, or move across the retina too rapidly, each time the head moves.

These functions are carried out by three main types of eye movements:

1. *Compensatory eye movements.* Humans are always moving their heads. The head is never completely stationary and moves to some extent even when we try to hold as still as possible. Compensatory eye movements, approximately equal in size and opposite in direction to the head movements, are generated continuously to counteract these head movements and keep the image relatively stationary on the retina. Compensatory eye movements are largely automatic reflexes, controlled by evolutionary old systems. These movements are functionally comparable to the image stabilization systems, built into many modern cameras, that enable sharp snapshots despite unsteady hands.

2. *Saccadic eye movements.* Saccades are rapid, stepwise rotations of the eye that take the point of gaze from one region of interest to the next. Saccades are the principal way of bringing images of selected objects to the fovea, where visual acuity is best. In most everyday life tasks, people make saccades in sequence from one selected object to another, allowing gaze to pause briefly at different portions of a visual scene. These brief pauses between saccades are sometimes referred to as *fixations*. Figure 1 shows an example of a sequence of saccadic eye movements made while counting a set of dots. The upper portion of the figure shows the position of the line of sight superimposed on the display of dots. The lower portion shows the identical pattern of eye movements in a different format, namely, as horizontal and vertical eye positions as a function of time. The rapid shifts in eye position are the saccades. Notice that the pauses between the saccades last only about one half to one third of a second.

3. *Vergence eye movements.* The visual fields of the two eyes overlap, providing a basis for binocular and stereoscopic (three-dimensional [3-D]) vision. Vergence eye movements are movements of

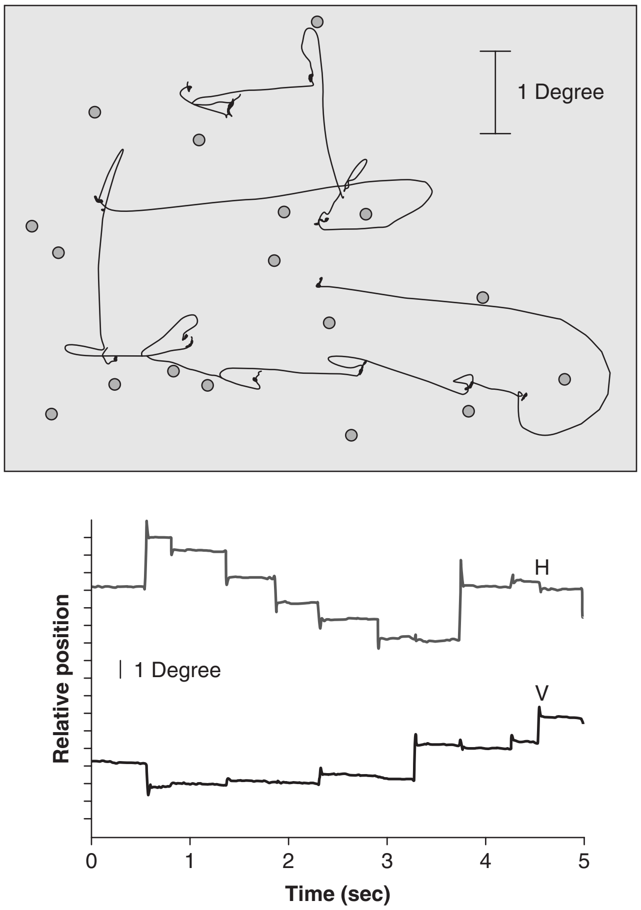

Figure 1 Sequence of Saccadic Eye Moments

Notes: (Top) Eye movements while counting dots. The line of sight began near the center of the display. The first saccade was made down and to the right. The next five saccades stepped across to the left, followed by four more saccades in the upper portion of the display. (Bottom) Horizontal and vertical eye positions over time. The rapid shifts in position are the saccades.

the eyes relative to each other that control the spatial registration (*correspondence)* of the two retinal images. Static vergence keeps the two eyes aligned, and dynamic vergence adjusts the angle between the lines of sight during binocular shifts of gaze between objects at different distances.

In addition to these three main types of eye movements, two other eye movement behaviors, maintained fixation and smooth pursuit, occur when we need to maintain a particular image on the fovea for extended periods. Both of these share characteristics with the types of eye movements listed, but each has special features that warrant a separate discussion. This entry discusses these three types of eye movements.

Compensatory Eye Movements

Rapid motion of the image on the retina produces blurring and smearing that will degrade vision. If the eyes were locked in their orbits, image motion on the retina would routinely reach unacceptably high levels with even the slightest movement of the head. The first line of defense against excessive retinal image motion is the vestibulo-ocular reflex (VOR). The vestibular organs (semicircular canals and otolith organs) sense motions of the head and relay this information to the oculomotor muscles. An approximately equal and opposite eye rotation is generated after a latency of only .008 seconds so that the direction of gaze is largely maintained. The VOR is supplemented by the slower optokinetic system (latency .08 seconds) that detects the global motion of the retinal image and elicits a smooth ocular following response. Compensatory eye movement systems, particularly the VOR, monitor their own effectiveness. They sense the amount of motion of the retinal image and alter the magnitude of the response by means of an adaptation process that maintains retinal image motion at a level optimal for seeing.

What is the optimal level of image motion for seeing? Excessive amounts of motion will degrade vision because of the image blur and smear. Conversely, a perfectly stationary retinal image is also undesirable: Experiments that have used optical methods to compensate for eye movements, so the image remains stationary on the retina, have shown that stabilized retinal images fade from view. Even slowly moving images are perceived poorly. To estimate the effectiveness of compensatory systems, and the resulting motion of the retinal image, Robert Steinman, Han Collewijn, and colleagues developed instrumentation to measure the movements of the eyes and head in three dimensions while people sit, stand, or engage in everyday life tasks, such as reaching or pointing. Their studies showed that the retinal image motions typically ranged from about 0.5 to 5 angular degrees/second. Interestingly, separate studies of effects of retinal image motion on vision showed that vision is usually best with image motions falling in this range.

Saccadic Eye Movements

Saccadic eye movements are rapid jumps of the eye used to bring the line of sight from one object of interest to the next. They can occur as often as three times per second and are found when we read, perform most any visuomotor activity, or casually inspect the environment.

Saccades can be made voluntarily, as can be demonstrated by deliberately looking from one side of a scene to another. Despite this voluntary character, most saccades occur without overt effort or awareness. For example, people are often surprised to discover that when reading the line of sight is continually jumping across the text, rather than moving smoothly. The lack of awareness of our own saccades is comparable with that of other motor activities. While walking, for example, a person can follow a specified manner of stepping or a marked trajectory, but such effortful performance is not natural. Normal walking is automatically guided by the layout of the surroundings and the level of urgency. Likewise, in natural situations, saccades are generated effortlessly, guided by the interest in exploring different portions of the environment.

Saccades are produced by brief, intense activity of the oculomotor muscles. Saccades typically last from .02 to .2 seconds, with saccade duration increasing with size. In natural activities, saccades are accompanied by rotations of the head. Early work on head-eye coordination led to the belief that during gaze shifts, the VOR automatically reduces the amount of eye rotation in the orbit by an amount equal to the head rotation, thus ensuring that gaze will land on the selected target regardless of how much the head moves. Recent work by Julie Epelboim and colleagues did not support this simple model and showed that the contribution of the VOR was constantly changing depending on whether the task required high levels of gaze accuracy or high gaze shift speeds.

Perceptual Consequences of Saccades

The frequent occurrence of saccadic eye movements is necessary for most visual tasks, but also presents formidable challenges to the visual system. As a result of saccades, the visual signal reaching the brain consists of a sequence of brief glimpses, lasting less than a half second, each centered on a different location (see Figure 1). Remarkably, subjective visual experience betrays none of this sequential quality. The world we perceive is stable and clear, with no perceptible jumps, interruptions, abrupt shifts of position, or awareness of the motion of retinal image during the saccades themselves. Three processes contribute to creating the impression of a clear and stable world.

1. *The suppression of vision during the saccade.* This phenomenon, termed *saccadic suppression,* refers to the inhibition of the visual signals generated during a saccade. Although many processes contribute to saccadic suppression, the major factor responsible is intra-saccadic visual masking. In intra-saccadic masking, the visual messages derived from the relatively stationary retinal images during the fixation pauses can suppress the messages generated from the rapidly moving image during the saccade.

2. *Nonvisual (extraretinal) signals representing saccadic commands.* Hermann von Helmholtz, working in the 19th century, proposed that during normal saccades a signal representing the saccadic command ("effort of the will," later termed *efference copy* or *corollary discharge*) is sent to the visual system to allow it to distinguish motion on the retina produced by saccades from genuine motion of the visual scene. Modern researchers have supported and developed Helmholtz's idea. Helmholtz's theory explains why illusory motion is perceived when attempting to move an eye that is paralyzed as a result of neurological disorders. An accurate and timely signal that represents the position of the eye can account for the ability to determine the true location of objects as we look around—an ability that is crucial for controlling reaching and locomotion in natural tasks.

3. *Selective attention.* If it were possible to construct a detailed representation of the world during each brief pause between saccades, the visual system would be confronted with a daunting task every time gaze shifts from one location to another. Every detail recorded before each saccade would need to be spatially aligned with the corresponding detail after each saccade to build a representation of a single and stable visual environment. Fortunately,

such painstaking construction is not needed because we perceive only a small portion of the visual environment during any fixation pause. Powerful, ever-present attentional filters limit immediate visual experience to what is most critical for the task at hand. Only attended information is preserved across saccades, and often in an abstracted (rather than point-by-point) representation. The same attentional filters that control access to perception also are involved in choosing the goal location of each saccade, a highly efficient way to share limited processing resources between perceptual and motor operations.

Vergence Eye Movements

Vergence eye movements align the lines of sight of the two eyes. Vergence is particularly important when we look at an approaching object, or when we look between two objects at different distances. Vergence facilitates the fusion of the views seen by left and right eyes into a single coherent percept, as well as the use of binocular vision to perceive a 3-D world (*stereopsis*). When you look from a distant to a near object (say, from a chair across the room to a paper on your desk) the lines of sight converge (rotate inward). When you look back to the distant object, the lines of sight diverge (rotate outward). The vergence eye movements made to look between near and far objects are rapid—much like the saccadic shifts of gaze made to look from left to right across a room.

Maintained Fixation and Smooth Pursuit

The discussion of eye movements so far has emphasized what the eyes do when shifting gaze from one object to another, or when compensating for movements of the head. Two other types of eye movements, maintained fixation and smooth pursuit, use the same neural systems that control saccades or compensatory movements, but are found in special situations that are important for vision, so their characteristics are worth noting.

Maintained fixation refers to the eye movements that occur when trying to look steadily at a single, stationary object for many seconds on end. Fixation was studied avidly in the 1950s and 1960s using an instrument, the contact lens–optical lever (a tight fitting large contact lens with a mirror attached), that was especially suitable for recording small eye movements at high resolution. Studies of maintained fixation were sparked by interest in theories that related visual acuity to the dynamic aspects of receptor responses.

In the laboratory, maintained fixation is studied when movements of the head are restricted by devices such as chinrests or bite bars. Under such conditions, fixation is remarkably precise, with the line of sight remaining most of the time in a region with a diameter of only eight photoreceptors. Nicole Putnam and colleagues, using new advanced adaptive optics methods of observing the retinal image directly, confirmed this level of precision, and showed that the preferred retinal locus of the fixation target was slightly displaced from the location of maximum cone density.

The eye is not perfectly stable during maintained fixation. Slow oscillations of the eye are interrupted periodically (once every 2 seconds to 2 or 3 times per second) by small saccades (less than 0.2 angular degrees). Fixational eye movements provide sufficient motion of the retinal image to maintain the visibility of the target. When head movements are permitted, the motions of the image on the retina are considerably faster, and more suitable for maintaining visibility of visual objects of a variety of sizes, eccentricities and contrasts.

Smooth pursuit eye movements occur when tracking an object that is moving smoothly across space. For objects moving either at a constant velocity or in a simple repetitive trajectory, smooth pursuit can attain velocities almost equal to that of the target. By contrast, smooth pursuit of targets that move in complex trajectories is poor because of the time required to detect and respond to changes in the stimulus path. The oculomotor system has an ingenious way to compensate for these processing delays, namely, by using available cues in the environment to predict the future trajectory of the target motion and generate smooth movements in advance of expected changes to the target path. Thus, it is possible to maintain acceptable levels of smooth pursuit provided that the motion of the target can be predicted with reasonable accuracy. In the case of truly random target motions—such as when following an insect or prey that can generate evasive patterns of motion—no predictive strategy will succeed in generating an accurate response.

EYE MOVEMENTS: EFFECTS OF NEUROLOGICAL AND MENTAL DISORDERS ON

Eye movement recordings provide powerful information about the decisions that a person's brain has made about whether something is important. Eye fixations cause the image of an object to fall on the fovea, the cone-rich high-acuity area of the retina, and so provide visual information at a high spatial resolution. The richness of the data provided by eye tracking is revealed in the plethora of dependent measures it provides. Moreover, the neural substrates of eye movement measures are largely known. Therefore, measurement of eye movements may provide insight into the underlying neuropathology of disorders affecting eye movements. Finally, because eye tracking is noninvasive, and tasks can be made simple yet still provide extremely rich data (e.g., participants can merely look at pictures of faces and natural scenes), the methodology is quite well suited to conducting critical developmental studies in young children. This entry describes how the visual scanpaths (the pattern of eye movements that occur when an individual processes a complex stimulus) of affected individuals are altered in some neurodevelopmental and psychiatric disorders. It highlights what the observation of altered scanpaths can reveal about underlying mechanisms in these disorders at the cognitive and neural levels of analysis.

Several basic types of eye movements either shift or stabilize gaze. Movements for shifting gaze direction include saccadic movements, which are rapid, ballistic movements of both eyes in the same direction; smooth pursuit movements that carefully follow a moving object; and vergence movements, which converge or diverge the eyes to focus appropriately on an object at various distances from the viewer. Gaze stabilizing movements include vestibulo-ocular movements (reflexes that stabilize images on the retina during head movements via the production of an eye movement in the direction opposite to the head movement) and the optokinetic reflex, which allows the eye to follow objects in motion when the head remains stationary. Most of the studies of eye movements in psychiatric and neurodevelopmental disorders have focused on movements that shift gaze. Disorders have included attention deficit hyperactivity disorder (ADHD), autism, schizophrenia, Tourette's syndrome, obsessive-compulsive disorder, anxiety, and depression. To illustrate this line of research, findings from studies of ADHD, schizophrenia, and autism are discussed here.

In an antisaccade task, an observer holds his or her fixation on a particular location, then a stimulus appears somewhere within the subject's visual field. The subject must move his or her eyes in the direction opposite of the visual onset. Success on this task requires inhibiting a reflexive saccade to the onset location, and purposefully moving the eye in the opposite direction. Neuroscience studies have revealed a critical role for prefrontal cortical regions in antisaccade tasks. An extensive body of research has demonstrated that ADHD is characterized by an increase of errors on antisaccade tasks (i.e., eye movements made in the wrong direction). These findings further characterize and quantify a cognitive mechanism underlying key aspects of the ADHD phenotype; those having ADHD have difficulties in response inhibition. Further, the work underscores abnormal development of the prefrontal cortex as an etiological factor.

Smooth pursuit movements have been studied extensively in individuals with schizophrenia. Such movements are under voluntary control in the sense that the observer can choose whether or not to track a moving stimulus. The brain systems involved in controlling smooth pursuit eye movements largely overlap with those involved in controlling saccades, and these movements work in an integrative way. The available studies consistently implicate reduced gain (ratio of eye velocity to the target velocity) as a characteristic marker in schizophrenia, meaning that their pursuit tends to lag behind moving (especially quickly moving) objects instead of smoothly and accurately "locking" onto and following the target as seen in neurotypical individuals. Of particular interest is that this attribute has been observed across children at risk for developing schizophrenia, children and adolescents with schizophrenia (i.e., childhood onset schizophrenia), and adults with schizophrenia.

Moving beyond the study of basic eye movements, some studies have examined visual scanpaths. Scanpaths are observed by monitoring point-of-regard over time. The eyes carry out a saccadic movement, fixate or rest momentarily, and then jump to a new region of interest.

Studies of how individuals with autism look at faces exemplify the power of recording visual scanpaths. When presented with a face, typically developing adults direct most of their attention to the core features of the face (i.e., eyes, nose, and mouth) and spend little time on other areas. In stark contrast, individuals with autism do not look at the eyes or the other core features of the faces. Instead, those with autism scan the faces in a seemingly random fashion. Such findings suggest a failure to understand the significance of the features for social understanding and could represent a mechanism leading to a failure to develop the normal specialization of some brain regions for processing social information.

Some of the most exciting recent work involves the study of young children at risk for developing disorders such as autism, ADHD, or schizophrenia by virtue of having a first-degree relative with the disorder. Ample evidence indicates the importance of genetic factors in the etiology of each. In searching for the causes of and potential treatments for these disorders, vital work is now underway to determine whether disrupted eye movements appear before the onset of the full phenotype. Eye tracking could be combined with computational modeling such that recorded visual scanpaths can be compared with the scanpaths predicted by models of visual attention that compute the "visual salience" of specific components of the scene via algorithms that use assumptions about how the brain works with regard to the operation of "bottom-up" (e.g., images are all analyzed the same way based on characteristics such as pixel brightness or darkness) and "top-down" (e.g., images are analyzed differently depending on the meaning of the image) perceptual and cognitive mechanisms. By thus comparing what saliency models predict for fixations of a particular image, and how subjects actually fixate that image, researchers could evaluate the relative contributions that bottom-up and top-down information processing mechanisms make to guiding eye movements. These contributions can then be compared in subjects with and without particular brain disorders.

EYE MOVEMENTS: PHYSIOLOGICAL

The *physiology of eye movements* refers to the brain regions and the connections between nerve cells in the various parts of the brain that are responsible for controlling how we aim and move our eyes. Because vision starts at the retina and the retina is attached to the back of the eye, visual perception depends on the proper operation of these brain circuits for eye movements.

If you have experienced how confusing it is to watch movies taken with a shaky camera, then you can readily appreciate how the ability to see and perceive the world depends on how the eyes are held and moved. Accordingly, one class of brain mechanisms, present in a wide variety of species, is responsible for keeping the eyes stabilized with respect to the visual world.

There are additional challenges for vertebrates such as primates, whose retina contains specialized regions (the fovea) that can be used to see a more limited portion of the visual scene at a much higher resolution. To make the best use of our visual system, we use a second class of mechanisms to move our eyes with respect to the visual world. These movements act to place and keep the images of interesting things within this specialized region of the retina, where they can be best seen. This entry describes physiological aspects of eye movements.

Behavior

Maintaining the Line of Sight

Two types of eye movements maintain the line of sight: the vestibulo-ocular reflex (VOR) and the optokinetic response (OKR). The VOR uses signals from the bony labyrinth of the inner ear that indicate how the head is moving in space. A direct three-neuron pathway relays these signals quickly (in less than 1 one-hundredth of a second!) to counter-rotate the eyeballs to keep the retinal images of the world stable during head movements. For example, as you look at this text, try shaking your head back and forth, and notice that your eyes automatically and rapidly move in the opposite direction, so that your ability to see the text remains unperturbed. As your head moves to the right, sensory neurons for the right inner ear increase their activity, whereas those in the left ear decrease their activity. These changes in activity are relayed by inter-neurons in the brain stem to the motor neurons that control the six muscles that move each eye. In addition, a copy of the signals from the inner ear are summed over time and stored in a process akin to mathematical integration; this integrated signal is also applied to the eye motor-neurons, so that your eyes are held in position when you stop moving your head.

The OKR also stabilizes the eyes, but uses visual signals about the movement of images across the retina. Because sensory transduction takes longer for vision than for the vestibular system, the OKR reacts slower than the VOR does (after 100 milliseconds rather than 10 milliseconds). However, unlike the signals from the inner ear, which decay after a few seconds of head movement, visual signals persist as long as images move across the retina. Thus, the OKR can compensate for low speeds and constant motions, even when there are no signals detected by the inner ear. For example, as you look at this text, try holding your head still and slowly move the page; the OKR will move your eyes to automatically follow the motion of the page, so that your ability to see the text again remains intact. The signals for this behavior come from areas of the brain that are specialized for processing visual motion. Some of these areas are located in the mantle of the cerebral cortex that covers most of the brain in primates, and others are located in nuclei underneath the cortex. Neurons in these areas provide inputs to the same inter-neurons and motor neurons in the brain stem that are used for the VOR. This shared brain stem circuit for holding and moving the eyes, which is used by all eye movement systems, is referred to as "the final common pathway."

Changing the Line of Sight

Vertebrates with foveal vision use two primary mechanisms for changing the line of sight: saccades and smooth pursuit. Saccades quickly move the image of a part of the visual scene from an eccentric location on the retina to the center of the retina where it can be seen best. For example, as you read this text, you use a sequence of saccades to flick your line of sight from word to word across the page. Saccades can be guided by any modality, and they occur frequently—a typical person makes several saccades each second. Saccades are fast and brief (lasting only tens of milliseconds), and they follow a stereotyped movement profile that is determined by a specialized circuit in the brain stem referred to as the *saccadic burst generator*. Within this circuit, several classes of neurons work together to produce the "burst" of activity that is needed to quickly rotate the eyes, as well as the "step" of activity that keeps the eyes in place after each saccadic eye movement ends. The properties of this circuit are finely tuned by pathways involving another brain structure, the cerebellum, which is the same brain structure necessary to execute other fine motor skills, such as playing the piano.

Smooth pursuit eye movements slowly rotate the eyes to match the motion of the visual target, such as a person walking across the field of view, and thus help avoid the blurry vision that would occur if the image of the target were allowed to slide across the retina. Unlike saccades, smooth pursuit is slower (speeds of less than 50 degrees per second) and is continuously updated by feedback about how well the target is being tracked. Notably, pursuit typically cannot be generated in the absence of a moving stimulus, although motion sensed with modalities other than vision can be used. Consequently, the motor circuits for pursuit do not construct the eye movement commands from scratch, but instead rely on descending signals from areas of the cerebral cortex that define the motion of the target to be tracked. These descending signals about target motion reach the final motor circuits through several routes. The most prominent pathway passes from the cortex through a set of relay nuclei at the base of the brain stem to parts of the cerebellum, which then change the activity of the same neurons involved in generating the VOR. In this way, pursuit eye movements commandeer the brain circuits also used for the VOR, but substitute a target-motion signal generated by the cortex for the head-motion signal provided by the inner ear.

These circuits in the brain stem for changing the line of sight are controlled by signals from higher centers located on the roof of the midbrain and several areas in the cerebral cortex of the forebrain. These connections with higher centers form the functional bridge between perception and the motor control of eye movements.

Brain Regions

Superior Colliculus

One of the most important sources of descending control signals is the superior colliculus (SC), located on the roof (tectum) of the midbrain. Neurons in the SC are organized to form a retinotopically organized map of the visual world—adjacent points in visual space are represented by adjacent SC neurons. The SC is a primary source of the signals needed by the saccadic burst generator to construct the motor commands for saccades. Because the final motor command is a precisely timed "burst" and "step" of activity, constructing these saccade commands involves a transformation from the spatial (i.e., retinotopic) code in the SC to the temporal code needed to properly control the activity of motor-neurons. This property of the brain mechanisms becomes evident when neural activity is artificially increased by passing small amounts of electrical current into the SC. Such stimulation evokes a saccadic eye movement with a particular direction and amplitude that depends on the location in the SC map. Stimulating for longer periods does not cause bigger movements, but instead evokes a sequence of several saccades, all of similar direction and amplitude, often referred to as a "staircase" because the plot of eye position over time resembles a set of stairs.

Activity in the SC is related both to the eye movements themselves and to the stimuli and events that elicit them: Some neurons show mostly movement activity, others show mostly sensory activity, and many show combinations of both. Many SC neurons also exhibit activity related to the remembered or perceived location of targets in the environment. Recent studies have shown that many SC neurons are involved in the preceding steps of identifying and selecting the target as well as in preparing to make eye movements. Other studies suggest that activity in the SC may be part of the neuronal circuits that control visual attention.

Cerebral Cortex

Several areas in the mantle of the cerebral cortex overlying the brain are important for eye movements, the most prominent of which is the frontal eye fields (FEF). As in the superior colliculus, stimulating the FEF with electrical currents can artificially induce saccadic eye movements with particular directions and amplitudes. Stimulation of an adjacent area of the cortex—the frontal pursuit area—causes smooth pursuit eye movements and is the only cortical area where stimulation can directly cause pursuit. Damage to the FEF impairs the generation of eye movements, especially when there are distracting stimuli, but these effects are temporary; in contrast, combined damage to both the SC and FEF causes a permanent deficit in the ability to voluntarily move the eyes. Neurons in the FEF show a range of properties: Some mostly respond to visual stimuli, some are active only during eye movements, and many exhibit activity for both sensory and motor events. The visual neurons also appear to play a role in identifying salient visual stimuli even in the absence of eye movements. Moreover, stimulation of the FEF with currents too low to cause eye movements can mimic the effects of directing attention to a particular location in space.

Several other areas in the cerebral cortex are important for generating eye movements. The lateral intraparietal area (LIP) plays a major role in the control of visual attention as well as eye movements and is often described as containing a "salience map" for visually guided behavior. The supplementary eye fields (SEF) play a less direct role in eye movements, but appear to be important for tasks that involve more arbitrary rules (for example, "move your eyes in the direction away from the visual stimulus"). The middle temporal area (MT) and the medial superior temporal area (MST) are important areas of the visual cortex for extracting the visual-motion signals necessary to drive smooth pursuit eye movements, as well as to support the perception of visual motion.

Basal Ganglia and Thalamus

In addition to the descending control signals provided by the SC and areas of the cerebral cortex, important regulatory circuits involve the basal ganglia and thalamus. The basal ganglia exert a strong inhibitory effect on the activity of neurons in the SC. By transiently stopping this inhibition (called disinhibition), the basal ganglia act like a gate to allow signals for eye movements to flow through the SC and exert their effects on the motor circuits. The basal ganglia appear to be especially important for eye movements involving reward and motivation, and this role likely involves the same neurotransmitter (dopamine) and neurons implicated in Parkinson's disease.

Ascending pathways through the thalamus back up to areas of the cerebral cortex involved in eye movement control. These regions of the thalamus collect signals from many of the structures described earlier (SC, cerebellum, basal ganglia, brain stem) and convey this information to the cortex. The function of this feedback is not fully understood, but it appears to update the visual and motor processes that take place in the cortex. In particular, by providing copies of the outgoing motor commands, the corollary discharge signals provided by the thalamus may allow us to correct for the sensory consequences of our own eye movements. For example, even though the visual world sweeps across our retina during eye movements, we correctly perceive the world as stable; this ability to maintain perceptual stability during eye movements may depend on these feedback pathways.

EYE MOVEMENTS AND ACTION IN EVERYDAY LIFE

We are largely unaware of the importance of eye movements in gathering the visual information that is used by the brain to perform even the simplest everyday actions. Take, for example, the eye movements involved in making a sandwich. If we watch what the eyes are doing we will see that they make a series of rapid jumps from one place to another, every few hundred milliseconds, much more rapidly than we are aware of, gathering visual information and guiding the movements of the hands. These rapid shifts of the eye from one place to another are called saccadic eye movements and are one of the primary eye movements involved in gathering information from different locations in a visual scene. These movements are necessary because we cannot see with equal clarity across the entire visual scene, but instead must move our eyes so that the object of interest falls on the high-resolution foveal region at the center of the retina. Objects off the line of sight are seen much less clearly, so if we want to grasp an object, such as a knife, we direct the center of gaze toward the regions where the fingers make contact. Almost without exception, whenever we pick up an object in everyday life, we direct our eyes to the object to guide the grasp. Similarly, we almost always direct our eyes at the things we are most interested in at the moment. Thus, eye movements are a critical component of everyday visually guided behavior, as this entry describes.

Eye Tracking in Natural Behavior

Despite this importance, the study of eye movements and their role in visual perception and action has historically been restricted to simple controlled experimental conditions. Part of the reason for this has been the general strategy in experimental psychology of investigating the simplest components of perception and movements with the goal of understanding complex behavior in terms of its elemental components. Perhaps the more important reason, however, has been the difficulty of measuring eye movements in an unconstrained observer. The high optical power of the eye means that a tiny eye rotation translates into a significant change in the direction of gaze in the world, such as a change in gaze from one word to the next during reading. To measure such tiny rotations, early eye position measurement devices involved awkward and often painful attachments to the eye that necessitated stabilizing the head. Subsequent systems, such as electromagnetic eye coils and the dual Purkinje image tracker were more comfortable, but still required the head to be held fixed. However, during the last 10 to 15 years, the advent and rapid refinement of eyetrackers mounted on the head have allowed considerable freedom of movement. Michael Land built one of the first of these, and a recent version by Jason Babcock and Jeff Pelz, shown in Figure 1(a) (see also the color insert, Figure 24a), is completely portable, using power from a battery carried in a small backpack. The new eyetrackers allow the study of eye movements over extended tasks in natural settings. As well as providing eye position in the head, or in space, these trackers also provide a video from the subject's viewpoint, with eye position superimposed. This is particularly useful in interpreting the eye movements because it shows the stage of the task corresponding to a particular gaze point.

Task Dependence of Gaze Patterns

Since the development of portable eyetrackers, eye movements in a variety of natural settings have

Figure 1 The RIT Wearable Eyetracker, Showing the Scene Camera and Eye Camera Mounted on a Lightweight Glasses Frame

Notes: (a) The backpack carries a battery and video camera, which tracks eye position relative to the scene the person is observing. (b) Composite image of a scene from the head-mounted video camera while the subject makes a peanut butter and jelly sandwich. The images from the camera were integrated over different head positions. The fixations are indicated by the white circles. Circle diameters reflect the duration of the fixation. See also color insert.

been investigated. We might have expected that in the natural world, gaze would roam randomly around the scene, stopping at salient points that stand out from the surroundings, such as bright regions, or regions of saturated color, or edges between regions. (Note that the periods when the eye is relatively stationary, in between the high velocity saccadic gaze shifts, are called fixations.) A large body of theoretical work by Laurent Itti and colleagues has attempted to predict fixation locations by analyzing the content of the image for regions that differ from the surrounds in this way. If subjects are inspecting still images of scenes, these saliency calculations can predict some of the fixations, but in natural behavior such as driving, walking, sports, and making tea or sandwiches, fixations are instead guided by the visual information that the subject needs at the moment. The central result from investigating natural behavior is that gaze locations are tightly linked to the task, and observers rarely look at regions or objects that are irrelevant to the task at hand, regardless of their image saliency. Figure 1(b) (color insert, Figure 24b) shows all the fixations made while making a sandwich. When viewing a video replay from the subject's viewpoint, with eye position superimposed, we can see that fixations are tightly linked to the actions, such as grasping and moving objects, moving on to the next object when the needs of the current action have been met. To understand this better, imagine a small segment of behavior, when the subject has finished making the sandwich and is about to cut the bread. Gaze will be directed at the knife handle to guide the hand to pick it up. As the hand closes on the knife, the eye will move to the corner of the sandwich where the knife tip will be placed to begin cutting. The gaze then moves slowly along the bread with the knife following shortly afterward. After the sandwich has been cut, the eye will move to a location on the table where the knife is to be placed. Thus, the basic structure of the task allows one to link the visual operations fairly closely in time with the occurrence of eye and hand movements.

The sequence of fixations is tightly linked to the task, and many of the fixations appear to have the purpose of obtaining quite specific information. For example, subjects fixate the middle of the jar for grasping with the hand in a vertical posture, and the rim for putting on the lid, with the hand in a horizontal posture. This suggests that the visual information being extracted controls the pre-shaping in one case and the orientation of the lid in the other. Dana Ballard and colleagues have called this a "just-in-time" strategy, where observers acquire the specific information they need just at the point it is required in the task. Interestingly, although subjects are in general aware that they are looking at the objects involved in the task, they are not aware of the speed and specificity of the eye movements, which occur more or less automatically. Moreover, when grasping a jar, for example, the subject might register size and location, but not be aware of the label on the jar or even the color if the contents. Thus, “seeing” is not a unitary process, despite our subjective impression that we effortlessly perceive everything at once. Rather, it is an active process and is inextricably linked to the observer’s behavioral goals.

Learning Where to Look

Implicit in much of the research on natural tasks is the finding that eye movement patterns must be learned. For example, in tea making, observers must have learnt what objects in the scene are relevant because almost no fixations fall on irrelevant objects. In driving, Hiroyushi Shinoda and colleagues showed that approximately 45% of fixations fell in the neighborhood of intersections. As a consequence, subjects were more likely to notice stop signs located at intersections rather than in the middle of a block. Thus, subjects have learnt that traffic signs are more likely near intersections. Subjects must also learn the optimal location for the information they need. For example, when pouring tea, fixation is located at the tip of the teapot spout. Presumably, flow from the spout is best controlled by fixating this location. Another important way in which eye movements reveal the influence of learning is that they are often anticipatory; that is, saccades are often made to a location in a scene in advance of an expected event. For example, in Michael Land and Peter McLeod’s investigation of cricket, batsmen anticipated the bounce point of the ball, and more skilled batsmen arrived at the bounce point about 100 milliseconds (ms) earlier than less skilled players. Anticipation is not limited to skilled sports players. Even in less skilled activities, such as catching a ball, subjects reveal similar anticipatory eye movements. Thus, eye movement patterns reflect learning of the dynamic properties of the world.

Another important and unexpected feature of eye movements in ordinary behavior is the reproducibility of the eye movement patterns and the similarity between observers. For example, when cutting a sandwich, subjects always fixate the initial point of contact with the knife and move their gaze along the locus of the cut, just ahead of the knife. Given the role of eye movements in gathering information to accomplish tasks, it makes sense that fixation patterns between individuals should be similar because they reflect the physical and dynamic properties of the environment. This stability in fixation patterns makes research on natural behavior unexpectedly accessible to experimental investigation.

Neural Mechanisms of Gaze Control

Advances in understanding the role of eye movements in everyday behavior have been paralleled by advances in understanding the neural mechanisms underlying these movements. It has become clear that internal reward mechanisms are intimately linked to the neural machinery controlling eye movements. Wolfram Schultz and colleagues have shown that dopaminergic neurons in the basal ganglia (an important mid-brain structure involved in the generation of movements) signal the reward expected from an action. Sensitivity to reward is manifest throughout the saccadic eye movement circuitry. The neurons involved in saccadic targeting respond in a graded manner to both the amount of expected reward and the probability of a reward, in the period before execution of the response. Sensitivity to both these variables is critical for learning and, consequently, for linking fixation patterns to task demands. Thus, at both behavioral and neural levels, the target selection mechanisms appear to be intimately related to behavioral outcomes.

Applications

A particular advantage of investigating eye movements in everyday behavior is that the outcomes are much more directly related to both applied and clinical problems than to work in simpler, more controlled experiments. For example, if we want to know the consequences for everyday life of visual losses from disease or injury, it is necessary to understand how information in the visual world is used for particular tasks, such as navigation, obstacle avoidance, or preparing a meal. There is a long history of investigation of reading, but more recently, investigators such as Kathleen Turano and Krystel Huxlin have examined gaze patterns in individuals with visual impairments in a wider range of tasks. Such work can reveal potential mechanisms for compensating for visual losses and indicate potential rehabilitation strategies. This is true for visual losses caused by central damage such as that caused by stroke, as well as losses from peripheral disease. The clinical applications of eye movements in everyday behavior are an important area of research that has been greatly facilitated by the development of more "user friendly" eyetrackers, so we can expect to see exciting developments in this area.

EYE MOVEMENTS AND READING

When we read, we have the impression that our eyes glide smoothly across the page. However, this is an illusion. The eyes stay relatively fixed for about 200 to 300 milliseconds (ms) and then quickly jump (in about 20–30 ms) to a new location. The stable periods are called *fixations* and the eye movements are called *saccades*. Vision is suppressed during saccades (to prevent the perception of blur during eye movements) and useful information is obtained only during fixations. Our eyes typically move forward through the text, although *regressions* (saccades going backward through the text) account for about 10 to 15% of the movements. When readers come to the end of a line, a large leftward eye movement (called a *return sweep*) is made to near the beginning of the next line of text.

It is now easy to record eye movements accurately. The most precise eyetrackers have a spatial accuracy of less than one half a character, and they provide a millisecond-by-millisecond record in the time domain. Eyetrackers that are cheaper and easier to use are still spatially accurate to about a character and to about 5 ms temporally. Thus, with the types of tracker being used today, one can be quite sure which word a reader is fixating and can measure the duration of a fixation with an accuracy of less than 5 milliseconds (ms). This precision is important because what the eyes are fixating on is closely linked to the underlying cognitive processes of reading, as this entry describes.

The Perceptual Span in Reading

The most direct way that a tight linkage between the location of the eyes and the underlying processing in reading has been demonstrated is through the *moving window* paradigm first used in classic experiments by George McConkie and Keith Rayner. In this paradigm, what the reader can process from text on the video monitor depends on where the eyes are. For example, in a one-word window condition, the word that is being currently fixated is normal, but all the letters in the other words are replaced by Xs or random letters. However, when the eyes move and the reader fixates a new word, that word is now normal on the

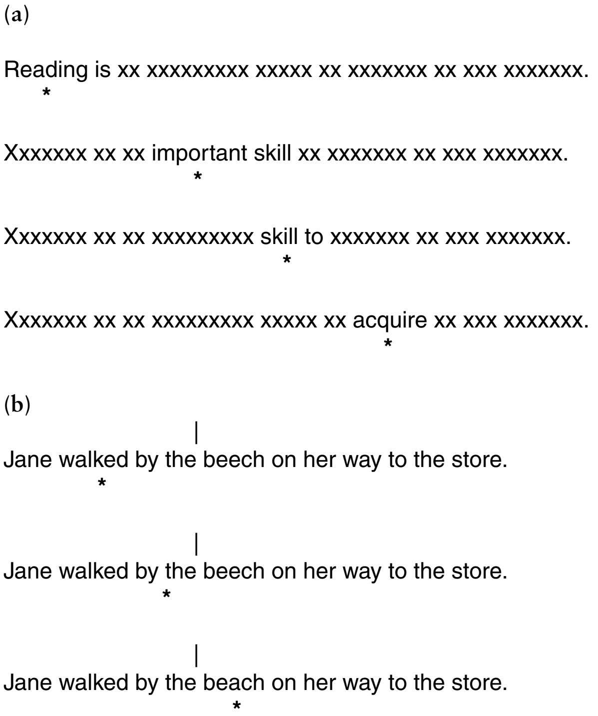

Figure 1 The Moving Window and Boundary Paradigms

Notes: (a) An illustration of the moving window paradigm. The size of the window in the illustration is two words: the fixated word indicated by the asterisks and the word to the right. As indicated in the text, the size of the window can be defined either by the number of letters or the number of words. In addition, the location of the window can be manipulated so that, for example, a two-word window could include the fixated word and the word to the left. (b) An illustration of the boundary paradigm. The vertical mark indicates the boundary (which is not visible to the participant). The display change involves only a single word location, and the only display change occurs when the boundary is first crossed. In this illustration, a homophone of the target word is the preview. Other possible previews could be bench, broad, bsfhfs, or xxxxx. Fixation time on the target word is shorter when "beech" is the preview rather than "bench" (indicating phonological coding of the preview), but "bench" is a better preview than any of the others, indicating orthographic coding of the preview.

next fixation and all the other words (including the previously fixated word) have their letters replaced by Xs (see Figure 1a). Thus, this paradigm is like a custom "slide show," where there is a new slide on each fixation (tailored to the fixation location). Provided that the window isn't less than a word, readers are generally not aware of the window; it just seems like normal reading.

The logic of the paradigm is that if all that was encoded on a fixation was the word being fixated, then readers would read normally with a one-word window. However, the reading rate in the one-word window condition is about 200 words per minute, which is about 60% of the normal reading rate. In a two-word window condition (in which the window contains the fixated word and the word to the right) reading is about 90% of normal, and in a three-word window condition (the window contains the fixated word and the two words to the right) reading is normal. Thus, the *perceptual span* (the region where readers extract information at least some of the time) appears to be three words (or more precisely, 3 to 4 letters to the left of fixation to about 14 to 15 letter spaces to the right of fixation). There is also nothing magic about the exact size of the window, however, because it is smaller if the text is quite difficult to decode. It's also smaller for beginning and dyslexic readers than for skilled readers, likely because they have more difficulty encoding the words in the center of vision than more skilled readers do. The asymmetry of the perceptual span observed in English is also not a hardwired "biological" constraint. In Hebrew, which is read from right-to-left, the perceptual span is asymmetric to the left. Thus, ongoing processing and visual attention modulate both the size and shape of the span.

The outer limits of the window to the right, however, are largely defined by visual acuity constraints: acuity is greatest in central vision (the fovea) and drops off quite quickly. However, it is best to think of the window as being defined by the number of characters instead of visual angle because there is a trade-off in acuity if the distance of the text or the size of the font changes. That is, when the text is larger, the letters are bigger (which makes them easier to process), but they are also further from the fovea, and those two factors generally compensate. Finally, the perceptual span for readers of languages that are more densely packed than English tends to be smaller than for English; for example, the perceptual span in Chinese extends about 1 character to the left of fixation to two to three characters to the right.

Eye Fixations Reflect Ongoing Cognitive Processing

The results of the moving window experiments described suggest that a major part of the agenda on a fixation is to encode the word that is fixated (though readers also get preview information from the next word). A host of evidence supports this point, most notably that characteristics of the fixated word—such as length, frequency in the language, and predictability from the prior context—affect the amount of time spent on the word. Word length, frequency, and predictability are highly correlated. Short words tend to be frequent and predictable, especially function words (articles, prepositions, conjunctions, and pronouns). Experiments, however, can unconfound these variables. For example, to examine word frequency, two words matched in length and predictability, but varying in frequency, would be inserted into the same sentence frame with the sentences closely matched on naturalness. A given reader would only read one of the two sentences, but in the counterbalanced design, equal numbers of readers would read each sentence.

These experiments indicate that the average fixation time on low-frequency words is 30 to 50 ms longer than those on high-frequency words. This difference does not merely reflect a few long times on low-frequency words; the difference is seen largely as a shift of the entire distribution of fixation times. Similar findings are observed for word length and predictability (when the other factors are equated); fixation times are shorter on predictable words than on unpredictable words and on shorter words than on longer words. These variables also influence the probability of skipping a word. Shorter, more frequent, and more predictable words are skipped more often; skipped words are processed on the fixation before the skip.

The discussion to this point has documented that the time to identify a word strongly influences how long the word is fixated and that these variables influence whether a word is skipped. This suggests that word identification is the primary engine driving the eyes forward in reading and is the process that largely determines reading speed. Rather direct evidence for this assertion comes from experiments in which the text disappears (or is masked) early in a fixation. If readers get to see the text for 50 to 60 ms before it disappears, reading proceeds quite normally because this is enough time for the visual information to be processed. Even though the word is no longer there, readers keep their eyes in place longer for low-frequency words than for high-frequency words!

The Processing of Words

It is sometimes suggested that skilled readers go directly from print to meaning without accessing the sound of the language. However, the involvement of phonological coding (i.e., translation to sound) is an important part of the process of identifying words. One demonstration of how early phonological coding enters into silent reading is with the *boundary paradigm,* which is similar to the moving window paradigm (but with only a single display change). An invisible boundary is set just to the left of a target word (see Figure 1b). Before the reader crosses the boundary, there is typically a preview different from the target word; when the eyes cross the boundary, the preview is replaced by the target word. The sentence makes sense with the target word, and readers are unaware of the identity of the preview and of the display change. Experiments using this technique have demonstrated that if there is letter overlap between the preview and the target, fixation times are shorter on the target word than if the preview shared no letters with the target. This indicates that partial information from the preview is extracted that facilitates processing of the word when it is fixated. However, this could either be orthographic (letter) information or phonological information. To test whether phonological information is involved in this process, experiments employed previews that were either homophones of the target word, for example, or control words that were matched on the number of letters they had in common with the target word (see Figure 1b). Fixation times on the target word were shorter when the homophone was the preview indicating that phonological coding occurs in early reading—even before a word is fixated.

Other properties of the fixated word besides length, frequency, and predictability also influence how long readers look at it. For example, the age when people first encounter a word yields a significant effect even when word frequency is controlled. In addition, whether a word has more than one distinct meaning (lexical ambiguity) and whether the prior context helps disambiguate the meaning of a lexically ambiguous word both influence how long readers look at the word. Besides ambiguity at the lexical and phonological level, ambiguities are also in written text at the level of syntax. Thus, a sentence such as, “While Mary was mending the sock fell off her lap,” is ambiguous because “the sock” can initially be taken as the object of “was mending” (an incorrect parse of the sentence) or as the beginning of a new clause (a correct parse of the sentence). Numerous studies using syntactically ambiguous sentences have examined readers’ parsing strategies, and the resulting eye movement data have been informative. It appears that readers usually construct only one of the possible syntactic structures, so that when the actual parse of the sentence is not what they expect, they often make either long fixations or regressions back to where they would have been led astray (or both). Thus, instead of computing all possibilities (which may overload memory), readers appear to be committed to one interpretation, but when they encounter information that contradicts that interpretation, they revise their initial parse.

The global meaning of a passage can also influence eye movements. Thus, readers often need to engage in anaphoric reference (e.g., tying an anaphor such as “he/she” to a prior antecedent). When there is ambiguity about what the antecedent is, fixation times increase and readers are also sometimes forced to make a regression back in the text. Likewise, clever experimental manipulations have revealed that when readers make inferences as they read, the nature of the inference can be inferred from the pattern of eye movements.

Models of Eye Movements During Skilled Reading

A number of computational models that account for the details of eye movements during reading have arisen to account for what has been learned about eye movements in reading. These models differ on some key dimensions, but they all do a reasonably good job of accounting for the findings described earlier. Although they have concentrated on the relationship between eye movements and word recognition rather than on higher level processes (such as syntax), the development of these models has been important in aiding our understanding of the relationship between eye movements and cognition during reading.

EYE MOVEMENTS DURING COGNITION AND CONVERSATION

Femme fatales, interrogators, and cult leaders know the importance of eye movements. Gaze can act as a signal of attraction, a window into someone’s thoughts, and a means of persuasion. The close link between eye movements and psychological processes results from the anatomy of the eyeball. Detailed information can only be discerned from a small region in the center of the field of view, the fovea. So, unlike a wide-angled closed-circuit television camera that can slowly and passively sweep a large area, the small fovea must be rapidly and constantly moved around the world. For these motions to be efficient, they have to be intelligent. Therefore, eye movements are closely linked to the beliefs, expectations, and intentions of the observer. This link between eye and mind has recently been exploited by cognitive psychologists, but, perhaps implicitly, we are all attuned to the gaze patterns of those around us and what they indicate about the observer’s mental state. This entry examines the connection between gaze and cognition, and the role this plays in social interaction and conversation.

The mental processes of a simple decision can be seen in how the eye moves between choices. For example, the distribution of eye movements among a set of faces will reveal relatively how much each is preferred. If someone is asked to make a simple judgment, such as placing a sound or an object into one of two categories presented on screen, that person's eye movements between the options will reflect how certain he or she is of each item's membership. Moreover, influencing how the eyes move can influence mental processes. Researchers recorded the eye movements of participants interpreting an ambiguous picture or solving a difficult deductive problem from a diagram. Using low-level visual cues, such as brightening some areas of the image, a second set of participants were then influenced to attend to the same regions of the picture. The second set of participants was more likely to form the same interpretation of the ambiguous picture, and remarkably, was more likely to solve the deductive problem.

We do not have to be looking at objects or pictures for gaze to reveal cognitive processes. When looking at a blank screen and recalling an image or a painting, the eyes tend to move as they did during the initial viewing. When recalling nonvisual, spoken facts, the eyes will return to areas of a blank screen that were associated with the information. Not just memory, but imagery too can drive eye movements. Gaze becomes more active during spatial mental imagery and vivid dreams, and the eyes will move either horizontally or vertically when listening to a story about a train leaving the station or a man rappelling down a canyon.

How we move our eyes when listening to people speak reveals the time course of language comprehension and the way in which we ground spoken information in the visual world. For example, when people were asked to "pick up the candle" from the table, half way through the last word, they would often look at a candy lying nearby. This demonstrates that language comprehension is incremental: Listeners continually search for potential referents of spoken words in the visual world. Similarly, eye movements are yoked to language production. Speakers reliably look at objects just under a second before naming them. When two people talk to each while looking at the same visual scene, while watching a movie for example, their eye movements are closely coupled. The degree to which their eye movements are coordinated relates to how well they understand each other.

Eye movements during face-to-face conversation are governed by social forces and the process of coordinating dialogue. We can perceive each other's gaze accurately, and it is a powerful attentional cue. From infancy to adulthood, we use others' eye movements to infer their mental states. We are particularly sensitive to gaze that is directed at us. We can detect a millimeter displacement of a viewer's gaze away from the bridge of our own nose, which is at the limit of the visual acuity of the eye. Mutual gaze has two consequences. First, it correlates with many interpersonal factors, such as attractiveness, authority, and perceived sincerity. Second, the timing of mutual gaze is used to coordinate dialogue. Typically, a listener will look more at the speaker than vice versa. The speaker will periodically cast looks at the listener, creating a period of mutual gaze. At this point, the listener is likely to respond with a nod or "mhm," prompting the speaker to continue. In this way, eye movements are employed as part of the composite signal used in the collaborative act of conversation.

Too much can be made of gaze patterns, however. Neuro-linguistic programming holds that eye movements in certain directions correspond to the activation of certain brain regions or types of mental representation so that, for example, one can tell when someone is lying by the direction that he or she look. The wealth of scientific data discrediting neuro-linguistic programming is, however, matched by the volume of seminars and training courses promoting its use.

Uniquely poised between perception and cognition, eye movements are an invaluable tool for psychologists. Compared with the single data point provided by a button-press reaction time, the eye movements of a subject can provide researchers with a rich, dynamic data source concerning the temporal dynamics and psychological processes that led up to the response.

EYE MOVEMENTS DURING FIXATION

As you read this, your eyes are rapidly flicking from left to right in small hops, bringing each word sequentially into focus. When you stare at an object, your eyes will similarly dart here and there, resting momentarily at one place on the object, and then moving to another. But these large eye movements, called saccades (see color insert, Figure 25a), turn out to be just a small part of the daily workout your eye muscles are getting. Your eyes *never* stop moving, even when they are apparently settled, say, on a person's nose or a sailboat bobbing on the horizon. When the eyes fixate on something, as they do for 80% of your waking hours, they still jump and jiggle imperceptibly in ways that turn out to be essential for seeing. The tiny eye motions that you produce whenever you fixate your gaze are called fixational eye movements (see color insert, Figure 25b). If you could somehow halt these miniature motions while fixating your gaze, a static scene would simply fade from view. This entry discusses neural adaptation, visual fading, and microsaccades,

Neural Adaptation and Visual Fading

That the eyes move constantly has been known for centuries. In 1860, Hermann von Helmholtz pointed out that keeping one's eyes motionless was a difficult proposition and suggested that "wandering of the gaze" prevented the retina from becoming tired.

Animal nervous systems may have evolved to detect changes in the environment because spotting differences promotes survival. Motion in the visual field may indicate that a predator is approaching or that prey is escaping. Such changes prompt visual neurons to respond with neural impulses. Unchanging objects do not generally pose a threat, so animal brains—and visual systems,—did not evolve to notice them. Frogs are an extreme case because they produce no spontaneous eye movements in the absence of head movements. For a resting frog, such lack of eye movements results in the visual fading of all stationary objects. Jerome Lettvin and colleagues stated that a frog "will starve to death surrounded by food if it is not moving" (1968; p. 234). Thus, a fly sitting still on the wall will be invisible to a resting frog, but once the fly is aloft, the frog will immediately detect it and capture it with its tongue.

Frogs cannot see unmoving objects because an unchanging stimulus leads to *neural adaptation.* That is, under constant stimulation, visual neurons adjust their gain so they gradually stop responding. Neural adaptation saves energy but also limits sensory perception. Human neurons also adapt to sameness. However, the human visual system does much better than a frog's at detecting unmoving objects because human eyes create their own motion, even during visual fixation. Fixational eye movements shift the visual scene across the retina, prodding visual neurons into action and counteracting neural adaptation. Thus, eye movements prevent stationary objects from fading away.

In 1804, Ignaz Paul Vital Troxler reported that precisely fixating your gaze on an object of interest causes stationary images in the surrounding region gradually to fade away. Thus, even a small reduction in the rate and size of your eye movements greatly impairs your vision, even outside of the laboratory and for observers with healthy eyes and brains (see color insert, Figure 25c).

Eliminating *all* eye movements, however, can only be achieved in a laboratory. In the early 1950s, some research teams achieved this stilling effect by mounting a tiny slide projector onto a contact lens and affixing the lens to a person's eye with a suction device. In this set up, a person views the projected image through this lens, which moves with the eye. Using such a retinal stabilization technique, the image shifts every time the eye shifts. Thus, it remains still with respect to the eye, causing the visual neurons to adapt and the image to fade away. Nowadays, researchers create this same result by measuring eye movements with a camera pointed at the eye. The cameras transmit the eye-position data to a projection system that moves the image with the eye, thereby stabilizing the image on the retina.

Around the same time, researchers characterized three different types of fixational eye movements. *Microsaccades* are small, involuntary saccades that are produced when the subjects attempt to fixate their gaze on a visual target. They are the largest and fastest of the fixational eye movements, carrying an image across dozens to several hundreds of photoreceptors. *Drifts* are slow meandering motions that occur between the fast, linear microsaccades. *Tremor* is a tiny, fast oscillation superimposed on drifts. Tremor is the smallest type of fixational eye movement, its motion no bigger than the size of one photo-receptor.

Microsaccades in Visual Physiology, Perception, and Cognition

Since the late 1990s, fixational eye movement research has focused on microsaccades. Physiological experiments found that microsaccades increase the firing of neurons in the visual cortex and lateral geniculate nucleus by moving the images of stationary stimuli in and out of neuronal receptive fields. Perceptual experiments showed that the visual fading phenomenon described by Troxler is caused by the reduction of microsaccades that occurs during precise fixation.

Recent studies have shown that microsaccade rates are modulated by attentional shifts. Microsaccade directions may also be biased toward the spatial location of surreptitiously attended targets.

Fewer studies have addressed the neural and perceptual consequences of drifts and tremor. However, all fixational eye movements are likely to contribute significantly to visual perception. Their relative contributions may depend on stimulation conditions. For example, receptive fields near the fovea may be so small that drifts and tremor can maintain vision in the absence of microsaccades. Receptive fields in the periphery may be so large that only microsaccades are large and fast enough, compared with drifts and tremor, to prevent visual fading, especially with low-contrast stimuli. But it is also possible that if drifts and tremor could be eliminated altogether, microsaccades alone could suffice to sustain central vision during fixation.

EYES: EVOLUTION OF

Eyes detect the peak in the sun's electromagnetic radiation—light—and come in limited, convergent forms because of constraints set by the physics of light. Eyes are the sensory organs at the beginning of visual systems. A visual system such as our own, with its associated processing unit, is a complex of parts that have different functions and that are unrelated in their initial evolutionary history. A lens focuses light to form an image, retinal cells convert light waves to electrical signals, optic nerves carry those signals to the brain, the brain re-constructs the image and constructs color, and another part of the brain makes a decision about how the body will react to that image.

Eyes themselves can be classified as either chamber (or simple) or compound types. Chamber eyes have a single entrance for light, compound eyes have multiple entrances. But both produce an image on a retina—light sensors that do not cannot be branded eyes. The evolution of simple light sensors to become the first eyes during life's history holds hidden significance for eye evolution. This entry describes the evolution of the first eye, how the eye evolved, deficiencies of the eye, and the Cambrian explosion.

When Did the First Eye Evolve

For the first few hundred million years of multi-celled life on Earth, animals were blind, yet the selection pressures for vision were always immense. Holding back visual evolution was likely the high energy costs to build and maintain an eye.

That first eye, however, evolved in a trilobite (an arthropod predator, a distant relative of shrimps), around 524 million years ago (see Figure 1). Before that, animals possessed only simple light sensors. This is where the difference between an eye and a light sensor really matters. Light sensors provide information about night and day, or up and down in the water column. Eyes, on the other hand, allow animals to interact with each other using light as a stimulus. Eyes have evolved independently many times since, but the first eye to evolve introduced the sense of vision.

Notes: Around 524 million years old, frontal view. Eyes are protruding from the head shield (left eye is casting a shadow)—this was one of the first animals on Earth with eyes.

How the Eye Evolved

To understand the evolution of the eye, a computer model was developed that replicated the stages of evolution (Figure 2). This model showed

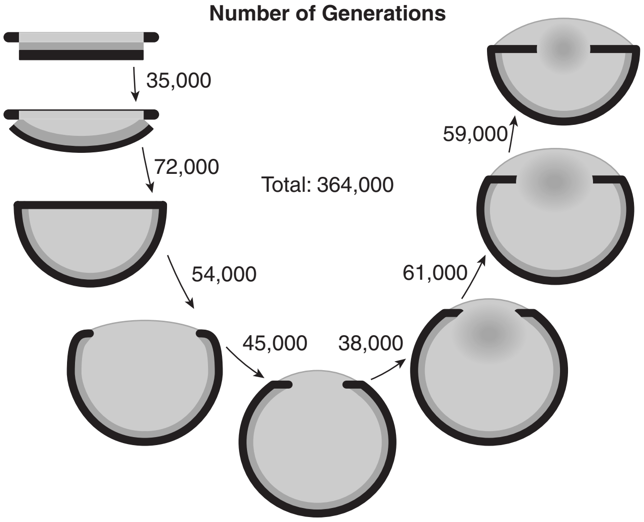

Figure 2 Dan-Eric Nilsson and Susan Pelger's Computer Model of the Evolution of a Chamber Eye

Source: From Land and Nilsson (2002).

Notes: A patch of light sensitive cells, with an outer (transparent) protective layer and a background dark, absorbing layer, evolves under a continuous selection for improved vision. The remaining parts of the visual system, however, do not necessarily evolve in parallel—imperfect vision can exist.

how a patch of light-sensitive skin could gradually transform into a chamber eye within 2,000 sequential changes, or just 364,000 generations (as a pessimistic estimate). The organ alters to first determine between sunlight-on or sunlight-off, then to sense the direction of sunlight, and finally to form an increasingly well-resolved image. The important point is that each stage confers an improvement in light perception or vision over its predecessor.

Recent research has centered on photoreceptor evolution based on molecular biological advances. Gene encoding opsin—the protein component of the light-sensitive visual pigment—and some developmental genes date back beyond the first eye and were recruited repeatedly during the evolution of different eyes, possibly between 40 and 65 times. Researchers can demonstrate the role of these developmental genes in the model organism *Drosophila*. By activating the developmental genes in different cells within a developing embryo, eyes will sprout on the legs and wings of the adult fly.

The evolution of lenses may owe something to physical phenomena such as molecular self-assembly or crystallization. If an enzyme, such as a liver enzyme, is overproduced within a cell, it will crystallize; our own lenses are formed this way. The phenomenon of crystallization enhances the effects of genetic mutation in the evolutionary process. Work underway aims to demonstrate this using the living cells that make the unusual calcitic lenses in brittle stars.

Deficiencies

There are signs of deficiencies—or what some might call imperfections—in all eyes. For example, in comparison with the retina of other animals, the human retina is inside out, with nerve fibers running back into the path of light rather than behind the retina (as they do in the eyes of squid).

Imperfections can also include failure to deliver on visual requirements. Such shortcomings can be revealed within the competition that exists between the eye of a predator and the color of its prey, for instance. Humans posses trichromatic vision (three types of cones in the retina, each responding to a different wavelength range), so we can see cuttlefish resting on the sea bottom, but cuttlefish predators cannot. Predators, in this case, are dolphins with monochromatic vision (they see in black and white because they have only one type of cone cell in their retinas), under which the cuttlefish are well camouflaged. A limitation of the human visual system is that we do not see ultraviolet light and, consequently, miss the ultraviolet patterns of flowers that attract insects.

Cambrian Explosion

Today, vision is the most universally powerful sense in its impact on animal interactions and behavior. With the evolution of the first eye, the size, shape, color, and behavior of animals were revealed for the first time—the position and movement of animals could be accurately tracked. Hence, the introduction of vision can be considered to be the launch of the most powerful weapon on Earth. And it evolved relatively quickly in evolutionary time. The evolutionary countermeasures sparked within the other, non-sighted, soft-bodied animals of the time were likely significant. Beginning immediately after this was the main event of the Cambrian explosion (approximately 540 million years ago), when animals simultaneously and independently evolved their hard parts. According to the light switch theory, the eye was the impetus for this event.

Since that first eye, vision has remained on Earth. Although only 6 of the approximately 37 animal phyla possess eyes, more than 95% of all species belong to these. Vision has been a powerful weapon and a successful innovation in the animal kingdom.

EYEWITNESS TESTIMONY

Texas resident Larry Fuller was officially pardoned in 2007 for a rape he did not commit and for which he spent 19 years in prison—one of more than 200 erroneous convictions overturned by DNA evidence in the United States since 1989. In at least 75% of these cases, as in Fuller's, eyewitness error contributed to wrongful conviction. Partly to understand such errors, eyewitness scientists have built on 100 years of memory research in psychology to develop principles of perception and memory specific to the eyewitness experience. In the process, memory myths frequently held by both professionals and laypersons have been challenged. For example, research findings during the past three decades contradict the common belief that memories for traumatic events lie hidden in pristine and recoverable form. A more sophisticated and nuanced understanding has emerged—that any experienced event is perceived and encoded incompletely into memory and later recalled as an amalgam of true recollection and intruding non-memory elements. This entry describes issues relating to eyewitness testimony.

A police investigator might describe the perfect eyewitness as an observer who is attentive to all that transpires during a crime, who draws all meaningful crime details into memory, retains that information across time, and later recollects the crime with total accuracy. This ideal memory process—encoding, retention, and retrieval of experienced events—begins with perception. Before any information can be encoded into memory, an eyewitness's perceptual systems must be successfully deployed. Visual acuity, sharp hearing, and such properties of the senses, along with one basic requirement, namely that the witness is paying attention, will affect the quality of information available for encoding crucial details into memory. Unlike the ideal, however, actual eyewitnesses have less than perfect perception, a problem compounded by the complexities of the crime and the viewing environment (e.g., distance, illumination, visual obstructions, and perpetrator disguise). The limitations of human perception constrain the quality of resulting memory.

The eyewitness literature catalogues many perceptual difficulties for eyewitnesses, that is, factors that reduce the likelihood that useful, veridical details of a crime, including details about the perpetrator, are brought into and retained in the observer's memory. First, the eyewitness's attention to the event is crucial. The *weapon focus effect* exemplifies the intersection of crime context and perceptual processes. During a crime of short duration that involves a weapon, the eyewitness's attention is typically riveted on the threatening weapon that is suddenly central to his or her well-being. Later attempts to recollect peripheral details and recognize the perpetrator are less successful than for those eyewitnesses exposed to the same stimulus event without a weapon. This narrowing of visual attention can even interfere with the perception of auditory information. Also, witnesses tend to focus on action rather than persons, resulting in incomplete memory for the offender. Field demonstrations of *change blindness* further indicate that observers who concentrate on a central action or task fail to notice even large adjustments in the broader visual field. For example, 50% of persons who were asked by a stranger for campus directions and then unknowingly subjected to an experimental sleight-of-hand in which the stranger was surreptitiously replaced by a different person (as construction workers carried a large door between the subject and requester, temporarily blocking the subject's view of the stranger) failed to recognize the change even as they continued to provide the requested directions.

The short duration of many crimes also is disruptive to perception. Faces and events seen for only a brief time are difficult to scan completely or to perceive at a detailed level. Consequently, an offender of average appearance (absent a salient or distinguishing feature) may generate a nonspecific and blurry memory in the eyewitness. A perpetrator's disguise by hat, mask, or hood will reduce the facial-feature cues necessary for later identification, particularly if the hair or hairline is masked, as will a change in perpetrator appearance between event and later attempts at identification. Also, eyewitnesses are prone to distorted perception: Perpetrators are likely to seem taller and the duration of a brief crime longer than objective reality.

The stress of a crime will often constrain perceptual and encoding processes. Contrary to lay belief that a high level of stress will enhance memory ("I was terrified . . . his face is burned into my memory"), research in both lab and field demonstrates that although stress heightens alertness, high stress may disrupt effective encoding of details. A recent field test of military personnel in rigorous survival school interrogations documented dramatic reductions in eyewitness identification accuracy (later recognition of their interrogators) for high, versus low, stress conditions.

Individual witness characteristics may determine what the eyewitness pays attention to and the detail that is encoded. For example, a car buff may quickly discern the model of the get-away vehicle, or a gun expert may recognize the type of weapon. The high stimulus load of a complex crime event, criminal or civil, may be difficult to meaningfully encode by an eyewitness who is startled by or cognitively unprepared for such an occurrence. Similarly, an intriguing aspect of crime perception—and a principle that presumably rests on the past experience of the witness as well as the viewing opportunity—is the ability of eyewitnesses to more accurately perceive and later recognize the face of a same-race offender (the *own-race bias*). Finally, individual expectations about events influence how crimes are perceived. In general, we have a tendency to see what experience and beliefs have taught us to expect.

Scientists now understand that the content of perception—what the witness believes he or she saw at the time of the crime event—can be disrupted and changed through subsequent experience. Research has established beyond question that information from outside the true event can unwittingly fill memory gaps and rewrite memory, even for the face of the offender, a phenomenon dubbed the *misinformation effect.* More dramatically, whole episodic memories can be constructed from imagination in the absence of true experience. Indeed, laboratory participants have been led to believe that in childhood they were lost in a shopping mall for an extended time, broke a window and cut themselves, were attacked by an animal, or endured other upsetting experiences—"memories" in the absence of direct perception of a real personal event.

The trustworthiness of eyewitness testimony is further damaged by the fact that eyewitness confidence is distorted by factors external to true memory, for example, an investigator's confirmation that the eyewitness has chosen the police suspect from a lineup, or a therapist's affirmation of belief in the veracity of a client's recovered memory. Of particular relevance to perception processes is *the post-identification feedback effect.* An eyewitness who has received confirmatory feedback after a police lineup decision ("Good, you identified the suspect"), even if the choice is wrong, will report significantly more certainty about the identification than will a witness who did not receive feedback. Even more unsettling, the witness whose identification choice is confirmed will convey distorted retrospective memory for how the event *was perceived,* claiming a better view and greater attention paid to the perpetrator. The testimony of this eyewitness is likely to be quite believable at trial because he or she truly accepts this version of reality.

To improve the probative value of eyewitness evidence, scientists continue to investigate procedural strategies for interviewing and evidence-gathering, to protect the memory of the eyewitness and to keep the eyewitness's retrieved memory in close synchrony with original perception. Science-based eyewitness procedures help minimize future risk for the kind of tragedy that befell Larry Fuller and other victims of false identification and wrongful conviction.

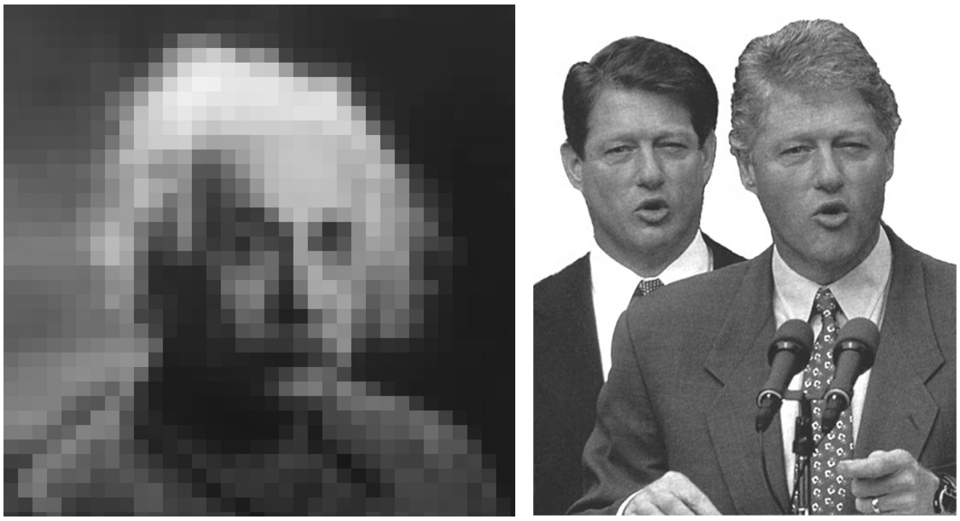
FACE PERCEPTION

Faces constitute one of the most pervasive and important classes of objects in our visual environment. The human visual system is remarkably proficient at various face perception tasks, including identification, emotion assessment, gaze estimation, and gender, race, and age classification. Much research effort has been directed toward elucidating the facial cues that underlie these different assessments, with identification attracting the lion's share. This entry provides an overview of four key aspects of human face perception performance: (1) tolerance for degradations, (2) relative contribution of geometric and photometric cues, (3) development of face perception skills, and (4) neural correlates of face perception.

Limits of Human Face Recognition Skills

The high resolution of foveal vision allows the human visual system, in principle, to discriminate between individuals on the basis of fine differences in their facial features. Analogously, progressive improvements in camera resolution make it possible to use increasing amounts of detail in face representations in machine vision systems. The advent of iris-based biometric systems, which use the fine details of iris patterns as identifying signatures, is a case in point. However, the problem that such details-based schemes often have to contend with is that high-resolution images are not always available. This is particularly true in situations where individuals have to be recognized at a distance. When seen from a distance, the image of a face occupies a small area of the retina, and thus is sampled by only a few photoreceptors. In effect, only the coarse low-resolution structure of distant faces is available for further processing. Precisely how does face identification performance change as a function of image resolution? This question is relevant for characterizing human face recognition performance, and for understanding the fundamental face representation strategies used by the visual system.

Working with block averaged images of familiar faces of the kind shown in Figure 1(a), researchers have found that observers can recognize faces well above chance levels with image resolutions of merely 7 × 10 pixels, and reach ceiling levels by resolutions of 25 × 30 pixels. The remarkable tolerance of the human visual system to resolution reduction demonstrates that fine featural details are not necessary to obtain good face recognition performance. Furthermore, given the indistinctness of the individual features at low resolutions, it appears likely that diagnosticity resides in their overall configuration. However, precisely which aspects of this configuration are important, and how we can computationally encode them, are largely open questions. Tentative clues to the answer come from experiments probing the relative saliencies of different facial features. Figure 1(b), for instance, demonstrates the perceptual importance of overall head configuration for face recognition. The internal features on their own and even their mutual configuration appear to be



(a) (b)

Notes: (a) Images such as the one shown here have been used by several researchers to assess the limits of human face identification processes. (b) Although this image appears to be a fairly run-of-the-mill picture of Bill Clinton and Al Gore, a closer inspection reveals that both men have been digitally given identical inner face features and their mutual configuration. Only the external features are different. It appears, therefore, that the human visual system makes strong use of the overall head shape to determine facial identity.

insufficient to account for the impressive recognition performance of subjects with full face images.

Cues for Face Recognition

For a cue to be useful for recognition, it must differ across faces and be consistent for a given face. Such a cue would be an *intrinsic* attribute of the face, such as its two- and three-dimensional shape, or pigmentation. A cue that differs indiscriminately, irrespective of facial identity, would be expected to be ignored by the human visual system. This would be an *extrinsic* cue, such as illumination. How perceptually important are these two sources of facial image variability?

Illumination greatly affects the image level appearance of a face. Surprisingly, humans appear to be unable to completely ignore illumination induced image changes while performing recognition tasks. When observers are asked to match different images of the same face, performance is worse when the two images of a face to be matched are illuminated differently. However, this confound is less pronounced for familiar faces, and naming performance for such faces is largely invariant across different illumination conditions, except for some unusual circumstances, such as lighting from below. Taken together, these results suggest that illumination-induced image changes are included in facial representations, but with increasing familiarity with a face (and, presumably, viewing it across many different lighting conditions), the contribution of illumination to recognition performance becomes less pronounced.

Besides lighting, two additional sources of variability for faces are their shape and their pigmentation. Given that we can recognize individuals even in unpainted stone busts, it is clear that shape cues on their own can support recognition. These anecdotal observations are supported by results from systematic studies with three-dimensional (3-D) laser-scanned faces that similarly lack variation in pigmentation. However, the ability to recognize a face in the absence of pigmentation cues does not mean that pigmentation cues are not used when available. Indeed, pigmentation may also be important for face recognition. Unlike other objects, faces are much more difficult to recognize from a line drawing than from a photograph, which suggests that the missing pigmentation cues may well be important.

Recently, some researchers have attempted to directly compare the relative importance of shape and pigmentation cues for face recognition. The basic approach is to create a set of face representations with the shape of a particular face and the average pigmentation of a large group of faces, and a separate set of face representations with the pigmentation of an actual face and the average shape of many faces. The rationale here is that to distinguish among the faces from the set that all have the same pigmentation, subjects must use shape cues, and vice versa for the set of faces with the same shape. Subjects are trained with one or the other set of face images and are subsequently tested for memory. Recognition performance is found to be about equal with both the shape and pigmentation sets, suggesting that both cues are important for recognition.

Evidence indicates that all sources of facial image variability affect the internal representations. When considering extrinsic cues such as illumination, this is somewhat of a drawback because a factor that is unrelated to facial identity ends up influencing performance. However, for the intrinsic cues of shape and pigmentation, the visual system behaves in an appropriately opportunistic fashion, making use of all cues that vary across exemplars of this class to achieve its impressive face recognition skills.

Development of Human Face Recognition Skills

Basic face perception skills develop surprisingly rapidly during an infant's development. As early as a few days after birth, infants appear to be able to distinguish their mother's face from other faces. Yet, after this initial phase of rapid progression in face recognition abilities, the full maturing of children's face-processing abilities is a long drawn out process, estimated to take more than a decade. This section outlines the trajectory of development of face processing.

Evidence From Newborns

As is the case for most visual skills, face processing must be connected with some primitive mechanism from which more advanced processes can be learned. A key question is are infants born with some innate abilities to process faces or are those abilities a consequence of general visual learning mechanisms? To examine this issue, newborns are assessed for various abilities as soon as is practical after birth. Three major findings have historically been taken as evidence for innate facial processing abilities: (1) the initial preference for faces over non-faces, (2) the ability to distinguish the mother from strangers, and (3) imitation of facial gestures.

Innate Facial Preference

Are infants pre-wired with a face detection algorithm? If infants knew how to locate the faces in an image, it would be a valuable first step in the subsequent learning of face recognition processes. John Morton and Mark Johnson formalized this idea into a theory called *CONSPEC and CONLERN.* CONSPEC is the structural information that guides newborn preferences for face-like patterns. CONLERN is a learning process that extracts further visual characteristics from patterns localized based on CONSPEC.

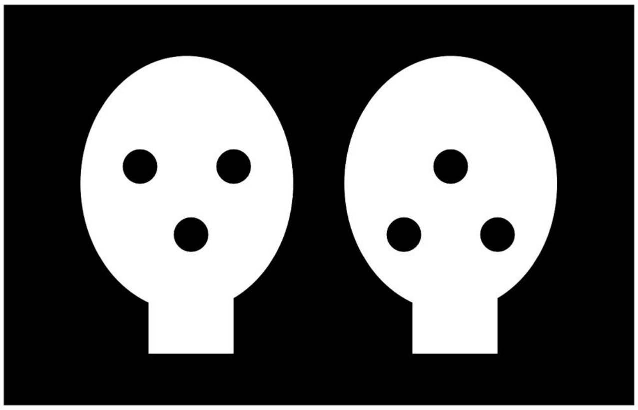

Figure 2 Newborn Gaze Orientation

Source: Johnson & Morton, 1991.

Notes: Newborns preferentially orient their gaze to the face-like pattern on the left, rather than the one shown on the right, suggesting some innately specified representation for faces.

Some supporting evidence for this theory comes from the fact that newborns do indeed preferentially orient their gaze to face-like patterns. When presented with a rudimentary drawing of a face, upright or inverted (Figure 2), newborns are reported to gaze longer at the upright pattern. The two patterns are largely identical except for their "faceness" and the infants have had little visual experience before the presentation, so this finding is interpreted as a demonstration of newborns' innate preference for faces.

Distinguishing the Mother From Strangers

Further evidence for innate mechanisms for facial processing comes from the remarkable ability of newborn infants within less than 50 hours of birth to discriminate their mothers from strangers. Newborns suck more vigorously when viewing their mother's face on a videotaped image. They also are capable of habituating to a mother's image, eventually preferring a novel image of a stranger, showing a classic novelty preference. External facial features, especially hair, are believed to underlie much of this discriminative performance of newborns.

Imitation of Facial Expressions

It has been reported that newborns are capable of imitating their caregivers' facial expressions. This would entail the infant's recognizing the expression, then mapping it to its own motor functions. Many studies have shown evidence of imitation. However, there have been some failures to replicate this result. Moreover, consistent positive results have been found primarily for one expression, namely, tongue protrusion. This action might be an innate releasing mechanism, perhaps to a surprising stimulus, or an attempt at oral exploration. Thus, the action might be a response to the stimulus, rather than a recognition of it followed by imitation.

Developmental Progression Beyond Infancy

Although infant face recognition proficiency develops rapidly within the first few months of life, performance continues to improve to the age of 10 years or even later. The best-studied progression is the use of featural versus configural facial cues.

Adults match upright faces more easily than inverted faces (the so-called inversion effect). This is believed to be a consequence of the disruption in configural processing in inverted faces. Interestingly, 4-month-old infants do not show this decrement in performance if the images to be matched are otherwise identical. However, the inversion effect does appear in 4-month olds if, for instance, pose is manipulated at each presentation of the face. Thus, evidence indicates that configural cues start to play some role in face processing at this early age, although the processing of these cues is still rudimentary. Processing based on features appears to play the primary role in infant facial recognition. Given the early onset of the usage of configural cues in child face recognition, rudimentary though it may be, one would expect that full maturation of such a fundamental system would ensue rapidly. However, numerous studies have found that, although face recognition based on features reaches near-adult levels by the age of 6 years, configural processing still lags behind until at least 10 years of age, with a gradual progression of greater accuracy and dependence on configural cues.

Neural Underpinnings of Human Face Perception

Whether faces constitute a "special" class of visual stimuli has been debated for many years. Since the first demonstrations of the inversion effect described previously, it has been suspected that unique cognitive and neural mechanisms may exist for face processing in the human visual system.

A great deal of evidence shows that the primary locus for human face processing may be found on the fusiform gyrus of the extrastriate visual cortex. This region shows an intriguing pattern of selectivity (schematic faces do not give rise to much activity) and generality (animal faces do elicit a good response), suggesting a strong domain-specific response for faces. In keeping with behavioral results, the fusiform face area (FFA) also appears to exhibit an inversion effect. Overall, the characterization of the FFA as a dedicated face-processing module appears strong. Developmental studies indicate a progressive strengthening of FFA activity with age. In a paradigm comparing the passive viewing of faces versus houses, younger children (8–10 years) showed weaker activation in the fusiform gyrus, relative to older (12–14 years) children. Thus, although the neuroimaging data are preliminary at the present, they do appear to be broadly consistent with the behavioral data showing continuing development of face processing well into adolescence.
