Cheese — Cosmology

Cheese

A food product selectively concentrated from major milk components. It is generally rich in flavor and contains high-quality nutrients. There are many varieties of cheese, all produced in the following general manner: Raw or pasteurized milk is clotted by acid, rennet, or both. The curd is cut and shaped into the special form of the cheese with or without pressing. Salt is added, or the cheese is brined after pressing.

Acid is produced during manufacture of cheese by fermentation of the milk sugar, lactose. This fermentation is initiated by the addition of a culture of specially selected acid bacteria (starter culture) to the milk. Acid production in cheese curd retards growth of bacteria that cause undesirable fermentations in cheese. Moreover, it favors the expulsion of the whey and the fusion of the curd particles. Fresh cheese (cottage or cream cheese) does not require any ripening, and it is sold soon after it is made. Other varieties of cheese are cured or ripened to obtain the desirable consistency, flavor, and aroma. The flavor and aroma of cheese are obtained by a partial breakdown of milk proteins and fat by the action of microbial, milk, and rennet enzymes. In hard varieties (Cheddar, Gouda, Edam, Emmentaler or Swiss, and provolone) this is done by the microorganisms in the interior of cheese; in semisoft or soft types (Limburger, Camembert, and Roquefort) by the organisms on, or in contact with, the surface of cheese. *See* MILK.

Cheese Microbiology

Microorganisms are essential to the manufacture of cheese, imparting distinctive flavor, aroma, consistency, and appearance.

Starter cultures. Lactic acid starter cultures are important in making cheese. Different types of lactic acid bacteria (*Lactococcus lactis, L. lactis cremoris, Streptoccus thermophilus*, and homofermentative lactobacilli) are used, depending upon the kind of cheese desired. The starter (both single and mixed strains of bacteria are used) must convert all milk sugar left in the curd into lactic acid within a reasonable time. Several factors may prevent this: the occurrence of natural inhibitors in milk, antibiotics, and bacteriophages.

Some antibiotics (such as nisin) which affect the activity of the starter may be produced by microbes in the milk. Others may be excreted into the milk by cows treated for a particular disease; this happens if penicillin is used to treat mastitis. *See* ANTIBIOTIC.

Bacteriophages, or phages, are viruses which lyse sensitive bacterial cells (**Fig. 1**) and produce new phage particles. Phage particles may get into the milk with infected starter cultures or through contamination with phage-carrying dust particles. Phage

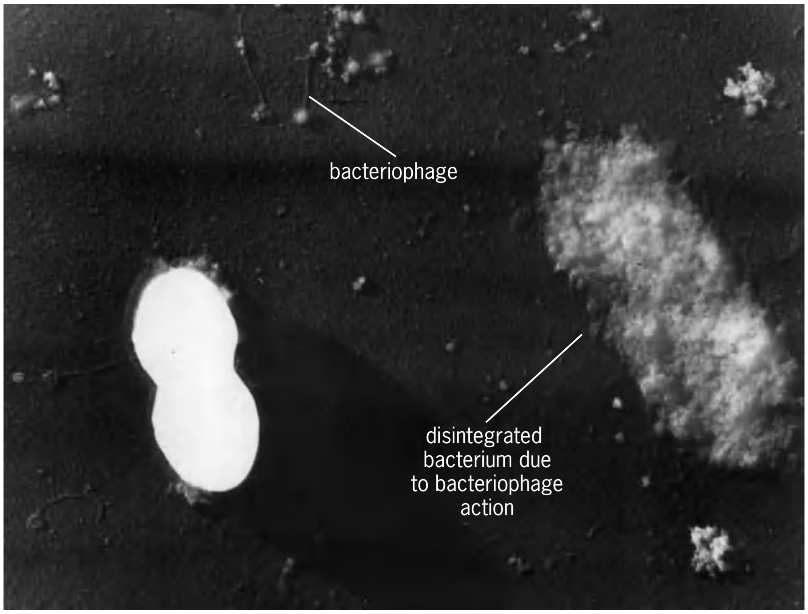

Fig. 1. Electron photomicrograph of *Lactococcus lactis* attacked by phages.

particles slow down or totally inhibit the activity of the starter culture, causing insufficient souring and spoilage of cheese. Phage multiplication is influenced by temperature, pH, and calcium content of the medium. Phage outbreaks cause serious economic losses. They can be controlled by rigorous hygienic handling of starters, by culture rotation, or by culturing starters in calcium-free media. Attempts to isolate phage-resistant strains have not met with success. *See* BACTERIOPHAGE; STREPTOCOCCUS.

Flora of cheese. Cheeses of the hard type contain lactic acid lactococci and other bacteria present in the starter. Moreover, they contain all the microorganisms originally present in the raw milk or pasteurized milk. The types of bacteria most important for ripening are the lactococci, lactobacilli, micrococci, and propionic acid bacteria. They, together with the enzymes of rennet and milk, break down the proteins to peptides and amino acids, hydrolyze the milk fat to fatty acids, and frequently produce carbon dioxide gas which causes the holes in cheese (**Fig. 2**). The structure of cheese is greatly changed during ripening.

In semisoft and soft cheeses the lactic acid originally produced by the starter is broken down afterward by molds, yeasts, and bacteria on the surface. The same flora decomposes the protein and the fat to a much greater extent than in hard cheeses. As a result, strong flavors are produced and the structure of the cheese becomes much softer. For the production of blue-veined cheese, needles are pushed into the interior to bring *Penicillium roqueforti* or the other molds, added during the manufacturing of the cheese, into contact with air they need for growth. The blue color is the color of the mold spores. The red color on the surface of some soft cheeses is caused by *Brevibacterium* (*Bacterium*) *linens* and micrococci. For good surface growth, soft cheeses must be cured in high-humidity air (caves or air-conditioned rooms).

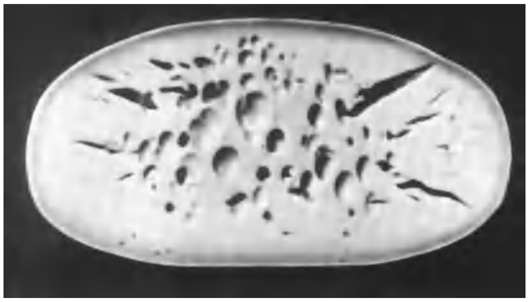

Fig. 3. Late blowing in Gouda cheese.

Fig. 4. Evidence of late gas production during the cheese ripening process.

Defects of cheese. In hard cheeses an abnormal gas formation is a problem. It can occur at almost any stage of manufacture or ripening. Early gas production can be caused by coliform bacteria or heterofermentative lactic bacteria. Gas production during cheese ripening (late gas, as in **Figs. 3** and **4**) may be caused by certain sporeforming bacteria, propionic acid bacteria, *Leuconostoc* species, and *Lactococcus lactis lactis* (biovar *diacetylactis*). The use of *L. lactis lactis* (biovar *diacetylactis*) and *L. lactis* as lactic starter cultures can cause fruity flavors, as well as gas formation, in Cheddar cheese. Other defects of hard cheese include insufficient or excessive acidity, various off flavors, and discoloration. Soft cheeses may be spoiled by gas production, excessive acidity, improper development of surface flora, and contamination with atypical molds.

Cheese blending. Cheeses of different ages are blended. The mixture, melted with the aid of emulsifying salts (citrates and phosphates), is packed in sealed containers (tins, paperboard, foil, or plastic). Few bacteria other than sporeformers survive the heat treatment. No substantial growth of the flora takes place in well-preserved processed cheese, but spoilage by anaerobic sporeformers may occur.

Clostridium sporogenes causes putrefaction and slit openness and *C. tyrobutyricum* causes blowing of tins and packages. Acidity, salt content, and temperature of storage are important in controlling spoilage. *See* INDUSTRIAL MICROBIOLOGY. Norman Olson

Cheese Manufacture

More than 150 countries make cheese, but 34 countries produce the major commercial quantities. Primitive cheesemaking exists in much of Africa, Latin America, and southwestern Asia, but advanced techniques are also found in these regions. Cheese manufacturing in developed world areas may be simple too, including that for the sheep-milk Broccio of Corsica, the mountain cheese of the Alps, the queso blanco of Venezuela, and the Pennsylvania pot cheese of the United States, but generally it is highly mechanized. Whether the method is primitive or sophisticated, the quality of the resulting cheese is usually excellent.

The primary objective of cheesemaking is to form a smooth acid curd, to reduce the size of the curd block and remove the whey, with or without prior cooking, and to salt and shape the curds. A different type of cheese emerges when the intensity of approximately eight steps is stressed or minimized as required; when special applications, usually microbial, are introduced; and when the environment is transformed to fit the optimum needs of a specific cheese type.

Materials. Key materials for cheesemaking include fresh or precultured milk, cultures, milk-coagulating enzyme preparations, special microorganisms, salt, and beta carotene or annatto color. The amounts used and the manner in which these materials are applied strongly influence the cheese character. Cheese may be made from the milk of the cow, sheep, goat, water buffalo, and other mammals, but the milk of the cow is most widely used despite some limitations. Sheep milk and water buffalo milk generally give more flavor to the cheeses, and the color is uniformly white because of a lack of carotene in such mammalian milks, but they are more expensive to make into cheese.

Major classes of cheeses. Two major classes of cheeses exist, fresh and ripened. Fresh cheeses are simpler to make than ripened, are more perishable, and do not develop as intense flavors, but give a mild acid, slightly aromatic flavor and soft, smooth texture.

Fresh cheeses. Three basic groups characterize fresh cheese types: group I—ricotta and Broccio; group II—cottage, Neufchâtel, and cream; and group III—mozzarella. Curd formation for these fresh cheese groups results from a combination of acid (pH 6.0) and heat (176°F or 80°C), as in group I; from acid alone to give a pH 4.6, as in group II; or from rennet (an enzyme preparation) at pH 6.3, as in group III. Essentially a dehydration of protein occurs, along with a partial or complete reduction of the negative electrical charges which surround the surfaces of the milk proteins. At a critical point, precipitation occurs, leading to a smooth gelatinous curd of varying strength. The curd may be scooped directly into cloth bags or perforated containers for immediate draining and eventual packaging, or the curd is cut and cooked, followed by drainage of whey, salting, and creaming.

Ricotta. Ricotta, or recooked cheese, in its most acceptable form is made from acidified whole milk heated to 176°F (80°C). By introducing large amounts of lactic starter culture, acid whey powder, food-grade acetic or citric acids, and small amounts of salt to cold milk and heating to the above temperatures in a kettle, smooth white particles appear which rise to the top and collect as a curd bed, which is left undisturbed. In about 30 min the hot curd is scooped into perforated containers for drainage and cooled. Later it is removed and consumer-packaged. The product is utilized directly or in a variety of Italian dishes.

Cottage. Cottage cheese is made from pasteurized skim milk, and in uniform discrete particles classified as small or large curd. A curd forms when the increasing lactic acid of milk during fermentation attains the isoelectric point of casein at pH 4.6. This soft curd additionally contains lactose, salt, and water. Later the curd matrix is cut and cooked to about 126°F (52°C). Separation of whey from the curd is rapid, and is followed by two or three water washings at warm to chill temperatures. Washing removes whey residues and acts as a cooling medium. After drainage of the last wash water, the chilled curd is blended with a viscous, salted creaming dressing to give 4.2% fat and 1% salt, and is packaged. One unsalted, uncreamed, nonfat form of cottage cheese has less flavor, calories, and sodium than standard cottage cheese. Another form is creamed to 9–11% fat and pressed as farmer's pressed cheese. *See* ISOELECTRIC POINT.

Cream and Neufchâtel. Cream and Neufchâtel cheeses resemble cottage cheese in manufacture, but they are made from high-fat mixes instead of skim milk, and no effort is undertaken to attain discrete particles. The minimum fat content of Neufchâtel cheese is 20%, and of cream cheese 33%. The cloth bags traditionally used to separate the whey from the curd have been replaced by centrifugal curd concentrators, which separate the stirred curds and whey at 165°F (74°C). The curd thereafter is pasteurized, treated with stabilizer or gums to prevent water leakage, and salted and homogenized hot. This hot mass is packaged and sealed directly, and tempered at room temperature for a number of hours. The products are used as spreads, in salads, and in cheesecake.

Cottage cheese keeps well at refrigerated temperatures for at least several weeks, but hot-pack cream and Neufchâtel cheeses, because of earlier exposure to high temperature and sealing hot in packages, maintain freshness for up to 2 months or more. Common microbial spoilage agents are molds and yeasts and frequently *Pseudomonas* bacteria which grow at low temperatures.

Mozzarella. Natural mozzarella cheese is normally made from pasteurized whole milk, but milks of 1 or 2% fat may be used if the cheeses are properly labeled. The warm cheese milk is incubated with lactic acid bacteria (*Lactococcus lactis*, *Streptococcus thermophilus*, or *Lactobacillus delbreuckii bulgaricus*), or may be directly acidified by the addition of food-grade acids such as acetic or citric. Added rennet coagulates the milk to a smooth curd, which is cut with wire knives. The curds, without cooking, may be drained of whey shortly after cutting or, depending upon the type of bacteria, may be cooked to 117°F (47°C) before whey removal. The blocks or patties of curd which result from this action are retained until a pH 5.2–5.5 is achieved, and then are milled into small cubes, placed in hot water, and stretched and molded until smooth. The resulting rectangular blocks are cooled and brined for 2–8 h, depending upon size, and dried and vacuum-packaged.

Acceptable natural mozzarella cheese has a bland, slightly acid flavor. It melts uniformly and smoothly when exposed to hot oven temperatures of 428°F (220°C) for a few minutes and, depending upon type, maintains its quality from several weeks to several months. Natural mozzarella cheese is used in a wide assortment of Italian dishes. Imitations containing vegetable fats, artificial flavors, and a variety of additives are made mainly for institutional and food supplementation use.

Ripened cheese. Ripened cheese is exposed to an optimum environment of temperature and moisture for a period of time to attain characteristic flavor, texture, and appearance. It may be made from raw, heat-treated, or pasteurized milk that is coagulated with a rennet preparation to form a smooth curd. After cutting and cooking to 95–131°F (35–55°C), the curds are salted, before or after pressing, and shaped. The pressed curds, usually salted, may be given a special microbial application, and then are usually held at 41–59°F (5–15°C) in rooms under controlled humidity (85–95%) to develop the desired traits. All standard ripened cheeses are salted, and the milks from which they are made are always coagulated with rennet, usually in the presence of small amounts of lactic acid and sometimes added calcium chloride.

Rennet milk coagulation occurs when rennin, a protease from rennet, hydrolyzes or splits kappa casein from casein into a whey-soluble component, glycomacropeptide. The cleavage of kappa casein by rennin destabilizes the casein molecule, permitting its dominant alpha and beta casein components in micelle form to precipitate. Such coagulated proteins are filamentous and, through strand overlapping under quiescent conditions, appear as a smooth, homogeneous, sweet (pH 6.3) gel or curd. This curd is cut and cooked, leading to a contraction which expresses whey. The dry curds thereafter are salted, pressed, and ripened. *See* MICELLE; RENNIN.

During ripening, many flavor compounds arise in the cheese. They include free fatty acids, amino acids, ketones, diacetyl, and alcohols. Their amounts in a balanced ratio, along with major components of the cheese, largely determine the characteristic flavor. Agents involved through proteolytic, lipolytic, decarboxylation, and deamination reactions include rennin, natural bacteria of milk, added microorganisms, natural milk enzymes, microbial enzymes, and added food-grade enzyme preparations. The microbial enzymes evolve from millions of microbial cells present in cheese; the sources of the added food-grade enzyme preparations usually are fungal.

Most ripened cheeses are contained in one of six basic groups. The characteristic cheeses in each group include: group I—Cheddar and Monterey; group II—Swiss (Emmentaler) and Gruyère; group III—Edam and Gouda; group IV—Muenster, brick, and Limburger; group V—provolone; and group VI—Camembert, Brie, and blue.

Cheddar and Monterey. For these cheeses the curds are formed at 88°F (31°C) by 0.2 qt (200 ml) of rennet in 2200 lb (1000 kg) of underheated whole milk previously inoculated with 1–2% lactic-type starter for 15–30 min. The curds are cut with wire knives, and cooked to 99°F (37°C) for 30–60 min. Then the whey is run off, and the curd bed is cut into rectangular blocks weighing approximately 11 lb (5 kg). These blocks usually are turned over every 15 min for 2 h in a step known as cheddaring, and the stringy nature of the curd evolves as sufficient lactic acid develops to give a pH of 5.3. The blocks, now flatter than at the start, are milled to small cubes, and dry-salted at the rate of 5 lb (2.3 kg) of salt per 220 lb (100 kg) of curd. These salted curds are pressed in single-service paper or cloth-lined stainless steel boxes. The standard 44- to 66-lb (20- to 30-kg) forms which result are removed, and repressed in plastic films of low oxygen permeability. The film-wrapped Cheddar cheese is ripened up to 1 year at 41–50°F (5–10°C). It is generally manufactured into various-size forms prior to reduction into consumer packages.

In modern industrial cheesemaking, another form of Cheddar cheese, known as barrel, is made by the stirred-curd step in contrast to the cheddaring. This avoids the more lengthy period required for the latter. In the stirred-curd step, individual small cut curd particles, after cooking and whey separation, are stirred for about 30 min, salted, and packed into large film-lined metal or fiber barrels of 640-lb (290-kg) capacity. Here, after excess whey is removed, the curds are pressed and the containers sealed and placed in ripening rooms. Later, the cheese is removed and used largely for making processed cheese. Ripening cheese in large blocks appears to improve typical flavor quality, so that some cheese that is cheddared and destined for long ripening, too, may be held in 640-lb (290-kg) capacity film-lined, sealed boxes.

Monterey cheese resembles Cheddar, but has a higher moisture level and ripens more rapidly. Its curds are washed with water in the vat and not cheddared, but are stirred prior to salting and then added to lined standard stainless steel forms for pressing and eventual ripening.

Swiss (Emmentaler) and Gruyère. Swiss and Emmentaler cheeses are the same, but in the United States the term Swiss is widely used, whereas in Europe and elsewhere the name is Emmentaler. The cheeses are made in block or round forms, but in the United States the former shape dominates because it is easier to slice for sandwiches. Also, economics of production are enhanced.

Underheated milk (158°F or 70°C for 16 s), standardized or partly skimmed, is set with rennet to form a curd, accompanied by three special bacterial cultures, *Streptococcus thermophilus, Lactobacillus delbrueckii bulgaricus*, and *Propionibacterium shermanii*. These cultures influence the acid, eye, flavor, and texture development of the cheese. *Propionibacterium shermanii* is mainly responsible for eye and typical flavor formation.

Renneting requires about 30 min by using 0.2 qt (180 ml) of rennet per 2200 lb (1000 kg) of warm (88°F or 31°C) milk. The size of the curds after cutting is very small, about like peas. These are cooked to about 126°F (52°C) in 60 min, and stirred until the pH decreases to 6.3.

To make block Swiss cheese, these stirred, cooked curds and considerable whey are pumped into cloth-lined, perforated stainless steel chambers. Here a large block is formed under the warm whey, the whey is removed, and the bed of curd remaining is cut into about 100-lb (45-kg) sections. These are immersed in cool brine for up to several days. After removal and drying, the blocks are sealed with plastic or rubberized film, placed in wooden boxes, with room for expansion, and covered by lids. Exposure to warm temperature, about 73°F (23°C) for 2–3 weeks, produces the typical eyes and sweet, hazelnut flavor. Further ripening continues at 41°F (5°C) for 4–12 months before the cheese is ready for market.

Gruyère cheese shows eyes like Swiss or Emmental, but they are usually smaller. This 125-lb (57-kg) round wheel cheese is made mostly in France, Switzerland, and Finland. The surfaces of Gruyère cheese, unlike the larger 224-lb (102-kg) round wheel Emmentals, are not washed daily or wiped with cloths. This leads to a special microbial growth on the surface which imparts to the cheese more flavor of a unique nature best typified by the Comté Gruyère of the French Jura area.

Edam and Gouda. Both of these cheese types may contain eyes, but these are small and lack uniform distribution. Edam cheese is produced in its normal size as 5-lb (2.3-kg) round balls waxed in red. Gouda cheese, softer in body because whole milk is invariably used, appears as orange- or yellow-waxed, medium-sized flat wheels of about 11–22 lb (5–11 kg). Manufacturing is essentially similar for both.

Pasteurized milk is set with lactic culture and rennet, but acid development is constrained usually by removing some of the whey and replacing it with water. Before the cheese is pressed, the pH is usually 5.4. This higher pH gives a sweeter flavor to the cheese and permits other species of bacteria to function. In Europe, where most of this cheese is made, sodium nitrate may be added to the cheese milk to suppress spoilage bacteria, but the practice is diminishing, and instead a continuous bacterial spore centrifugal removal process is substituted. Where nitrates are used, only small amounts are introduced, most of which disappear during ripening.

Unique metal forms shape the cheese after light pressing. The cheeses are brined and waxed. Ripening occurs at 50°F (10°C) for 2–3 months.

Muenster, brick, and Limburger. Good-quality pasteurized milk is required for these cheeses. At times, as for brick cheese, the renneted curd may be washed with water to reduce the acidity and to increase moisture. A reddish bacterium, *Bacterium linens*, along with yeasts, grows on the cheese surfaces at 59°F (15°C) in a highly moist room for 11 days. The surfaces take on the brick-reddish color of the bacterium. The three cheeses are differentiated by the intensity of their flavor, softness of body, and sizes and shapes. Muenster has least intensity of flavor, followed by brick cheese.

Provolone. Originating in Italy, provolone cheese also is manufactured in large quantities in Argentina and the United States. It is a pasta filàta, or pulled-curd ripened cheese, and is generally smoked. The texture is smooth and flaky and the flavor highly aromatic or piquante. Initially, the cheese is made almost exactly like that of a fresh, low-moisture mozzarella using *Lactobacillus delbrueckii bulgaricus* as the starter. Following proper acid development in the vat, the curd is stretched and formed into various shapes: cylindrical, pear, or ball. Thereafter, it is bound with ropes or twine and hung in hickory smoke–filled rooms for 3 weeks or exposed to smoke compounds. Ripening occurs at about 44°F (7°C) for up to 12 months, and cheese sizes range from 3 to 500 lb (1.4 to 227 kg). A related Italian type is caciocovàllo, literally meaning horse cheese.

Camembert, Brie, and blue. These are all rennet cheeses, and Camembert and Brie are made with pasteurized milk cultured to about 0.2% titratable acidity. The curds are not cooked and, following whey drainage and hooping in round forms, they are modified by the special application of white or blue-green mold spores. Introduction of the spores to the cheese may result from inoculating the milk, brine, or curds, or inoculating all three media.

Camembert and Brie are white mold cheeses about 1 in. (2.5 cm) thick whose manufacture is similar except that the diameter of the latter is larger. The characteristic feature of these cheeses is the appearance of a snow-white mat of *Penicillium caseicolum* or *P. camemberti* mold on the surfaces. These molds grow well only in an excessive air environment, and hence their appearance on the surface. They ripen the cheese from outside into the center through release of their many active enzymes, which transform the curds to a smooth, soft state. The cheeses are ready for consumption in 12–14 days at 50°F (10°C) and 95% relative humidity. Held thereafter in a refrigerated state for 40 days in supermarkets, the cheeses eventually become overripe. Ammoniacal flavor with the white surfaces becoming brown and the inner sections becoming light tan confirm an overripe state.

Blue cheese requires spores of *Penicillium roqueforti* or *P. glaucum*. These spores, appearing as a black powder, are present throughout the wheel of pressed, highly salted curd, and grow as filamentous blue-green mycelia when minimum air is supplied. In practice, the mold-inoculated wheels of cheese, from 5 to 12 lb (2.3 to 5.4 kg), are penetrated by a mechanical head containing 50 needles which create the long air channels. The mold grows along these air channels, and moves farther into the cheese if natural openings exist. Here the many lipolytic and proteolytic enzymes originating from the mold mycelia attack the cheese to give characteristic flavor. Molding occurs in 30 days after air channel formation at 50°F (10°C) and 95% relative humidity. Then the cheese is held at 41°F (5°C) during 2–6 months for more complete ripening.

The most famous blue cheese is Roquefort, made in southern France from sheep milk. Other widely known related cheeses are Stilton, Gorgonzola, Danish blue, and American blue.

Processed cheese. Processed cheese is made from natural types. Nearly any natural cheese can be processed, except that for blue cheese technical difficulties cause blackening of the blue mold due to the high heat.

Processed cheese is produced by grinding selected lots of natural cheese and adding cream, color, salt, and emulsifying agents. The mixture is blended and sent to cookers which heat the mass to 165–185°F (74–85°C). During the cooking, fat normally separates from the protein and water, but this is corrected by adding anhydrous citrate and phosphate salts, usually at 3% levels. The salts raise the cheese pH to about 5.6–5.8, making the protein more soluble. Under these circumstances a stable emulsion of protein, fat, and water occurs to give a smooth homogeneous mass. The hot mass is packaged directly. Processed cheese foods and spreads are made similarly, but include more water and less protein, fat, and other solids.

Sliced processed cheese is attained by spreading the hot process cheese mass emerging from the cookers over moving cold steel rolls. The chilled cheese in thin, wide sheets passes over rotary knives and cutting bars to give squares lying on top of each other, which are packaged in film wrappers.

Production developments. The cheese industries of the world have become rapid-growth industries with high consumer acceptance of their product. Cheese-manufacturing plants may be very large, utilizing more than 2.2×10^6 lb (10^6 kg) of cheese milk daily. In the operational areas, cheese vats of 5500-lb (2500-kg) capacity are common, as are giant presses.

Mechanization of cheesemaking too has advanced through the introduction of ingenious cheddaring towers, block formers, and moving web belts. This has led to significantly higher rates of production, with less manual labor, while maintaining quality. True continuous making methods of natural cheese have yet to be realized. However, a unique process incorporating ultrafiltration membrane technology has potential for continuous manufacture of certain cheeses.

Membrane separation is an application of biotechnology to cheesemaking. In this process, skim or whole milk is pumped at low pressure, 48 lb/in.^{2} (3.4 kg/cm^2), through tubes or plates containing many small pores, with a molecular-weight cutoff of 20,000. The milk passes across the membranes, usually at 126–129°F (52–54°C). Much of its water, lactose, soluble salts, and nonprotein nitrogen pass through the pores as permeate. Retained are all the fat, protein, insoluble salts, and some serum, which contains water, lactose, soluble salts, and nonprotein nitrogen. This retentate increases in concentration with time, so that its fat and protein may be five times greater than that of the starting milk. Emerging from the ultrafiltration unit in its final concentrated form as a plastic fluid, this retentate has the same composition as some cheeses. Cheesemaking is completed without vats, as there is no whey to separate. Simple mechanical injection of culture, rennet, salt, color, and fungal spores into the plastic fluid concentrate may follow. A curd develops within 5–10 min, and is placed directly in a ripening room. This is a French process, known as MMV after the names of the inventors, Maubois, Mocquot, and Vassal. Its major advantages are much greater cheese yields due to complete retention of whey protein in the cheese, lower requirements for rennet, a high potential for continuous-process application, and production of a neutral-pH permeate with a reduced biochemical oxygen demand (BOD) value. Much cheese in Europe is made in this manner, particularly fresh, soft acid cheeses—Feta, Camembert, and St. Paulin.

Other variations of ultrafiltration retentate application to cheesemaking include milk retentate supplementation and direct ultrafiltration of cheese milks, but only up to 2:1 protein concentration. The advantages of this alternative ultrafiltration process include improved cheesemaking efficiency, energy savings, and higher quality of marginal cheeses. Use of milk retentates in cheesemaking in this manner has led to the production of natural Cheddar cheese of good quality with significantly reduced sodium levels, 0.015 oz/3.5 oz cheese (420 mg/100 g) or less, compared with approximately 0.02 oz (700 mg) for commercial Cheddar cheeses.

Ultrafiltration has led to whey protein concentrates of 90–95% protein. This nonfat product can be modified to give a texture similar to cheese and is used as a food ingredient to replace butterfat by up to 50% for the making of commercial low-fat cheese. Another technology for the fluid milk and cheese industries is microfiltration. This system follows the same principles as those for ultrafiltration except for membrane pore size. Ultrafiltration retains fat, casein, bacteria, and insoluble salts. Passage through a micromembrane retains fat, bacteria, and insoluble solids, but no protein, making the resulting permeate an almost sterile skim milk. The creamlike retentate obtained is heated to 302°F (150°C) for 2 s, and then it is blended with the almost-sterile skim milk, pasteurized, and cooled to proper temperatures for use in milk and cheese processing. Results from Europe, where much research has been conducted on this subject, indicate an almost 99.5% reduction in total bacteria. Also, quality cheese without gas defects or loss of flavor was produced. *See* ULTRAFILTRATION.

Cheilostomata

An order of ectoproct bryozoans (in which the anus opens outside the ring of tentacles) in the class Gymnolaemata. Cheilostomes possess delicate colonies composed of loosely grouped, highly complex, short, uncurved, box- or vase-shaped zooecia (chamber in which the animal lives), with solid, porous, chitinous, or calcareous walls, and with apertures closed by lidlike opercula. *See* BRYOZOA; GYMNOLAEMATA.

Morphology. Cheilostome colonies (**Fig. 1***a*–*e*) may be encrusting threadlike networks (*Pyripora*); thin encrusting sheets (*Membranipora*, *Steginoporella*); tabular, nodular, or globular masses (*Schizoporella*, *Celleporaria*); free-living (unattached) domes (*Cupuladria*); or erect tuftlike (*Bugula*, *Scrupocellaria*), twiglike (*Vincularia*), frondlike (*Coscinopleura*, *Flustra*), or trellislike (*Retepora*, *Sertella*) growths. These colonies are not divisible into distinct endozone (thin-walled, fragile, inner or lower portion of colony) and exozone (thick-walled, sturdy, outer or upper portion of colony) regions. All cheilostome colonies lack stolons (elongated projections of the body wall from which buds are formed, giving rise to new zooids) and monticules (or maculae; raised formations of zooids on the colony surface that control incurrent and excurrent flow). Some have rhizoids (individual rootlike outgrowths that reinforce the colony's attachment to a substrate) or small coelomic chambers, and most cheilostome colonies bear ovicells (or ooecia; brood chambers that protect developing embryonic larvae) developed at the distal ends of the normal autozooecia (feeding zooids; **Fig. 2**). Autozooecia possess several tentacles arranged in a circle (lophophore) around the mouth and held out to form a bell or funnel when protruded for feeding. Many cheilostome colonies are polymorphic, that is, they possess either one or both of two types of specialized zooids (heterozooids): avicularia, which are bird-head-like or mouse-trap-like heterozooids with a movable mandible that can be snapped at small animals attempting to settle on the colony, and vibracula, heterozooids with a bristlelike seta that sweeps animals and debris from the colony surface.

The walls of adjacent zooecia within a cheilostome colony are distinctly separate rather than fused together, and may be perforated by small openings filled with soft tissue. The zooecial walls may be thin chitinous membranes, moderately thick and firm chitinous walls, or thin to thick calcareous walls (in most species, they are made of calcite), displaying a great variety of pores, pits, granules, spines, and lacy fretwork (especially the frontal walls, which form the external surface of the colony). Zooecia lack internal transverse partitions (diaphragms). Round to

Bassler, Treatise on Invertebrate Paleontology, © 1953 Geological Society of America and University of Kansas Press***)

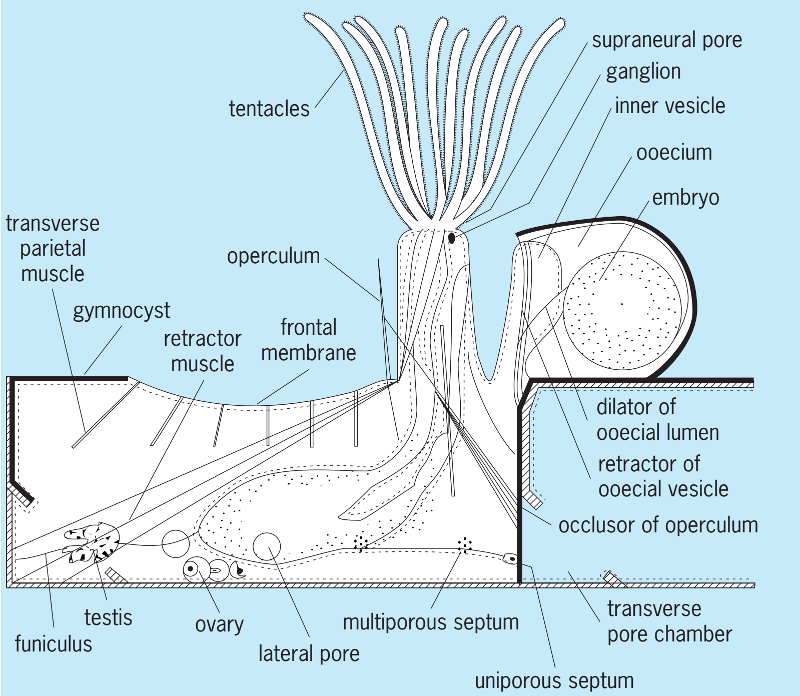

Fig. 2. Anascan cheilostome zooid, showing soft parts and zooecium, with tentacles extended. (***Reprinted with permission from R. J. Cuffey and J. E. Utgaard, Bryozoans, in R. Singer, ed., Encyclopedia of Paleontology, Fitzroy Dearborn, 1999***)

highly complicated in outline, and noticeably smaller in transverse diameter than the zooecium itself, the aperture is closed by a membranous or chitinous lid (operculum) hinged to the proximal edge of, and fitting snugly over, the aperture. The aperture may be flush with the colony surface or surrounded by spines or an elevated rim (peristome).

Life cycle. Usually sheltered in various ways by the parent (female) zooid, each cheilostome zygote develops into one larva. The larva in most species swims freely for less than a day, feeding on its own yolk (that is, it is lecithotrophic), and then attaches to a substrate and metamorphoses (with complete degeneration of its larval organs) into a primary zooid (ancestrula). In a few species, the zygote is shed directly into the water and develops there into a larva (cyphonautes) that swims freely for up to several weeks before settling. Afterward, repeated asexual budding from the ancestrula produces the rest of the cheilostome colony.

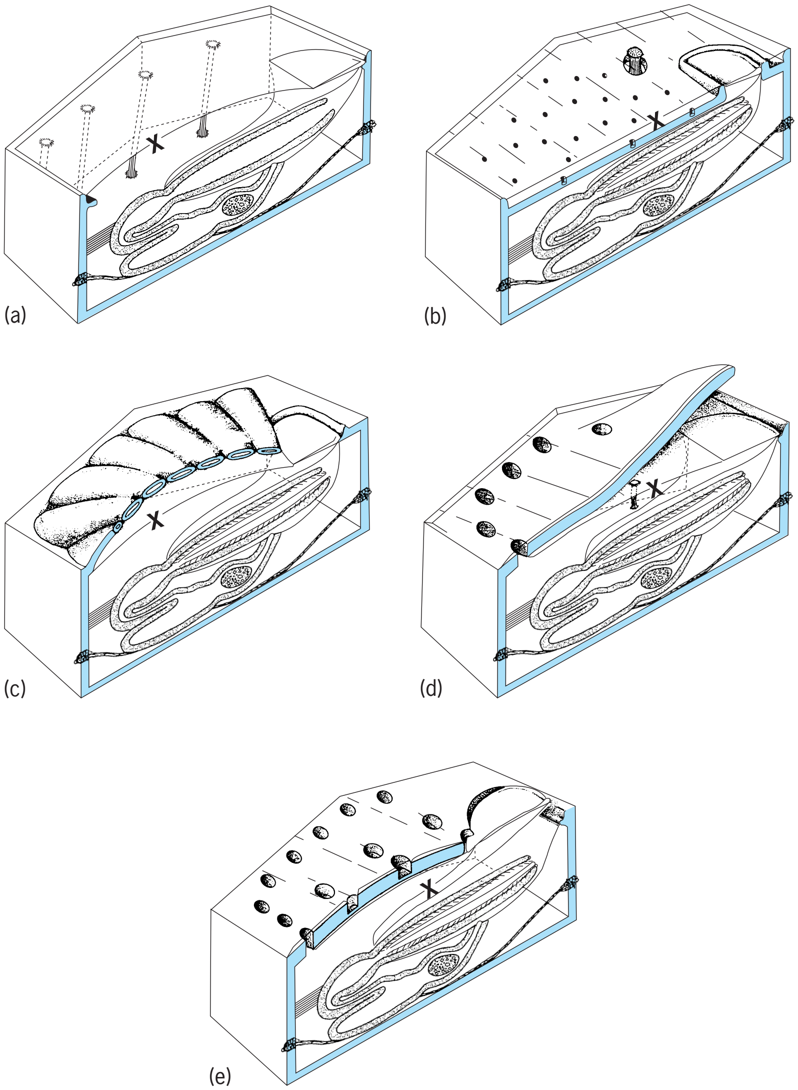

Fig. 3. Arrangements of frontal walls in Cheilostomata. The X indicates the membrane that can be pulled by muscles in order to displace fluid/liquid that pushes the polypide (shaded) out so that the tentacles can feed in the space above the skeleton. (*a*) Anascan with noncalcified frontal wall and retracted polypide unprotected by shield. (*b*) Anascan with perforated skeletal shelf (cryptocyst) below the outer, depressible cuticle. (*c*) Cribrimorph with shield of fused spines arched above the depressible cuticle. (*d*) “Umbonuloid” ascophoran with the frontal cuticle folded back on itself and the upper surface of the middle sheet of the frontal cuticle calcified, above the portion that is depressible. (*e*) Ascophoran as traditionally understood, with a small inflatable sac (ascus) formed by extension of the frontal cuticle lying immediately below the solid frontal wall/skeleton. (*After F. K. McKinney and J. B. C. Jackson, Bryozoan Evolution, Unwin Hyman, Boston, 1989*)

History and classification. Cheilostomes apparently evolved from ctenostomes as a single clade (monophyletic). First appearing in the latest Jurassic, the cheilostomes rapidly expanded during the Cretaceous to become the dominant bryozoan group throughout the Cenozoic, a position which they still maintain today. *See* CTENOSTOMATA.

Although cheilostomes are predominantly marine (ranging from intertidal to abyssal depths), some range into brackish waters, but none are found in freshwater. The oldest cheilostomes occupied near-shore habitats, but they soon invaded deep-water marine environments before the end of the Cretaceous. Maximum taxonomic, life-habit, and growth-form diversities are found near the shelf-slope break. In addition to being abundant in level-bottom communities, cheilostomes extensively but inconspicuously encrust the framework of many Cenozoic and modern coral reefs.

The cheilostomes have diversified into three major groups (anascans, cribrimorphs, and ascophorans) that appeared consecutively in geologic time and can be distinguished on the basis of differences in the frontal or upper wall (Fig. 1*f–i*). They are often classified as suborders, but may be considered as morphological grades of increasing complexity with time.

Anascan cheilostomes, the earliest, have a flexible, membranous, chitinous frontal wall that is completely open to the surrounding water (Fig. 1*f–g*; Fig. 2). Upon fossilization, the cuticle decays, leaving a top opening (opesium) that is much larger than the aperture would have been. Anascans protrude their tentacles via muscles that pull down on the membranous frontal wall, thereby squeezing the liquid body contents out through the aperture or orifice (**Fig. 3*a***). In some anascans, a porous calcareous plate (cryptocyst) may be secreted below, but detached from, the frontal membrane or cuticle (Fig. 3*b*). The primary radiation of anascans occurred in the Late Cretaceous, but they have maintained their high diversity to the present.

Cribrimorph cheilostomes (Fig. 1*h*) possess similar flexible frontal walls but are partially protected externally by overarching, partly fused, calcareous spines that meet above the midline of the zooid or zoeecium; they extend their tentacles in basically the same manner as anascans (Fig. 3*c*). Water passes in and out through the spaces between the spines as the underlying cuticle is flexed to displace polypides (internal contents of the zooid) out or to accommodate displaced fluid as polypides are retracted. The cribrimorphs had evolved by the early Late Cretaceous, reached a moderate diversity during the Late Cretaceous, and then persisted at a reduced or low diversity until the present.

Ascophoran cheilostomes (Fig. 1*i*), the most highly evolved, appeared by the mid-Late

Cretaceous, and display solid, shieldlike, calcareous frontal walls, below which is a special flexible sac (an ascus or compensatrix) used hydrostatically to protrude and retract the lophophore. The ascophoran condition, or grade, evolved several times and involved various ways of maintaining an inflatable structure below the rigid calcified frontal wall. In some (the umbonuloids), the frontal cuticle is deeply folded just behind the orifice (Fig. 3*d*). The reflected portion of the cuticle is calcified on its upper surface, while other portions remain uncalcified. Muscles pull the inner portion of the frontal membrane inward to protrude the polypide. Other ascophorans have developed a calcified plate under the frontal cuticle, and a balloonlike cuticular sac extends down through a pore in the calcified plate just behind or along the proximal edge of the operculum (Fig. 3*e*). By the end of the Cretaceous, ascophorans were diversifying rapidly, and have continued to diversify throughout the Cenozoic.

Many morphological and ecological innovations in cheilostomes originated in the mid-Cretaceous during a period of rapid diversification. Articulated spines, frontal budding, brood chambers, erect rigid and articulated colonies, free-living colonies, avicularia, and cribrimorph and ascophoran conditions originated between the late Early Cretaceous and mid-Late Cretaceous. Another (later) Early Cenozoic phase of rapid diversification primarily involved ascophorans and was accompanied by increased prevalence of frontal budding and more colonially integrated types of zooidal budding along the colony margins. Chelation

A chemical reaction or process involving chelate ring formation and characterized by multiple coordinate bonding between two or more of the electron-pair-donor groups of a multidentate ligand and an electron-pair-acceptor metal ion. The multidentate ligand is usually called a chelating agent, and the product is known as a metal chelate compound or metal chelate complex. Metal chelate chemistry is a subdivision of coordination chemistry and is characterized by the special properties resulting from the utilization of ligands possessing bridged donor groups, two or more of which coordinate simultaneously to a metal ion. *See* COORDINATION CHEMISTRY.

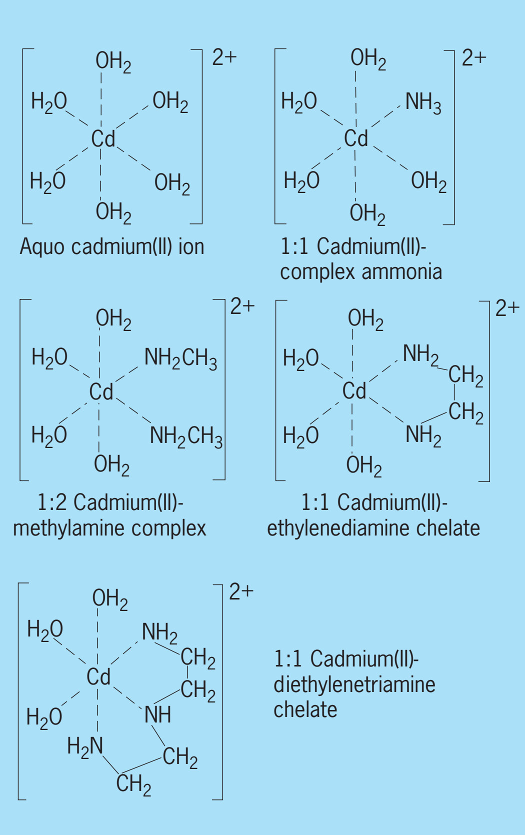

Fig. 1. Formulas of hydrated cadmium(II) ion, two cadmium(II) complexes, and two cadmium(II) chelates.

Ethylenediamine, $H_2NCH_2CH_2NH_2$, is a good example of a bidentate chelating agent consisting of two amino donor groups joined to each other by a two-carbon bridge. The coordination of both nitrogen atoms to the same metal ion would result in the formation of a five-membered chelate ring. If a chelating agent has three groups capable of attaching to a metal ion, as in diethylenetriamine, $NH_2CH_2CH_2NHCH_2CH_2NH_2$, it is tridentate (terdentate); if four, tetradentate (quadridentate); five, pentadentate (quinquidentate); six, hexadentate (sexadentate); and so on. In general, these chelating agents may be designated as multidentate or polydentate ligands. All chelating agents must be at least bidentate; tridentate agents give fused rings. An example of a nonchelated complex and two chelated complexes of the Cd(II) ion are illustrated in **Fig. 1**. In aqueous solution, metal ions are completely solvated, or hydrated, to give an aquo complex, as indicated for the Cd(II) ion in Fig. 1. Thus formation of a complex of a unidentate ligand involves the replacement of a water molecule by the unidentate donor group. Two water molecules are replaced by a single molecule of a bidentate ligand; three water molecules are replaced by a molecule of a terdentate ligand, and so on.

Many of the functional groups of both synthetic and naturally occurring organic compounds can form coordinate bonds to metal ions, producing metal-organic complexes or chelates, many of which

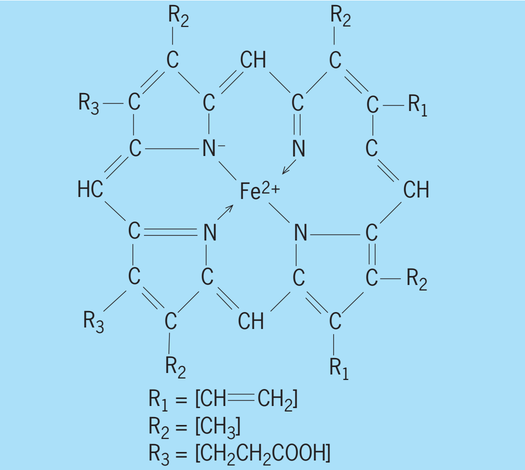

Fig. 2. Heme, a tetradentate chelate of iron(II).

are biologically active. Thus chelate compounds are frequently found in an interdisciplinary field of science called bioinorganic chemistry. The biological significance of chelates can be readily recognized if one notes that a large number of biologically important compounds are either metal chelates or chelating agents. This list includes the alpha amino acids, peptides, proteins, enzymes, porphyrins (such as hemoglobin), corrins (such as vitamin B_{12}), catechols, hydroxypolycarboxylic acids (such as citric acid), ascorbic acid (vitamin C), polyphosphates, nucleosides and other genetic compounds, pyridoxal phosphate (vitamin B_6), and sugars. The ubiquitous green plant pigment, chlorophyll, is a magnesium chelate of a tetradentate ligand formed from a modified porphin compound, and similarly the oxygen transport heme of red blood cells contains an Fe(II) chelate of the type illustrated in **Fig. 2**. *See* BIOINORGANIC CHEMISTRY; ORGANOMETALLIC COMPOUND.

A rapidly growing body of experimental evidence indicates that chelation may be important in the pharmacological action of many drugs. The use of chelating agents to remove certain toxic cations such as lead and plutonium from the body is now widely recognized in medical practice. Intensive research has been undertaken to either develop or discover an effective synthetic or natural chelating agent for the removal of iron deposits in the body that result from certain hereditary metabolic disorders.

Applications. The ability of chelating agents to reduce the chemical activity of metal ions has found extensive application in many areas of science and industry. Ethylenediaminetetraacetic acid (EDTA), a hexadentate chelating agent (**Fig. 3**), has been employed commercially for water softening, boiler scale removal, industrial cleaning, soil metal micronutrient transport, and food preservation. Nitrilotriacetic acid (NTA) is a tetradentate chelating agent (**Fig. 4**) which, because of lower cost, has taken over some of the commercial applications of EDTA. Chelating agents of related type have been used in biological systems to produce metal-ion buffers. By selection of the appropriate chelating agent, the free metal-ion concentration can be maintained at a very low and constant concentration level, just as a relatively constant pH can be maintained through the use of a conventional hydrogen-ion buffer system. Furthermore, the colors of certain chelating agents are sensitive to metal-ion concentration in a manner completely analogous to the pH-dependent color changes observed with acid-base indicators; such chelating agents serve as metal-ion indicators in analytical chemistry. The solubility of many chelating agents and metal chelates in organic solvents permits their use in solvent extraction of aqueous solutions for the separation or analysis of metal ions.

Many commercially important dyes and pigments, such as copper phthalocyanines, are chelate compounds. Humic and fulvic acids are plant degradation products in lake and seawater sediments that have been suggested as important chelating agents which regulate metal-ion balance in natural waters. By virtue of its abundance, low toxicity, low cost, and good chelating tendencies for metal ions that produce water hardness, the tripolyphosphate ion (as its sodium salt) is used in large quantities as a builder in synthetic detergents. Both synthetic ion exchangers and the mineral zeolites are chelating ion-exchange resins which are used in analytical and water-softening applications. As final examples, less conventional chelating agents are the multidentate, cyclic ligands, termed collectively crown ethers, which are particularly suited for the complexation of the alkali and alkaline-earth metals.

Stabilities of metal chelates in solution. One of the most striking properties of chelate ring compounds is their unusual thermodynamic and thermal stability. In this respect, they resemble the aromatic rings of organic chemistry. For example, in reaction (1),

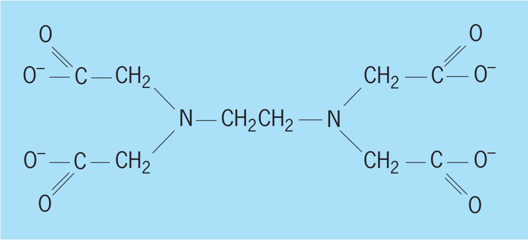

Fig. 3. Structural formula of anion of EDTA, a sexadentate ligand.

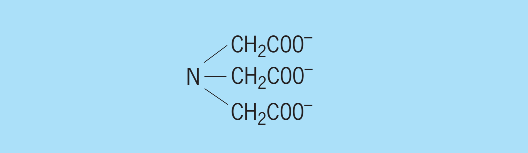

Fig. 4. Structural formula of NTA anion, a quadridentate ligand.

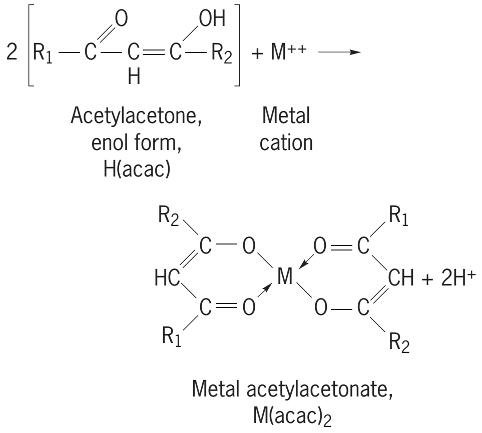

(1)

β-diketones in the enol form can lose a hydrogen ion and coordinate with a metal cation to give a six-membered ring of unusual thermal stability.

Beryllium acetylacetonate boils without decomposition at 270°C (518°F), and G. T. Morgan reported that scandium acetylacetonate, Sc(acac)$_3$, shows very little decomposition at 370°C (698°F). This remarkable stability contrasts sharply with the very low stability of coordination compounds containing simpler monodentate ketones, such as acetone.

Because of enhanced thermodynamic stability in solution, chelating agents may greatly alter the behavior of metal ions. The very insoluble compound, ferric hydroxide, will dissolve in a strongly alkaline solution of triethanol amine, $N(CH_2CH_2OH)_3$. Alternatively, the concentration of the ferric ion can be made vanishingly small at pH 2 by the addition of an equimolar amount of bis(orthohydroxybenzyl)-ethylenediamine-*N,N′*-diacetic acid (HBED; **Fig. 5**).

Since about 1940, both theoretical and practical considerations have focused attention on the factors which contribute to chelate stability. It is convenient to list such factors under three headings: (1) the nature of the metal cation, (2) the nature of the ligand, and (3) the formation of the chelate ring. It should be emphasized that these factors operate together, and their separation is somewhat artificial, but helpful for discussion purposes.

Role of metal in chelate stability. Since nitrogen, oxygen, and sulfur serve as the electron donor atoms in a majority of chelating agents, it is of interest to seek a relationship between the donor atom and the type of metal acceptor atom with which it combines. A large majority of the chelates of Li$^+$, Na$^+$, K$^+$, Rb$^+$, Cs$^+$, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Al^{3+}, Ga^{3+}, In^{3+}, Tl^{3+}, Ti^{4+}, Zr^{4+}, Th^{4+}, Si^{4+}, Ge^{4+}, and Sn^{4+} contain oxygen as at least one of the donor atoms. It may be furnished as an acid, alcohol, ether, ketone, or other group. These ions coordinate less frequently through two nitrogen or sulfur atoms. Cations of other metals such as vanadium, niobium, tantalum, molybdenum, and uranium, and the cations Be^{2+}, Al^{3+}, and Fe^{3+} show a preference for oxygen as the donor atom, but they may coordinate through nitrogen, sulfur, or phosphorus under special conditions. Cr^{3+}, Fe^{2+}, and the platinum metals show increasing preference for coordination through nitrogen as opposed to oxygen, while Cu$^+$, Zn^{2+}, Ag$^+$, Au$^+$, Cu^{2+}, Cd^{2+}, Hg^{2+}, V^{3+}, Co^{3+}, and Ni^{2+} show a marked preference for nitrogen and sulfur as the donor atoms. The ions of the last group retain the ability to coordinate with oxygen in even greater degree than do the ions of the first group, but their tendency to form bonds through nitrogen is so great that it exceeds their oxygen-binding tendency.

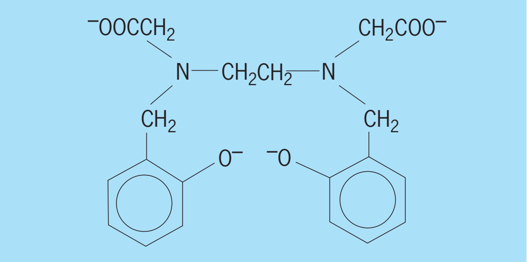

Fig. 5. Structural formula of anion of HBED, a sexadentate ligand.

It must be recognized that broad generalizations such as these have many exceptions, particularly in intermediate regions. On the other hand, such generalizations indicate clearly that attempts to arrange elements in the order of their chelating ability can be of significance only when cations of comparable type are selected. Thus, the stabilities of the alkali-metal, the alkaline-earth, and the rare-earth chelates decrease as the charge on the cation decreases or as the size of the cation increases. For example, the chelates of the alkaline-earth metal ions become less stable as the metal ion becomes larger (if the number of chelate rings remains the same), in the order Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Ra^{2+}. The relationship between ion size and chelate stability is of major importance in the separation of the rare-earth and transuranium elements by ion-exchange processes. The selectivity of the ion-exchange column is increased by the use of appropriate chelating agents in the eluting solution.

Stability sequences established for other metal ions are somewhat less satisfactory. Metal chelates of several substituted β-diketones decrease in stability in the order: $Hg^{2+} > (Cu^{2+}, Be^{2+}) > Ni^{2+} > Co^{2+} > Zn^{2+} > Pb^{2+} > Mn^{2+} > Cd^{2+} > Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+}$. If one restricts stability comparisons to bivalent metals of the first transition series, the following order is obtained: $Zn^{2+} < Cu^{2+} > Ni^{2+} > Co^{2+} > Fe^{2+} > Mn^{2+}$. This latter listing of stabilities appears to be valid for a large variety of chelating ligands.

Lower valence states such as Ir(I) and Rh(I) are effectively coordinated by chelating ligands containing trivalent phosphorus or trivalent arsenic donor groups. For example, recently synthetic coordination chemists have synthesized a series of unusual chelating agents containing trivalent phosphorus, analogous to polyamines, an example of which is illustrated in **Fig. 6**.

General principles of selective coordination of metal ions by various types of donor atoms have now been worked out, and are described through concepts such as the principles of hard and soft acids

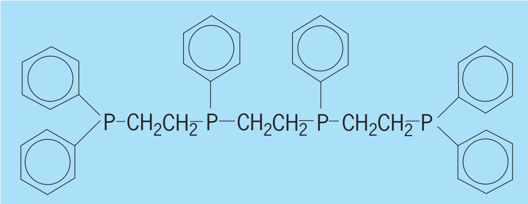

Fig. 6. "Tetraphos," a quadridentate ligand.

Fig. 7. Chelating ligands indicating the types of donor groups available for coordination.

and bases, and type A and B character of metal ions. These qualitative principles are based on well-known laws of ionic attraction and polarizabilities of atoms, ions, or molecular groups, as well as on general principles of molecular orbital theory.

Role of ligand in chelate stability. Two general types of groups give rise to coordinate bonds between ligands and metal. These are (1) primary acid groups in which the metal ion can replace hydrogen ions and (2) neutral groups which contain an atom with a free electron pair suitable for bond formation. If two groups from either class 1 or 2, or from both classes, are present in the same molecule in such positions that both groups can form bonds with the same metal ion, a chelate ring may be formed. For example, as shown in **Fig. 7**, in oxalic acid two groups of type 1 are present; in ethylenediamine two groups of type 2 are present; glycine possesses one of each type; and pyridoxylidine-glycine (the Schiff base of glycine and vitamin B_6) possesses a carboxylate (type 1), an aromatic phenolate (type 1), and an imino group (type 2) available for chelate formation around a metal ion.

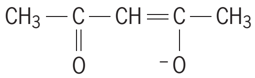
In general, anything which increases the localization of negative charge on the donor atom increases its ability to coordinate to a metal atom. Since a hydrogen ion is bound to a ligand by an electron pair in groups of type 1, an increase in electron density on the donor atom will increase the ability of the donor to bind either hydrogen ion or metal cation. The ability of a ligand to bind hydrogen ion is frequently referred to as its basic strength. It is surprising then that, for ligands of rather similar type, an increase in ligand basic strength implies an increase in its metal-chelating ability. A number of researchers have indicated this relationship by plotting the log of the equilibrium constant for the process represented by Eq. (2) against the log of the equilibrium con-

$$H^+ + L^- \rightleftharpoons HL \qquad K_1 = \frac{[HL]}{[H^+][L^-]} \qquad (2)$$

stant for the process of chelate dissociation shown by Eq. (3).

$$M^{n+} + L^- \rightleftharpoons M^{(n-1)+} \qquad K_2 = \frac{[ML^{(n-1)+}]}{[M^{n+}][L^-]} \qquad (3)$$

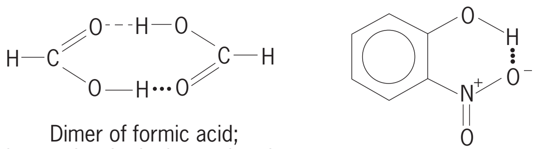
L^- is the chelating anion, such as the acetylacetonate anion,



$$CH_3-\underset{\underset{O}{\|}}{C}-CH=\underset{\underset{^-O}{|}}{C}-CH_3$$

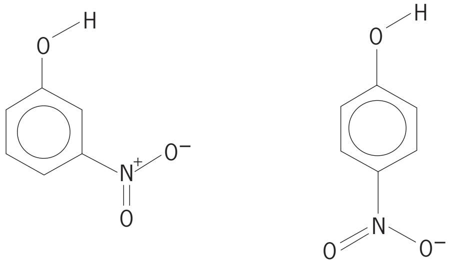
The constant K_1 is the protonation constant (its reciprocal is the acid dissociation constant), and K_2 is designated the stability constant of the metal chelate.

For the organic chemist, the analogy between the hydrogen cation and the metal cation is even more clearly drawn. Rings formed by hydrogen bonding are referred to as chelates; thus, formic acid dimerizes through hydrogen-bond chelation as shown in **Fig. 8**. The high volatility of *o*-nitrophenol compared with the much lower volatility of its meta or para isomers (Fig. 8) can only be explained in terms of



Dimer of formic acid; intermolecular hydrogen bonds

o-Nitrophenol; strong intramolecular hydrogen bond, relatively volatile



m-Nitrophenol; low volatility

p-Nitrophenol; low volatility

Fig. 8. Compounds forming intramolecular and intermolecular hydrogen bonds.

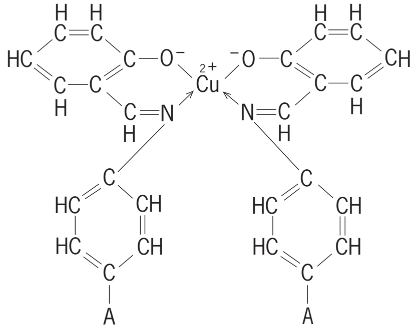


Fig. 9. Structure of a chelated copper compound.

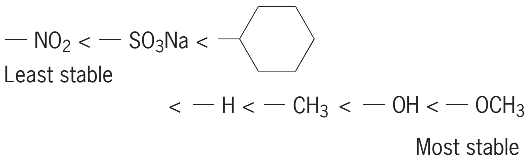
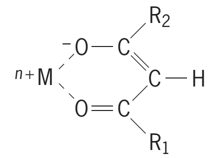
intramolecular versus intermolecular hydrogen bonding. The properties of salicylaldehyde, enhanced enolization in acetoacetic ester, and many other organic compounds are altered by internal chelate-ring formation involving hydrogen bonds. *See* HYDROGEN BOND.

The role of ligand structure on chelate stability is illustrated by studies which have been conducted on compounds of the type shown by **Fig. 9**, where A represents an electron-attracting group. In general, it was found that with an increase in the electron-attracting power of group A, electrons were pulled away from the nitrogen atom, resulting in both lower base strength and lower chelating ability for the ligand. As A is changed successively through the groups shown below, chelate stability increases in the order:

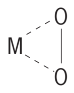


Similar studies on substitute *β*-diketone chelates of the type



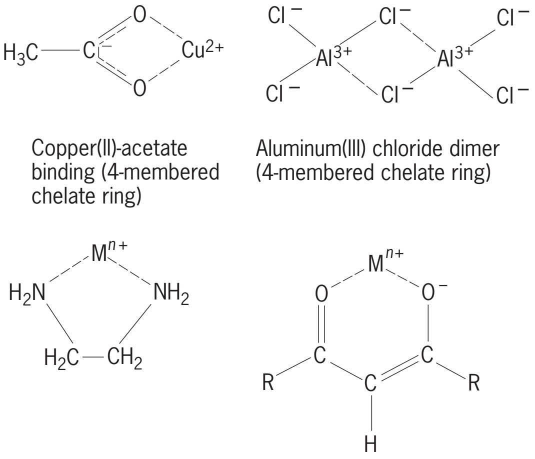
showed that, if R_1 were changed from a methyl group to an electron-withdrawing trifluoromethyl group, the stability of the resulting chelate is greatly decreased. In general, all molecular charge effects which can be invoked to shift charge in an organic molecule, such as inductive and resonance effects, will influence chelate stability. Thus the principles governing charge distribution and bond hybridization in organic chemistry are useful in working out the relationships between ligand structure and chelate stability.

Role of ring closure in chelate stability. The stability factors discussed above are applicable to coordination compounds generally, not to chelates alone. On the other hand, a number of stability factors may be considered to apply uniquely to chelates because of their ring structure. The most obvious variable in this category is ring size, a factor which is uniquely determined by the position of the donor atoms in the chelating ligand. When the groups are present in such a position as to form a five or six-membered ring, the resulting complex is the most stable although four-, seven-, eight-membered, and even larger rings are known. Examples of these would be found among biological ligands as well as in ion exchange resins. The existence of three-membered rings has not been established. Hydrazine, H_2NNH_2, which might in theory form a three-membered chelate ring, appears to be monodentate. There is some evidence for intermediate structures of metal-oxygen complexes



which may be considered three-membered chelate rings. Such compounds may be important reaction intermediates but are generally unstable and present in relatively low concentrations. The four-membered chelate rings are frequently strained. Examples of four-membered chelate rings are copper(II)-carboxylate complexes, and the aluminum chloride dimer (**Fig. 10**). While five-membered rings are very common and are formed preferentially by saturated organic ligands, ligands containing two double bonds tend to form six-membered structures. If only one double bond is present, five- or six-membered rings may form; five-membered saturated rings are illustrated in Fig. 10 by ethylene-diamine-metal chelates, and the conjugated six-membered rings by the metal acetylacetonates.

Rings of seven or more members are comparatively uncommon, but their existence is well established. As the length of the chain between the two donor atoms increases, so does the tendency of the ligand to form polymetallic complexes. Under such circumstances, the two donor atoms on the same chelate molecule coordinate with different



Copper(II)-acetate binding (4-membered chelate ring)

Aluminum(III) chloride dimer (4-membered chelate ring)

Fig. 10. Metal chelates containing four-, five-, and six-membered rings.

metal atoms rather than with one; thus, a polymeric chain, $M^+—NH_2CH_2CH_2CH_2CH_2NH_2—M^+$, may result instead of a ring structure.

The fact that chelate complexes are usually more stable than comparable nonchelate structures has been called the chelate effect. This effect is partly attributable to the fact that simultaneous rupture of both bonds holding the ligand to the metal is highly improbable, and if only one bond breaks there is a high probability that the broken bond will reform before the second bond is ruptured. As the chain length between the two donor atoms increases, the chance for reformation of the broken bond declines; thus, large rings usually show a decrease in stability. On the other hand, in fused ring systems, formed by polydentate ligands such as ethylenediaminetetraacetic acid, the probability that at least one bond will reform before all bonds are ruptured results in increased complex stability. When the bonding atoms are rigidly positioned around the metal by the organic framework, as in the porphins, the resulting increase in stability is extremely high. It has been reported that the copper phthalocyanine complex, with a completely interlocked ring system, is stable in the vapor phase near 500°C (930°F).

Chelate compounds are differentiated from their nonchelate analogs by several properties besides high stability. Although not all chelates are volatile, the existence of low-boiling metal acetylacetonates and related structures is noteworthy. If the coordination number of the metal cation for the oxygen atoms of the acetylacetone (that is, the number of nearest oxygens around the cation) is equal to twice the ionic charge of the cation, the resulting acetylacetonate is volatile; thus, beryllium with a charge of 2 and a coordination number of 4 forms an acetylacetonate which boils at 270°C (518°F); aluminum with a charge of 3 and a coordination number of 6 forms an acetylacetonate which boils at 314°C (597°F). If the coordination number of the central cation is less than twice the ionic charge, less volatile saltlike complexes are formed.

Isomerism of all types, so important in organic chemistry, is of major concern in chelation, particularly to the biochemist, since desired biological properties are frequently restricted to a particular chelate isomer. Ring formation may result in optical activity where analogous nonchelate structures are inactive. Thus, the ethylenediamine chelate structures shown in **Fig. 11** are optical isomers, whereas the analogous methylamine complexes represented in **Fig. 12** are optically inactive. *See* CHEMICAL BONDING; CHEMICAL EQUILIBRIUM; COORDINATION COMPLEXES; STEREOCHEMISTRY; STERIC EFFECT (CHEMISTRY).

Chelicerata

A subphylum of the phylum Arthropoda. The Chelicerata can be defined as those arthropods with the anteriormost appendages as a pair of small pincers (chelicerae) followed usually by pedipalps and four pairs of walking legs, and with the body divided into two parts: the prosoma (corresponding approximately to the cephalothorax of many crustaceans) and the opisthosoma (or abdomen). There are never antennae or mandibles (lateral jaws). The Chelicerata comprise three classes: the enormous group Arachnida (spiders, ticks, mites, scorpions, and related forms); the Pycnogonida (sea spiders or nobodycrabs); and the Merostomata (including the extant Xiphosurida or horseshoe crabs). *See* ARACHNIDA; MEROSTOMATA; PYCNOGONIDA; XIPHOSURIDA.

With a few exceptions, the distinctive body and limb pattern of chelicerates is diagnostic. The Acarina (mites) have the prosoma and opisthosoma fused in a single armored globe. The segments of the prosoma are always fused (except in the minor order Solfugae or sun spiders), and the opisthosoma never bears locomotor appendages (although in the xiphosurids there are paired gills on six segments of the opisthosoma). Chelicerae are always present, but the form of the pedipalps varies greatly from tiny sensory appendages to enormous crablike chelae (in scorpions and certain minor orders). Four pairs of locomotor appendages follow the chelicerae and pedipalp on the prosoma; only in a few species of pycnogonids are there five or six pairs of walking legs. *See* ACARI.

Both Merostomata and Pycnogonida are marine, but the enormous numbers and varied forms of the

Arachnida are almost entirely terrestrial. The respiratory structures of chelicerates include gills, booklungs, and tracheae. Sexes are normally separate, with genital openings at the anterior end of the opisthosoma. Some mites and other small chelicerates are omnivorous scavengers, but the majority of species of larger chelicerates are predaceous carnivores at relatively high trophic levels in their particular ecotopes. *See* ARTHROPODA. W. D. Russell-Hunter

Chelonia

An order of the Reptilia, subclass Anapsida, including the turtles, terrapins, and tortoises. This order is also known as the Testudines. The group first appeared in the Triassic, and its representatives are among the commonest fossils from that time on. Members of the order are most frequently found in freshwater streams, lakes, and ponds or in marshy areas. However, a number of strictly terrestrial species are known, and several are marine. Turtles occur on all the major continents and continental islands in tropic and temperature regions. The marine forms are basically tropic in distribution, but some individuals stray into temperate waters. *See* ANAPSIDA.

The largest carapace length attained by living forms is around 8 ft (2.4 m) in the marine leatherback turtle (*Dermochelys*), which weighs 1500 lb (675 kg). Members of the large land tortoise group (*Geochelone*) reach lengths of 4 ft (1.2 m) and weights of about 560 lb (250 kg). The smallest living species is probably the stinkpot (*Kinosternon odoratus*) of eastern North America, which attains a maximum length of about $4^{1}/_{2}$ in. (11 cm). The longevity of turtles is well known, with many captive tortoises having lived 50–60 years and others estimated to be as old as 150 years.

Taxonomy. The living turtles are usually divided into two major groups, the suborders Pleurodira and Cryptodira, based upon the structures of the head and neck. Both lines are thought to be evolved from primitive forms placed in the suborder Amphichelydia (Triassic to Eocene). This latter group differs most markedly from recent species in having elongate neural spines on the neck vertebrae so that the neck is not retractible into the shell (**Fig. 1**). Correlated with the lack of retractibility, the skull is not emarginated to make room for attachment of muscle from the cervical region. The pleurodires, on the other hand, have spines on only the most posterior cervicals and the head is retractile laterally. The skull is emarginate. In the cryptodires the cervical spines are uniformly reduced, the skull is usually emarginate, and the head is folded directly back to within the shell. In several cryptodires, notably in the marine turtles, the neck is secondarily nonretractible because of a reduction in the shell, and the skull is nonmarginate. The **table** shows the principal groups and distribution of the approximately 225 living species of the order.

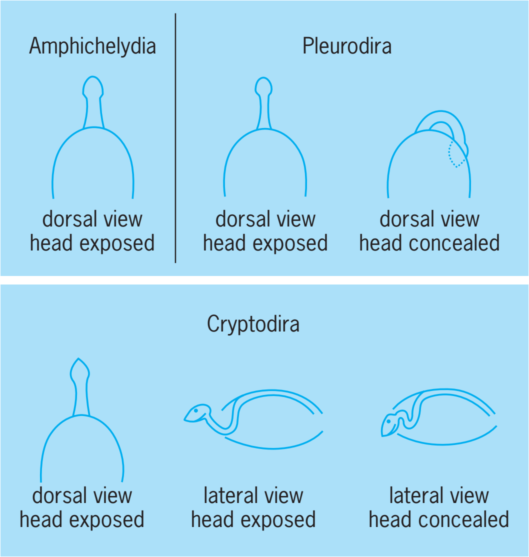

Fig. 1. Characteristics of turtle suborders, showing head in exposed and concealed positions.

Morphology. The Chelonia differ from most other vertebrates in possessing a hard bony shell which encompasses and protects the body (**Fig. 2**). The shell is made up of a dorsal portion, the carapace, and a ventral segment, the plastron, connected by soft ligamentous tissue or a bony bridge. The carapace is composed of the greatly expanded ribs and dorsal vertebrae overlain by a series of enlarged dermal ossifications and an outer covering of tough skin or horny scales. The plastron is similarly arranged

Families of the Chelonia

Group	Common name	Number of species	Distribution
Suborder Pleurodira			
Family Pelomedusidae	Side-necked turtles	14	Southern Africa, Madagascar, South America
Family Chelidae	Side-necked turtles	32	Australia, New Guinea, South America
Suborder Cryptodira			
Family Kinosternidae	Mud and musk turtles	22	North, Middle, and South America
Family Chelydridae	Snapping turtles	3	Middle and northern South America
Family Emydidae	Pond turtles and allies	102	All continents except Australia; only one or two South American species
Family Testudinidae	Tortoises	30	All continents except Australia; two South American species
Family Cheloniidae	Hawksbill, loggerhead, and green sea turtles	6	Tropical and subtropical seas
Family Dermocheylidae	Leatherback turtle	1	Tropical and subtropical seas
Family Trionychidae	Soft-shelled turtles	14	North America, Asia, central and southern Africa
Family Carretochelyidae	Fly River turtle	1	New Guinea

Shomon*, *ed*., *Virginia Wildlife*, *15*(*6*):*27*, *1954*)

with remnants of the interclavicle, clavicles, and gastralia fused with dermal ossifications and covered by skin or scales. Other peculiarities associated with the shell include the fusion of the ribs to the vertebrae and the reduction of trunk muscles, the presence of the pectoral girdle completely inside the ribs (found in no other animal), the highly modified short, thick humerus and femur, and the lungs attached dorsally to the shell. In addition, living turtles differ from the tuatara, snakes, lizards, and crocodilians in having an anapsid skull, no true teeth but horny beaks on the jaws, an immovable quadrate, and a single median penis in males. Teeth are present in ancient primitive turtles.

The rigid bony shell of turtles imposes a basic body plan subject to relatively little variation. Turtles are always recognizable as such, and the principal obvious differences between them are in the shell shape, limbs, head, and neck. The general outline of the shell is variable, but in most forms the shell is moderately high-arched and covered with epidermal scales. In some of the tortoises, such as *Geochelone*, the shell is very high, equaling the breadth. In the soft-shelled turtles, Trionychidae, and the saxicolous African tortoise (*Malacochersus*), the shell is greatly depressed to a thin, almost platelike form. No scales are present on the shells of the families Dermochelyidae, Carrettochelyidae, and Trionychidae, which are covered by thick skin.

The majority of turtles have limbs more or less adapted to aquatic or semiaquatic life with moderate to well-developed palmate webbed feet. However, in strictly terrestrial forms such as the tortoises, the limbs are elephantine with the weight of the body being borne on the flattened sole of the feet. The marine turtles and the river turtle (*Carrettochelys*) of southern New Guinea have the anterior limbs modified into paddlelike flippers, used to propel them through the water rapidly.

Physiology. Associated with the tendency of most turtles toward a life in or near water is the auditory apparatus. Even though an eardrum is present, hearing is adapted to picking up sounds transmitted through the water or substratum. However, there is evidence that airborne sound can be heard. Vision is also important, and turtles have color vision. Sounds are produced by many species through expulsion of air through the glottis. Respiration is by means of the rather rigid lungs, which are inflated and deflated by a series of special muscles. Several species with aquatic habits have special vacularized areas in the mouth or cloaca which act as auxiliary respiratory devices and make possible gaseous exchanges when the turtle is submerged in water. Most forms emit highly pungent oily substances from specialized cloacal glands, and these secretions probably are useful as recognition cues in the water. Most of the species are gregarious and diurnal, and territoriality is unknown in the order.

Reproduction. The courtship patterns of various turtles are distinctive. In general, aquatic forms mate in the water, but tortoises breed on land. The male mounts the female from above, and fertilization is internal. Sperm may be stored in the cloacal region of the female for extended periods before fertilization. Because of the presence of the large median penis in males, the sexes of many species can be distinguished by the longer and broader tail of the male. In addition, in many forms the plastron of the male is concave while in the female it is moderately to strongly convex. No doubt this characteristic of the female is associated with the spatial requirements for egg production and storage. All turtles lay shelled eggs which are buried in sand or soil in areas where females congregate. The shell is calcareous in most forms, but the marine turtles have leathery shells. Eggs are rather numerous, as many as 200 being laid by a single individual in some species, and are highly valued as human food. Incubation takes 60–90 days,

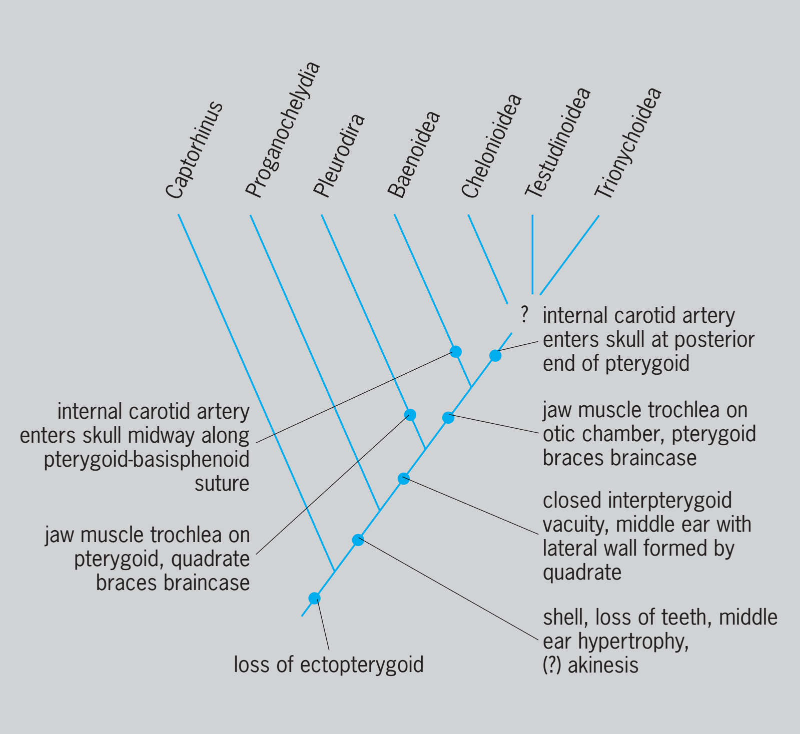

Fig. 3. Relationships of Chelonia derived from analysis of cranial features.

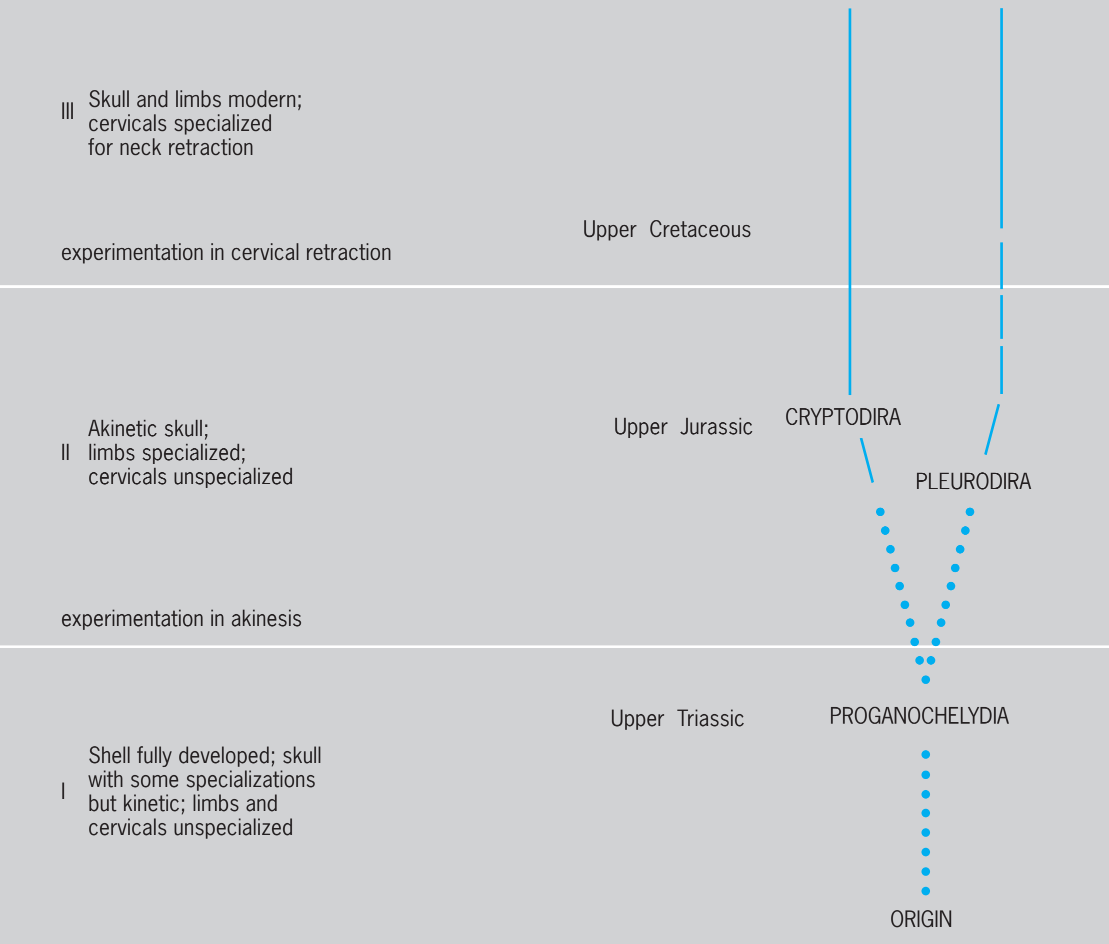

Fig. 4. Levels of organization in the order Chelonia.

and the little turtle cuts its way out of the shell with a small horny egg caruncle at the end of the snout.

Nutrition. Turtles feed on all types of organisms. Aquatic species may eat algae, higher plants, mollusks, crustaceans, insects, or fishes; terrestrial forms are similarly catholic in tastes. Most species are omnivores, but some have very specialized diets. The edges and internal surfaces of the horny beaks of these reptiles are frequently denticulate and modified to form specialized mechanisms adapted to handle particular food items. Jay M. Savage

Phylogeny. Turtles have long been considered a "primitive" or relict reptile group that has maintained a consistent morphologic structure since its origin. Phylogenetic and functional work on the skulls of fossil and modern turtles suggest that this approach is incorrect. The Cryptodira and the Pleurodira probably represent a very early dichotomy which took place soon after the origin of the turtles. These two groups passed through similar stages during their phylogeny and repeatedly evolved parallel adaptations.

The basicranium of turtles has rarely been used in a comparative sense, and the morphology of this region is still poorly known in many families of turtles. Nonetheless, the basicranium is one of the most useful regions for phylogenetic work because of its extreme complexity and relative conservativism compared with other areas. The main arterial and venous circulation of the head, the cranial nerves, the brain, and the neck and jaw musculature are all related to features in the basicranium. Changes in any of these systems can usually be seen in the basicranium. Although turtle skulls are rare compared to shells, the fossil record contains a good series with basicrania dating from the Upper Triassic to the Recent.

Previous phylogenies, however, have been based primarily on shell criteria and vertebral characters. Two major living groups are usually distinguished: the Cryptodira, with vertical neck retraction, and the Pleurodira, with horizontal neck retraction. A few of the shell characters also distinguish the living forms: pelvis sutured to carapace and plastron in pleurodires, pelvis free in cryptodires. These features rather clearly separate living turtles into two groups, but when fossils are examined it becomes difficult to distinguish pleurodires and cryptodires. The neck retractile mechanisms had not evolved until the end of the Mesozoic; thus the earlier phylogeny of the two groups is difficult to determine by neck characters.

Work on the skulls of fossil and recent turtles, however, has resulted in the development of a new hypothesis of chelonian relationships. The use of cranial features in a shared-derived character analysis is expressed in **Fig. 3**. Arterial characters provide the basis for relating the major groups of cryptodires, whereas jaw mechanics and middle ear morphology are used in comparing Proganochelydia, Pleurodira, and Cryptodira. By using these characters, pleurodires and cryptodires can be recognized well into the Mesozoic as distinct lineages, and the divergence of the two groups from a common ancestor probably took place before the Jurassic.

The new phylogenetic information has enabled functional interpretations to be made concerning the biologic significance of the differences between cryptodires and pleurodires. These interpretations show that the two lineages have developed similar structures in parallel during their evolution (**Fig. 4**). A similar but nonhomologous jaw mechanism involving a trochlea to compensate for the expanded otic chamber (**Fig. 5**) and a method of bracing the palatoquadrate against the braincase are complex features evolved independently in both groups. Later in their evolution the neck retractile mechanisms evolved, but by this time the two groups had been separate for many millions of years.

Origin. The origin of turtles is more in doubt than ever. Previous workers have emphasized the peculiar adaptations of a Permian reptile from South Africa, *Eunotosaurus*. This animal, represented by postcranial remains but very little skull material, was suggested as an ancestor for turtles on the basis of its expanded ribs, which form a rudimentary shell. However, T. S. Parsons and E. E. Williams in 1961 and, in particular, C. B. Cox in 1969 showed that *Eunotosaurus* is not related to turtles. Cox stated that *Eunotosaurus* is a captorhinomorph and that its Chelonia-like features are due to structural convergence with turtles. *Eunotosaurus* lacks separate ribs on its last dorsal vertebra, and Cox held that this feature prevents *Eunotosaurus* from being a chelonian ancestor. No reptile known to science

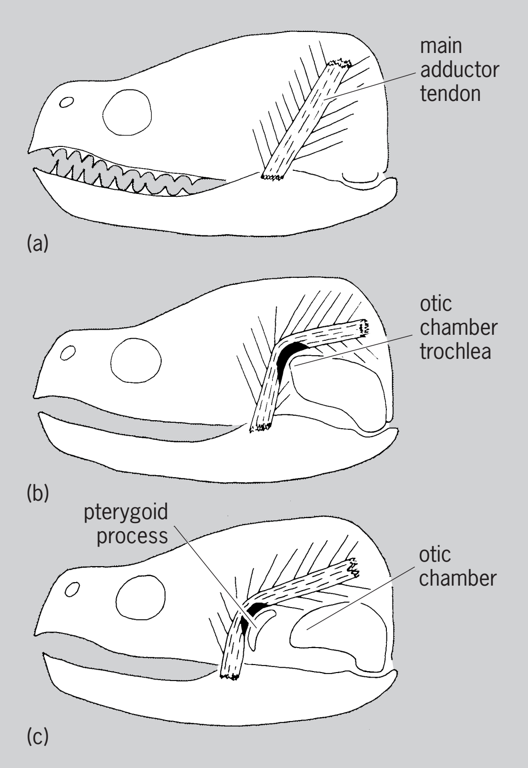

Fig. 5. Position of main jaw muscle tendon in (*a*) early reptiles, (*b*) cryptodires, and (*c*) pleurodires. The trochlea or pulley formed in turtles to get around the expanded otic chamber is independently derived in pleurodires and cryptodires.

definitely possesses specialized characters in common with turtles that would allow it to be a close relative or ancestor of that order. Presumably the stem reptile group Captorhinomorpha includes the eventual forebears of turtles since captorhinomorphs probably were ancestral to all reptiles, but the intermediate forms are unknown. *See* REPTILIA.

Chemical bonding

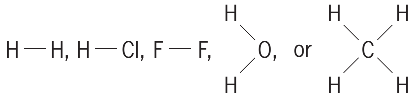
The force that holds atoms together in molecules and solids. Chemical bonds are very strong. To break one bond in each molecule in a mole of material typically requires an energy of many tens of kilocalories.

It is convenient to classify chemical bonding into several types, although all real cases are mixtures of these idealized cases. The theory of the various bond types has been well developed and tested by theoretical chemists. *See* COMPUTATIONAL CHEMISTRY; MOLECULAR ORBITAL THEORY; QUANTUM CHEMISTRY.

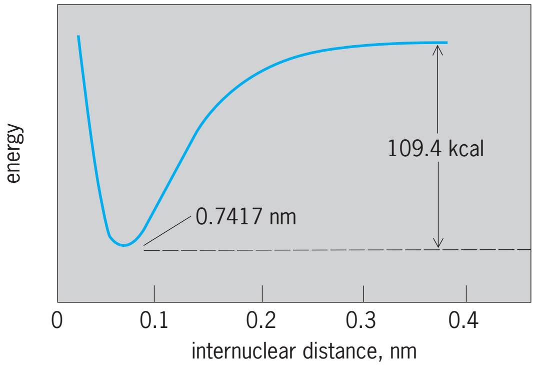
The simplest chemical bonds to describe are those resulting from direct coulombic attractions between ions of opposite charge, as in most crystalline salts. These are termed ionic bonds. *See* COULOMB'S LAW; IONIC CRYSTALS; STRUCTURAL CHEMISTRY.

Other chemical bonds include a wide variety of types, ranging from the very weak van der Waals attractions, which bind neon atoms together in solid neon, to metallic bonds or metallike bonds, in which very many electrons are spread over a lattice of positively charged atom cores and give rise to a stable configuration for those cores. *See* CRYSTAL STRUCTURE; INTERMOLECULAR FORCES.

Covalent bond. But it is the normal covalent bond, in which two electrons bind two atoms together, as in



that is the most characteristic link in chemistry. The theory that accounts for it is a cornerstone of chemical science. The physical and chemical properties of any molecule are direct consequences of its particular detailed electronic structure. Yet the theory of any one covalent chemical bond, for example, the H—H bond in the hydrogen molecule, has much in common with the theory of any other covalent bond, for example, the O—H bond in the water molecule. The current theory of covalent bonds both treats their qualitative features and quantitatively accounts for the molecular properties which are a consequence of those features. The theory is a branch of quantum theory. *See* NONRELATIVISTIC QUANTUM THEORY; QUANTUM CHEMISTRY.



Potential energy of the hydrogen molecule.

Hydrogen molecule. A brief outline of the application of quantum theory to the bond in the hydrogen molecule H—H follows. Here two electrons, each of charge $-e$, bind together two protons, each of charge $+e$, with the electrons much lighter than the protons. What must be explained, above all else, is that these particles form an entity with the protons 0.074 nanometer apart, more stable by $D = 109$ kcal (456 kilojoules) per mole than two separate hydrogen atoms, where D is the binding energy. In more detail, a molecular energy is involved (ignoring nuclear kinetic energy) that depends on internuclear distance, as shown in the **illustration**. This curve can be determined experimentally, and it can be used to interpret the characteristic spectroscopic properties of hydrogen gas. *See* MOLECULAR STRUCTURE AND SPECTRA.

The quantum theory accounts for the properties of isolated atoms by assigning atomic orbitals for individual electrons to move in, not more than two electrons at a time. For the hydrogen atom, the orbitals are labeled $1s$, $2s$., $2p_x$, $2p_y$, $2p_z$, and so on, with $1s$ the one having the lowest energy. For the molecule H_2 one electron, say electron 1, might be assigned to a $1s$ orbital on proton A, with $1s_A(1)$ written to signify this; similarly electron 2 might be assigned to the same kind of orbital on proton B, written as $1s_B(2)$. Since independent probabilities multiply and orbitals represent probability amplitudes, the description for the combined system shown in Eq. (1) is arrived

$$\phi(1, 2) = 1s_A(1)1s_B(2) \qquad (1)$$

at. Unfortunately, this fails to account for the bond properties; it gives a binding energy of only 10 kcal (41.9 kJ) per mole. *See* ATOMIC STRUCTURE AND SPECTRA; EXCLUSION PRINCIPLE.

An essential defect of Eq. (1) is the numbering of the electrons; it puts electron 1 on proton A, electron 2 on proton B. Electrons cannot be distinguished experimentally, so they should not be given unique numbers; the function $1s_A(2)1s_B(1)$ would be just as good as the foregoing. It is necessary to use a description that is not affected by interchange of electron labels, as in the additive combination of Eq. (2).

$$\phi(1,2) = 1s_A(1)1s_B(2) + 1s_A(2)1s_B(1) \qquad (2)$$

(The difference combination also is an acceptable description, but it represents an excited state of the molecule.)

Any complete molecular electronic wave function should include electron spin. Symmetric space wave functions like Eq. (2) must be multiplied by antisymmetric spin wave functions to give total wave functions that are antisymmetrical with respect to interchange of electrons. For the ground state of hydrogen, and for the normal covalent bond elsewhere, this requirement means that the electron spins must be paired to give a total electron spin of zero.

The simple relationship described by Eq. (2) qualitatively accounts for the existence of the covalent bond; the predicted binding energy is $D = 74$ kcal (310 kJ) per mole; and the shape of the curve, with the minimum appearing at 0.080 nm, is right.

The description of Eq. (2) can be systematically improved. The charge acting on the electron may be changed from $+1e$ to the larger value, $+Ze$, which is more realistic for the actual molecule. With $Z = 1.17$ this gives $D = 87$ kcal (364 kJ) per mole. Polarization effects may be introduced by taking Eq. (3), where

$$\phi(1,2) = 1\sigma_A(1)1\sigma_B(2) + 1\sigma_A(2)1\sigma_B(1) \qquad (3)$$

$1\sigma_A = 1s_A + \lambda 2pz_A$ and $1\sigma_B = 1s_B + \lambda 2pz_B$. This gives $D = 93$ kcal (389 kJ). Ionic terms may be introduced, acknowledging the possibility that both electrons may be on one atom, by taking Eq. (4) where C

$$\phi(1,2) = C_1[1s_A(1)1s_B(2) + 1s_A(2)1s_B(1)] + C_2[1s_A(1)1s_A(2) + 1s_B(1)1s_B(2)] \qquad (4)$$

represents a constant. This also gives (with $Z = 1.19$) $D = 93$ kcal (389 kJ). Another possible approach is to include both ionic terms and polarization effects, and other terms involving $2s$, $3d$, $4f$, and other orbitals. If this is done, eventually one obtains the observed D value and a potential curve that is in complete agreement with experiment.

The linear mixing of terms such as $1s_A(1)1s_B(2)$ is called resonance; the method of mixing covalent and ionic structures is called the valence bond (VB) method. The particular mixing coefficients can be found by the variational principle: The best values for such parameters are those that make the total energy of the molecule, properly computed from quantum mechanics, a minimum. The energy expression contains only terms that have a direct classical interpretation: the kinetic energy of the electrons, their energy of repulsion for one another, their energy of attraction for the nuclei, and the nuclear-nuclear repulsion energy. *See* RESONANCE (MOLECULAR STRUCTURE).

Alternative descriptions of H_2 are possible, of which the most important is provided by the molecular orbital (MO) method. Here electrons are put one at a time into orbitals which are spread over the whole molecule, usually approximating these orbitals by linear combinations of atomic orbitals (LCAO). For H_2 the lowest molecular orbital is $\phi_1 \approx 1s_A + 1s_B$, the next $\phi_2 \approx 1s_A - 1s_B$. The simplest molecular orbital description is displayed in Eq. (5),

$$\phi(1,2) = \phi_1(1)\phi_2(2) \qquad (5)$$

which represents an equal weighting of covalent and ionic structures; it gives $D = 61$ kcal (255 kJ) for $Z = 1.00$ and $D = 80$ kcal (335 kJ) for $Z = 1.20$. More suitable is a mixture of this function with the function obtained by promoting both electrons from ϕ_1 to ϕ_2. The result of this configuration interaction process has the form of Eq. (6), and it is identical with the va-

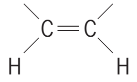
$$\phi(1,2) = D_1\phi_1(2) + D_2\phi_2(1)\phi_2(2) \qquad (6)$$

lence bond function of Eq. (4). In this manner more terms can be added, using more orbitals, until, again, the accurate potential energy curve is obtained.

The most accurate description known for the chemical bond in H_2 is a very complicated electronic wave function. The calculated and observed values of D and other properties agree absolutely.

Complex molecules. The problem of the proper description of chemical bonds in molecules that are more complicated than H_2 has many inherent difficulties. The qualitative theory of chemical bonding in complex molecules preserves the use of many chemical concepts that predate quantum chemistry itself; among these are electrostatic and steric factors, tautomerism, and electronegativity. The quantitative theory is highly computational in nature and involves extensive use of computers and supercomputers.

The number of covalent bonds which an atom can form is called the covalence and is determined by the detailed electron configuration of the atom. An extremely important case is that of carbon. In most of its compounds, carbon forms four bonds. When these connect it to four other atoms, the directions of the bonds to these other atoms normally make angles of about 109° to one another, unless the attached atoms are crowded or constrained by other bonds. That is, covalent bonds have preferred directions. However, in accord with the idea that carbon forms four bonds, it is necessary to introduce the notion of double and triple bonds. Thus in the structural formula of ethylene, C_2H_4 (**1**), all lines denote covalent bonds, the double line connecting the carbon atoms being a double bond. Such double bonds are distinctly shorter, almost twice as stiff, and require considerably more energy to break completely than do single bonds. However, they do not require twice as much energy to break as a single bond. Similarly,



(**1**)

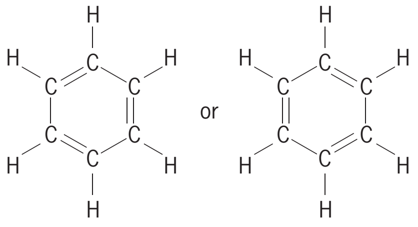
acetylene (**2**) is written with a triple bond, which

$$H{-}C{\equiv}C{-}H$$

(**2**)

is still shorter than a double bond. A carbon-carbon single bond has a length close to 1.54×10^{-8} cm, whereas the triple bond is about 1.21×10^{-8} cm long. *See* BOND ANGLE AND DISTANCE; VALENCE.

In many compounds the rules for writing bond formulas are not unique. For example, benzene, C_6H_6 (**3**), can be written in two forms. Evidence proves that all six C-C bonds are equivalent, so neither formula can be correct. The correct picture is a blend of the two, in which the bonds have many properties intermediate between those of double and single bonds but in which the whole molecule displays an additional stability. This resonance occurs whenever the structure is such that two or more different bond formulas can legitimately be drawn for the same geometry. *See* BENZENE; ELECTRON CONFIGURATION.



(**3**)

Many substances have some bonds which are covalent and others which are ionic. Thus in crystalline ammonium chloride, NH_4Cl, the hydrogens are bound to nitrogen by electron pairs, but the NH_4 group is a positive ion and the chlorine is a negative ion.

Both electrons of a covalent bond may come from one of the atoms. Such a bond is called a coordinate or dative covalent bond or semipolar double bond, and is one example of the combination of ionic and covalent bonding.

The hydrogen bond is a special bond in which a hydrogen atom links a pair of other atoms. The linked atoms are normally oxygen, fluorine, chlorine, or nitrogen. These four elements are all quite electronegative, a fact which favors a partially ionic interpretation of this kind of bonding. *See* ELECTRONEGATIVITY; HYDROGEN BOND.

To illustrate the level of accuracy of contemporary quantum-chemical calculations, the **table** gives observed and calculated values for certain spectroscopic properties of the H_2O molecule.

Chemical conversion

A chemical manufacturing process in which chemical transformation takes place, that is, the product differs chemically from the starting materials. Most chemical manufacturing processes consist of a sequence of steps, each of which involves making some sort of change in either chemical makeup, concentration, phase state, energy level, or a combination of these, in the materials passing through the particular step. If the changes are of a strictly physical nature (for example, mixing, distillation, drying, filtration, adsorption, condensation), the step is referred to as a unit operation. If the changes are of a chemical nature, where conversion from one chemical species to another takes place (for example, combustion, polymerization, chlorination, fermentation, reduction, hydrolysis), the step is called a unit process. Some steps involve both, for example, gas absorption with an accompanying chemical reaction in the liquid phase. The term chemical conversion is used not only in describing overall processes involving chemical transformation, but in certain contexts as a synonym for the term unit process. The chemical process industry as a whole has tended to favor the former usage, while the petroleum industry has favored the latter. *See* CHEMICAL PROCESS INDUSTRY; UNIT PROCESSES.

Another usage of the term chemical conversion is to define the percentage of reactants converted to products inside a chemical reactor or unit process. This quantitative usage is expressed as percent conversion per pass, in the case of reactors where unconverted reactants are recovered from the product stream and recycled to the reactor inlet. *See* CHEMICAL ENGINEERING.

Chemical dynamics

That branch of physical chemistry which seeks to explain time-dependent phenomena, such as energy transfer and chemical reaction, in terms of the detailed motion of the nuclei and electrons which constitute the system.

Molecular Dynamics

In principle, it is possible to prepare two reagents in specific quantum states and to determine the quantum-state distribution of the products. In practice, this is very difficult, and experiments have mostly been limited to preparing one reagent or to determining some aspect of the product distribution. This approach yields data concerning the detailed aspects of the dynamics.

Bimolecular reactions. Molecular-beam and luminescence techniques have played a major role in the development of chemical dynamics. Since these techniques largely complement each other, they are illustrated by discussing the results of a single reaction, the formation of deuterium chloride (DCl) from atomic deuterium (D) and molecular chlorine (Cl_2), reaction (1).

$$D + Cl_2 \rightarrow DCl + Cl \qquad (1)$$

Chemiluminescence. Reaction (1) is 46 kilocalories per mole (192 kilojoules per mole) exoergic. If all of the exoergicity were to go into vibration of the newly formed DCl molecule, enough energy would be available to populate the $v' = 9$ vibrational level. In a gas-phase reaction at high pressure, much of this energy would be dissipated as heat at the walls of the container; but at very low pressures, where the frequency of collisions is small, DCl molecules in excited vibrational states, DCl^*, will emit infrared emission prior to undergoing a collision.

An apparatus to study this infrared chemiluminescence is shown in **Fig. 1**. Deuterium atoms are made by dissociating D_2 gas in an electrical discharge, and together with Cl_2 are injected into the observation cell at the top. The reagents mix and react inside a vessel with walls maintained at 77 K (−320°F), which freeze out species hitting the wall. The pressure is kept low to minimize vibrationally deactivating collisions. Infrared emission from the products is gathered by mirrors at the end, taken out through the sapphire window, and analyzed with an infrared spectrometer. By analyzing the spectrum, it is possible to determine which vibration-rotation states are emitting and, as a consequence, which vibration-rotation states are formed in the reaction. **Figure 2** shows the relative distribution of vibrational states from the reaction, and also shows, for comparison, the relative distribution of vibrational states calculated from the Boltzmann equation for hot DCl (6000 K or 10,800°F). Thermal distributions at any other temperatures would still show a monotonic decline. (The population for $v' = 0$ is not determined by the chemiluminescence experiments, because that state does not emit.) The DCl formed in the reaction clearly has different properties than hot DCl: the vibrational population displays an inversion, and this system (the hydrogen isotope) was the active medium for the first chemically pumped laser. *See* CHEMILUMINESCENCE.

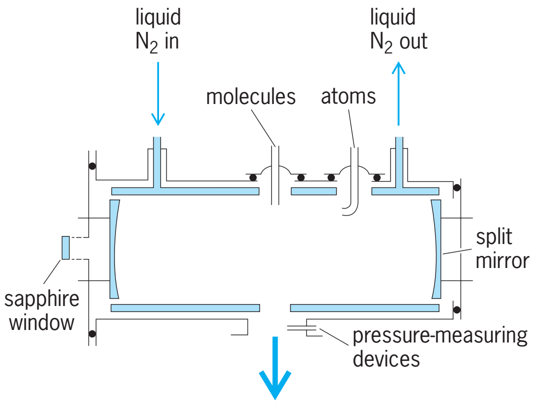

Fig. 1. Reaction vessel for studying infrared chemiluminescence between atoms and molecules at low pressure. (*After D. H. Maylotte, J. C. Polanyi, and K. B. Woodall, J. Chem. Phys., 57:1547–1561, 1972*)

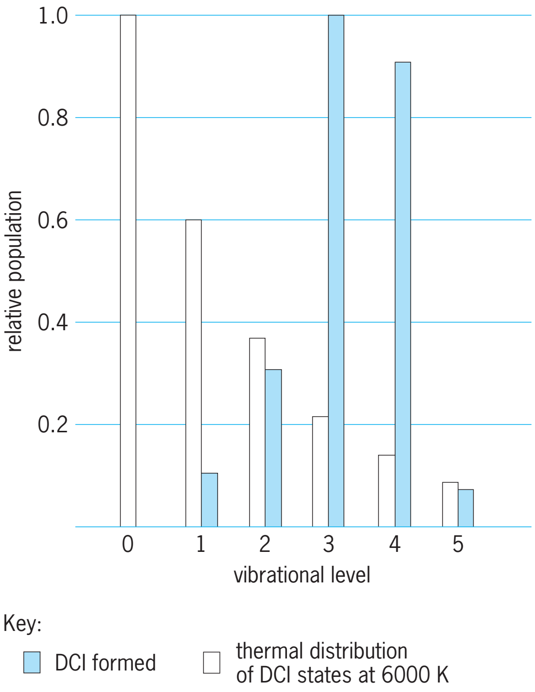

Fig. 2. Relative populations of DCl molecules in different vibrational states formed in the reaction $D + Cl_2 \rightarrow DCl + Cl$. 6000 K = 10,800°F.

Molecular-beam experiments. Molecules can be isolated in molecular beams, and collisions between these isolated molecules can be observed by crossing two tenuous molecular beams in a region of otherwise high vacuum. **Figure 3** shows such an experiment. Gaseous atoms or molecules emerge from the ovens, and collimating slits select the particles which are all going in the same direction. The molecular beams cross at the center of rotation of a large platform which can be rotated under vacuum relative to the two beams. Large vacuum pumps maintain a high vacuum, which ensures that collisions take place only at the intersection of the two beams. Product molecules are ionized by electron bombardment, and detected with a quadrupole mass spectrometer housed within a region of ultrahigh vacuum.

Measurements are made of the scattered product intensity and speed at various scattering angles. For ease of interpretation, these data are transformed into the center-of-mass system in which the two reagents approach each other with equal and opposite momenta. **Figure 4** shows a contour map of the DCl intensity in the center-of-mass coordinate system

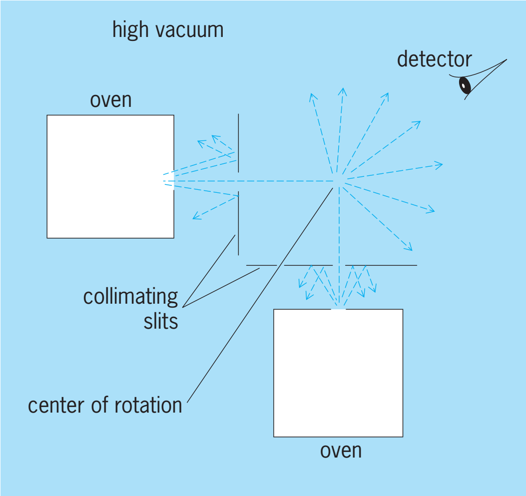

Fig. 3. Schematic of a molecular beam experiment; entire apparatus is under high vacuum.

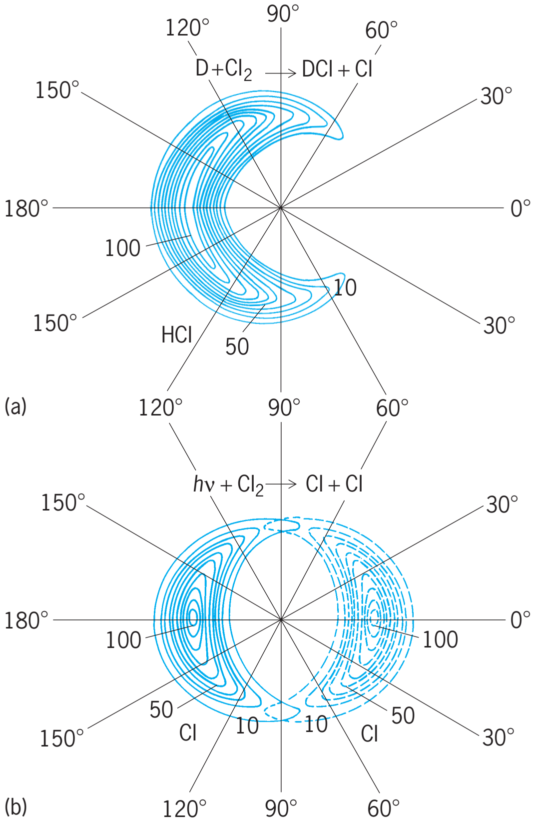

Fig. 4. Contour map of the DCl intensity. (*a*) Center-of-mass angular distribution of DCl from the reaction D + Cl_2. (*b*) Angular distribution of Cl atoms from photodissociation of Cl_2 molecules. Broken lines correspond to the second Cl atom. (*After D. R. Herschbach, Molecular dynamics of chemical reactions, Pure Appl. Chem., 47:61–73, 1976*)

in which the D atom is incident from the left and the Cl_2 molecule is incident from the right. The product DCl recoils backward (in the direction from which the D came) in a broad but nonetheless anisotropic distribution. The speed of the product is high, and corresponds to about half of the reaction exoergicity appearing in translation recoil of the products, with the balance appearing in vibration and rotation of the DCl; this is consistent with the chemiluminescence results. *See* MOLECULAR BEAMS.

The anisotropic product distribution shows that reaction occurs in a time of less than a molecular rotation, about 1 picosecond. The partitioning of energy roughly equally between vibration and translation suggests that the major amount of energy is released in repulsion between the DCl and Cl. This repulsion is similar to that experienced by a Cl_2 molecule in photodissociation, also shown in Fig. 4. Because the deuterium atom is so light, the direction in which the product is expelled is a measure of the orientation of the Cl_2 molecule during reaction. For this reaction the collinear arrangement D-Cl-Cl is preferred, whereas bent arrangements are preferred for D + I_2.

Other investigations. Molecular-beam machines (and to some extent chemiluminescence machines) have been modified in various ways to explore even finer details of specific reactions. For example, electric and magnetic fields have been used to prepare reagents in various orientations or to determine the magnitude and polarization of the product rotational angular momentum; lasers have been used to prepare reagents in initial vibrational states and to determine the final vibration-rotation state of products by inducing fluorescence from the products; and reactions may be conducted at hyperthermal energies to produce dissociation or even ionization.

Advances in subnanosecond laser technology have made it possible to study a few bulk phase reactions under nearly collision-free circumstances. For example, H atoms can be formed by dissociating a hydrogen halide (HX) with a fast laser pulse, and reaction of the H can be monitored by a second pulse delayed enough to probe reaction products after only a few collisions. *See* ULTRAFAST MOLECULAR PROCESSES.

Information about chemical reactions has so far come from observations made on the disappearance of reagents or appearance of products. However, several experiments on systems such as H + H_2, K + NaCl, and ICN (iodine cyanide) have shown that it is possible to use lasers to probe the chemical system during the very short time in which the chemical bonds are rearranging. This forms the basis of a new spectroscopy of the transition region. *See* LASER PHOTOCHEMISTRY.

Unimolecular reactions. Unimolecular reactions are possible when the energy of an isolated molecule lies above the energy of the asymptotically separated products. Molecules were traditionally energized by collisions, and unimolecular reactions have been studied by using collisional excitation in both crossbeam and chemiluminescence experiments. Several laser methods—multiphoton excitation, stimulated emission pumping, and overtone excitation—can also be used to populate a very narrow range of energy levels in isolated molecules to study unimolecular reactions as well as the related process of photodissociation.

Considerable insight into unimolecular processes has been obtained. Energy initially deposited locally is distributed on a picosecond time scale, and most processes seem to be described by a statistical model. Furthermore, bond-selective photochemistry (in which different reactions would occur for excitation of different molecular vibrations) seems unlikely, because reaction is usually slow compared to the energy redistribution process. *See* PHOTOCHEMISTRY.

Philip R. Brooks

Theoretical Methods

The goal of chemical dynamics is to understand kinetic phenomena from the basic laws of molecular mechanics, and it is thus a field which sees close interplay between experimental and theoretical research.

Energy distribution. An important question regarding the dynamics of chemical reactions has to do with the product energy distribution in exothermic reactions. For example, because the hydrogen fluoride (HF) molecule is more strongly bound than the H_2 molecule, reaction (2) releases a considerable amount of energy (more than 30 kcal/mol or 126 kJ/mol). The two possible paths for this energy release to follow are into translations, that is, with HF and H speeding away from each other, or into vibrational motion of HF.

$$\mathrm{F} + \mathrm{H_2} \longrightarrow \mathrm{HF} + \mathrm{H} \qquad (2)$$

In this case it is vibration, and this has rather dramatic consequences; the reaction creates a population inversion among the vibrational energy levels of HF—that is, the higher vibrational levels have more population than the lower levels—and the emission of infrared light from these excited vibrational levels can be made to form a chemical laser. A number of other reactions such as reaction (1) also give a population inversion among the vibrational energy levels, and can thus be used to make lasers.

Most effective energy. The rates of most chemical reactions are increased if they are given more energy. In macroscopic kinetics this corresponds to increasing the temperature, and most reactions are faster at higher temperatures. It seems reasonable, though, that some types of energy will be more effective in accelerating the reaction than others. For example, in reaction (3), where potassium (K) reacts with hydrogen chloride (HCl) to form potassium chloride (KCl), studies in a molecular beam have shown that if HCl is vibrationally excited (by using a laser), this reaction is found to proceed approximately 100 times faster, while the same amount of energy in translational kinetic energy has a smaller effect. Here, therefore, vibrational energy is much more effective than translational energy in accelerating the reaction.

$$\mathrm{K} + \mathrm{HCl} \longrightarrow \mathrm{KCl} + \mathrm{H} \qquad (3)$$

For reaction (2), however, translational energy is more effective than vibrational energy in accelerating the reaction. The general rule of thumb is that vibrational energy is more effective for endothermic reactions (those for which the new molecule is less stable than the original molecule), while translational energy is most effective for exothermic reactions.

Lasers. As seen from the above, lasers are also an important supplement to molecular-beam techniques for probing the dynamics of chemical reactions. Because they are light sources with a very narrow wavelength, they are able to excite molecules to specific quantum states (and also to detect what states molecules are in), an example of which is reaction (3). For polyatomic molecules—that is, those with more than two atoms—there is the even more interesting question of how the rate of reaction depends on which vibration is excited.

For example, when the molecule allyl isocyanide, $CH_2{=}CH{-}CH_2{-}NC$, is given sufficient vibrational energy, the isocyanide part (—NC) will rearrange to the cyanide (—CN) configuration. A laser can be used to excite a C-H bond vibrationally. An interesting question is whether the rate of the rearrangement process depends on which C-H bond is excited. Only with a laser is it possible to excite different C-H bonds and begin to answer such questions. This question of mode-specific chemistry, that is, the question of whether excitation of specific modes of a molecule causes specific chemistry to result, has been a subject of great interest. (For the example above, the reaction is fastest if the C-H bond closest to the NC group is excited.) Mode-specific chemistry would allow much greater control over the course of chemical reactions, and it would be possible to accelerate the rate of some reactions (or reactions at one part of a molecule) and not others. *See* LASER.

Models and methods. Many different theoretical models and methods have been useful in understanding and analyzing all of the phenomena described above. Probably the single most useful approach has been the calculation of classical trajectories. Assuming that the potential energy function or a reasonable approximation is known for the three atoms in reaction (2), for example, it is possible by use of electronic computers to calculate the classical motion of the three atoms. It is thus an easy matter to give the initial molecule more or less vibrational or translational energy, and then compute the probability of reaction. Similarly, the final molecule and atom can be studied to see where the energy appears, that is, as translation or as vibration.

It is thus a relatively straightforward matter theoretically to answer the questions and to see whether or not mode-specific excitation leads to significantly different chemistry than simply increasing the temperature under bulk conditions.

The most crucial step in carrying out these calculations is obtaining the potential energy surface—that is, the potential energy as a function of the positions of the atoms—for the system. **Figure 5** shows a plot of the contours of the potential energy surface for reaction (2). Even without carrying out classical trajectory calculations, it is possible to deduce some of the dynamical features of this reaction; for example, the motion of the system first surmounts a small potential barrier, and then it slides down a steep hill,

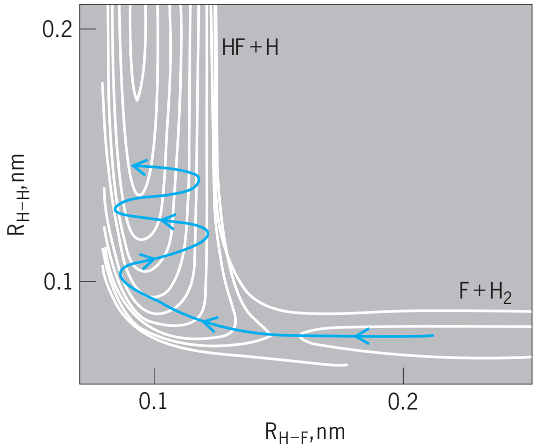

Fig. 5. Contour plot of the potential energy surface for the reaction $F + H_2 = HF + H$, with a typical reactive trajectory indicated.

turning the corner at the bottom of the hill. It is evident that such motion will cause much of the energy released in going down the hill to appear in vibrational motion of HF.

This and other theoretical methods have interacted strongly with experimental research in helping to understand the dynamics of chemical reactions. *See* CHEMICAL KINETICS; INORGANIC PHOTOCHEMISTRY.

Chemical ecology

The study of ecological interactions mediated by the chemicals that organisms produce. These substances, known as allelochemicals, serve a variety of functions, the growing list of which reflects the rapid discoveries made in this discipline. These compounds influence or regulate interspecific and intraspecific interactions of microorganisms, plants, and animals, and operate within and between all trophic levels—producers, consumers, and decomposers—and in terrestrial, fresh-water, and marine ecosystems.

Function is an important criterion for the classification of allelochemicals. Allelochemicals beneficial to the emitter are called allomones; those beneficial to the recipient are called kairomones. An allomone to one organism can be a kairomone to another. For example, floral scents benefit the plant (allomones) by encouraging pollinators, but also benefit the insect (kairomones) by providing a cue for the location of nectar.

The chemicals involved are diverse in structure and are often of low molecular weight (<10,000). They may be volatile (for example, monoterpene essential oils from peppermint, cyanide from trefoil, musks of mammals, mustard oils from cabbage, aldehyde pheromones in insects) or nonvolatile (such as nicotine alkaloids in tobacco, flavonoids in most plants), and water-soluble (phenols in many insect defenses) or fat-soluble (leaf waxes). Proteins, polypeptides, and amino acids are also found to play an important role.

Plant allelochemicals are often called secondary compounds or metabolites to distinguish them from those chemicals involved in primary metabolism, although this distinction is not always clear. The functions of secondary chemicals were a mystery until 1959, when G. Fraenkel emphasized their potential importance in the interactions of plants and animals. The role of chemicals in the ecology of microorganisms and of animals was recognized earlier: since the discovery of penicillin, scientists have known that fungi can produce substances that destroy bacteria, and the odors of such animals as stink bugs and skunks serve an obvious function.

Chemical defense in plants. Perhaps to compensate for their immobility, plants have made wide use of chemicals for protection against competitors, pathogens, herbivores, and abiotic stresses.

Production of defenses by plants is not cost-free; it requires energy that could be used for other purposes. Although the actual cost is usually not known, many plants do concentrate defensive compounds in those tissues that contain the highest energy reserves or growth potential, such as new leaves or seeds. Some plants may also change the amount of resources used for defense, in response to changes in their environment, and the availability of the raw materials for making defenses, for example, carbon from photosynthesis and nitrogen from soil.

Allelopathy. A chemically mediated competitive interaction between higher plants is referred to as allelopathy. This is one of the few examples in plants where the effects of chemicals can be obvious: observations that areas around the bases of walnut trees are free of plant growth led to the first description of allelopathy. In walnuts, the mechanism involves leaching of the chemical juglone (5-hydroxy napthoquinone) from the leaves to the ground, and this inhibits growth and germination of a variety of plants. Allelopathy appears to occur in many plants, may involve phenolics or terpenoids that are modified in the soil by microorganisms, and is at least partly responsible for the organization of some plant communities. *See* ALLELOPATHY.

Active and passive defenses. Chemicals that are mobilized in response to stress or attack are referred to as active or inducible chemicals, while those that are always present in the plant are referred to as passive or constitutive. In many plants, fungus attack induces the production of defensive compounds called phytoalexins, a diverse chemical group that includes isoflavonoids, terpenoids, polyacetylenes, and furanocoumarins. The phytoalexin is produced in the area immediately surrounding the fungus and probably acts by interfering with the nutrition or membrane permeability of the fungal cells. Plant susceptibility to fungus attack is partly related to the speed of production of phytoalexins. *See* PHYTOALEXINS.

Defensive chemicals can be induced by herbivore attack. For example, when snowshoe hares feed on paper birch there is an increase in the levels of phenolic resins in new growth. These levels decrease with time, and the activity of these induced chemicals is thought to cause population cycles of hares. There has been increasing evidence that inducible defenses, such as phenolics, are important in plant–insect interactions.

Constitutive defenses include the chemical hydrogen cyanide. Trefoil, clover, and ferns have been found to exist in two genetically different forms, one containing cyanide (cyanogenic) and one lacking it (acyanogenic); acyanogenic forms are often preferred by several herbivores. Acacia trees also have these two forms; the acyanogenic forms are protected from herbivores by ants that live in the tree and feed on special food bodies on the leaves. Other constitutive chemicals include some phenolic acids, flavonoids, pyrethrins, and alkaloids. *See* ALKALOID; FLAVONOID; PHENOL.

Diversity of activities. Chemical defenses frequently occur together with certain structures which act as physical defenses, such as spines and hairs. In tomatoes, glandular trichomes (hairlike structures) on the leaf surface contain the toxic chemical 2-tridecanone that is active against many insects, while other glands contain phenolics that polymerize like fast-setting glue.

While many chemicals protect plants by deterring herbivore feeding or by direct toxic effects, other defenses may act more indirectly. Chemicals that mimic juvenile hormones, the antijuvenile hormone substances found in some plants, either arrest development or cause premature development in certain susceptible insect species.

Plant chemicals potentially affect not only the herbivores that feed directly on the plant, but also the microorganisms, predators, or parasites of the herbivore. For example, the tomato plant contains an alkaloid, tomatine, that is effective against certain insect herbivores. The tomato hornworm, however, is capable of detoxifying this alkaloid and can thus use the plant successfully—but a wasp parasite of the hornworm cannot detoxify tomatine, and its effectiveness in parasitizing the hornworm is reduced. Therefore, one indirect effect of the chemical in the plant may be to reduce the effectiveness of natural enemies of the plant pest, thereby actually working to the disadvantage of the plant.

Types of plant defenses. Most plant chemicals can affect a wide variety of herbivores and microorganisms, because the modes of action of the chemicals they manufacture are based on a similarity of biochemical reaction in most target organisms (for example, cyanide is toxic to most organisms). In addition, many plant chemicals may serve multiple roles: resins in the creosote bush serve to defend against herbivores and pathogens, conserve water, and protect against ultraviolet radiation.

It is argued that there are two different types of defensive chemicals in plants. The first type occurs in relatively small amounts, is often toxic in small doses, and poisons the herbivore. These compounds, for example, some phenolic acids, alkaloids, and monoterpenes, may also change in concentration in response to plant damage; that is, they are inducible. These kinds of qualitative defensive compounds are the most common in short-lived or weedy species that are often referred to as unapparent. They are also characteristic of fast-growing species with short-lived leaves. In contrast, the second type of defensive chemicals often occurs in high concentrations, is not very toxic, but may inhibit digestion by herbivores and is not very inducible. These quantitative defenses, such as tannins, are most common in long-lived, so-called apparent plants such as trees that have slow growth rates and long-lived leaves. Some plants may use both types of defenses.

Aquatic habitats. There is accumulating evidence that marine plants may be protected against grazing by similar classes of chemicals to those found in terrestrial plants. In algae, for example, phenols appear to be an important defense against limpets. One interesting difference in the marine environment is the large number of halogenated organic compounds that are rare in terrestrial and fresh-water systems.

Evolution of defenses and adaptation. Through evolution, as plants accumulate defenses, herbivores that are able to bypass the defense in some way are selected for and leave more offspring than others. This in turn selects for new defenses on the part of the plant in a continuing process called coevolution.

Animals that can exploit many plant taxa are called generalists, while those that are restricted to one or a few taxa are called specialists. Specialists often have particular detoxification mechanisms to deal with specific defenses. For example, certain bruchid beetles that feed on seeds containing the toxic nonprotein amino acid canavanine possess enzyme systems that recognize this "false" amino acid and avoid incorporating it into proteins. In addition, they are able to convert the amino acid to ammonia via urea and generate energy in the process. Some generalists possess powerful, inducible detoxification enzymes, while others exhibit morphological adaptations of the gut which prevent absorption of compounds such as tannins, or provide reservoirs for microorganisms that accomplish the detoxification. Animals may avoid eating plants, or parts of plants, with toxins. For instance, monkeys choose low-toxin, high-nutrient plant tissues and are capable of learning which plants to avoid.

Some herbivores that have completely surmounted the plant toxin barrier use the toxin itself as a cue to aid in locating plants. The common white butterfly, *Pieris rapae*, for example, uses mustard oil glycosides, which are a deterrent and toxic to many organisms, to find its mustard family hosts. The monarch butterfly and other insects have gone so far as to store plant defensive chemicals in their bodies as protection against predators.

Chemical defense in animals. Many animals make their own defensive chemicals—such as all of the venoms produced by social insects (bees, wasps, ants), as well as snakes and mites. These venoms are usually proteins, acids or bases, alkaloids, or combinations of chemicals. They are generally injected by biting or stinging, while other defenses are produced as sprays, froths, or droplets from glands. For instance, the bombardier beetle expels hot quinones as a spray from its posterior. A response of one predatory mouse to this action is to bury the beetle's dangerous posterior into the sand before biting the head. There are also darkling beetles that mimic the bombardier's actions but do not have a defensive spray. While insects provide the best examples of chemical defense in animals, such defenses are also found in other groups, such as in stinging cells of jellyfish and in poisonous spurs on the duckbill platypus.

Animals frequently make the same types of toxins as plants, presumably because their function as protective agents is similar. Examples include the production of cyanide by millipedes and bracken fern, phenols in the secretions of grasshoppers and in most plant leaves, alkaloids in ant venoms and pepper plants, and cardiac glycosides in milkweed plants and beetles.

Other organisms, particularly insects, use plant chemicals to defend themselves. For example, the monarch butterfly sequesters or stores cardenolides from the milkweed plant, and the lubber grasshopper can sequester a variety of plant chemicals into its defensive secretion by feeding exclusively on certain plants. Sequestration may be a low-cost defense mechanism and probably arises when insects specialize on particular plants.

Microbial defenses. Competitive microbial interactions are regulated by many chemical exchanges involving toxins. They include compounds such as aflatoxin, botulinus toxin, odors of rotting food, hallucinogens, and a variety of antibiotics. *See* ANTIBIOTIC; TOXIN.

Microorganisms also play a role in chemical interaction with plants and animals that range from the production of toxins that kill insects, such as those produced by the common biological pest control agent *Bacillus thuringiensis*, to cooperative biochemical detoxification of plant toxins by animal symbionts.

Information exchange. A large area of chemical ecology concerns the isolation and identification of chemicals used for communication.

Insects. Pheromones, substances produced by an organism that induce a behavioral or physiological response in an individual of the same species, have been studied particularly well in insects. These signals are compounds that are mutually beneficial to the emitter and sender, such as sex attractants, trail markers, and alarm and aggregation signals.

Sex pheromones are volatile substances, usually produced by the female to attract males. Each species has a characteristic compound that may differ from that of other species by as little as a few atoms. For example, the pheromone of the cabbage looper moth is *cis*-7-dodecenyl acetate; the oriental fruit fly's is *cis*-8-dodecenyl acetate. The activity of these compounds can be destroyed by minor changes in their structure. In addition, sex pheromones generally are active at extremely low concentrations—a few molecules impinging on a moth's antenna may be sufficient to stimulate a response. The pheromone blend released by a female moth may be dominated by one or two components but also contains many trace components. The dominant compounds may attract males, but the full repertoire of male behavior that results in successful mating also involves the trace components.

Pheromones are typically synthesized directly by the animal and are usually derived from fatty acids. In a few cases the pheromone or its immediate precursors may be derived from plants, as in danaid butterflies. Male danaids visit certain nonhost plants solely to obtain pyrrolizidine alkaloids, which are used to make pheromones used in courtship.

Trail pheromones are used by social insects and some lepidopterans to recruit others of its species to a food source. These are synthesized by the animal as well as acquired from hosts, and are diverse in structure. The honeybee uses geraniol, which it acquires from nectar. Methyl 4-methylpyrrole 2-carboxylate, the trail pheromone of the leaf-cutting ant, may be synthesized in the gut by bacteria. The ideal trail pheromone loses its potency over time unless reinforced, and is therefore relatively unstable and difficult to analyze chemically. *See* PHEROMONE.

Vertebrates. Very little work has been done in identifying specific pheromones in vertebrates, particularly mammals. It is known, however, that they are important in marking territory, in individual recognition, and in mating and warning signals. Frequently these signals involve sebaceous oils from the skin, urine, or feces. Some mammals have a very complex series of glands; it is possible that microorganisms on these glands convert urine compounds to components of the signal chemical. The complexity of this chemical mix, and the complexity of the animal, means that the strong positive or negative response to single compounds that is found in some insects is not found as often in mammalian systems. In female primates of several species, mixtures of short-chain organic acids, such as acetic and butanoic, lead to sexual excitation in the male. These same chemicals have been found in human females, but in different concentrations. *See* REPRODUCTIVE BEHAVIOR; SCENT GLAND; TERRITORIALITY.

Plants and microorganisms. Chemical communication may also occur among plants and microorganisms, although it is rarer and less obvious than in animals. The release of ethylene by ripening fruit stimulates the ripening of nearby fruit, thus ensuring simultaneous presentation of an attractive mass for potential dispersers. Certain plants produce high concentrations of volatile isoprenes. The concentrations and composition of these compounds change under stress, but it is not known whether this signal, if it is one, is recognized by other plants.

Bacterial contact and recognition is accomplished by cell wall proteins and by secretions. This type of communication is important in strain recognition, and also takes place in fungi such as *Mucor* prior to mating. Here chemical communication is at the cellular level.

Value. The chemicals involved in chemical interactions between organisms are important in the pharmaceutical, perfume, and many other chemical industries. These substances, together with many antibiotics and pesticides, are based on compounds found in plants. However, information about chemical ecology is only just beginning to be exploited, particularly in the field of plant protection. For example, pheromones which are highly specific and nontoxic are used to trap insect pests for a variety of purposes, including monitoring and population reduction. As the mechanisms of pathogen resistance are understood, the proper chemical attributes may be bred or genetically engineered into plants. For example, the genes for production of a legume seed protein toxin have been transferred to tobacco leaves. The genes were expressed and the leaves became protected from insect attack. The potential for exploiting naturally occurring defenses may thus reduce reliance on costly, potentially hazardous synthetic chemicals. *See* ECOLOGY; GENETIC ENGINEERING; INSECT CONTROL, BIOLOGICAL; INSECTICIDE. Chemical energy

A useful but obsolescent term for the energy available from elements and compounds when they react, as in a combustion reaction. In precise terminology, there is no such thing as chemical energy, since all energy is stored in matter as either kinetic energy or potential energy. *See* COMBUSTION; ENERGY.

When a chemical reaction takes place, the atoms of the reactants change their bonding pattern and become products. The breaking of bonds in the reactants requires energy, and the formation of bonds in the products releases energy. The net change in energy is commonly referred to as chemical energy. To be more precise, when a reaction takes place, there is an overall change in the enthalpy H of the system as bonds are broken and new bonds are formed. This change in enthalpy is denoted ΔH. Under standard conditions [a pressure of 1 bar (100 kilopascals) and all substances pure], the change is noted ΔH° and called the standard enthalpy of reaction. Provided the pressure is constant, the standard enthalpy can be identified with the energy released as heat (when $\Delta H^\circ < 0$) or gained as heat ($\Delta H^\circ > 0$) when the reaction takes place. Reactions for which $\Delta H^\circ < 0$ are classified as exothermic; those for which $\Delta H^\circ > 0$ are classified as endothermic. All combustions are exothermic, the released heat being used either to provide warmth or to raise the temperature of a working fluid in an engine of some kind. There are very few common endothermic reactions; one example is the dissolution of ammonium nitrate in water (a process utilized in medical cold packs). *See* CHEMICAL EQUILIBRIUM; CHEMICAL THERMODYNAMICS; ENTHALPY; THERMOCHEMISTRY.

The "chemical energy" available from a typical fuel (that is, the enthalpy change accompanying the combustion of the fuel, when carbon-hydrogen bonds are replaced by stronger carbon-oxygen and hydrogen-oxygen bonds) is commonly reported as either the specific enthalpy or the enthalpy density. The specific enthalpy is the standard enthalpy of combustion divided by the mass of the reactant. The enthalpy density is the standard enthalpy of combustion divided by the volume of the reactant. The former is of primary concern when mass is an important consideration, as in raising a rocket into orbit. The latter is of primary concern when storage space is a limitation. The specific enthalpy of hydrogen gas is relatively high (142 kilojoules/g), but its enthalpy density is low (13 kJ/L). The values for octane, a compound representative of gasoline, are 48 kJ/g and 38 MJ/L, respectively (note the change in units). The high enthalpy density of octane means that a gasoline tank need not be large to store a lot of "chemical energy." *See* AIRCRAFT FUEL; ENERGY SOURCES; GASOLINE; ROCKET PROPULSION. Peter W. Atkins

Chemical engineering

The branch of engineering involved in the research, design, improvement, operation, and commercialization of plants, processes, and products for the chemical industry and related fields, such as biotechnology, energy, and materials. The work of chemical engineers has evolved continuously with the changing needs of society. Chemical engineering arose from attempts at inventing ways to make products such as gunpowder and wine. Early on (in the nineteenth century), the large-scale and efficient manufacturing of inorganic chemicals, such as salt, soda ash, sulfuric acid, and nitrogen fixation, were the main occupation of American chemical engineers. However, for the small-scale dyestuff and drug industries in Europe, chemical engineers were less involved. In the twentieth century, large-scale petroleum refining, petrochemicals, and polymers were the dominant industrial problems. In the twenty-first century, the focus has shifted to smaller-scale processes across many disciplines of science and technology, such as molecular biology, genetics, information technology, and nanotechnology. *See* GENETICS; INFORMATION TECHNOLOGY; INORGANIC CHEMISTRY; NANOTECHNOLOGY; PETROCHEMICAL; POLYMER; PROCESS ENGINEERING.

Professional work and achievements. Chemical engineers work in the development, manufacturing, and service sectors. They are engaged in the design, construction, and operation of equipment and plants. Increasingly, chemical engineers are involved in product engineering, which is the design of new products and the improvement of existing products such as controlled drug-delivery devices, biodegradable polymers, and fuel cells. In addition, chemical engineers play an important role in the commercialization of novel medicines, materials, and environmental remediation and recycling technology. *See* DRUG DELIVERY SYSTEMS; FUEL CELL; RECYCLING TECHNOLOGY.

Chemical engineers often play leading roles in the manufacturing industries of basic chemicals and petroleum refining. They work in pharmaceutical, biochemical, biomedical, food, agricultural chemicals, plastics, rubber, textile fibers, paper, ink, soap and cosmetics, and water purification industries. In the electronics industry, the manufacture of integrated circuits and other microelectronic devices involves chemical processing. Chemical engineers also are employed in services, such as education, government, business and professional services, and, increasingly, health care. *See* BIOCHEMICAL ENGINEERING; BIOMEDICAL CHEMICAL ENGINEERING; CHEMICAL PROCESS INDUSTRY; FOOD ENGINEERING; INK; MANUFACTURED FIBER; MICROLITHOGRAPHY; PAPER; PHARMACEUTICAL CHEMISTRY; RUBBER; TEXTILE.

Some characteristic operations in chemical engineering involve the conversion of raw materials (such as petroleum) into useful products (such as gasoline, jet fuel, and asphalt), as well as the conversion and recycling of environmental pollutants (such as municipal waste). Other conversions involve chemical reactions such as the fixation of nitrogen from air into fertilizers for agriculture, physical modifications such as blowing polymers into films and extruding polymers into fibers, and biochemical reactions such as the fermentation of sugar into alcohol. These conversions also involve separations, such as making freshwater out of seawater, recovering penicillin from very dilute solutions in fermentation tanks, and extracting water and waste products from blood in artificial kidneys. *See* CHEMICAL CONVERSION; CHEMICAL SEPARATION; FERMENTATION; NITROGEN FIXATION; PETROLEUM PROCESSING AND REFINING; PLASTICS PROCESSING; WATER DESALINATION.

Education and professional training. Chemical engineers require knowledge in chemistry, biology, mathematics, physics, and machinery. The education and training of chemical engineers includes a rigorous curriculum of courses, laboratories, design projects, and quite often periods of industrial practice or internships. In common with other engineers, mathematics and physics form the core curriculum. The major distinction of chemical engineers is their understanding of chemistry, and increasingly of molecular and cell biology and materials science. *See* CELL BIOLOGY; MATERIALS SCIENCE; MATHEMATICS; MOLECULAR BIOLOGY; PHYSICS.

The earliest engineering education program began in France, where mathematics played a decisive role. The modern chemical engineering curriculum evolved from a program in 1888 at the Massachusetts Institute of Technology by L. M. Norton, which was centered on the study of the applied chemistry of specific inorganic chemicals. The first paradigm, or systemic knowledge, that could be applied to many problems was the concept of unit operations, introduced in 1923 in the *Principles of Chemical Engineering* by W. H. Walker, W. K. Lewis, and W. H. McAdams. The concept of unit operations became the standard taught everywhere and provided the effective tools for the graduates to engineer new chemical industries. Thermodynamics and chemical reaction engineering were added later, and the accreditation of chemical engineering degrees was based on the mastery of these subjects. *See* CHEMICAL REACTOR; CHEMICAL THERMODYNAMICS; UNIT OPERATIONS.

After World War II, during which scientists with no engineering background made the atomic bomb, engineering educators turned toward science for inspiration. Transport phenomena began as the second paradigm of chemical engineering, with the publication (1960) of *Transport Phenomena* by R. B. Bird, W. E. Stewart, and E. N. Lightfoot. The transport of momentum, heat, and mass is fundamental to the unit operations and chemical reactors. Applied mathematics and computation formed the basis for the rational modeling and design of chemical machinery and operations, as well as the systematic optimization of entire chemical plants. *See* TRANSPORT PROCESSES.

In the United States, the American Institute of Chemical Engineers, founded in 1908, is the principal professional society. Chemical engineering became a worldwide force with the founding of the Institution of Chemical Engineers in 1953 and the World Chemical Engineering Council in 2001.

Chemical equilibrium

In a dynamic or kinetic sense, chemical equilibrium is a condition in which a chemical reaction is occurring at equal rates in its forward and reverse directions, so that the concentrations of the reactant and product substances do not change with time. In a thermodynamic sense, it is the condition in which there is no tendency for the composition of the system to change. From the viewpoint of statistical mechanics, the equilibrium state places the system in a condition of maximum freedom (or minimum restraint) compatible with the energy, volume, and composition of the system. The statistical approach has been merged with thermodynamics into a field called statistical thermodynamics; this merger has been of immense value for its intellectual stimulus, as well as for its practical contributions to the study of equilibria. *See* CHEMICAL THERMODYNAMICS; STATISTICAL MECHANICS.

Because thermodynamics is concerned with relationships among observable properties, such as temperature, pressure, concentration, heat, and work, the relationships possess general validity, independent of theories of molecular behavior. Because of the simplicity of the concepts involved, this article utilizes the thermodynamic approach.

Chemical potential. Thermodynamics attributes to each chemical substance a property called the chemical potential, which may be thought of as the tendency of the substance to enter into chemical (or physical) change. Although the absolute chemical potential of a substance cannot be measured directly, differences in chemical potential are measurable. The units of chemical potential are joules per mole.

The importance of the chemical potential lies in its relation to the affinity or driving force of a chemical reaction. It is useful to consider the general reaction (1), and let μ_A be the chemical potential of substance A, μ_B be the chemical potential of B, and so on. Then, according to one of the fundamental principles of thermodynamics (the second law), the reaction will be spontaneous (left to right) when the total chemical potential of the reactants is greater than that of the products. Thus, for spontaneous change (naturally occurring processes), notation (2) applies.

$$aA + bB \rightleftharpoons gG + hH \tag{1}$$

$$[g\mu_G + h\mu_H] - [a\mu_A + b\mu_B] < 0 \tag{2}$$

When equilibrium is reached, the total chemical potentials of products and reactants become equal; thus Eq. (3) holds at equilibrium. The difference in chemical potentials in Eqs. (2) and (3) is called the driving force or affinity of the process or reaction; the affinity is zero when the chemical system is in chemical equilibrium.

$$[g\mu_G + h\mu_H] - [a\mu_A + b\mu_B] = 0 \tag{3}$$

For reactions at constant temperature and pressure (the usual restraints in a chemical laboratory), the difference in chemical potentials becomes equal to the Gibbs energy change $\Delta_r G$ for the process in Eq. (4). The decrease in Gibbs energy represents the maximum net work obtainable from the process. When no more work is obtainable, then the system is at equilibrium. Conversely, if the value of $\Delta_r G$ for a process is positive, some useful work will have to be expended upon the process, or reaction, in order to make it proceed from left to right; the process cannot proceed naturally or spontaneously. The term "spontaneously" as used here implies only that a process can occur. It does not imply that the reaction will actually occur. Thus, the reaction between hydrogen and oxygen is a spontaneous process in the sense of the term as used here, even though a mixture of hydrogen and oxygen can remain unchanged for years unless ignited or exposed to a catalyst.

$$\Delta_r G = [g\mu_G + h\mu_H] - [a\mu_A + b\mu_B] \tag{4}$$

Because, by definition, a catalyst does not undergo a net chemical change during the reaction, its chemical potential does not appear in Eqs. (2), (3), and (4). A catalyst, therefore, can contribute nothing to the driving force of a reaction, nor can it, in consequence, alter the position of the chemical equilibrium in a system. *See* CATALYSIS.

In addition to furnishing a criterion for the equilibrium state of a chemical system, the thermodynamic method goes much further. In many cases, it yields a relation between the change in chemical potentials (or change in Gibbs energy) and the equilibrium concentrations of the substances involved in the reaction. To do this, the chemical potential must be expressed as a function of concentration and possibly other properties of the substance.

The chemical potential μ is usually represented by Eq. (5), where R is the gas constant, T is the absolute temperature, x is the concentration of the substance, γ is the activity coefficient of the substance, and μ^0 is the chemical potential of the substance in its standard state. *See* CONCENTRATION SCALES.

$$\mu = \mu^0 + RT \ln x + RT \ln \gamma \tag{5}$$

For substances obeying the laws of ideal solutions (or ideal gases), the last term, $RT\ln\gamma$, is zero ($\gamma = 1$), because it is a measure of the deviation from ideal behavior caused by intermolecular or inter-ionic forces. An ideal solution would then be a solution for which $RT\ln\gamma$ is zero ($\gamma = 1$) over the whole concentration range. For real solutions, the state standard (where γ is unity) is generally chosen as the pure substance [mole fraction = 1 at 1 bar (100 kilopascals) and the temperature of interest] for solids and solvents, and as the hypothetical ideal gas or the unit concentration solute in solution at 1 bar and the temperature of interest. Although the activity coefficient γ is dimensionless, its numerical values depend upon the particular concentration scale x with which it is associated.

Although the choice of concentration scales is a matter of convenience, the following are conventionally used: $x = p$ = partial pressure, for gases; $x = c$

(or m) = molar (or molal) concentrations, respectively, for solutes in electrolytic solutions; x = mole fraction, for solids and solvents. When the choice is not established by convention, the mole fraction scale is preferred.

Activity and standard states. It is often convenient to utilize the product, γx, called the activity of the substance and defined by $a = \gamma x$. The activity may be looked upon as an effective concentration of the substance, measured in the same units as the concentration x with which it is associated. The standard state of the substance is then defined as the state of unit activity (where $a = x = 1$) at 1 bar and the temperature of interest and is characterized by the standard chemical potential μ^0. Clearly, the terms μ^0, γ, and x are not independent; the choice of the activity scale serves to fix the standard state. For example, for hydrochloric acid, the standard state for the solute (HCl) would be an (hypothetical) ideal 1 molar (or 1 molal) solution, and for the solvent (H_2O) the standard state would be pure water (mole fraction = 1), both at 1 bar and the temperature of interest. The reference state would be an infinitely dilute solution; here the activity coefficients would be unity for both solute and solvent. For the vapor of HCl above the solution, the standard state would be the hypothetical gaseous state at 1 bar partial pressure. For gases, the term "fugacity" is often used instead of "activity." *See* FUGACITY.

Equilibrium constant. If the general reaction in Eq. (1) occurs at constant temperature T and pressure P when all of the substances involved are in their standard states of unit activity, Eq. (4) would become Eq. (6). The quantity $\Delta_r G^0$ is known as the standard

$$\Delta_r G^0 = \left[g\mu^0_{\mathrm{G}} + h\mu^0_{\mathrm{H}}\right] - \left[a\mu^0_{\mathrm{A}} + b\mu^0_{\mathrm{B}}\right] \qquad (6)$$

Gibbs energy change for the reaction at the temperature and pressure for the chosen standard states. (Standard state properties are commonly designated by a superscript zero, as in $\Delta_r G^0$, μ^0.) Since each of the standard chemical potentials (μ^0_i) is a unique property determined by the temperature, pressure, standard state, and chemical identity of the substance concerned, the standard free energy change ΔG^0 is a constant characteristic of the particular reaction for the chosen temperature, pressure, and standard states.

If, for Eq. (1), at constant temperature and pressure, the chemical potential of each substance is expressed in terms of Eq. (5), then the Gibbs energy change for the reaction, from Eq. (4), becomes Eq. (7) in terms of the activities and the standard

$$\Delta_r G = \Delta_r G^0 + RT \ln \frac{a^g_{\mathrm{G}} a^h_{\mathrm{H}}}{a^a_{\mathrm{A}} a^b_{\mathrm{B}}} \qquad (7)$$

Gibbs energy change, Eq. (6). Equation (7) is often written in the form of Eq. (8), where Q is the ratio

$$\Delta_r G = \Delta_r G^0 + RT \ln Q \qquad (8)$$

of the activities of products to the activities of reactants, each activity bearing as an exponent the corresponding coefficient in the balanced equation for the reaction [as in Eq. (7)]. The standard Gibbs energy change $\Delta_r G^0$ serves as a reference point from which the actual Gibbs energy change $\Delta_r G$ can be calculated in terms of the activities of the reacting substances.

When the system has come to chemical equilibrium at constant temperature and pressure, $\Delta_r G = 0$, from Eq. (3). Equation (7) then leads to the very important relation shown in Eq. (9), where the value of K is shown as Eq. (10), and the activities are

$$\Delta_r G^0 = -RT \ln K \qquad (9)$$

$$K = \left[\frac{a^g_{\mathrm{G}} a^h_{\mathrm{H}}}{a^a_{\mathrm{A}} a^b_{\mathrm{B}}}\right] \qquad (10)$$

the equilibrium values. The quantity K is called the equilibrium constant for the reaction. The equilibrium constant is a characteristic property of the reaction system, because it is determined uniquely at a given temperature in terms of the standard Gibbs energy change. The term $-\Delta_r G^0$ represents the maximum net work that the reaction could make available when carried out at constant temperature and pressure with the substances in their standard states. It should be clear from Eq. (6) that the magnitude of $\Delta_r G^0$ is directly proportional to the amount of material represented in the reaction in Eq. (1). Likewise, Eqs. (7) through (10) denote this same proportionality through the exponents a, b, g, and h in the terms K and Q. Naturally, the value of $\Delta_r G^0$, as well as K and Q, will depend upon the particular concentration scales and standard states selected for the system. Therefore it is essential that sufficient information be stated about a system to fully describe the chosen standard states.

Equations (8) and (10) can be combined in the form of Eq. (11), sometimes denoted as the Lewis

$$\Delta_r G = RT \ln \frac{Q}{K} \qquad (11)$$

equation after G. N. Lewis, who was the first to formulate this equation. When Q for a specified set of conditions is larger than K (so that $\Delta_r G$ is positive), the proposed reaction cannot occur left to right. On the other hand, when Q is less than K, then the proposed process or reaction can occur. The equilibrium constant thus serves as a measure of the position of chemical equilibrium for a system. For a proposed process for which Q is greater than K, the reaction system would have to move away from its equilibrium state (impossible of its own accord) to proceed from left to right, and for a proposed process for which Q is less than K, the process would bring the system closer to its equilibrium state (as in all naturally occurring processes).

Instead of activities, values of concentrations and activity coefficients at equilibrium may be used to express the form of the equilibrium constant K in Eq. (12). This gives the equilibrium constant as a

$$K = \left[\frac{x^g_{\mathrm{G}} x^h_{\mathrm{H}}}{x^a_{\mathrm{A}} x^b_{\mathrm{B}}}\right] \cdot \left[\frac{\gamma^g_{\mathrm{G}} \gamma^h_{\mathrm{H}}}{\gamma^a_{\mathrm{A}} \gamma^b_{\mathrm{B}}}\right] \qquad (12)$$

product of two terms. The first term, involving concentrations, is directly measurable if the system can be analyzed at equilibrium. On the other hand, the activity coefficient term, as seen in Eq. (13), is frequently difficult to evaluate.

$$K_\gamma = \frac{\gamma_G^g \gamma_H^b}{\gamma_A^a \gamma_B^b} \tag{13}$$

Intensive studies of activity coefficients made upon a wide variety of chemical systems led to a number of simplifying principles and some useful theoretical treatments of the subject. For gases, the activity coefficients differ only slightly from unity for pressures up to a few atmospheres and often can be evaluated from equation-of-state data. For mixtures of nonelectrolytes, the values also are not far from unity in many cases. For solutions of electrolytes, the activity coefficients vary greatly with concentration, and in many cases approach unity only below a useful or even attainable concentration. The theoretical treatments of P. Debye, E. Hückel, and others have systematized the patterns of electrolyte behavior, making possible a reasonable estimate of the activity coefficients of electrolytes in many cases. *See* ACTIVITY (THERMODYNAMICS); SOLUTION.

In general, the function K_γ, Eq. (13), approaches unity as the composition of the system approaches ideal behavior, so in practice most equilibrium constants K are evaluated through some suitable extrapolation procedure involving Eq. (12). See the discussion following Eq. (5).

For many approximate calculations or when data for K_γ are scarce, it is common to express the equilibrium constant as the concentration term only; that is, Eq. (14) is applied.

$$K_{\text{app}} = \frac{x_G^g x_H^b}{x_A^a x_B^b} \approx K \tag{14}$$

Unless K_γ is a rather insensitive function of concentration, the so-called constants (K_{app} denotes an apparent or approximate value of K), obtained in this manner are not constant as the composition is varied, and even though approximately constant, may vary considerably from the true value of K. Although the practice of assigning K_γ a value of unity will often give useful results and is frequently the only expedient available, the results must be used with caution.

The kinetic concept of chemical equilibrium introduced by C. M. Guldberg and P. Waage (1864) led to the formulation of the equilibrium constant in terms of concentrations. Although the concept is correct in terms of the dynamic picture of opposing reactions occurring at equal speeds, it was not successful in coping with the problems of activity coefficients and cannot lead to the useful relations, Eqs. (4) and (11), in terms of an energetic criterion for the position of equilibrium. Conversely, the thermodynamic approach yields no relationship between the driving force at the reaction and the rate of approach to equilibrium. *See* CHEMICAL DYNAMICS.

The influence of temperature upon the chemical potentials, and hence upon the equilibrium constant, is given by the Gibbs-Helmholtz equation (15).

$$\frac{d \ln K}{dT} = \frac{\Delta_r H^0}{RT^2} \tag{15}$$

The derivative on the left represents the slope of the curve obtained when values of ln K for a reaction, obtained at different temperatures, are plotted against temperature. The standard enthalpy of reaction $\Delta_r H^0$ for the temperature T at which the slope is measured, is the heat effect which could also be observed by carrying out the reaction involving the standard states in a calorimeter at the corresponding temperature and 1 bar.

For endothermic reactions, which absorb heat ($\Delta_r H^0$ positive), K increases with increasing temperature. For exothermic reactions, which evolve heat ($\Delta_r H^0$ negative), K decreases with increasing temperature and the yield of products is reduced. A more useful arrangement of Eq. (15) is shown in Eq. (16).

$$\frac{d \ln K}{d(1/T)} = \frac{-\Delta_r H^0}{R} \tag{16}$$

Plots of ln K against $1/T$ are nearly linear for reactions where the value of $\Delta_r H^0$ changes slowly with temperature. Hence, over small temperature ranges, Eq. (16) becomes, in integrated form, Eq. (17).

$$\ln \frac{K_2}{K_1} = \frac{\Delta_r H^0}{R} \left[\frac{T_2 - T_1}{T_1 T_2} \right] \tag{17}$$

This relation is much used for calculating heats of reaction from two equilibrium measurements or for determining an equilibrium constant K_2 at temperature T_2 from values of K_1, and $\Delta_r H^0$.

For accurate work, or for extending the calculations over a wide range of temperature, $\Delta_r H^0$ must be known as a function of temperature before Eq. (15) or (16) can be integrated. When sufficient heat capacity data are available, Kirchhoff's equation, involving the difference in heat capacities between the products and reactants, Eq. (18), may be combined with Eq. (15) to yield Eq. (19).

$$\Delta_r H^0 = \Delta_r H_0^0 + \alpha T + \frac{\beta T^2}{2} + \frac{\delta T^3}{3} \tag{18}$$

$$R \ln K = -\frac{\Delta_r H_0^0}{T} + \alpha \ln T + \frac{\beta T}{2} + \frac{\delta T^2}{6} + I \tag{19}$$

In these equations, the coefficients α, β, and δ are determined from heat capacity data; the constants $\Delta_r H_0^0$ and I require knowledge of one value of $\Delta_r H^0$ and one value of K, or values of K at two temperatures. *See* HEAT CAPACITY; THERMOCHEMISTRY.

Homogeneous equilibria. These equilibria involve single-phase systems: gaseous, liquid, or solid solutions.

A representative gas-phase equilibrium is the ammonia synthesis shown in Eq. (20), where (g) denotes a gas-phase species.

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g) \tag{20}$$

The most natural concentration measures are mole fraction or partial pressure. The partial pressures p_i are defined in terms of mole fractions x_i, and the total pressure P by $p_i = x_i P$. For low pressures, where activity coefficients are practically unity, Eq. (21) holds. Equation (21) is a special case of Eq. (22), where Δn is the change in

$$K_p = \frac{p^2_{\mathrm{NH_3}}}{p_{\mathrm{N_2}} p^3_{\mathrm{H_2}}} = \frac{x^2_{\mathrm{NH_3}}}{x_{\mathrm{N_2}} x^3_{\mathrm{H_2}}} P^{-2} \qquad (21)$$

$$K_p = K_x P^{\Delta n} \qquad (22)$$

the number of moles of gases [$\Delta r = -2$ for Eq. (20)]. The mole fraction equilibrium constant K_x is pressure dependent, but K_p is independent of pressure. Consequently, an increase in total pressure P must lead to an increase in K_x in this case. If the increase in total pressure is due to a decrease in volume of the system, then the result will be an increased yield of products (NH_3). An increase in pressure brought about by injection of an inert gas into a constant volume system would not affect the partial pressures of the reacting gases nor the ultimate yield of products. The value of K_x, and thus that of $\Delta_r G_x$, will be affected by a change in total pressure owing to a change in the net work of mixing and unmixing the gases. The reaction described by Eq. (20) is exothermic, so better yields will be obtained at lower temperatures. However, the rate of attainment of equilibrium in this case is very slow at low temperatures [Eq. (15)].

A typical liquid-phase equilibrium is the deprotonation of acetic acid in water, reaction (23) and Eq. (24), where (aq) denotes an aqueous-phase

$$\mathrm{HC_2H_3O_2(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + C_2H_3O_2^-(aq)} \qquad (23)$$

$$\frac{K}{K_\gamma} = \frac{(m_{\mathrm{H_3O^+}})(m_{\mathrm{C_2H_3O_2^-}})}{m_{\mathrm{HC_2H_3O_2}} a_{\mathrm{H_2O}}} \qquad (24)$$

species and (l) denotes a liquid-phase solvent. In this particular case, the activity coefficient ratio K_γ is less than unity in dilute solutions. The activity of water $a_{\mathrm{H_2}}\mathrm{O} \simeq x_{\mathrm{H_2}}\mathrm{O}$ at low molalities (≤ 1 *m*) is close to unity. For this reason, $a_{\mathrm{H_2}}\mathrm{O}$ is commonly omitted in the formulation of the equilibrium constant expressions of this type, because $a_{\mathrm{H_2}}\mathrm{O} \simeq 1$. *See* IONIC EQUILIBRIUM.

Heterogeneous equilibria. These are usually studied at constant pressure, because at least one of the phases will be a solid or a liquid. The imposed pressure may be that of an equilibrium gaseous phase, or it may be an externally controlled pressure.

In describing such systems, as for all reaction systems, the nature of each phase must be specified. In the examples to follow, s, l, g, aq, and soln identify solid, liquid, gaseous, aqueous, and nonaqueous phases, respectively. For solutions or mixtures, the composition is needed, in addition to the temperature and pressure, to complete the specification of the system; the nature of any solvent also must be specified.

In the equilibrium shown as (25), the relationship of Eq. (26) holds. Here $K \approx p/x$, the ratio of

$$\mathrm{H_2O(l) \rightleftharpoons H_2O(g)} \qquad (25)$$

$$\Delta_r G^0 = \mu_g^0 - \mu_l^0 = -RT \ln \frac{p}{x} \qquad (26)$$

the vapor pressure p to the liquid mole fraction x. For pure water, the equilibrium constant is approximately equal to the vapor pressure of water at least at low pressures. When a small amount of solute is added, thereby decreasing the mole fraction of solvent, the vapor pressure p must be lowered to maintain equilibrium (Raoult's law). The effect of the total applied pressure P upon the vapor pressure p of the liquid is given by the Gibbs-Poynting equation (27). Here V_l and V_g are the molar volumes

$$\left[\frac{dp}{dP}\right]_T = \frac{V_l}{V_g} \qquad (27)$$

of liquid and vapor, respectively. The equilibrium vapor pressure will increase as the total pressure is increased (both V_l and V_g are positive and the activity of the liquid increases with pressure). If the external pressure is applied to a solution by a semipermeable membrane, then an applied pressure can be found which will restore the vapor pressure (or activity) of the solvent to its standard state value. *See* OSMOSIS.

For a solid, such as barium sulfate, $BaSO_4$, which dissolves in water as shown in Eq. (28), the equilibrium relationship is shown in Eq. (29). When the

$$\mathrm{BaSO_4(s) \rightleftharpoons Ba^{2+}(aq) + SO_4^{2-}(aq)} \qquad (28)$$

$$K^0 = \frac{a_{\mathrm{Ba^{2+}}} + a_{\mathrm{SO_4{}^{2-}}}}{a_{\mathrm{BaSO_4(s)}}} \qquad (29)$$

solid state is pure, its activity is unity at 1 bar. If the solid is extremely finely divided, then its activity is greater than unity; with this increase in the activity of the solid state, the solubility must increase to maintain equilibrium. On the other hand, inclusion of foreign ions in the crystal lattice (solid solution formation) lowers the activity of the solid state.

When a gas, such as CO_2, is dissolved in a liquid, its equilibrium with the gas phase is as shown in Eq. (30). Equation (31), Henry's law, represents the

$$\mathrm{CO_2(soln) \rightleftharpoons CO_2(g)} \qquad (30)$$

$$K = \frac{a_{\mathrm{CO_2(g)}}}{a_{\mathrm{CO_2(soln)}}} \approx \frac{P_{\mathrm{CO_2}}}{m_{\mathrm{CO_2}}} \qquad (31)$$

equilibrium constant for this equation, where *m* is the molality of dissolved CO_2. When the gas dissociates in the liquid, as in reaction (32), Eq. (33) may

$$\mathrm{H^+(aq) + Cl^-(aq) \rightleftharpoons HCl(g)} \qquad (32)$$

$$K = \frac{p}{m^2_{\mathrm{HCl}}} \cdot K_\gamma \qquad (33)$$

be utilized. Here *m* is the molality of dissolved HCl.

Similarly, when a solute distributes itself between two immiscible phases, that is, $nA(\text{soln } 1) \rightleftharpoons A_n(\text{soln } 2)$, the equilibrium constant takes the form of Eq. (34). The equilibrium concentrations c_i in

$$K = \frac{c_{A_n}}{c_A^n} \cdot K_\gamma \qquad (34)$$

Eq. (34) reflect the relative solubilities of the solute in the two phases; since solubilities may vary widely, solvent extraction may provide an effective means for concentrating a widely dispersed solute. *See* EXTRACTION.

When components form immiscible phases at equilibrium, each condensed phase will be a saturated solution; complete immiscibility is impossible in principle, because the chemical potential of any component must be the same in all phases. The separation of a liquid system into two liquid phases is a manifestation of the nonideality of the solutions. For practical purposes, however, many solids may be regarded as immiscible because of the stringent requirements associated with formation of solid solutions.

In reactions involving condensed and immiscible phases, for example, reaction (35), there can be no

$$\mathrm{Pb(s)} + 2\mathrm{AgCl(s)} \rightleftharpoons \mathrm{PbCl_2(s)} + 2\mathrm{Ag(s)} \qquad (35)$$

change in concentration of any phase during the reaction. In such a case the Q term in Eq. (10) will be constant, and $\Delta_r G$ is fixed at a given pressure and temperature. Although a reaction is possible, there is at most one pressure at each temperature for which $\Delta_r G$ could be zero. Such is the case in transition phenomena, or melting-freezing phenomena. From the phase-rule viewpoint, the system in reaction (35) has only one degree of freedom if reaction is possible, so once a value of P or T is chosen, the remaining variable (T or P) is fixed by nature at equilibrium. *See* PHASE RULE.

Chemical fuel

The principal fuels used in internal combustion engines (automobiles, diesel, and turbojet) and in the furnaces of stationary power plants are organic fossil fuels. These fuels, and others derived from them by various refining and separation processes, are found in the earth in the solid (coal), liquid (petroleum), and gas (natural gas) phases.

Special fuels to improve the performance of combustion engines are obtained by synthetic chemical procedures. These special fuels serve to increase the fuel specific impulse of the engine (specific impulse is the force produced by the engine multiplied by the time over which it is produced, divided by the mass of the fuel) or to increase the heat of combustion available to the engine per unit mass or per unit volume of the fuel. A special fuel which possesses a very high heat of combustion per unit mass is liquid hydrogen. It has been used along with liquid oxygen in rocket engines. Because of its low liquid density, liquid hydrogen is not too useful in systems requiring high heats of combustion per unit volume of fuel (“volume-limited” systems). In combination with liquid fluorine, liquid hydrogen produces extremely large specific impulses. *See* AIRCRAFT FUEL.

A special fuel which produces high flame temperatures of the order of 9000°F (5000°C) is gaseous cyanogen, C_2N_2. This is used with gaseous oxygen as the oxidizer. The liquid fuel hydrazine, N_2H_4, and other hydrazine-based fuels, with the liquid oxidizer nitrogen tetroxide, N_2O_4, are used in many space-oriented rocket engines. The boron hydrides, such as diborane, B_2H_6, and pentaborane, B_5H_9, are high-energy fuels which are being used in advanced rocket engines. *See* BORANE.

For air-breathing propulsion engines (turbojets and ramjets), hydrocarbon fuels are most often used. For some applications, metal alkyl fuels which are pyrophoric (that is, ignite spontaneously in the presence of air), and even liquid hydrogen, are being used.

A partial list of additional liquid fuels and their associated oxidizers is shown in the **table**.

Fuels which liberate heat in the absence of an oxidizer while decomposing either spontaneously or because of the presence of a catalyst are called monopropellants and have been used in rocket engines. Examples of these monopropellants are hydrogen peroxide, H_2O_2, and nitromethane, CH_3NO_2.

Liquid fuels and oxidizers are used in most large-thrust (large propulsive force) rocket engines. When thrust is not a consideration, solid-propellant fuels and oxidizers are frequently employed because of the lack of moving parts such as valves and pumps, and the consequent simplicity of this type of rocket engine. Solid fuels fall into two broad classes, double-base and composites. Double-base fuels are compounded of nitroglycerin (glycerol trinitrate) and nitrocellulose, with no separate oxidizer required. The nitroglycerin plasticizes and swells the nitrocellulose, leading to a propellant of relatively high strength and low elongation. The double-base propellant is generally formed in a mold into the desired shape (called a grain) required for the rocket case. Composite propellants are made of a fuel and

Liquid fuels and their associated oxidizers

Fuel	Oxidizer
Ammonia	Liquid oxygen
95% Ethyl alcohol	Liquid oxygen
Methyl alcohol	87% Hydrogen peroxide
Aniline	Red fuming nitric acid
Furfural alcohol	Red fuming nitric acid

an oxidizer. The latter could be an inorganic perchlorate such as ammonium perchlorate, NH_4ClO_4, or potassium perchlorate, $KClO_4$, or a nitrate such as ammonium nitrate, NH_4NO_3, potassium nitrate, KNO_3, or sodium nitrate, $NaNO_3$. Fuels for composite propellants are generally the asphalt-oil-type, thermosetting plastics (phenol formaldehyde and phenolfurfural resins have been used) or several types of synthetic rubber and gumlike substances. Recently, metal particles such as boron, aluminum, and beryllium have been added to solid propellants to increase their heats of combustion and to eliminate certain types of combustion instability. *See* HYDROGEN PEROXIDE; ROCKET PROPULSION. Chemical kinetics

A branch of physical chemistry that seeks to measure the rates of chemical reactions, describe them in terms of elementary steps, and understand them in terms of the fundamental interactions between molecules.

Reaction Kinetics

Although the ultimate state of a chemical system is specified by thermodynamics, the time required to reach that equilibrium state is highly dependent upon the reaction. For example, diamonds are thermodynamically unstable with respect to graphite, but the rate of transformation of diamonds to graphite is negligible. As a consequence, determining the rate of chemical reactions has proved to be important for practical reasons. Rate studies have also yielded fundamental information about the details of the nuclear rearrangements which constitute the chemical reaction.

Traditional chemical kinetic investigations of the reaction between species X and Y to form Z and W, reaction (1), sought a rate of the form given in Eq. (2),

$$\mathrm{X + Y \rightarrow Z + W} \qquad (1)$$

$$d[\mathrm{Z}]/dt = kf([X], [Y], [Z], [W]) \qquad (2)$$

where $d[\mathrm{Z}]/dt$ is the rate of appearance of product Z, f is some function of concentrations of X, Y, Z, and W which are themselves functions of time, and k is the rate constant. Chemical reactions are incredibly diverse, and often the function f is quite complicated, even for seemingly simple reactions such as that in which hydrogen and bromine combine directly to form hydrogen bromide (HBr). This is an example of a complex reaction which proceeds through a sequence of simpler reactions, called elementary reactions. For reaction (3*d*), the sequence of elementary reactions is a chain mechanism known to involve a series of steps, reactions (3*a*)–(3*c*). This sequence of elementary reactions was formerly known

$$\mathrm{Br_2 \rightarrow 2Br} \qquad (3a)$$

$$\mathrm{Br + H_2 \rightarrow HBr + Br} \qquad (3b)$$

$$\mathrm{H + Br_2 \rightarrow HBr + Br} \qquad (3c)$$

$$\mathrm{H_2 + Br_2 \rightarrow 2HBr} \qquad (3d)$$

as the reaction mechanism, but in the chemical dynamical sense the word mechanism is reserved to mean the detailed motion of the nuclei during a collision.

Bimolecular processes. An elementary reaction is considered to occur exactly as written. Reaction (3*b*) is assumed to occur when a bromine atom hits a hydrogen molecule. The products of the collision are a hydrogen bromide molecule and a hydrogen atom. On the other hand, the overall reaction is a sequence of these elementary steps and on a molecular basis does not occur as reaction (3*d*) is written. With few exceptions, the rate law for an elementary reaction $\mathrm{A + B \rightarrow C + D}$ is given by $d[\mathrm{C}]/dt = k[\mathrm{A}][\mathrm{B}]$. The order (sum of the exponents of the concentrations) is two, which is expected if the reaction is bimolecular (requires only species A to collide with species B). The rate constant k for such a reaction depends very strongly on temperature, and is usually expressed as $k = Z_{\mathrm{AB}}\rho \exp(-E_a/RT)$. Z_{AB} is the frequency of collision between A and B calculated from molecular diameters and temperature; ρ is an empirically determined steric factor which arises because only collisions with the proper orientation of reagents will be effective; and E_a, the experimentally determined activation energy, apparently reflects the need to overcome repulsive forces before the reagents can get close enough to react.

Unimolecular processes. In some instances, especially for decompositions, $\mathrm{AB \rightarrow A + B}$, the elementary reaction step is first-order, Eq. (4), which

$$d[\mathrm{A}]/dt = d[\mathrm{B}]/dt = k[\mathrm{AB}] \qquad (4)$$

means that the reaction is unimolecular. The species AB does not spontaneously dissociate; it must first be given some critical amount of energy, usually through collisions, to form an excited species AB^*. It is the species AB^* which decomposes unimolecularly. Philip R. Brooks

Relaxation Methods

Considerable use has been made of perturbation techniques to measure rates and determine mechanisms of rapid chemical reactions. These methods provide measurements of chemical reaction rates by displacing equilibria. In situations where the reaction of interest occurs in a system at equilibrium, perturbation techniques called relaxation methods have been found most effective for determining reaction rate constants.

A chemical system at equilibrium is one in which the rate of a forward reaction is exactly balanced by the rate of the corresponding back reaction. Examples are chemical reactions occurring in liquid solutions, such as the familiar equilibrium in pure water, shown in reaction (5). The molar equilibrium constant at 25°C (77°F) is given by Eq. (6), where

$$\mathrm{H_2O} \underset{k_b}{\rightleftharpoons} \mathrm{H^+}(aq) + \mathrm{OH^-}(aq) \tag{5}$$

$$K_{\mathrm{eq}} = \frac{[\mathrm{H^+}][\mathrm{OH^-}]}{[\mathrm{H_2O}]} = \frac{10^{-14}}{55.5} = 1.8 \times 10^{-16} \tag{6}$$

bracketed quantities indicate molar concentrations. It arises naturally from the equality of forward and backward reaction rates, Eq. (7). Here k_f and k_b are

$$k_f[\mathrm{H_2O}] = k_b[\mathrm{H^+}][\mathrm{OH^-}] \tag{7}$$

the respective rate constants that depend on temperature but not concentrations. Furthermore, the combination of Eqs. (6) and (7) gives rise to Eq. (8).

$$K_{\mathrm{eq}} = k_f/k_b = 1.8 \times 10^{-16} \tag{8}$$

Thus a reasonable question might be what the numerical values of k_f in units of $\mathrm{s^{-1}}$ and k_b in units of $\mathrm{dm^3\ mol^{-1}\ s^{-1}}$ must be to satisfy Eqs. (6) through (8) in water at room temperature. Stated another way, when a liter of 1 *M* hydrochloric acid is poured into a liter of 1 *M* sodium hydroxide (with considerable hazardous sputtering), how rapidly do the hydronium ions, $\mathrm{H^+}(aq)$, react with hydroxide ions, $\mathrm{OH^-}(aq)$, to produce a warm 0.5 *M* aqueous solution of sodium chloride? In the early 1950s it was asserted that such a reaction is instantaneous. Turbulent mixing techniques were (and still are) insufficiently fast (mixing time of the order of 1 ms) for this particular reaction to occur outside the mixing chamber. The relaxation techniques were conceived by M. Eigen, who accepted the implied challenge of measuring the rates of seemingly immeasurably fast reactions. *See* ULTRAFAST MOLECULAR PROCESSES.

The essence of any of the relaxation methods is the perturbation of a chemical equilibrium (by a small change in temperature, pressure, electric-field intensity, or solvent composition) in so sudden a fashion that the chemical system, in seeking to reachieve equilibrium, is forced by the comparative slowness of the chemical reactions to lag behind the perturbation (**Fig. 1**).

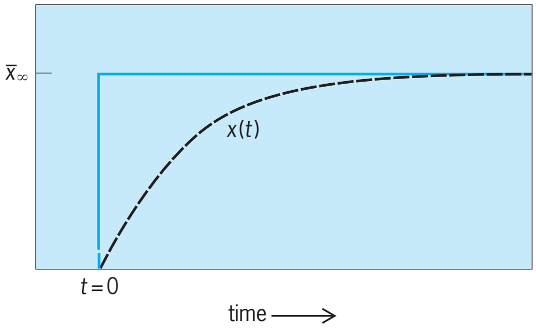

Fig. 1. Relaxational response to a rectangular step function in an external parameter such as temperature or pressure. The broken line represents the time course of the adjustment (relaxation) of the chemical equilibrium to the new temperature or pressure. (*After C. Bernasconi, Relaxation Kinetics, Academic Press, 1976*)

Temperature jump. Reaction (5) has a nonzero standard enthalpy change, ΔH°, associated with it, so that a small increase in the temperature of the water ($\mathrm{H_2O}$) requires the concentrations of hydrogen ions $[\mathrm{H^+}]$ and hydroxide ions $[\mathrm{OH^-}]$ to increase slightly, and $[\mathrm{H_2O}]$ to decrease correspondingly, for chemical equilibrium to be restored at the new higher temperature. Thus a small sample cell containing a very pure sample of water may be made one arm of a Wheatstone conductance bridge, and further configured so that a pulse of energy from a microwave source (or infrared laser of appropriate wavelength) is dissipated in the sample liquid. The resulting rise in temperature of about 2°C (3.6°F) will produce a small increase in conductance that will have an exponential shape and a time constant or relaxation time $\tau \simeq 27$ microseconds; τ is the time required for the signal amplitude to drop to $1/e = 1/2.718$ of its initial value, where e is the base of natural logarithms.

In pure water at 25°C (77°F), $[\mathrm{H^+}] = [\mathrm{OH^-}] = 10^{-7}$ *M*, and for small perturbations, the value for τ is given by Eq. (9), from which it follows that $k_b \simeq 1.8 \times 10^{11}\ \mathrm{dm^3\ mol^{-1}\ s^{-1}}$. This is an exceptionally large rate constant for a bimolecular reaction between oppositely charged ions in aqueous solution and is, in fact, larger than that for any other diffusive encounter between ions in water. Eigen and L. DeMaeyer, who first determined this rate constant (using another relaxation method called the electric-field jump method), attributed the great speed of the back reaction of the equilibrium, reaction (5), to the exceptionally rapid motion of a proton through water, accomplished by the successive rotations of a long string of neighboring water molecules (Grotthuss mechanism). Since sample solutions can be heated by a mode-locked laser on a picosecond time scale or by a bunsen burner on a time scale of minutes, the temperature jump (T-jump) relaxation method just described is very versatile. The choice of the particular means of effecting the temperature perturbation is dictated only by the requirement that the temperature rise somewhat more rapidly than the time constant of the chemical reaction to be explored, so that a tedious deconvolution can be avoided. The discharge of a high-voltage (15–30-kV) capacitor through the sample liquid containing sufficient inert electrolyte to make it a good electrical conductor is the now classic Joule heating T-jump method used by Eigen and coworkers in their pioneering studies. A schematic of such an apparatus is shown in **Fig. 2**. The 30-kV voltage generator charges the 0.1-microfarad condenser to the voltage at which the spark gap breaks down. The condenser then discharges across the spark gap and through the sample cell, containing

$$\begin{aligned} \tau^{-1} &= k_b([\mathrm{H^+}] + [\mathrm{OH^-}]) + k_f \\ &= k_b([\mathrm{H^+}] + [\mathrm{OH^-}] + K_{\mathrm{eq}}) \end{aligned} \tag{9}$$

an aqueous 0.1 *M* ionic strength solution, to ground. The sample cell is an approximately 50 ml (3.05 in.^3) Plexiglas cell containing two platinum electrodes spaced 1 cm (0.4 in.) apart and immersed in an aqueous 0.1 *M* ionic strength solution. The surge of current raises the temperature of the 1-ml (0.061-in.^3) volume of solution between the electrodes by 10°C (18°F) in a few microseconds.

Electric-field jump. In a situation, such as reaction (8), in which electrically neutral reactant species dissociate into oppositely charged ions, an especially sensitive tool for measuring rate constants of forward and backward reactions is the electric-field jump (E-jump) technique with conductometric detection. In a strong electric field (of the order of 4×10^6 V m^{-1}), a weak acid in solution is caused to dissociate to a greater degree than it would in the absence of the electric field. For weak electrolytes, such as aqueous acetic acid or ammonia, the effect is the order of 10% or less of the total normal dissociation, even at very high electric-field strengths. However, with a sensitive, high-voltage, Wheatstone bridge, the exponential increase with time in the concentration of ions following a precipitous increase in electric-field strength is readily detected. The measured relaxation time (τ) is clearly that corresponding to the high-electric-field environment, but since the rate constants for these reactions differ little in and out of the electric field, no serious problem is posed.

A more serious concern is that the sample solution may have a very high electrical resistance, so that the supposedly square step function in the electric-field strength is distorted by a significant voltage drop with concomitant heating of the sample liquid. Problems of working with high voltages, balancing capacitive and inductive effects in a very sensitive conductance bridge (now often circumvented by spectrophotometric detection), and the comparative difficulty of evaluating amplitudes of relaxations (as opposed to their readily determined time constants) are all factors that have worked against the wide use of the E-jump technique. There are many more ways of achieving a T-jump than an E-jump, and ΔH° values for chemical equilibria are readily available in the thermodynamic literature, whereas the extent to which a chemical equilibrium is displaced by an electric-field increment is rarely already known and is difficult to determine. Thus the commercialization of the T-jump method and the comparative neglect of the E-jump relaxation technique are readily understood.

Notwithstanding these difficulties, the E-jump technique is without peer for the investigation of the kinetics of solvent autoionization or for the exploration of the properties of weak electrolyte solutes in exotic solvents such as acetonitrile or xenon (the latter liquefied under a pressure of about 50 atm or 5 megapascals), so long as the relaxation time to be measured lies in the range 30 nanoseconds $< \tau < 100\ \mu\text{s}$.

Ultrasonic absorption. Two other relaxation methods more widely used than the E-jump technique are pressure jump (P-jump) and ultrasonic absorption. Each relies for its effectiveness on a volume change, ΔV°, occurring in an aqueous sample equilibrium undergoing kinetic investigation. (In a nonaqueous solvent it will frequently be more important that ΔH° be large than that ΔV° be so for the equilibrium to be susceptible to study by these two relaxation techniques.) As electrically neutral, weak electrolyte solute species dissociate into ions in aqueous solution, there is an increase in the number of solvent molecules drawn into a highly ordered solvation sheath. The higher the charge density of the ion, the more water molecule dipoles are bound and the greater the change in V° as reactants become products. Thus the dissociation of an aqueous neodymium(III) sulfate complex is particularly susceptible to study by one or more of the four or five ultrasonic absorption methods that cover the $f \simeq$ 100 kHz–1 GHz sound frequency range. Unlike the T-jump and E-jump relaxation methods, which usually employ step function perturbations, the ultrasonic absorption techniques are continuous-wave experiments in which the sample chemical equilibrium absorbs a measurable amount of the sound wave's energy when the frequency of the sound wave (f) and the relaxation time of the chemical equilibrium bear the relation to one another given by Eq. (10).

$$\tau^{-1} = 2\pi f \qquad (10)$$

A particularly easy ultrasonic absorption experiment to understand and perform is the laser Debye-Sears technique. A continuously variable frequency sound wave is introduced by a quartz piezoelectric transducer into a 30-ml (1.83-in.^3) sample cell that has entrance and exit windows for a visible laser light beam that passes through the cell at about 90° to the direction of travel of the planar sound wave. The regions of compression and rarefaction in the sound wave act as a diffraction grating for the laser light beam. If a chemical equilibrium in the sample strongly absorbs a particular frequency of sound (f), the definition of the "diffraction grating" will deteriorate and the measured intensity of the first-order diffracted laser light will diminish. The frequency of minimum diffracted light intensity will be that of Eq. (10). **Figure 3** shows a diagram of the

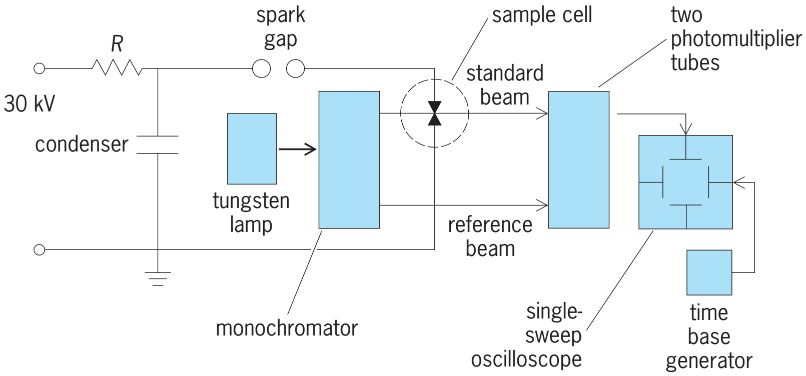

Fig. 2. Schematic of a Joule heating temperature-jump apparatus. (*After H. Eyring and E. M. Eyring, Modern Chemical Kinetics, Reinhold, 1963*)

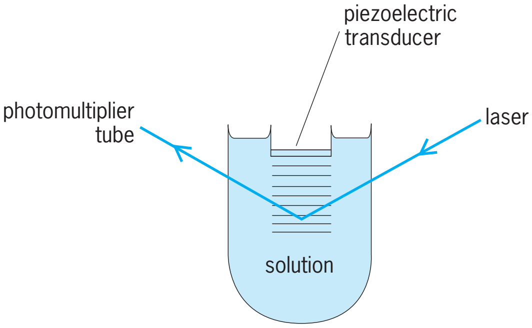

Fig. 3. Schematic of laser Debye-Sears apparatus for measuring ultrasonic absorption (about 15–300 MHz) in a sample liquid. (*After W. J. Gettins and E. Wyn-Jones, Techniques and Applications of Fast Reactions in Solution, D. Reidel, 1979*)

apparatus. The piezoelectric (quartz) tranducer cemented to the bottom of a plastic rod that is driven up and down by a stepping motor is controlled by a mini computer. The angle of diffraction of the laser beam by the alternating regions of compression and rarefaction in the liquid (suggested by the horizontal lines) is exaggerated in the diagram.

Ultrasonic absorption techniques have been used in kinetic investigations of complicated biophysical systems such as the order-disorder transitions that occur in liquid crystalline phospholipid membranes. While the ultrasonic techniques look through a conveniently broad time window at kinetic processes in solution, this picture window is difficult to "see through" in that many equilibrium processes in solution can absorb sound energy and the responsible process is not instantly identified by a characteristic absorption of electromagnetic radiation as in a spectrophotometric T-jump or E-jump experiment. A further disadvantage arises from the great breadth of the ultrasonic absorption "peaks" in a plot of normalized sound absorption versus sound frequency. Unless multiple relaxation times in a chemical system are quite widely separated in time, they are difficult to resolve in an ultrasonic absorption spectrum. *See* ULTRASONICS.

Pressure jump. The typical pressure-jump (P-jump) experiment is one in which a liquid sample under about 200 atm (20 MPa) pressure is suddenly brought to atmospheric pressure by the bursting of a metal membrane in the sample cell autoclave. Relaxation times measured spectrophotometrically or conductometrically are thus accessible if $\tau > 100\ \mu s$. This technique has proven particularly useful in the elucidation of micellar systems of great interest for catalysis and for petroleum recovery from apparently depleted oil fields.

The continuous- and stopped-flow techniques antedate somewhat the relaxation techniques described above, and have the sometimes important advantage of permitting kinetic measurements in chemical systems far from equilibrium. The stopped-flow experiment is one in which two different liquids in separate syringes are mixed rapidly in a tangential jet mixing chamber and then the rapid flow of mixed reactants is almost immediately brought to a halt in a spectrophotometric, conductometric, or calorimetric observation chamber. Reaction half-lives exceeding 2 ms are easily accessible. *See* SHOCK TUBE.

Other relaxation methods. Stopped-flow equipment has been used in concentration-jump and solvent-jump relaxation kinetic studies. An example of an application of the solvent-jump technique to a system insensitive to concentration-jump is a kinetic study of reaction (11) in mixed CCl_4-acetic acid solvents

$$\mathrm{NOCl} + n\mathrm{BuOH} \rightarrow n\mathrm{BuONO} + \mathrm{HCl} \qquad (11)$$

of varying composition (Bu = butyl). The thermodynamic treatment of the solvent jump is just about the only aspect of the presently known relaxation techniques that was not described in exhaustive detail by the earliest publications of Eigen and DeMaeyer. *See* CHEMICAL THERMODYNAMICS. Edward M. Eyring

Gas-Phase Reactions

The rates of thermal gas-phase chemical reactions are important in understanding processes such as combustion and atmospheric chemistry.

Elementary reactions, mechanisms, and rates. Chemical conversion of one stable, gas-phase molecule into another is an apparently simple process; yet it is highly unlikely to occur in just a single step, but as a web of sequential and parallel reactions involving many species. The oxidation of methane (CH_4) to carbon dioxide (CO_2) and water provides an excellent example. It occurs in combustion (for example, in burning natural gas, which is mostly methane) as well as in the atmosphere. In both cases, the net process may be written down as single reaction (12).

$$\mathrm{CH_4 + 2O_2 \rightarrow 2H_2O + CO_2} \qquad (12)$$

The reaction does not, however, result from collision of two oxygen (O_2) molecules with one methane molecule. Rather, it involves many separate steps. A simplified list of the steps involved in reaction (12) for both combustion and for the atmosphere is given below.

Combustion:

$$\begin{aligned}
\mathrm{CH_4 + OH} &\rightarrow \mathrm{CH_3 + H_2O}\\
\mathrm{CH_4 + M} &\rightarrow \mathrm{CH_3 + H + M}\\
\mathrm{CH_4 + H} &\rightarrow \mathrm{H_2 + CH_3}\\
\mathrm{CH_4 + O} &\rightarrow \mathrm{CH_3 + OH}\\
\mathrm{CH_4 + CH_2} &\rightarrow \mathrm{2CH_3}\\
\mathrm{CH_3 + M} &\rightarrow \mathrm{CH_2 + H + M}\\
\mathrm{CH_3 + H} &\rightarrow \mathrm{CH_2 + H_2}\\
\mathrm{CH_3 + O} &\rightarrow \mathrm{CH_2O + H}\\
\mathrm{CH_3 + OH} &\rightarrow \mathrm{CH_2 + H_2O}\\
\mathrm{CH_3 + O_2} &\rightarrow \mathrm{CH_2O + OH}\\
\mathrm{CH_3 + O_2} &\rightarrow \mathrm{CH_3O + O}\\
\mathrm{CH_3O + M} &\rightarrow \mathrm{CH_2O + H + M}\\
\mathrm{CH_3O + H} &\rightarrow \mathrm{CH_2O + H_2}\\
\mathrm{CH_3O + O} &\rightarrow \mathrm{CH_2O + OH}\\
\mathrm{CH_3O + OH} &\rightarrow \mathrm{CH_2O + H_2O}
\end{aligned}$$

$$\begin{aligned} \mathrm{CH_3O + O_2} &\rightarrow \mathrm{CH_2O + HO_2} \\ \mathrm{CH_2O + M} &\rightarrow \mathrm{HCO + H + M} \\ \mathrm{CH_2O + H} &\rightarrow \mathrm{HCO + H_2} \\ \mathrm{CH_2O + O} &\rightarrow \mathrm{HCO + OH} \\ \mathrm{HCO + O_2} &\rightarrow \mathrm{CO + HO_2} \\ \mathrm{CO + OH} &\rightarrow \mathrm{CO_2 + H} \end{aligned}$$

Atmospheric oxidation:

$$\begin{aligned} \mathrm{CH_4 + OH} &\rightarrow \mathrm{CH_3 + H_2O} \\ \mathrm{CH_3 + O_2 + M} &\rightarrow \mathrm{CH_3O_2 + M} \\ \mathrm{CH_3O_2 + NO} &\rightarrow \mathrm{CH_3 + NO_2} \\ \mathrm{CH_3O + O_2} &\rightarrow \mathrm{CH_2O + HO_2} \\ \mathrm{CH_2O} + h\nu &\rightarrow \mathrm{CHO + H} \\ \mathrm{CH_2O} + h\nu &\rightarrow \mathrm{CO + H_2} \\ \mathrm{CHO + O_2} &\rightarrow \mathrm{CO + HO_2} \\ \mathrm{CO + OH} &\rightarrow \mathrm{CO_2 + H} \end{aligned}$$

Even though the overall reaction is the same in both environments, the steps are quite different, as are the rates, temperature dependences, and byproducts. Each is called an elementary reaction, and the sum of the steps that makes up the overall reaction is called the mechanism. Currently, the major thrust of chemical kinetics is to elucidate such mechanisms and to measure (or calculate) the rates of the elementary reactions.

All elementary reactions fundamentally require a collision between two molecules. Even in the case of a unimolecular reaction, in which a single molecule breaks apart or isomerizes to another form, the energy required for the process comes from collision with other molecules. The species involved in many gas-phase elementary reactions are free radicals, molecules that have one or more unpaired electrons. Such species tend to be highly reactive, and they are responsible for carrying out most gas-phase chemistry.

A reaction rate is the rate at which the concentration of one of the reactants or products changes with time. The objective of a kinetics experiment is not to measure the reaction rate itself but to measure the rate coefficient, an intrinsic property of the reaction that relates the reactant concentrations to their time rates of change. For example, the mathematical expression for the rate of a biomolecular reaction, $\mathrm{A + B} \rightarrow$ products, is differential equation (13). The

$$-d[\mathrm{A}]/dt = -d[\mathrm{B}]/dt = k[\mathrm{A}][\mathrm{B}] \qquad (13)$$

square brackets denote the concentrations of A and B, and k is the rate coefficient described above. The dependence of the rate expression on reactant concentrations is determined experimentally, and it also arises from a fundamental tenet of chemistry known as the law of mass action. Once the rate constant is known, the rate of a reaction can be computed for any given set of concentrations.

Rate constants usually change with temperature because of the change in the mean energy of colliding molecules. The temperature dependence often follows an Arrhenius expression, $k = A \exp(-E_A/RT)$, where A is a preexponential factor that is related to the gas-phase collision rate, R is the universal gas constant, and T is the absolute temperature (in kelvins). The key quantity is the activation energy, E_A, the amount of energy required to induce a reaction. Pressure dependences are usually important only for association reactions, $\mathrm{A + B} \rightarrow \mathrm{AB}$, since collision of A with B will form an energized complex, AB^*, that will simply redissociate unless a subsequent collision carries away enough energy to stabilize the AB product. The probability of a stabilizing collision increases with the collision frequency and thus the total pressure.

In the simple case of a unimolecular reaction, $\mathrm{A} \rightarrow \mathrm{P}$, the rate expression is Eq. (14). Equation (14)

$$-d[\mathrm{A}]/dt = d[\mathrm{P}]/dt = k[\mathrm{A}] \qquad (14)$$

is first-order since the rate is proportional to the reactant concentration to the first power, and it leads to an expression for the change in the concentration of A or P with time (called an integrated rate expression), as in Eqs. (15). The subscripts denote

$$[\mathrm{A}]_t = [\mathrm{A}]_0 \exp(-kt) \qquad (15a)$$

$$[\mathrm{P}]_t = [\mathrm{A}]_0\{1 - \exp(-kt)\} \qquad (15b)$$

the concentrations at zero time (initial concentration) and an arbitrary time t. The concentration of A decreases (because it is reacting away) as a function of time, while the concentration of P increases with time such that the sum of the concentrations of A and P is always constant and equal to the initial concentration of A (**Fig. 4**). Because first-order reactions are mathematically simple, kineticists try to reduce all studied reactions (if at all possible) to this form. A second-order reaction, for example $\mathrm{A + B} \rightarrow$ products, has the rate expression given in Eq. (13). To reduce the second-order expression to the first-order expression, Eq. (14), one chooses one of the concentrations to be in large excess, for example $[\mathrm{B}] >> [\mathrm{A}]$. The concentration of B is then approximately constant during the course of the reaction, and it may be combined with the rate constant

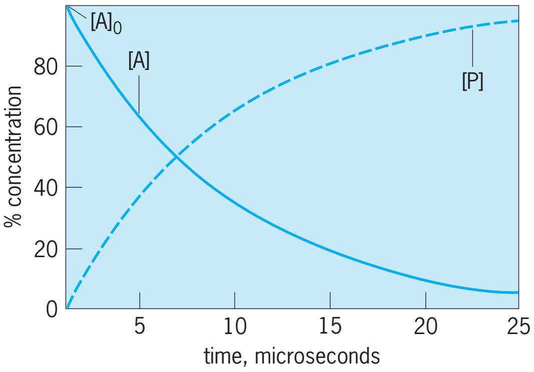

Fig. 4. Concentration of reactant (A) decreases while product (P) increases with time (arbitrarily shown in microseconds).

to give an expression identical to Eq. (14) that depends on the concentration of A alone.

Experimental methods. The experimental challenges to rate constant measurements include generation of reactive species of interest, the measurement of their concentration on a time scale fast enough to follow the course of the reaction, and the measurement of the reaction time itself. The capability for measurement of small concentrations (down to a few molecules in a milliliter) and short times (down to femtoseconds; 1 fs $= 10^{-15}$ s) has improved dramatically since the early 1980s and has enabled kineticists to study extremely fast gas-phase reactions. The following examples illustrate how rate constants are measured.

The rate constant for the bimolecular reaction of OH with methane is very important. **Figure 5*a*** illustrates its measurement via the commonly used pulsed photolysis–laser induced fluorescence (PP–LIF) technique. A pulse of short-wavelength ultraviolet light from a laser irradiates a gas mixture containing a precursor molecule, such as hydrogen peroxide (H_2O_2) or nitric acid (HNO_3), that absorbs the light and fragments instantaneously to produce OH. A second laser produces a pulse of light that is tuned to a color (wavelength) absorbed by the OH radicals, which in turn emit light (fluoresce) in all directions. The fluorescence intensity falling on a detector is proportional to the OH concentration. Both laser pulses have very short duration (typically $<2 \times 10^{-8}$ s or 20 nanoseconds) on the time scale of the reaction. The first pulse creates the OH radicals and defines zero time, and variation of the time delay between the two lasers varies the reaction time. Methane is present in large excess over OH, and thus its concentration, as measured by its pressure, is essentially constant during the course of the reaction. *See* LASER; LASER PHOTOCHEMISTRY.

The same rate coefficient may also be measured using the apparatus shown in Fig. 5*b*. In this case, a flow of gas containing hydrogen (H_2) passes through a microwave discharge, where H_2 breaks down to H atoms. Then it reacts with nitrogen dioxide (NO_2) to make OH and nitric oxide (NO). The NO is unreactive with methane and does not interfere with the OH reaction. Methane flows through a movable injector at the center of a flow tube. The two gas flows mix at the injector and initiate reaction between OH and methane. A laser-induced fluorescence detector, similar to the one described above, at the end of the tube measures the amount of OH present at that point. (Other detectors, such as a mass spectrometer, also can be used.) Since the gas flow velocity down the tube is constant, the distance from the injector to the mass spectrometer can be converted to a reaction time, and movement of the injector to different positions in the tube varies the reaction time. As above, its pressure in the flow tube gives the approximately constant methane concentration.

Both of the above examples are direct methods in which the time rate of concentration change is directly observed. Relative rate constant measurements can be done for the determination of the rate constant for reaction of OH with hydrofluorocarbon 134a (HFC-134a). This compound is used as an automobile refrigerant in place of the banned CFCs

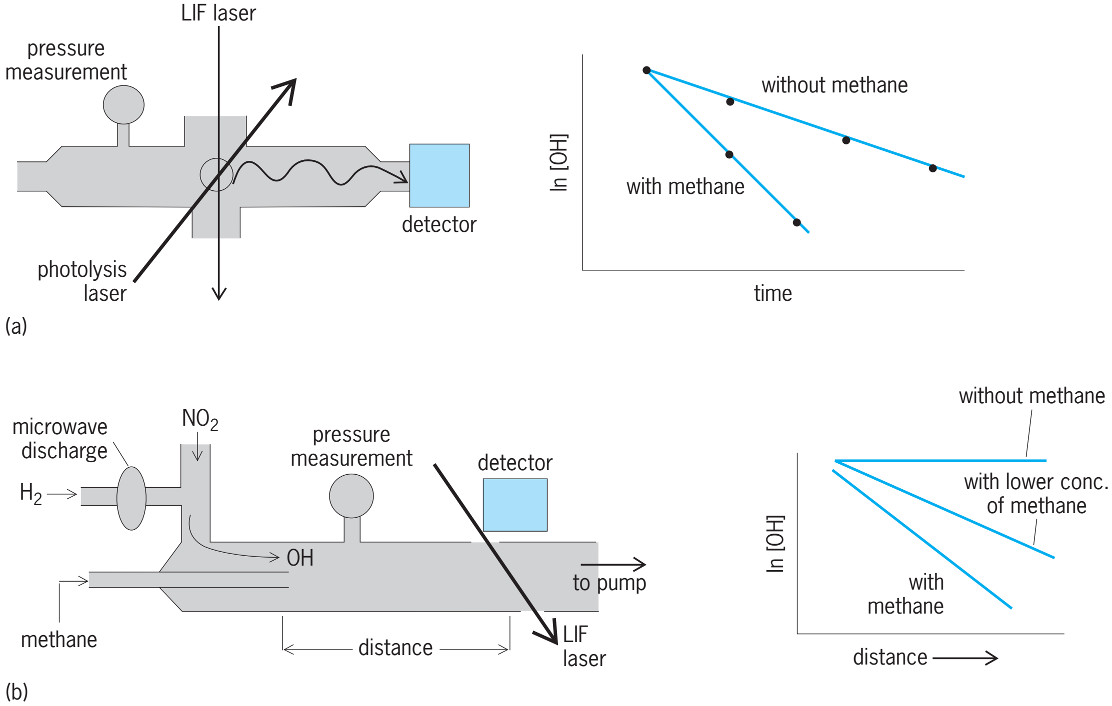

Fig. 5. Measurement of the rate constant for the bimolecular reaction of OH with methane. (*a*) Pulsed photolysis. OH concentrations are measured with methane and without methane. (*b*) Discharge flow. OH concentrations are detected at various distances from a detector. The plot shows OH concentrates measured with methane, with a lower concentration of methane, and without methane.

(chlorofluorocarbons), and, similar to methane, its reaction with OH determines its degradation rate in the atmosphere. The OH radicals are continuously produced in a mixture containing both methane and HFC-134a, and the depletion of methane and HFC-134a is measured. The ratio of the depletions is then proportional to the rate constants for reaction of OH with each compound. Since the rate constant for reaction of OH with methane is known, the measurement provides the previously unknown rate constant for reaction of OH with HFC-134a.

There are many other techniques for measurement of reactant or product concentrations, including ultraviolet, visible, and infrared light absorption, gas chromatography, and a host of additional fluorescence and mass spectrometric methods.

Outlook. Complex gas-phase chemical reactions may be broken down into elementary steps that describe reactions at the level of collisions between individual molecules. The rate constants for such elementary steps allow calculation of the reaction rates from reactant concentrations as well as kinetic modeling of larger chemical processes. Determination of elementary rate constants involves measurement of reactant or product concentrations on the time scale of the reaction. Rate constants may also be made in a relative fashion in cases where two reactions share a common reactant and one rate constant is known. A. R. Ravishankara; S. S. Brown

Chemical microscopy

A scientific discipline in which microscopes are used to solve chemical problems. The unique ability to form a visual image of a specimen, to select a small volume of the specimen, and to perform a chemical or structural analysis on the material in the selected volume makes chemical microscopy indispensable to modern chemical analysis. *See* MICROSCOPE.

Microscopes are instruments which form images of objects too small to be seen with the unaided eye. Microscopes can also be combined with most analytical instruments. For example, a light microscope can be combined with a spectroscope, making it possible to determine the molecular composition of microscopic objects or structures. Similarly, an x-ray spectrometer can be combined with an electron microscope to determine the elemental composition of small objects. *See* ELECTRON MICROSCOPE; SPECTROSCOPY; X-RAY SPECTROMETRY.

Phase analyses can also be made microscopically. The boundaries of amorphous phases can usually be distinguished in the microscope, and an elemental or physical analysis can be used to identify the phase. An example of a physical analysis is the measurement of refractive index. Crystalline phases are even more amenable to microscopical analysis. For example, a polarizing microscope can be used to measure the optical properties of a crystalline phase and thus identify it. Or a transmission electron microscope can be used to select a tiny area of a crystalline phase and identify the crystal structure by means of electron diffraction. *See* ELECTRON DIFFRACTION.

While the idea of selecting a small volume for analysis is straightforward, the minimum volume that can be analyzed varies widely with the instrument used. Light microscopes can be used to identify particles as small as 1 micrometer in diameter and weighing about 1 picogram. A field ion microscope has been combined with a mass spectrometer and used to identify single atoms extracted from the surface of a specimen. *See* FIELD-EMISSION MICROSCOPY; MASS SPECTROMETRY; OPTICAL MICROSCOPE.

After a portion of a specimen has been selected microscopically, it can be analyzed in many ways. An experienced microscopist may learn to recognize various structures by studying known materials, using published atlases, or an atlas that the individual microscopist has constructed. Analyses done in this fashion can be fast and simple. If the object or structure cannot be recognized, many means of analysis are available. For example, a polarizing microscope may be employed to identify the object by using optical crystallographic methods. Other light microscopes useful for chemical analysis include phasecontrast and interference-contrast microscopes, microspectrophotometers, the confocal scanning laser microscope, and the laser Raman microscope. Physicochemical methods may be used to measure melting points, or mixed-melt phenomena and dispersion staining may also be used. *See* INTERFERENCE MICROSCOPE; LASER SPECTROSCOPY; PHASE-CONTRAST MICROSCOPE; RAMAN EFFECT.

Microscopes using other types of image-forming beams serve for chemical analysis. Scanning or transmission electron microscopes are powerful tools for chemical microscopy. Scanning electron microscopes are often fitted with x-ray spectrometers which are capable of both qualitative and quantitative analysis for most of the elements. Other electron microscopes capable of chemical analysis are the Auger electron microscope, field electron microscope, scanning tunneling microscope, and cathodoluminescence microscope. Microscopes which use ion beams, neutron beams, and x-ray beams also have analytical capabilities. *See* AUGER EFFECT; NEUTRON SPECTROMETRY; SCANNING ELECTRON MICROSCOPE; X-RAY MICROSCOPE.

A specific example of a chemical microscopical analysis involves portland cement which is formulated for use in geothermal-energy extraction wells (see **illustration**). In this micrograph, two types of crystals can be recognized by their morphology.

Micrograph of a portland cement formulation cured at 390–450°F (200–230°C) for 72 h; gypsum and xonotlite crystals are growing into a cavity.

If the microscopist does not recognize the crystals from their morphology, the crystals must be analyzed. This can be done in a number of ways. With a light microscope, it is possible to identify the crystals by scraping them from the sample and determining their optical properties through a variety of standard techniques. Another method is to examine each of the crystals by using x-ray or electron diffraction techniques. A third option is to perform an elemental analysis with an electron microscope fitted with an x-ray spectrometer. From the elemental analysis, it should be possible to identify the chemical compound that makes up the crystal. There should be no confusion resulting from the fact that the sample consists of more than one crystalline compound, because with the electron microscope a single crystal or a small portion of a crystal can be analyzed. Each crystal that appears different from the other can be analyzed quantitatively for its elemental composition. Knowledge of the combination of elemental composition and diffraction data nearly always leads to the identification of the crystals in the sample. This does require that the diffraction pattern for the crystals has been published and is accessible to the microscopist. If this information is not available, the microscopist can usually construct a list of data for the materials considered, so that in future work the individual crystals or amorphous materials can be recognized when they are encountered again.

In the example illustrated, only the commonly available microscopes, that is, the polarizing microscope, the scanning electron microscope, and the transmission electron microscope, were considered. Less commonly available microscopes, such as the Auger microscope, the laser Raman microscope, and the microspectrophotometer, can be used to identify crystalline and amorphous phases. *See* ANALYTICAL CHEMISTRY. Chemical process industry

An industry, abbreviated CPI, in which the raw materials undergo chemical conversion during their processing into finished products, as well as (or instead of) the physical conversions common to industry in general. In the chemical process industry the products differ chemically from the raw materials as a result of undergoing one or more chemical reactions during the manufacturing process. The chemical process industries broadly include the traditional chemical industries, both organic and inorganic; the petroleum industry; the petrochemical industry, which produces the majority of plastics, synthetic fibers, and synthetic rubber from petroleum and natural-gas raw materials; and a series of allied industries in which chemical processing plays a substantial part. While the chemical process industries are primarily the realm of the chemical engineer and the chemist, they also involve a wide range of other scientific, engineering, and economic specialists.

For a discussion of the more prominent chemical process industries *see* ADHESIVE; BIOCHEMICAL ENGINEERING; BIOMEDICAL CHEMICAL ENGINEERING; CEMENT; CERAMICS; COAL CHEMICALS; COAL GASIFICATION; COAL LIQUEFACTION; DISTILLED SPIRITS; DYEING; ELECTROCHEMICAL PROCESS; EXPLOSIVE; FAT AND OIL; FERMENTATION; FERTILIZER; FOOD MANUFACTURING; FUEL GAS; GLASS; GRAPHITE; HYDROCRACKING; INSECTICIDE; LIME (INDUSTRY); MANUFACTURED FIBER; NUCLEAR CHEMICAL ENGINEERING; NUCLEAR FUELS; PAPER; PETROCHEMICAL; PETROLEUM PROCESSING AND REFINING; PETROLEUM PRODUCTS; PLASTICS PROCESSING; POLYMER; RADIOACTIVE WASTE MANAGEMENT; RUBBER; WATER SOFTENING. Chemical reactor

A vessel in which chemical reactions take place. A combination of vessels is known as a chemical reactor network. Chemical reactors have diverse sizes, shapes, and modes and conditions of operation based on the nature of the reaction system and its behavior as a function of temperature, pressure, catalyst properties, and other factors.

Laboratory chemical reactors are used to obtain reaction characteristics. Therefore, the shape and mode of operation of a reactor on this scale differ markedly from that of the large-scale industrial reactor, which is designed for efficient production rather than for gathering information. Laboratory reactors are best designed to achieve well-defined conditions of concentrations and temperature so that a reaction model can be developed which will prove useful in the design of a large-scale reactor model.

Chemical reactions may occur in the presence of a single phase (liquid or gas), in which case they are called homogeneous, or they may occur in the presence of more than one phase and are referred to as heterogeneous. In addition, chemical reactions may be catalyzed. Examples of homogeneous reactions are gaseous fuel combustion (gas phase) and acid-base neutralization (liquid phase). Examples of heterogeneous systems are carbon dioxide absorption into alkali (gas-liquid); coal combustion and automobile exhaust purification (gas-solid); water softening (liquid-solid); coal liquefaction and oil hydrogenation (gas-liquid-solid); and coke reduction of iron ore (solid-solid).

Modes of operation. Chemical reactors may be operated in batch, semibatch, or continuous modes.

Batch. When a reactor is operated in a batch mode, the reactants are charged, and the vessel is closed and brought to the desired temperature and pressure. These conditions are maintained for the time needed to achieve the desired conversion and selectivity, that is, the required quantity and quality of product. At the end of the reaction cycle, the entire mass is discharged and another cycle is begun. The complete cycle includes charging, heat-up, reaction (cook) time, cool-down, and discharge. Batch operation is labor-intensive and therefore is commonly used only in industries involved in limited production of fine chemicals, such as pharmaceuticals. *See* AUTOCLAVE.

Semibatch. In this type of reactor operation, one or more reactants are in the batch mode, while the coreactant is fed and withdrawn continuously. For example, a batch of liquid is exposed to a continuously fed and withdrawn gas phase, as in the hydrogenation of unsaturated oils catalyzed by a solid Raney nickel catalyst (a gas-liquid-solid system).

Continuous. In a chemical reactor designed for continuous operation, there is continuous addition to, and withdrawal of reactants and products from, the reactor system. The reaction time is the actual residence time of the molecules within the reactor. There are two extremes of residence or exposure time. If all molecules have the same reaction exposure time, the reactor is a plug- or piston-flow reactor (PFR); that is, reactant-product species move through the reactor as would a piston or plug, with no (zero) mixing in the direction of flow. If, however, the mixing is perfect (infinite) in the direction of flow, the reactor is a continuously fed stirred-tank reactor (CSTR). For this type of reactor, concentrations and temperature are uniform throughout the vessel due to vigor of agitation, and the residence times are distributed around the mean value. In contrast, in the piston-flow reactor, concentrations and temperature are distributed nonuniformly between reactor inlet and outlet, and residence time is unique.

Selection of reactor. The choice between a continuously fed stirred-tank reactor and a piston-flow reactor for continuous operation is determined by reaction characteristics. The reactor environment with respect to temperature is likewise determined, and may be isothermal (heat removal or addition matching heat generation or extraction), adiabatic (no heat removal or addition in the reaction zone), or the intermediate case (partial heat removal or addition).

An example is the sequence of reactions shown below, where k_1 and k_2 represent rate coefficients.

$$\text{Ethylene} \xrightarrow{k_1} \text{ethylene oxide} \xrightarrow{k_2} \text{carbon dioxide} + \text{water}$$

This reaction is exothermic (heat is released), and the rate coefficient k_1 increases with increase in temperature more slowly than does k_2. A decision must be made as to what reactor type, mode of operation, and environment should be employed. If large quantities of ethylene are to be treated annually, the continuous mode is economically justified. The desired product will determine the choice between a continuously stirred tank reactor and a piston-flow reactor.

The adiabatic environment is readily achieved in large-scale industrial reactors by the denial of heat exchange. Such an adiabatic reactor consists of a large-diameter tube packed with catalyst. The adiabatic temperature rise (in exothermic reactions) may require limitation due to safety and equilibrium factors in addition to integrity of the catalyst and reactor materials. These considerations led to the development of the staged adiabatic fixed-bed reactor system for sulfur dioxide oxidation and hydrocracking. In each case, interstage cooling is effected either by means of indirect heat exchange to generate steam or preheat reactants or by means of direct cooling by the addition of "cold" coreactant (cold-shot addition). The adiabatic reactor is the least expensive, since it does not require a costly heat-transfer surface area.

Gas-solid reactors. There are a number of different types of reactors designed for gas-solid heterogeneous reactions. These include fixed beds, tubular catalytic wall reactors, and fluid beds.

The design of these components involves consideration of the properties of solid catalysts. Catalytic agents (for example, platinum, palladium, vanadium pentoxide among other zeolites, metal oxides, sulfides) are usually supported upon porous solids, such as aluminum oxide and silicon dioxide. Thus the components are, typically, support, catalyst, and promoter. Characterization of these components is imperative, since deactivation over time periods of minutes (catalytic cracking), months (reforming), and years (ammonia synthesis) plagues all catalysts. The actual catalytic sites exposed to reactants may be partially inaccessible because of the diffusional limitations of the reactants and the nature of the sites dictated by the fluid-phase environment (oxidizing, reducing). Furthermore, the reactivity and yield selectivity per exposed catalyst site may change with catalyst crystallite size (dispersion), a phenomenon known as fractal behavior. Since the reactions and associated enthalpy changes are forcing functions that affect reactor performance, consideration of the complexities of heterogeneous catalytic phenomena is necessary both in reaction modeling and in reactor modeling. *See* HETEROGENEOUS CATALYSIS.

Fixed bed. A common catalytic reactor that consists of a tube or parallel array of tubes filled with solid catalyst particles is the fixed-bed reactor. It is commonly employed in processes such as partial oxidation, ammonia synthesis, and reforming.

Minimization of tube surface area (large tube diameter) invites adiabaticity. In the general case (nonisothermal or nonadiabatic), temperature varies in axial and radial directions and radial heat-transfer limitations can cause "hot" or "quench" spots with consequent threats to safety and product quality. Radial temperature gradients can be minimized by use of small tube diameter; however, there will be consequent increase in heat-transfer surface and reactor cost. Usually a piston-flow reactor is used. When catalyst decay is rapid (as in catalytic cracking), fresh catalyst is added and spent solid removed continuously. This arrangement is known as a moving bed. *See* CRACKING.

Tubular catalytic wall reactor. Resistance to radial heat transfer can be vastly reduced by using this type of reactor, in which all the catalyst is impregnated upon the alumina wash-coated wall. This is the monolith tubular reactor used in auto-exhaust fume abatement. Catalyst replacement is obviously more difficult in this instance than in the conventional fixed bed; the tubular catalytic wall reactor cannot host catalysts of short life.

Fluid bed. When a fluid is passed upward through an unretained bed of fine solid particles, a velocity can be induced so that the bed moves, with bubbles of gas passing through the agitated solids. The bed behaves as a boiling fluid. Intensity of gas dispersion in the usually baffled bed induces rapid motion and circulation of the solid. Reaction heat is thus nearly uniformly dispersed and, unlike the fixed bed, the fluid bed approaches isothermality. Fine particles can be used with increase in surface area and reaction efficiency. Since the fluid bed is a multiphase system (gas-and-solids emulsion phases), bypassing or short-circuiting of unreacted species can occur, which reduces reactor efficiency. Staging or horizontal baffling can minimize bypassing and deleterious bubble growth.

The fluid bed can be operated in batch or continuous fashion with respect to the solids phase, while the fluiding (gas or liquid) phase is continuous. If catalyst life is short (seconds or minutes) or noncatalytic solid coreactant is converted, the continuous fluid bed must be employed. Residence time is complex.

A variation of the fluidized bed is the spouted-bed reactor, in which a jet of gas is injected at one or more points to disperse even rather large-sized particles with which the gas interacts (for example, drying of wheat, gas-solid reaction, or solid-catalyzed reaction). Solids may be batch or continuous.

At sufficiently high fluid velocities, the fluidized bed becomes entrained; that is, solids are carried out of the bed when fluid velocity exceeds particle terminal velocity. In a transport line or riser reactor, fresh solids are continuously fed at the reactor bottom with the entraining fluid. This is an ideal unit for rapidly decaying catalyst or solid noncatalytic coreactants. Modern catalytic cracking of oils to produce gasoline is largely done in the transport line reactor. Residence time approaches the piston-flow reactor limit as opposed to more complex residence time behavior of the continuous fluidized bed. Reactant exposure times are of the order of seconds, during which deactivating coke is laid down upon the catalyst. Coked catalyst is separated from the product vapors at the top of the reactor and is then sent to a regenerator, where oxygen-bearing gas is contacted with the coked catalyst to burn off the coke. The product of this gas-solid reaction, the regenerated cracking catalyst, is returned to the inlet of the transport line cracker. *See* FLUIDIZATION; FLUIDIZED-BED COMBUSTION.

Gas-liquid-solid reactors. Many different types have been developed for specific reaction conditions. The trickle-bed reactor employs a fixed bed of solid catalyst over which a liquid phase trickles downward in the presence of a cocurrent gas phase. This three-phase reactor, commonly employed for the removal of sulfur or nitrogen from high-boiling oil feedstocks, can pose problems of catalyst wetting, gas-liquid-solid transport, and liquid-phase bypassing. Reasonable catalyst life is required in trickle-bed operation.

An alternative is the slurry reactor, a vessel within which coreactant gas is dispersed into a liquid phase bearing suspended catalyst or coreactant solid particles. Unlike the trickle bed, liquid-solid wetting is complete. With short catalyst life or solid consumption, continuous feed and withdrawal of the liquid-solid phase is feasible, but with attendant problems of solid-liquid separation. Slurry reactors are usually of the continuously stirred tank type.

At high ratios of reactor length to diameter, the gas-liquid-solid reactor is often termed an ebullating-bed (high solids concentration) or bubble column reactor (low solids concentration). A trickle bed operating at high liquid holdup and countercurrent (upward) flow of gas becomes an ebullating bed.

Gas-liquid reactors assume a form virtually identical to the absorbers utilized in physical absorption processes. *See* ADSORPTION OPERATIONS.

Solid-solid reactions are often conducted in rotary kilns which provide the necessary intimacy of contact between the solid coreactants. *See* KILN.

Chemical senses

In vertebrates, the senses of smell (olfaction) and taste (gustation) plus the so-called common chemical sense constitute the external chemical senses, as contrasted with such internal chemoreceptors as the carotid sinus detectors of carbon dioxide in blood, glucose receptors of brain and certain visceral organs, and so on. The olfactory cells of vertebrates, usually located in the olfactory mucosa of the upper nasal passages, are specialized neural elements that are responsive to chemicals in the vapor phase. The floral fragrance of roses and the putrid smell of hydrogen sulfide are two examples of human olfactory sensations. Taste buds of the oral cavity, especially the tongue, are composed of modified epithelial cells responsive to chemicals in solution. Sweet, salty, sour, and bitter are the basic taste qualities experienced by humans. In certain fish (for example, catfish), taste buds occur over the body surface and barbels. The common chemical senses are composed of free nerve endings in the mucous membrane of the eye, nose, mouth, and digestive tract and are responsive to irritants or other chemicals in either the vapor or liquid phase. *See* CAROTID BODY; CHEMORECEPTION.

Chemical sensitivity occurs in single-cell and other lower organisms. Among invertebrates, sense organs occur as specialized hairs and sensilla, or minute cones supplied with sensory nerves and nerve cells. Characteristic of male moths, for example, are their distinctive bushy antennae, by which they detect and locate females by sex pheromones. Rodents, ungulates, carnivores, and other mammals also show sexual attraction to female odors produced by specialized glands. Whether humans in general are susceptible to pheromonal influences from other humans is highly debatable. *See* CHEMICAL ECOLOGY; PHEROMONE.

Taste plays an important role in selection and acceptance of food. Although the "sweet tooth" is widespread throughout the animal kingdom as well as humans, there are great species differences in sweet sensitivity, especially for artificial sweetners. Besides the protective, inborn aversion to bitter (many poisons, but not all, are bitter), a single experience with the particular taste of a toxic substance which caused illness may establish a strong and persistent learned taste aversion. By contrast, a compensatory salt hunger may occur in persons or animals suffering salt deficiency. The intake of salt in civilized people, however, may be determined not only by physiological need but by social custom and habit, and excess intake with high incidences of hypertension has been reported in some groups. *See* HYPERTENSION; SALT (FOOD).

The limbic system of the brain, which modulates appetitive and emotional behavior and hedonic (pleasant vs. unpleasant) experiences, has both taste and olfactory neural pathways to it, providing the neural substrate for the pleasure or displeasure of sensations. *See* NEUROBIOLOGY; OLFACTION; SENSATION; TASTE.

Chemical separation (chemical engineering)

A process used to purify substances or to isolate them from other substances. In industrial applications, the ultimate goal is the isolation of a product of given purity. Most industrial chemical processes involve a separation stage. This may involve a preliminary purification stage before the reaction process, or a final stage involving the separation of the desired product. Two well-known processes are distillation and crystallization.

Distillation and crystallization. The distillation process is based on the relative volatilities (that is, vapor pressures) of the components. It involves the heating of the feed material (which is to be separated) in a boiler. The heated vapors enter a column and partially condense on the many plates or trays. These plates have a large surface area to facilitate the equilibrium between the vapor and the liquid. The vapor in the column is richer in the more volatile (lighter) component. As the vapor travels up the column, this process of enrichment is enhanced. The final stage of the distillation process is the complete condensation of this vapor as it leaves the column. This is done by cooling the vapor to a temperature well below its boiling point. The result is a separation of a light component or components (the condensate) from heavy components left in the boiler. The overall separation achieved depends not only on the relative vapor pressures of the components but also on the number of trays in the column. In spite of the high energy demands of the distillation process, 90% of all separation processes in the chemical and petrochemical industries worldwide are distillation processes. *See* DISTILLATION; VAPOR PRESSURE.

In the crystallization process, separation is based on the relative solubilities of the components. The separation of sea salt from water is usually done by crystallization through the evaporation of the water either by heating or by using solar energy. *See* CRYSTALLIZATION.

Thermodynamics offers a proper understanding of all separation processes. Not only is it useful in quantifying the separation of components, but thermodynamic relationships are also vital in the design of industrial separation plants.

Basic theory. When an equilibrium exists between phases (solids, liquids, or gases), the chemical potential, μ_i, for species *i* in each phase may be expressed by Eq. (1). For a vapor-liquid equilibrium process (distillation) this equality results in Eq. (2), the relationship between the vapor composition (y_i) and the liquid composition (x_i) at a temperature T.

$$\mu_i(\text{solid}) = \mu_i(\text{liquid}) = \mu_i(\text{gas}) \qquad (1)$$

$$y_i/x_i = \gamma_i P_i^0/P_{(\text{total})} \qquad (2)$$

Here, γ_i is the activity coefficient of species *i*, P_i^0 is the vapor pressure of pure *i* at T, and $P_{(\text{total})}$ is the total vapor pressure of the system. It is this ratio that defines the separating efficiency and is known as the distribution coefficient. Other relationships can be derived for other phase separation processes (such as crystallization), and in every case the results will be based on Eq. (1). *See* CHEMICAL EQUILIBRIUM.

Separation processes. Industrial separation processes involve all the possible phase pairs apart from solid-solid, which is kinetically too slow for useful applications (**Table 1**). *See* ADSORPTION OPERATIONS.

TABLE 1. Some important separation processes

Phase pair	Process	Industrial separation
Gas-liquid	Distillation	(i) Gasoline, paraffin and diesel fuel separated from oil (ii) Acetic acid from water
	Gas adsorption	Ammonia gas and air separated by passing the gas mixture through water
	Gas desorption	Ammonia and water mixture separated by passing air through the solution
	Pervaporation	Alcohols removed from esters and aroma compounds in aroma production
Gas-gas	Membrane	Methane gas or hydrogen gas separated from carbon dioxide
Gas-solid	Sublimation	Removal of water from heat-sensitive foodstuff by freeze drying; the food is cooled below 0°C and vacuum is applied, resulting in the sublimation of water
	Desorption	Drying of clay or wood by exposure to air
	Adsorption	Drying of wet air by passing over silica gel
Liquid-liquid	Solvent extraction	A mixture of acetone and water can be separated by adding carbon tetrachloride (CCl_4); phase separation takes place and the acetone is found in the CCl_4-rich layer
	Reverse osmosis	Seawater and brackish water purified by removal of salts
Liquid-solid	Supercritical fluid extraction	Separation of caffeine from coffee; the caffeine in the ground coffee beans readily dissolves in supercritical carbon dioxide
	Zone refining	Purification of benzene or metals to produce ultrapure compounds
	Fractional crystallization	Salts from seawater are usually separated on a basis of solubility

Supercritical fluid extraction. The process of supercritical fluid extraction is a relatively new separation technique. Interest in it is based on the high solubility of some solids in the supercritical solvent, the high degree of selectivity, the ease of separating the required product, and the ease with which the solvent can be recovered. To understand the process requires an understanding of the critical point. *See* SUPERCRITICAL FLUIDS.

The liquid-vapor phase line (as opposed to the solid-vapor and solid-liquid phase lines) for pressure and temperature discontinues at a certain point (**Fig. 1**), known as the critical point. At temperatures above the critical temperature (T_c), it is not possible to liquefy the gas by pressure alone. In other words, it is impossible to produce a liquid meniscus from the gas phase by pressure alone. At conditions above the critical temperature and pressure (P_c), the gas is known as a supercritical fluid (Fig. 1).

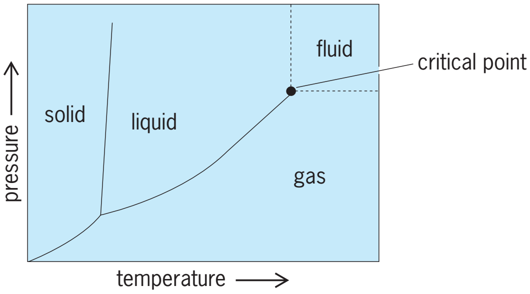

Fig. 1. Typical pressure-temperature (*P-T*) phase diagram showing the critical point discontinuity.

For an understanding of the general process, it is best to look at the most important supercritical fluid extraction process, the decaffeination of coffee using carbon dioxide. Carbon dioxide fluid, at a pressure of 200 atm (20 megapascals) and a temperature of 50°C (122°F) [in excess of $P_c\,(CO_2) = 73$ atm and $T_c\,(CO_2) = 31°C$ (88°F)], is pumped through the extraction cell containing the ground coffee in a mesh basket. The supercritical carbon dioxide has the unique capacity for dissolving only the caffeine and not the compounds that give coffee its taste and flavor. The carbon dioxide fluid, now containing dissolved caffeine, leaves the cell, and its pressure is reduced to below its critical value. As a result, the fluid vaporizes to a gas and the solid caffeine precipitates as it is not soluble in gaseous carbon dioxide. The coffee without caffeine is recovered and the carbon dioxide compressed and recycled. Apart from the simplicity of the process and the fact that it is done at a low temperature (it apparently does not affect the coffee taste or flavor), its main advantage is that the solvent is a natural substance and if any residue is left in the coffee it will be harmless. This is not true for some other decaffeination processes which use organic solvents such as methylene chloride.

TABLE 2. Examples of separations based on membrane processes

Membrane	Mixture	Preferentially selective for	Process
		Gas separation	
Polyimide	O_2/N_2	O_2	Oxygen enrichment
Polyethersulfone	CH_4/CO_2	CO_2	CO_2 recovery
Cellulose acetate	H_2/CO_2 or H_2/N_2	H_2	Hydrogen recovery
		Reverse osmosis	
Cellulose acetate, aromatic polyamides	Seawater	Water	Desalination
	Sugar solutions	Water	Concentration of food ingredients
	Fruit juices	Water	Concentration of food ingredients
		Pervaporation	
Poly(vinyl alcohol)	Water+alcohol	Water	Dehydration
Polyoctylmethylsiloxanes	Water+alcohol	Alcohol	Dealcoholization
Polyoctylmethylsiloxanes	Aroma compounds in water	Aroma compounds	Aroma production

Carbon dioxide is the most popular solvent used in supercritical fluid extraction. This is largely due to its relatively low critical pressure and temperature, and the ease with which the supercritical state can be achieved. It is extensively used in the perfume industry, where high temperatures would destroy the chemicals. It is used, for example, in separating oxygenated compounds (such as geranyl acetate), valuable as perfumes, from lemon oil, which consists largely of terpenes of low value, such as limonene.

Water has received much attention as a possible solvent for supercritical fluid extraction. Its critical properties are, however, too high for convenience [$P_c = 218$ atm (22.1 MPa) and $T_c = 374°C$ (705°F)], but it does have the interesting property of dissolving nonpolar liquids such as hexane. This is not possible at ambient temperature and pressure.

Membrane separation processes. An important new technology uses membranes to effect separation. The membrane is usually a thin plastic film (0.1–5 micrometers) on a thick porous and inert support layer (100–500 μm) [**Fig. 2**]. The driving force pushing the permeate across the membrane is invariably a pressure difference between the feed mixture and the permeate. The membranes are made of synthetic polymers such as poly(vinyl alcohol), for separating water and alcohol liquids; polyurethane, for separating aromatic liquids from cycloalkane liquids; polyimides, for separating gases such as oxygen and nitrogen; and cellulose acetate, for separating pure water from seawater. *See* MEMBRANE SEPARATIONS.

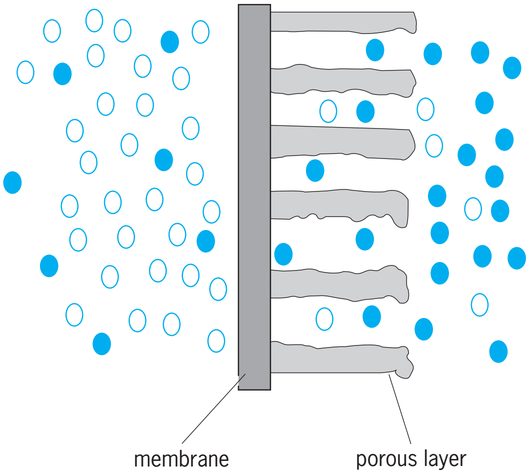

Fig. 2. General description of the membrane separation process. Molecules A (white) and B (black) are separated by a membrane supported on a porous layer and driven by a flux, which is usually pressure.

When the feed and the permeate are both gases, the process is known as gas separation. The pressure difference is usually between 10 and 100 atm (1 and 10 MPa), with the pressure of the permeate being about 1 atm (0.1 MPa). When the feed and permeate are liquids, the process is reverse osmosis, and it is best known for desalination of dilute aqueous solutions such as seawater, brackish water, and industrial wastewater. The pressure applied on the feed side is usually 80–100 atm (8–10 MPa), while the permeate is kept at ambient pressure. If the feed is a liquid under its own saturation pressure and the permeate is a gas or vapor kept at a low pressure ($5–20 \times 10^{-3}$ atm or 0.5–2 kPa) by a suitable vacuum pump, the process is known as pervaporation. The permeate is recovered in a cooling trap. *See* WASTEWATER REUSE; WATER DESALINATION.

Perhaps the main advantage of the membrane technique is that it is possible to tailor-make a membrane for a particular separation. Its limitations include chemical breakdown of the membrane with time and its slowness. The mechanism of the process is complex and involves properties such as the relative solubilities and relative diffusion coefficients of the feed chemicals in the membrane (**Table 2**).

Henley, *Separation Process Principles*, 1999.

Chemical separation techniques

A method used in chemistry to purify substances or to isolate them from other substances, for either preparative or analytical purposes. In industrial applications the ultimate goal is the isolation of a product of given purity, whereas in analysis the primary goal is the determination of the amount or concentration of that substance in a sample. In principle it is always more convenient to carry out quantitative determinations directly on portions of the original sample. In cases where the analytical methods available are not sufficiently selective to permit this direct approach, it is necessary to employ preliminary separations to reduce the concentration of, or to remove completely, those substances which interfere in the final estimation.

Although special considerations arise in a comparison of separation methods for engineering or laboratory analytical purposes because of differences in the scales of operations, the various separation processes are based on the same principles. There are three factors of importance to be considered in all separations: (1) the completeness of recovery of the substance being isolated, (2) the extent of separation from associated substances, and (3) the efficiency of the separation. The recovery factor or yield R_A of a separation of substance A is defined as Eq. (1) where

$$R_A = \frac{Q_A}{(Q_A)_0} \qquad (1)$$

Q_A and $(Q_A)_0$ are the amount of A after and before the separation.

The degree of separation $S_{B/A}$ of two substances A and B is given by the separation factor R_B for B with respect to A, and is defined as Eq. (2). Although

$$S_{B/A} = \frac{(Q_A)_0 Q_B}{(Q_B)_0 Q_A} \cong \frac{Q_B}{(Q_B)_0} \cong R_B \qquad (2)$$

complete separations are usually preferred, they are not always necessary in analytical applications. The degree of purity will depend upon the choice of the method of final estimation. Sometimes merely a reduction in the quantity of foreign substance present is enough to simplify the subsequent analytical task.

The third factor, efficiency, is a measure of the amount of work required to obtain a given amount of product with a prescribed purity. This consideration is of much greater consequence in industrial separations in which both the scale and the cost of the operation are important.

There are many types of separations based on a variety of properties of materials. Among the most commonly used properties are those involving solubility, volatility, adsorption, and electrical and magnetic effects, although others have been used to advantage. The most efficient separation will obviously be obtained under conditions for which the differences in properties between two substances undergoing separation are at a maximum.

The common aspect of all separation methods is the need for two phases. The desired substance will partition or distribute between the two phases in a definite manner, and the separation is completed by physically separating the two phases. The ratio of the concentrations of a substance in the two phases is called its partition or distribution coefficient.

In analytical work the original phase is usually a liquid, that is, a solution of the sample, and the separation is brought about through the addition or formation of a solid, a liquid, or a gaseous second phase. Although the actual separation of the phases may be physical in nature, chemical reactions are usually required to convert or modify the substance to a form which permits the formation of the new phase or the partition of the substance to the second phase. In some separation methods this step may also be accomplished by physical means.

If two substances have very similar distribution coefficients, many successive steps may be required for a separation. The resulting process is called a fractionation.

Based on the nature of the second phase, the more commonly used methods of separation are classified as follows: (1) Methods involving a solid second phase include precipitation, electrodeposition, chromatography (adsorption), ion exchange, and crystallization. These methods involve a solid second phase either through the formation of a slightly soluble product, deposition as a metal on the surface of an electrode, or by physical or chemical adsorption on a suitable solid material. (2) The outstanding method involving a liquid second phase is solvent extraction, in which the original solution is placed in contact with another liquid phase immiscible with the first. Separations are achieved as a result of differences in the distribution of solutes between the two phases. Solid materials may also be separated by extraction with organic solvents. (3) Methods involving a gaseous second phase include gas evolution, distillation, sublimation, and gas chromatography. Mixtures of volatile substances can often be separated by fractional distillation. *See* CHROMATOGRAPHY; EXTRACTION.

Chemical symbols and formulas

A system of symbols and notation for the chemical elements and the combinations of these elements which form numerous chemical compounds. This system of symbols, devised since about 1800 by chemists, consists of letters, numerals, and marks that are designed to denote the chemical element, formula, or structure of the molecule or compound. These symbols give a concise and instantly recognizable description of the element or compound. In many cases, through the efforts of international conferences, the symbols are recognized throughout the scientific world, and they greatly simplify the universal languge of chemistry.

Elements. Of the 115 elements known as of mid-2000, 109 have been given symbols, usually derived from the name of the element. Examples of names and symbols are chlorine, Cl; fluorine, F; beryllium, Be; aluminum, Al; oxygen, O; and carbon, C. However, symbols for some elements are derived from Latin or other names for the element. Examples are Au, gold (from *aurum*); Fe, iron (from *ferrum*); Pb, lead (from *plumbum*); Na, sodium (from *natrium*); and K, potassium (from *kalium*). The symbols consist of one or, more commonly, two letters. The first letter is always a capital letter and is followed by a lowercase second letter.

Inorganic molecules and compounds. Simple diatomic molecules of a single element are designated by the symbol for the element with a subscript 2, indicating that it contains two atoms. Thus the hydrogen molecule is H_2; the nitrogen molecule, N_2; and the oxygen molecule, O_2. Polyatomic molecules of a single element are designated by the symbol for the element with a numerical subscript corresponding to the number of atoms in the molecule. Examples are the phosphorus molecule, P_4; the sulfur molecule, S_8; and the arsenic molecule, As_4.

Diatomic covalent molecules containing unlike elements are given a similar designation. The formula for hydrogen chloride is HCl; for iodine monochloride, ICl; and for hydrogen iodide, HI. The more electropositive element is always designated first in the formula.

For polyatomic covalent molecules containing unlike elements, numerical subscripts are used to designate the number of atoms of each element that are present in the molecule. Examples are phosphorus(III) chloride, PCl_3; arsine, AsH_3; ammonia, NH_3; and water, H_2O. Again, as in diatomic molecules, the more electropositive element is placed first in the formula.

Ionic inorganic compounds are designated by a similar notation. The positive ion is given first in the formula, followed by the negative ion; subscripts are again used to denote the number of ions of each element present in the compound. The formulas for several common compounds are sodium chloride, NaCl; ammonium nitrate, NH_4NO_3; aluminum sulfate, $Al_2(SO_4)_3$; and iron(III) oxide, Fe_2O_3.

More complex inorganic compounds are designated in a manner similar to that above. The positive ion is given first, but may contain attached or coordinated groups, and this is followed by the negative ion. Examples are hexammine-cobalt(III) chloride, $[Co(NH_3)_6]Cl_3$; dichlorobis(ethylenediamine)chromium(III) nitrate, $[Cr(en)_2Cl_2](NO_3)_3$, where en is the abbreviation for ethylenediamine; and potassium trioxalatoferrate(III), $K_3[Fe(C_2O_4)_3]$. Hydrates of inorganic compounds, such as copper(II) sulfate pentahydrate, are designated by the formula of the compound followed by the formula for water, the number of water molecules being designated by a numerical prefix. Thus the symbol for the above compound is $CuSO_4 \cdot 5H_2O$.

Organic compounds. Because there are many more organic than inorganic compounds, the designation or notation for the first group becomes exceedingly complex. Many different types of organic compounds are known; in the case of hydrocarbons, there are aromatic and aliphatic, saturated and unsaturated, cyclic and polycyclic, and so on. The system of notation used must distinguish between the various hydrocarbons themselves as well as setting this group of compounds apart from others such as alcohols, ethers, amines, esters, and phenols. *See* CHEMISTRY; COORDINATION COMPLEXES; INORGANIC CHEMISTRY; ORGANIC CHEMISTRY. Wesley Wendlandt

Chemical thermodynamics

The application of thermodynamic principles to systems involving physical and chemical transformations is carried out in order to (1) develop quantitative relationships among the identifiable forms of energy and their conjugate variables, (2) establish the criteria for spontaneous change, for equilibrium, and for thermodynamic stability, and (3) provide the macroscopic base for the statistical-mechanical bridge to atomic and molecular properties. The thermodynamic principles applied are the conservation of energy as embodied in the first law of thermodynamics, the principle of entropy production as embodied in the second law, and the principle of absolute entropy and its statistical thermodynamic formulation as embodied in the third law of thermodynamics.

Basic concepts. The basic goal of thermodynamics is to provide a description of a system of interest in order to investigate the nature and extent of changes in the state of that system as it undergoes spontaneous change toward equilibrium and interacts with its surroundings. This goal implicitly carries with it the concept that there are measurable properties of the system which can be used to describe adequately the state of the system, and that the system is enclosed by a boundary or wall which separates the system and its surroundings. Properties that define the state of the system can be classified as extensive and intensive. Extensive properties are proportional to the total mass of the system, whereas intensive properties are not. Typical extensive properties are the energy, volume, and numbers of moles of each component in the system, while typical intensive properties are temperature, pressure, density, and the mole fractions or concentrations of the components.

Extensive properties can be expressed as functions of other extensive properties, for instance, as in Eq. (1), where the volume V of the system is expressed in terms of the internal energy U, the entropy S, and $\{n_i\}$, the set of numbers of moles of the various components labeled by the index i. A suitable transformation procedure can be used to replace extensive variables by conjugate intensive variables. For example, the volume can be expressed as in Eq. (2*a*) or (2*b*).

$$V = V(U, S, \{n_i\}) \qquad (1)$$

$$V = V(P, S, \{n_i\}) \qquad (2a)$$

$$V = V(P, T, \{n_i\}) \qquad (2b)$$

Because temperature T and pressure P are particularly convenient variables to control and measure in chemical systems, the form of Eq. (2*b*) is of great utility. All extensive thermodynamic properties X can be rewritten in this form, as Eq. (3). Because all such properties are linear homogeneous functions of the mass, it can be shown that at a given temperature and pressure Eq. (4) holds, where $\bar{X}_i$ is the partial molar value of the extensive property for the ith component. The value of $\bar{X}_i$ is given by Eq. (5), where the notation $\{n_i\}'$ means that all amounts are constant, except the ith one involved in the derivative. The variable $\bar{X}_i$ is itself intensive.

$$X = X(T, P, \{n_i\}) \qquad (3)$$

$$X = \sum_i n_i \bar{X}_i \qquad (4)$$

$$\bar{X}_i = (\partial X/\partial n_i)_{T,P,\{n_i\}'} \qquad (5)$$

Specification of boundaries. The concept of a boundary enclosing the system and separating it from the surroundings requires specification of the nature of the boundary and of any constraints that the boundary places upon the interaction of the system and its surroundings. Boundaries that restrain a system to a particular value of an extensive property are said to be restrictive with respect to that property. A boundary which restrains the system to a given volume V is a fixed, rigid wall. A boundary which is restrictive to one component of a system but not to the other components is called a semipermeable wall or membrane. A system whose boundaries are restrictive to energy and to mass of components is said to be an isolated system. A system whose boundaries are restrictive only to mass of components is called a closed system, whereas an open system has nonrestrictive walls and hence can exchange energy, volume, and mass with its surroundings. Boundaries can be restrictive with respect to specific forms of energy. Two important types are those restrictive to thermal energy but not work (adiabatic walls), and those restrictive to work but not thermal energy (diathermic walls).

First law of thermodynamics. Thermodynamics concerns the conversion of energy. The laws of thermodynamics differ from other scientific laws in that they are stated in terms of the impossibility of achieving certain types of energy transfers. The laws are usually stated in terms of the primary thermodynamic variables of temperature, energy, heat, work, and entropy.

Stated in terms of the primary thermodynamic functions of temperature, energy, and entropy, the laws of thermodynamics for any actual (that is, nonhypothetical) process are the first law: the total energy is conserved (that is, remains unchanged); the second law: the total entropy increases in any real process; and the third law: the absolute zero of temperature always cannot be reached in any real process.

Temperature. A device designed to measure temperature is called a thermometer. Familiar examples are the liquid-in-glass capillary, thermocouples, and resistance thermometers. All these devices have a property that varies monotonically with temperature. The fundamental thermometer is the constant-volume–ideal-gas thermometer, which is based on the fact that gases for which the constituent molecules do not combine or disassociate (that is, $A + A \rightleftharpoons A_2$ or $A_2 \rightleftharpoons 2A$) obey the ideal-gas equation (6) in the limit as $P \to 0$, where P is the pressure of the gas, V is the volume, n is the number of moles of the gas, and R is the gas constant. With a constant-volume gas thermometer, the temperature of a fixed reference point, such as the melting point of lead metal, is measured using Eq. (7).

$$PV = nRT \qquad (6)$$

$$T = (273.16\ \mathrm{K}) \lim_{P_{273.16\ \mathrm{K}} \to 0} \left[\frac{P_T}{P_{273.16\ \mathrm{K}}} \right] \qquad (7)$$

The pressure, P_T, of the fixed mass of the gas at temperature T is measured for progressively smaller values of the mass of the gas. The resulting calculated values of temperature are extrapolated to zero pressure to obtain the thermodynamic temperature. The value of $P_{273.16\ \mathrm{K}}$ is the corresponding measured pressure of the gas when the thermometer bulb is in contact with water at its triple point. The triple point of water is the single most important reference point in thermometry. It is arbitrarily assigned a temperature of exactly 273.16 K simply in order to preserve a close numerical agreement with older temperature scales, such as the Celsius scale. *See* TRIPLE POINT.

The temperature scale defined by Eq. (7) is an absolute scale. Zero is the lowest possible temperature, and all measurable temperatures on this scale are positive. This temperature scale is called the absolute Kelvin temperature scale, and temperatures are expressed as kelvins. Celsius temperatures are related to Kelvin temperatures via Eq. (8). The temperatures of fixed reference points obtained in the manner

$$t(^\circ\mathrm{C}) = T(\mathrm{K}) - 273.15 \qquad (8)$$

outlined above are, in turn, used to calibrate other, more convenient thermometers. *See* ABSOLUTE ZERO; GAS THERMOMETRY; TEMPERATURE; THERMOMETER.

Energy, work, and heat. Energy is an abstract mathematical concept that is characterized by an energy function, U. Some other thermodynamic functions also are called energy functions (Gibbs energy, Helmholtz energy) and are chosen specifically as state functions that yield exact differentials in terms of experimentally convenient variables such as temperature and pressure. Energy is not a thing. There are no meters capable of the direct measurement of energy, yet there are instruments that measure electric current, gas flow, volume, mass, pressure, length, time, and temperature. These measurable properties are used to calculate energy changes. Determination of the amount of energy transferred from one system to another always involves measurements of the appropriate physical parameters, followed by calculations involving the appropriate energy formulas. *See* ENERGY.

The principle of energy conservation amounts to the statement that, for any real process, the total energy of the system remains unchanged during the process. Energy can be transferred and transformed, but it cannot be created or destroyed. Work and heat are the two modes of energy transfer between systems. The transfer of energy as work requires the existence of an unbalanced force between a system and its surroundings. The transfer of energy as heat requires the existence of a temperature difference between the system and its surroundings. When a force F acts on a system and displaces the system by a differential amount dx, then the work done on the system is given by Eq. (9).

$$\delta w = -F\,dx \tag{9}$$

See CONSERVATION OF ENERGY.

The work w done on a system depends on the path along which the process is carried out, which must be specified before w can be calculated. When the path must be specified before the integral in Eq. (9) can be evaluated, then the integral is called a line integral. If the work done is independent of the path, then the force F is said to be conservative. A conservative force can always be expressed as the negative derivative of a potential energy, ϕ, with respect to the displacement, as in Eq. (10). Thus, for a conservative force, Eq. (11) holds for the process.

$$F = -\frac{d\phi}{dx} \tag{10}$$

$$w = -\int F\,dx = \int_1^2 \frac{d\phi}{dx}\,dx = \int_1^2 d\phi = \phi_2 - \phi_1 \tag{11}$$

Equation (11) shows that, if the force is conservative, then the work done depends only on the end states (1 and 2) and is thus path-independent. *See* WORK.

If at any stage in the process energy is transferred as heat, then the forces acting on the system cannot be conservative, the value of w depends on the path, and the discipline that describes the process moves from classical mechanics to thermodynamics. For a general process involving both work and heat transfers, the first law of thermodynamics is given by Eq. (12). *See* HEAT.

$$dU = \delta q + \delta w \tag{12}$$

The energy function, U, is called the internal energy, and it is a thermodynamic state function. The differential of a thermodynamic state function is said to be exact because the value of $\Delta U = U_2 - U_1$ for the process is path-independent, even if energy is transferred as heat and work in the process, as in Eq. (13).

$$\begin{aligned}\int_1^2 dU &= U_2 - U_1 = \Delta U\\ &= \int_1^2 \delta q + \int_1^2 \delta w = q + w\end{aligned} \tag{13}$$

See DIFFERENTIAL EQUATION; INTERNAL ENERGY.

A key point is that for a given change in state (that is, $1 \rightarrow 2$) the value of $U_2 - U_1$ is independent of path, whereas the values of both q and w depend on the path. It is only the sum $q + w$ that is independent of path. This statement constitutes the essence of the first law of thermodynamics. The following special cases are notable. If the process is adiabatic (that is, $\delta q = 0$), then δw is exact, because $w = \Delta U$. If no work is done (that is, $\delta w = 0$), then δq is exact (pure heat transfer), because $q = \Delta U$. *See* ADIABATIC PROCESS.

Reversible and irreversible processes. Changes in the state of the system can result from processes taking place within the system and from processes involving exchanges of mass or energy with the surroundings. After a process is carried out, if it is possible to restore both the system and the surroundings completely to their original states, then the process is said to be reversible; otherwise the process is irreversible. All naturally occurring spontaneous processes are more or less irreversible.

The internal energy of the system is given by the fundamental equation of state (14). Processes which

$$U = U(S, V, \{n_i\}, \{X_j\}) \tag{14}$$

give rise to a change in U are then limited to those for which Eq. (15) holds. Because all the extensive

$$\begin{aligned}dU = {} & (\partial U/\partial S)_{V,\{n_i\},\{X_j\}}\,dS + (\partial U/\partial V)_{S,\{n_i\},\{X_j\}}\,dV\\ & + \sum_i (\partial U/\partial n_i)_{S,V,\{n_i\}',\{X_j\}}\,dn_i\\ & + \sum_j (\partial U/\partial X_j)_{X,V,\{n_i\},\{X_j\}'}\,dX_j\end{aligned} \tag{15}$$

state properties are linear homogeneous functions, the coefficients of the differential terms are themselves intensive functions and correspond in each case to the conjugate variable of the respective extensive variable. Their product is thus the differential work associated with the appropriate form of energy transfer. The **table** lists several forms of internal energy transfer, their conjugate pair of variables, and their corresponding work terms.

Internal energy and generalized work

Type of energy	Intensive factor	Extensive factor	Element of work
Mechanical			
Expansion	Pressure (P)	Volume (V)	$-PdV$
Stretching	Surface tension (γ)	Area (A)	γdA
Extension	Tensile stretch (F)	Length (l)	Fdl
Thermal	Temperature (T)	Entropy (S)	TdS
Chemical	Chemical potential (μ)	Amount (n)	μdn
Electrical	Electric potential (E)	Charge (Q)	EdQ
Gravitational	Gravitational field strength (mg)	Height (h)	$mgdh$
Polarization			
Electrostatic	Electric field strength ($\mathcal{E}$)	Total electric polarization (dP)	$\mathcal{E}dP$
Magnetic	Magnetic field strength ($\mathcal{H}$)	Total magnetic polarization (M)	$\mathcal{H}dM$

Equation (15) can be rewritten as Eq. (16), where

$$dU = T\,dS - p\,dV + \sum_i \mu_i\,dn_i + \sum_j I_j\,dX_j \tag{16}$$

μ_i is the chemical potential of the ith component and I_j is the conjugate potential for X_j. The internal energy change given by Eq. (16) is dependent only upon the state properties of the system, and hence is independent of the process causing the change.

Enthalpy and heat capacity. A process involving only pressure-volume work may be described by Eq. (17).

$$\delta w = -F\,dx = -(F/A)A\,dx = -P_{\text{ext}}\,dV \tag{17}$$

Here, P_{ext} denotes the externally applied pressure, the definition of pressure $P = F/A$ = force/area is employed, and the volume element dV = (area of the base) × (vertical displacement) = $A\,dx$. Combination of Eqs. (12) and (17) yields Eq. (18).

$$dU = \delta q - P_{\text{ext}}\,dV \tag{18}$$

The enthalpy H, a thermodynamic state function, is defined by Eq. (19), and differentiation of this equation yields Eq. (20).

$$H = U + PV \tag{19}$$

$$dH = dU + P\,dV + V\,dP \tag{20}$$

Combination of Eqs. (18) and (20) yields Eq. (21), and, at constant pressure ($dP = 0$), Eq. (22) holds.

$$dH = \delta q + V\,dP \tag{21}$$

$$dH = \delta q_p \tag{22}$$

From this equation it follows that the addition or removal of energy as heat from a system at constant pressure is equal to the change in enthalpy of the system ($\Delta H = q_p$). *See* ENTHALPY.

The heat capacity of a system is a quantitative measure of the capacity of a system to take up or supply energy as heat. The greater the heat capacity of a system, the smaller the change in temperature produced by the input of energy as heat. The heat capacity is necessarily positive. The heat capacity C_x of a system at constant x (where x is a thermodynamic state function, such as pressure) is defined by Eq. (23), where $C_x(x, T)$ denotes that C_x is a function of both x and T.

$$C_x = \lim_{\Delta T \to 0}\left(\frac{q_x}{\Delta T}\right) = C_x(x, T) \tag{23}$$

For a constant-pressure process, it follows from Eqs. (22) and (23) that Eq. (24) holds.

$$C_p = \lim_{\Delta T \to 0}\left(\frac{q_p}{\Delta T}\right) = \lim_{\Delta T \to 0}\left(\frac{\Delta H}{\Delta T}\right)_p = \left(\frac{\partial H}{\partial T}\right)_p \tag{24}$$

Also, from Eqs. (24) and (22), it follows that Eq. (25) is valid.

$$q_p = \int_1^2 C_p\,dT \tag{25}$$

A large heat capacity indicates that the system can take up substantial amounts of energy as heat, owing to storage of the energy in the internal modes (translation, rotation, vibration, molecular dissociation) of the constituent particles. For example, the molar heat capacities of solid (s), liquid (l), and gaseous (g) water over the temperature range 250 to 500 K (−23 to 227°C or −10 to 440°F) are as follows:

$$\text{H}_2\text{O(s)}: C_p = 37.66\ \text{J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$$

$$\text{H}_2\text{O(l)}: C_p = 75.32\ \text{J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$$

$$\text{H}_2\text{O(g)}: C_p = 30.54\ \text{J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1} + (1.03 \times 10^{-2}\ \text{T})\ \text{J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$$

The roughly twofold greater heat capacity of liquid water relative to solid or gaseous water results from the fact that a substantial (roughly half) part of the heat input to liquid water is absorbed in breaking the hydrogen bonds between water molecules in liquid water (about 20 kJ/mol). Ice absorbs energy as heat below its melting point without breaking any hydrogen bonds and thus has a lower value of C_p than liquid water, whereas there are no hydrogen bonds in gaseous water and thus this mode of energy uptake is absent for the gas. *See* HEAT CAPACITY.

Second law of thermodynamics. Most naturally occurring processes involve the transfer of energy as heat. The first law of thermodynamics places no restrictions on energy transfers other than that of conservation of energy. There are, however, other restrictions on energy transfer, namely:

1. Heat always flows spontaneously from higher- to lower-temperature systems.

2. Heat can be induced to flow from a lower- to a higher-temperature system only through the use of energy as work to drive the transfer.

3. When a system undergoes a change in thermodynamic state, then the system and its surroundings cannot both be restored exactly to their original states. All naturally occurring processes are in this sense irreversible.

A mathematical statement of the second law of thermodynamics is that the change in entropy of the system, dS_{sys}, obeys inequality (26), where T is the

$$dS_{\mathrm{sys}} \geq \frac{\delta q_{\mathrm{sys}}}{T} \qquad (26)$$

absolute thermodynamic temperature [measured in kelvins (K)]. The equality sign holds if the process is reversible, and the inequality sign holds if the process is irreversible. The entropy S is a thermodynamic state function, and it is expressed in units of joules per kelvin (J/K).

It is useful to consider a system and its surroundings between which energy can be transferred. If the system undergoes a change in state, then the total entropy change is given by Eq. (27). If the process is

$$dS_{\mathrm{tot}} = dS_{\mathrm{sys}} + dS_{\mathrm{sur}} \qquad (27)$$

adiabatic, then $\delta q_{\mathrm{sys}} = \delta q_{\mathrm{sur}} = 0$ and from Eq. (26) $dS_{\mathrm{sur}} \geq 0$ and $dS_{\mathrm{sys}} \geq 0$. Thus $dS_{\mathrm{tot}} \geq 0$, or $\Delta S_{\mathrm{tot}} \geq 0$.

If the system undergoes an isothermal process, then $T = T_{\mathrm{sys}} = T_{\mathrm{sur}}$. From the second law, it follows that the system and the surroundings obey inequalities (28), but $q_{\mathrm{sys}} = -q_{\mathrm{sur}}$ and thus $\Delta S_{\mathrm{tot}} \geq 0$. Note

$$dS_{\mathrm{sys}} \geq \frac{\delta q_{\mathrm{sys}}}{T} \quad \text{and} \quad dS_{\mathrm{sur}} \geq \frac{\delta q_{\mathrm{sur}}}{T} \qquad (28)$$

that in both cases there is a net entropy production if the process is irreversible, but the total entropy remains unchanged if the process is reversible.

All real processes involve some degree of irreversibility and thus lead to an increase in the total entropy. Entropy is not conserved, except in the hypothetical limiting case of a reversible process.

A thermodynamic system is said to be in an equilibrium state when it can no longer undergo any spontaneous (entropy-producing) processes. The increase in total entropy that occurs in an irreversible process is a consequence of the failure to fully exploit the potential of the system for performing work. When less than the maximum possible work is performed in a process, then net entropy production inevitably results. The total entropy can never decrease and, for a given energy and volume for a closed system, a maximum in entropy indicates the most stable configuration of the system, that is, equilibrium.

Because entropy is a state function, Eq. (29) is

$$\int_1^2 dS = S_2 - S_1 = \Delta S \qquad (29)$$

satisfied. For a given change in state (1 → 2) the change in entropy of the system (but not the total entropy change, $\Delta S_{\mathrm{tot}} = \Delta S_{\mathrm{sys}} + \Delta S_{\mathrm{sur}}$) is independent of the path that the system takes from state 1 to state 2.

There are no entropy meters. Rather, entropy changes are calculated from measurable quantities, such as temperature, pressure, volume, and heat capacity. The total entropy of a system is a measure of the spatial and energy disorder (randomness) in a system.

Compared at the same pressure and temperature, liquids are more disordered than solids and gases are more disordered than liquids. This results follows from the fact that the molecules of a gas have more freedom to move around than the molecules of a liquid. The same holds true for the molecules or ions of a liquid as compared to those of a solid. The melting of a solid involves an entropy increase in the range 8–40 $\mathrm{J \cdot K^{-1} \cdot mol^{-1}}$. The temperature dependence of the entropy is found from Eqs. (26) and (24). From Eq. (26) it follows that $q_p = T\Delta S$ for an isothermal pure heat transfer (that is, $\delta w = 0$) at constant pressure. Substitution of this result into Eq. (24) yields Eq. (30). Thus, Eqs. (31) and (32) are valid.

$$\begin{aligned} C_p &= \lim_{\Delta T \to 0} \left(\frac{q_p}{\Delta T} \right) \\ &= T \lim_{\Delta T \to 0} \left(\frac{\Delta S}{\Delta T} \right)_p = T \left(\frac{\partial S}{\partial T} \right)_p \qquad (30) \end{aligned}$$

$$\left(\frac{\partial S}{\partial T} \right)_p = \frac{C_p}{T} \qquad (31)$$

$$\Delta S = \int_1^2 \frac{C_p}{T}\, dT \quad (\text{constant } P) \qquad (32)$$

Because C_p is greater than 0, the entropy of a substance always increases with increasing temperature at constant pressure. The increase in the entropy of a substance that undergoes an increase in temperature at fixed pressure is a consequence of the increased thermal randomness of the molecules at the higher temperature. A greater amount of energy is more randomly distributed over the same number of particles. *See* ENTROPY.

Gibbs energy and Maxwell relations. Combination of the first law, Eq. (12), with the second law, Eq. (26), yields Eq. (33). If a process involves only pressure-volume work and occurs reversibly, then, applying Eq. (17), Eq. (33) becomes Eq. (34). Because U and

$$dU \geq T\, dS + \delta w \qquad (33)$$

$$dU = T\, dS - P\, dV \qquad (34)$$

S are state functions, the values of ΔU and ΔS can be computed along a reversible path between the given initial and final states of the actual process, and the results for ΔU and ΔS for the system can be equated to those for the actual irreversible process. The values of q and w differ for the two paths, but not the values of ΔU_{sys} or ΔS_{sys}.

Equation (34) is the differential equation used to calculate ΔU. It expresses the change in the dependent variable in terms of changes in the independent variables S and V; that is, $U = U(S, V)$. The variables S and V are not convenient independent variables because they are very difficult to control in the laboratory. More convenient independent variables for experimental work are pressure and temperature. Equation (34) can be transformed into a differential equation with P and T as independent variables through Eqs. (35).

$$dU - T\,dS + P\,dV = 0 \tag{35a}$$

$$dU - T\,dS + P\,dV - S\,dT + V\,dP = -S\,dT + V\,dP \tag{35b}$$

$$d(U - TS + PV) = -S\,dT + V\,dP \tag{35c}$$

For compactness, the thermodynamic energy state function G is defined by Eq. (36). It can be used as a

$$G = U + PV - TS = H - TS \tag{36}$$

criterion for system equilibrium in terms of the more convenient variables, T and P. Here, H is defined by Eq. (19).

The function G is called the Gibbs energy after its creator, J. W. Gibbs; it plays a central role in chemical thermodynamics. From Eqs. (34) and (36), it obeys Eq. (37), which gives the differential equation for

$$dG = -S\,dT + V\,dP \tag{37}$$

dG, where $G = G(T, P)$. Because dG is an exact differential, G is a state function, and from mathematics Eq. (38) holds. Comparison of Eqs. (38) and (37) leads to Eqs. (39) and (40). Equation (39) shows that

$$dG = \left(\frac{\partial G}{\partial T}\right)_p dT + \left(\frac{\partial G}{\partial P}\right)_T dP \tag{38}$$

$$\left(\frac{\partial G}{\partial T}\right)_p = -S \tag{39}$$

$$\left(\frac{\partial G}{\partial P}\right)_T = V \tag{40}$$

the temperature dependence of the Gibbs energy at constant pressure is determined by the entropy, and Eq. (40) shows that the pressure dependence of the Gibbs energy at constant temperature is determined by the volume.

Because dG is an exact differential, it follows directly that the second cross partial derivatives of Eq. (37) are equal, as given by Eq. (41). This prop-

$$\left[\frac{\partial}{\partial P}\left(\frac{\partial G}{\partial T}\right)_P\right]_T = \left[\frac{\partial}{\partial T}\left(\frac{\partial G}{\partial P}\right)_T\right]_P \tag{41}$$

erty is characteristic of an exact differential. Thus, from Eqs. (39), (40), and (41), the Maxwell relation, Eq. (42), is obtained. This relation tells how the

$$-\left(\frac{\partial S}{\partial P}\right)_T = \left(\frac{\partial V}{\partial T}\right)_P \tag{42}$$

entropy changes with pressure at constant temperature.

Affinity and chemical equilibrium. Many chemical systems can be considered closed systems in which a single parameter ξ can be defined as a measure of the extent of the reaction or the degree of advancement of a process. If the reaction proceeds or the process advances spontaneously, then entropy must be produced according to the second law, and the uncompensated heat, defined by Eq. (43), must

$$\delta a = T\,dS + \delta w - dU \tag{43}$$

be positive. In terms of the advancement parameter ξ, the uncompensated heat δa is given by Eq. (44),

$$\delta a = \mathcal{A}\,d\xi = T\,d_iS \tag{44}$$

where $\mathcal{A}$ is the affinity of the process or reaction. The affinity is related to internal entropy production d_iS by Eq. (45).

$$\mathcal{A} = T\,d_iS/d\xi \geq 0 \tag{45}$$

The condition that the entropy production is zero represents equilibrium, and hence $\mathcal{A} = 0$ is an equivalent condition for equilibrium in a closed system. For spontaneous processes, because the signs of $\mathcal{A}$ and $d\xi$ must be the same, for positive $\mathcal{A}$ the process must advance or go in a forward direction in the usual sense of chemical reactions or physical processes, while for negative $\mathcal{A}$ the process must proceed in the reverse direction.

For a process that involves only pressure-volume work, Eqs. (17), (36), (43), and (44) can be combined to give Eqs. (46). These equations indicate that the affinity is a state function, given by Eq. (47).

$$dG = -S\,dT + V\,dP - \delta a \tag{46a}$$

$$= -S\,dT + V\,dP - \mathcal{A}\,d\xi \tag{46b}$$

$$\mathcal{A} = -(\partial G/\partial \xi)_{P,T} = \mathcal{A}(T, P, \xi) \tag{47}$$

It is useful to consider a closed system in which a chemical reaction can be characterized by the stoichiometry of reaction (48). This stoichiometry re-

$$\alpha\mathrm{A} + \beta\mathrm{B} \rightarrow \gamma\mathrm{C} + \delta\mathrm{D} \tag{48}$$

quires that at each time element t in the reaction the number of moles of the ith component n_i be given by Eq. (49), where n_i^0 is the number of moles of i

$$n_i = n_i^0 + \upsilon_i\xi \tag{49}$$

in the initial or original state ($t = 0$). The quantity υ_i is the stoichiometric coefficient for the ith component as given in the balanced equation (the convention is that υ_i is positive for products and negative for reactants), and ξ is the degree-of-advancement parameter, whose range is zero to unity. In terms of differential changes in advancement, Eq. (50) holds.

$$dn_i = \upsilon_i\,d\xi \tag{50}$$

For closed systems (constant temperature and pressure) in which only thermal, expansion, and chemical work terms are included, Eqs. (51) and (52)

$$dG = \sum_i \mu_i \, dn_i = -\delta a \qquad (51a)$$

$$= \left(\sum_i \upsilon_i \mu_i \right) d\xi = -\mathcal{A} \, d\xi \qquad (51b)$$

$$\mathcal{A}(T, P, \xi) = -\sum_i \upsilon_i \mu_i \qquad (52)$$

hold. The condition for equilibrium is $\mathcal{A} = 0$, and thus for a chemical reaction, equilibrium is achieved when Eq. (53) holds. If electrical work is included in Eq. (51), Eqs. (54) and (55) hold, where z is the number of units of charge and F is the Faraday constant (the magnitude of the charge per mole of electrons); $F = eN_A$, where e is the electron charge and N_A is Avogadro's number. Because $\mathcal{A} = 0$ is the equilibrium condition, equilibrium in an electrochemical system is given by Eq. (56).

$$\sum_i \upsilon_i \mu_i = 0 \qquad (53)$$

$$dG = \sum_i \mu_i \, dn_i + E \, dQ = -\delta a \qquad (54a)$$

$$= \left(\sum_i \upsilon_i \mu_i + zFE \right) d\xi = -\mathcal{A} \, d\xi \qquad (54b)$$

$$\mathcal{A}(T, P, E, \xi) = -\sum_i \upsilon_i \mu_i - zFE \qquad (55)$$

$$\sum_i \upsilon_i \mu_i = -zFE \qquad (56)$$

More than one reaction can take place in a chemical system, each characterized by a degree-of-advancement parameter ξ_r, and thus for r independent reactions, Eqs. (57) and (58) hold, where the equilibrium condition is Eq. (59). At equilibrium, each of the affinities $\mathcal{A}_r$ must be zero; but for the spontaneous condition, inequality (60) holds. In a two-reaction system inequality (61) holds, but now $\mathcal{A}_1$ and $d\xi_1$ do not necessarily have the same sign. If their signs are different, then the first reaction can be driven in the nonspontaneous direction by the second reaction. The reactions are then said to be coupled; reaction coupling is a common situation in biological systems. *See* CHEMICAL EQUILIBRIUM.

$$dG = \sum_i \mu_i \, dn_i = -\delta a \qquad (57a)$$

$$= -\sum_r \mathcal{A}_r \, \delta\xi_r \qquad (57b)$$

$$= \sum_r \left(\sum_i \upsilon_{ir} \mu_i \, \delta\xi_r \right) \qquad (57c)$$

$$\mathcal{A}_r(T, P, \{\xi_r\}) = -\sum_i \upsilon_{ir} \mu_i \qquad (58)$$

$$\sum_r \mathcal{A}_r \, d\xi_r = 0 \qquad (59)$$

$$\sum_r \mathcal{A}_r \, d\xi_r > 0 \qquad (60)$$

$$\mathcal{A}_1 \, d\xi_1 + \mathcal{A}_2 \, d\xi_2 > 0 \qquad (61)$$

Third law of thermodynamics. Although implicit in the concept of the existence of the fundamental equations of state for U or S is an absolute value of these functions, and therefore an extensive quantity which could be calculated on the basis of molecular properties from quantum mechanics and statistical mechanics, neither the first nor second law considers anything but differences in these state functions. The second law does suggest the existence of an absolute zero for an intensive variable, the temperature, but this is not sufficient to bridge the areas of classical and statistical thermodynamics. *See* ABSOLUTE ZERO.

It is found experimentally, for many isothermal processes involving pure phases, that Eq. (62) applies. This equation includes phase transitions between different crystalline modifications, solid-state chemical reactions, and even the solid-liquid and liquid-liquid isotope transitions in helium. This equation along with Eq. (63), obtained from Eq. (31), implies that at zero absolute temperature the entropy of pure crystalline phases of the same substance or different substances are equal. If the entropies of pure phase are equal at $T = 0$, then it is reasonable to take the value of $S(0)$ to be zero. A statement of the third law then is that the entropy of all pure crystalline fully ordered phases at $T = 0$ is zero. This makes it possible, by using Eq. (63), to calculate the absolute or third-law entropy of a substance from experimental measurements of its heat capacities. Comparison of such experimental values with those calculated by statistical thermodynamic methods has provided evidence for the validity of the third law. In some cases, thorough investigation of apparent discrepancies from the third law has led to new conclusions concerning the molecular structure of the substances or new information on the energy level system for the molecules. Calculation of the thermodynamic properties for a gas from the spectroscopic properties of molecules is an important result stemming from the third law. An alternative statement of the third law is that the absolute zero of temperature is unattainable in any real process. *See* STATISTICAL MECHANICS.

$$\lim_{T \to 0} \Delta S = 0 \qquad (62)$$

$$S(T, P) - S(0, P) = \int_0^T (C_p/T) \, dT \qquad (63)$$

Thermodynamics of irreversible processes. From a mathematical standpoint, if the equations describing a time-dependent physical process change sign when the time variable t is changed to $-t$, then the process is said to be irreversible. If the substitution of t by $-t$ does not change the equations, then the process described is said to be reversible. An example of an irreversible thermodynamic process is the approach to thermal equilibrium, which is described by the Fourier equation (64), where T is the temperature, t

$$\frac{1}{\alpha}\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \qquad (64)$$

is the time, and α is a parameter called the thermal diffusivity. The physicochemical processes of diffusion, heat and electrical conduction, and chemical reactions are irreversible processes. *See* CONDUCTION (ELECTRICITY); CONDUCTION (HEAT); DIFFUSION.

By utilizing Eqs. (44) and (26), the entropy production is found to be given by Eq. (65), where $\mathcal{A}$,

$$dS = \frac{\delta q}{T} + \frac{\mathcal{A}\,d\xi}{T} = d_eS + d_iS \qquad (65)$$

the affinity of the chemical reaction, is related to the chemical potentials by Eq. (52). The reaction rate v is defined by Eq. (66), and thus Eq. (67) holds. It is clear

$$v = \frac{d\xi}{dt} \qquad (66)$$

$$\frac{d_iS}{dt} = \frac{\mathcal{A}v}{T} > 0 \qquad (67)$$

that $\mathcal{A}$ and v always have the same sign and that the affinity $\mathcal{A}$ is directly related to entropy production.

If several reactions are involved simultaneously, then Eq. (68) holds, where the affinities are related

$$d_iS = \frac{1}{T}\sum_k \mathcal{A}_k\,d\xi_k > 0 \qquad (68)$$

to the chemical potentials by Eq. (58). At equilibrium all of the affinities are zero. The entropy production per unit time is given by Eq. (69).

$$\frac{d_iS}{dt} = \frac{1}{T}\sum_k \mathcal{A}_k v_k > 0 \qquad (69)$$

The net entropy production arising from the simultaneous reactions must be positive. However, it is possible to have the inequalities (70) in a two-reaction system, provided that inequality (71) is satisfied. As noted above, such reactions are said to be

$$\mathcal{A}_1 v_1 < 0, \qquad \mathcal{A}_2 v_2 > 0 \qquad (70)$$

$$\mathcal{A}_1 v_1 + \mathcal{A}_2 v_2 > 0 \qquad (71)$$

coupled in that a reaction can proceed in a direction opposed to its affinity, a phenomenon frequently encountered in biological systems. For example, matter may diffuse against its concentration gradient with negative entropy production driven by positive entropy production arising from heat flow.

Equation (69) can be rewritten as Eq. (72), where J_k and X_k are defined by Eqs. (73). The variable J_k

$$\frac{d_iS}{dt} = \sum_k J_k X_k > 0 \qquad (72)$$

$$J_k = v_k, \qquad X_k = \frac{\mathcal{A}_k}{T} \qquad (73)$$

is called a flux (rate) and the variable X_k is called a (generalized) force. At thermodynamic equilibrium Eqs. (74) are satisfied for all values of k.

$$J_k = 0, \qquad X_k = 0 \qquad (74)$$

Close to equilibrium, various empirical laws, such as Fourier's law for heat flow and Fick's law for diffusion, show a linear relation between the J_k and X_k values. Such linear laws are called phenomenological relations. Although such relations do not necessarily hold far from equilibrium, it will be assumed that they do hold close to equilibrium.

It is useful to consider the case of two simultaneous irreversible processes which, in general, satisfy Eqs. (75). The coefficients L_{ij} are called phenomenological coupling coefficients. For example,

$$\begin{aligned} J_1 &= L_{11}X_1 + L_{12}X_2 \\ J_2 &= L_{21}X_1 + L_{22}X_2 \end{aligned} \qquad (75)$$

L_{11} and L_{22} may denote heat conductivity and diffusion, while L_{12} describes the interference between these two processes (that is, thermodiffusion). Thus the L_{ij} ($i \neq j$) are called interference coupling coefficients.

Substitution of Eq. (75) into Eq. (72) yields Eq. (76), where the equality sign prevails when

$$\frac{d_iS}{dt} = L_{11}X_1^2 + (L_{12} + L_{21})X_1X_2 + L_{22}X_2^2 \geq 0 \qquad (76)$$

$X_1 = X_2 = 0$. From algebra it follows that the L_{ij} values must satisfy inequalities (77) and (78). Thus

$$L_{11} > 0, \qquad L_{22} > 0 \qquad (77)$$

$$(L_{12} + L_{21})^2 < 4L_{11}L_{22} \qquad (78)$$

while L_{11} and L_{22} must be positive, L_{12} and L_{21} may be positive or negative.

Onsager's theorem states that the coupling coefficients satisfy Eq. (79), which is called the Onsager

$$L_{ij} = L_{ji} \qquad (79)$$

reciprocity relation after its derivation by Lars Onsager. These relations express the fact that if the flux J_i corresponding to the irreversible process i is coupled to the force X_j of the irreversible process j, then the flux J_j also is influenced by the force X_i through the same interference coefficient L_{ij}. *See* OPEN-SYSTEMS THERMODYNAMICS (BIOLOGY); OSMOREGULATORY MECHANISMS; THERMOELECTRICITY; THERMOMAGNETIC EFFECTS.

In the general case, Eq. (80) holds, and when

$$J_i = \sum_i L_{ij}X_j \qquad (80)$$

$L_{ij} \neq 0$ there is a coupling between the flux J_i and the force (gradient) X_j. The principle of microscopic reversibility implies that at least close to equilibrium $L_{ij} = L_{ji}$. Far from equilibrium the situation becomes much more complex, and a detailed molecular-level kinetic (as opposed to a phenomenological) approach is required in the analysis of such cases. *See* THERMODYNAMIC PRINCIPLES; THERMODYNAMIC PROCESSES. Chemical vapor deposition

The process of producing a microscopic solid-material structure through chemically reacting vapor- or gas-phase reactants on a heated surface. Many of today's most important and most common technologies make use of very thin films of electrically active materials. Chemical vapor deposition (CVD) is a widely used manufacturing technique for products such as electric circuits and processors. Development of novel CVD processes and of new materials for advanced electronics and sensors produced by CVD are active research areas at universities and laboratories around the world. *See* INTEGRATED CIRCUITS; MICROSENSOR.

Basic principle. The fundamental principle of the CVD process is that the chemical reactants, called precursors, are in the gas or vapor state when they arrive at the base material or substrate. A chemical reaction, which is usually activated by heat or some other energy source, occurs on the substrate surface. The products of the reaction are the desired solid-film material and a gaseous product. Layers of semiconductors, dielectrics, conductors, and insulators are built up on the substrate and further processed to produce electronic devices. Scientists study the way the chemistry, flow dynamics, and deposition rate affect the structure and composition of the films and their electrical properties. *See* DIELECTRIC MATERIALS; FILM (CHEMISTRY); SEMICONDUCTOR; SOLID-STATE CHEMISTRY.

Process sequence. The process is summarized in **Figs. 1** and **2.** Reactants and precursor chemicals either are gases or are vaporized from liquid and solid sources by spraying, bubbling, heating, or sublimation. The precursors are supplied as a gas or as vapors in a carrier gas to the reactor chamber. Once in the reactor, the vapors are transported by convection and gas dynamics to the substrate's surface, which is at the desired deposition temperature. Deposition of the thin film occurs on the substrate's surface through reaction of the vapors and gases, usually on a heated substrate. The exhaust products are removed from the reactor by vacuum and treated.

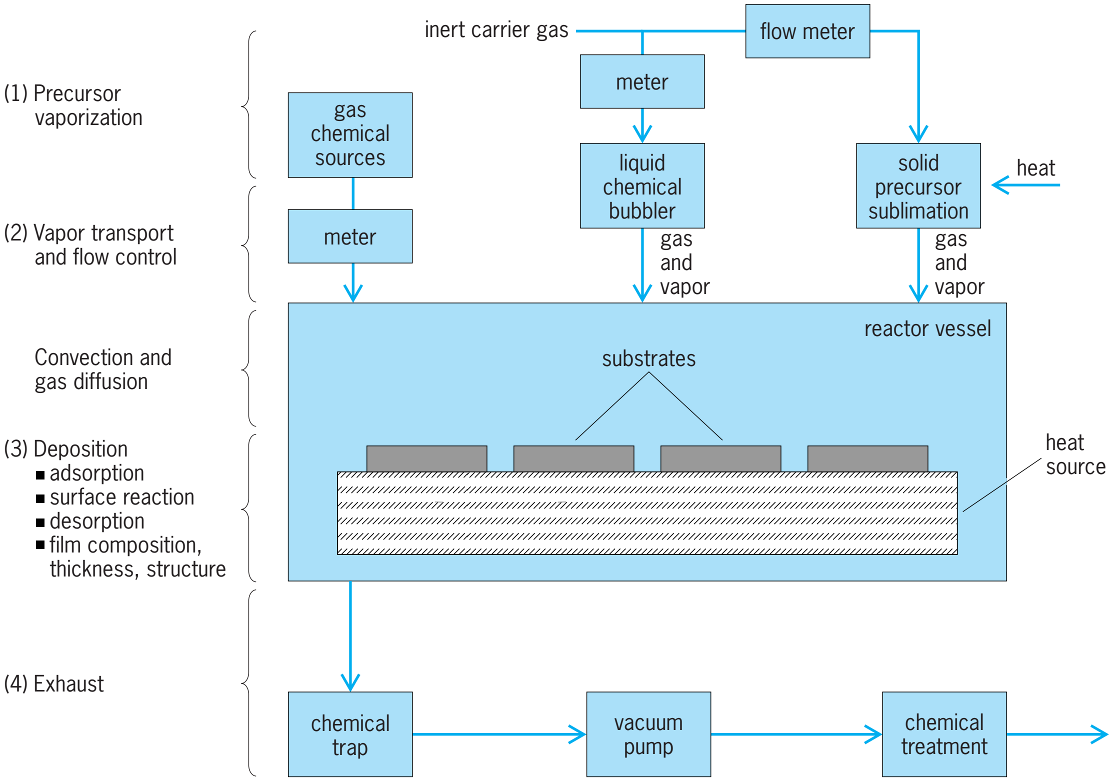

Fig. 1. The components of CVD manufacturing technology reflect the sequence of steps in the CVD process.

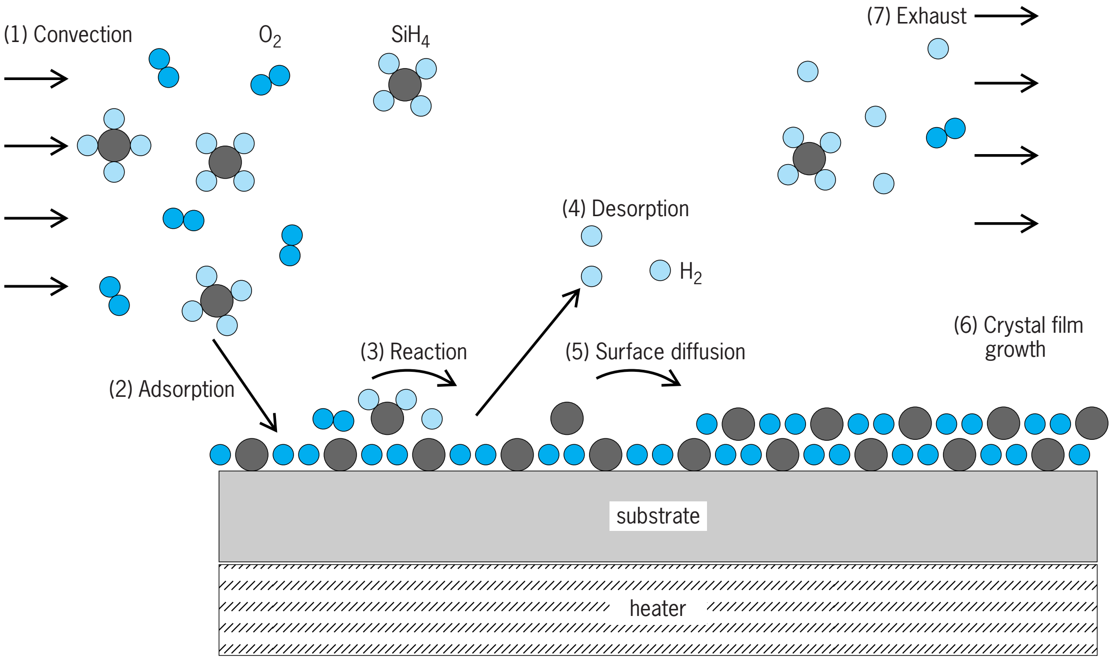

Fig. 2. Sequence of steps involved in the deposition and crystal growth of a solid material (SiO_2) from gas precursors ($SiH_4 + 2O_2$) on the surface of a heated substrate (Si).

Deposition rate. The quality and composition of the thin-film material depends directly on the rates of each step in the process sequence (Fig. 1). The evaporation rate of the precursors is controlled through the flow rate of carrier gases and the evaporation temperature. The feed rate of gas and vapors into the reactor and the pressure at which the reactor is maintained greatly affect the rate at which precursor molecules arrive at the substrate. In addition, the reaction rate at the surface is a strong function of the surface temperature and of the chemical thermodynamics and kinetics. *See* CHEMICAL KINETICS; CHEMICAL THERMODYNAMICS.

Thin-film applications. CVD manufacturing equipment is designed to control each step of the process in order to produce high-quality thin films with the desired properties. The chemistry involved can require the use of high-temperature and high-energy sources, such as plasma, and may require very high vacuum. However, many commercial CVD processes are done at atmospheric pressure, without extreme temperatures. Silicon dioxide (SiO_2) for solid-state electronic devices and optical fibers is produced in a relatively low-temperature (450°C or 840°F) process, using the chemical oxidation reaction of a common precursor, silane (SiH_4) with oxygen (Fig. 2). The CVD system to produce compound semiconductors for solar (photovoltaic) cells (for example, GaAs) must be capable of handling corrosive gases and temperatures over 600°C (1110°F). Batch reactors are used to modify the surface of steel drills and cutting tools by deposition of titanium nitride (TiN) from a precursor gas mixture of titanium tetrachloride ($TiCl_4$), nitrogen (N_2), and hydrogen (H_2) at 1000°C (1840°F). Self-cleaning glass with low reflectivity can be manufactured by deposition of an optically clear film of titanium dioxide (TiO_2) onto glass at less than 450°C (840°F) by using an organometallic precursor [$Ti(OC_3H_7)_4$]. While semiconductor CVD processes have been in practice for well over 20 years, the range of new materials, devices, and applications is expanding rapidly. *See* SEMICONDUCTOR HETEROSTRUCTURES; SOLAR CELL.

Process variations. There are two main categories for CVD processing: atmospheric pressure (APCVD) and low pressure (LPCVD). APCVD is often lower in cost, but it can be more difficult to control the vapor/gas transport processes. LPCVD is most common for electronics, as the low pressure helps ensure the purity necessary for electronically functional materials. When more energy is needed to activate the deposition reaction, plasma-enhanced (PECVD) and laser-enhanced (LECVD) processes are used. Relatively recent developments in a type of precursor chemicals called metal-organic compounds (MOCVD) has led to reduced toxic gas products and reduced processing temperatures.

Developments. CVD researchers investigate the properties of new materials, and the effects that different processing parameters have on these properties. Many scientists also work on reducing toxic-waste gas production through improving the conversion efficiency or through investigating new precursor chemicals. In an effort to reduce the cost of CVD equipment and to improve the control of the evaporation and transport steps in the process, several research groups have begun injecting liquid precursors directly into an evaporation chamber, sometimes using atomization to assist vaporization. For controlling structure, the rate of crystal growth has been found to be enhanced by pulsing, or turning on and off the precursor flow. This gives the crystal time to grow into more highly ordered structures with improved electrical and other properties. *See* CRYSTAL GROWTH; CRYSTAL STRUCTURE. Susan Krumdieck

Chemiluminescence

The type of luminescence wherein a chemical reaction supplies the energy responsible for the emission of light (ultraviolet, visible, or infrared) in excess of that of a blackbody (thermal radiation) at the same temperature and within the same spectral range. Below 900°F (500°C), the emission of any light during a chemical reaction is a chemiluminescence. The blue inner cone of a bunsen burner or the Coleman gas lamp are examples. *See* BLACKBODY.

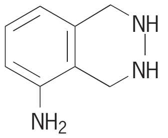
Reactions. Many chemical reactions generate energy. Usually this exothermicity appears as heat, that is, translational, rotational, and vibrational energy of the product molecules; whereas, for a visible chemiluminescence to occur, one of the reaction products must be generated in an excited electronic state (designated by an asterisk) from which it can undergo deactivation by emission of a photon. Hence a chemiluminescent reaction, as shown in reactions (1) and (2), can be regarded as the reverse of a photochemical reaction.

$$\mathrm{A} + \mathrm{B} \rightarrow \mathrm{C}^* + \mathrm{D} \tag{1}$$

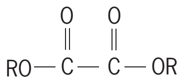
$$\mathrm{C}^* \rightarrow \mathrm{C} + h\nu \tag{2}$$

Energy. The energy of the light quantum $h\nu$ (where h is Planck's constant, and ν is the light frequency) depends on the separation between the ground and the first excited electronic state of C; and the spectrum of the chemiluminescence usually matches the fluorescence spectrum of the emitter. Occasionally, the reaction involves an additional step, the transfer of electronic energy from C* to another molecule, not necessarily otherwise involved in the reaction. Sometimes no discrete excited state can be specified, in which case the chemiluminescence spectrum is a structureless continuum associated with the formation of a molecule, as in the so-called air afterglow: $\mathrm{NO} + \mathrm{O} \rightarrow \mathrm{NO_2} + h\nu$ (green light). *See* HEAT RADIATION; LUMINESCENCE; PHOTOCHEMISTRY.

Efficiency. The efficiency of a chemiluminescence is expressed as its quantum yield ϕ, that is, the number of photons emitted per reacted molecule. Many reactions have quantum yields much lower (10^{-8} $h\nu$ per molecule) than the maximum of unity. Einsteins of visible light (1 einstein $= Nh\nu$, where N is Avogadro's number), with wavelengths from 400 to 700 nanometers, correspond to energies of about 70 to 40 kcal per mole (300 to 170 kilojoules per mole). Thus only very exothermic, or "exergonic," chemical processes can be expected to be chemiluminescent. Partly for this reason, most familiar examples of chemiluminescence involve oxygen and oxidation processes; the most efficient examples of these are the enzyme-mediated bioluminescences. The glow of phosphorus in air is a historically important case, although the mechanism of this complex reaction is not fully understood. The oxidation of many organic substances, such as aldehydes or alcohols, by oxygen, hydrogen peroxide, ozone, and so on, is chemiluminescent. The reaction of heated ether vapor with air results in a bluish "cold" flame, for example. The efficiency of some chemiluminescences in solution, such as the oxidation of luminol (**1**) and, especially, the reaction of some oxalate esters (**2**) with hydrogen peroxide, can be very high ($\phi = 30\%$).



(1)



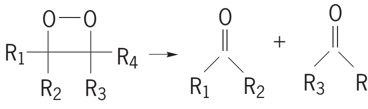
$$\mathrm{RO{-}\overset{\overset{\large O}{\|}}{C}{-}\overset{\overset{\large O}{\|}}{C}{-}OR}$$

(2)

See BIOLUMINESCENCE.

Other aspects. It is believed that the requirements for chemiluminescence are not only that there be sufficient exothermicity and the presence of a suitable emitter, but also that the chemical process be very fast and involve few geometrical changes, in order to minimize energy dissipation through vibrations. For example, the transfer of one electron from a powerful oxidant to a reductant (often two radical ions of opposite charge generated electrochemically) is a type of process which can result, in some cases, in very effective generation of electronic excitation. An example, with 9,10-diphenylanthracene (DPA), is shown in reaction (3). The same is true of the decomposition of four-membered cyclic peroxides (**3**) into carbonyl products, as shown in reaction (4),

$$\mathrm{DPA}^{\overset{-}{\cdot}} + \mathrm{DPA}^{\overset{+}{\cdot}} \rightarrow \mathrm{DPA}^* + \mathrm{DPA} \tag{3}$$



(4)

(3)

which may be the prototype of many chemiluminescences. Therese Wilson

Electrogenerated chemiluminescence. Also known as electrochemiluminescence, this is a luminescent chemical reaction in which the reactants are formed electrochemically. Electrochemical reactions are electron-transfer reactions occurring in an electrochemical cell. In such a reaction, light emission may occur as with chemiluminescence; however, the excitation is from the application of a voltage to an electrode. In chemiluminescence, the luminophore is excited to a higher energetic state by means of a chemical reaction initiated by mixing of the reagents. In electrogenerated chemiluminescence, the emitting luminophore is excited to a higher energy state by reactions of species that are generated at an electrode surface by the passage of current through the working electrode. Upon decay to the electronic ground state, light emitted by the luminophore (fluorescent or phosphorescent) can be detected. The luminophore is typically a polycyclic hydrocarbon, an aromatic heterocycle, or certain transition-metal chelates. *See* ELECTRON-TRANSFER REACTION.

Reaction mechanism. There are many reactions which give rise to electrogenerated chemiluminescence. However, they all share some common features. A typical reaction scheme involves the oxidation of a luminophore (Z), as in reaction, and reduction of a second molecule of the luminophore, as in reaction (5), and reduction of a second molecule of the luminophore, as in reaction (6) where e^- is an electron.

$$\mathrm{Z} \longrightarrow \mathrm{Z}^+ + e^- \qquad (5)$$

$$\mathrm{Z} + e^- \longrightarrow \mathrm{Z}^- \qquad (6)$$

The excited state of the luminophore (Z^*) is formed by a homogeneous charge-transfer reaction (7), between the oxidized and reduced luminophore. The excited luminophore decays to the ground state and emits a photon at a wavelength characteristic of the luminophore, which is measured by means of a photomultiplier detector [(8)].

$$\mathrm{Z}^+ + \mathrm{Z}^- \longrightarrow \mathrm{Z}^* + \mathrm{Z} \qquad (7)$$

$$\mathrm{Z}^* \xrightarrow{h\nu} \mathrm{Z} \qquad (8)$$

An example is the oxidative-reduction reaction using ruthenium tris(2,2′-bipyridine) [$Ru(bpy)_3^{2+}$], and oxalate $C_2O_4^{2-}$. The luminophore $Ru(bpy)_3^{2+}$ and oxalate are oxidized by application of a positive voltage to the electrode [reactions (9) and (10)].

$$\mathrm{Ru(bpy)_3}^{2+} \longrightarrow \mathrm{Ru(bpy)_3}^{3+} + \mathrm{e}^- \qquad (9)$$

$$\mathrm{C_2O_4}^{2-} \longrightarrow \mathrm{C_2O_4}^{-}\cdot + \mathrm{e}^- \qquad (10)$$

In both reactions, one electron is removed for each molecule of starting material. The oxidized oxalate rapidly disassociates [reaction (11)]. The products formed are carbon dioxide and, importantly, a strong reducing agent, $CO_{2-}\cdot$ radical anion. The term oxidative-reduction is descriptive of the process of forming a strong reducing agent through an electrochemical oxidation reaction. An exothermic and energetic reaction between the reducing agent and the oxidized luminophore occurs. Provided the enthalpy of the reaction is greater than the excitation energy, the excited state of the luminophore results from reaction (12). After the emission reaction [(8)], the luminophore is returned to the initial state and is able to again participate in the reaction sequence, and thus it is able to emit many photons during each measurement cycle.

$$\mathrm{C_2O_4^-}\ \cdot \longrightarrow \mathrm{CO_2} + \mathrm{CO_2^-}\ \cdot \qquad (11)$$

$$\mathrm{Ru(bpy)_3}^{3+} + \mathrm{CO_2^-}\ \cdot \longrightarrow \mathrm{Ru(bpy)_3}^{2+*} + \mathrm{CO_2} \qquad (12)$$

Applications. Chief among the developments since the early research and discovery of electrogenerated chemiluminescence was the construction of instrumentation for detection of electrogenerated chemiluminescence. These instruments made it possible for the methodology to be used by practitioners other than electrochemists.

Measurement of the light intensity of electrogenerated chemiluminescence is very sensitive and is proportional to the luminophore concentration. Trace amounts of luminophore as low as 10^{-13} mol/liter can be detected, making electrogenerated chemiluminescence very useful in analytical and diagnostic applications.

A commercial application of the phenomenon forms the basis of a highly sensitive technique for detection of biological analytes such as deoxyribonucleic acid (DNA), ribonucleic acid (RNA), proteins, antibodies, haptens, and therapeutic drugs in the clinical laboratory. The technique combines a binding assay method and a system for detecting electrogenerated chemiluminescence. The reaction is an oxidative-reduction type of mechanism using tripropyl amine and $Ru(bpy)_3^{2+}$. The concentration of analyte from a blood or serum sample is proportional to the intensity of the light from the electrogenerated chemiluminescence reaction. The reaction is carried out with a luminophore that is specially bound to the analyte of interest. The process of specifically binding a label (that is, a luminophore) to an analyte and measuring the extent of binding to determine concentration is referred to as a binding assay. An immunoassay uses as the binding reaction an antibody-antigen reaction. By covalently bonding the luminophore to the antibody, an electrogenerated chemiluminescence–active label is produced. The binding reaction may be of many types; antibody-antigen, ligand-receptor, DNA hybridization, and others.

Relating the intensity of the electrogenerated chemiluminescence to concentration requires the integration of several types of systems: a biological binding reaction that is selective for the analyte and attaches the luminophore; an electrochemiluminescent reaction causing the luminophore to emit light;

and an instrument which integrates the electrochemical cell, light measurement system, and means for sample handling and preparation.

Separation scientists requiring more sensitive detection system capabilities for chromatography have used electrogenerated chemiluminescence as a substitute for more traditional methods of detection, such as fluorescence and spectrophotometry.

Chemiosmosis

The coupling of metabolic and light energy to the performance of transmembrane work through the intermediary of electroosmotic gradients. Processes include synthesis of adenosine triphosphate (ATP) by oxidative phosphorylation or by photosynthesis, production of heat, accumulation of small molecules by active transport, movement of bacterial flagella, uptake of deoxyribonucleic acid (DNA) during bacterial conjugation, genetic transformation and bacteriophage infection, and insertion or secretion of proteins into or through membranes.

Oxidative phosphorylation. During the 1940s and 1950s, mitochondria were shown to be the powerhouses of the eukaryotic cell and the site of synthesis of ATP by oxidative phosphorylation. In the oxidation portion of ATP synthesis, reductants, such as reduced nicotinamide adenine dinucleotide (NADH) and succinate, are generated during metabolism of carbohydrates, lipids, and protein. These compounds are oxidized through the series of redox reactions performed by membrane-bound complexes, called electron transport or respiratory chains. The respiratory chains have common features. All are found associated with the inner mitochondrial membrane, and each chain pumps protons from inside the mitochondrion to the cytosol. Each begins with a membrane-bound dehydrogenase enzyme which oxidizes the soluble reductant. The dehydrogenase complex transfers electrons to a lipid-soluble quinone coenzyme, such as ubiquinone, which in turn passes electrons to a series of cytochromes. Cytochromes are proteins which have a heme moiety. Unlike the oxygen-carrier protein hemoglobin, which maintains its heme iron in the reduced state, the irons of cytochromes undergo a cycle of oxidation-reduction, alternating between the ferrous and ferric states. During reduction a cytochrome accepts an electron from the reduced side of the chain and passes it to the cytochrome on the oxidized side of the chain. The terminal cytochrome interacts with molecular oxygen, forming water. The overall reaction for the mitochondrial NADH oxidase is expressed in (1). The reaction

$$\mathrm{NADH} + \mathrm{H}^+ + {}^1/{}_2\mathrm{O}_2 \longrightarrow \mathrm{NAD}^+ + \mathrm{H}_2\mathrm{O} \qquad (1)$$

is exergonic, with a standard free-energy change ($\Delta G^{\circ\prime}$) at pH 7 of −52.6 kcal/mol. *See* CYTOCHROME; HEMOGLOBIN; MITOCHONDRIA.

The phosphorylation half of oxidative phosphorylation is catalyzed by a specific H^+-translocating adenosine triphosphatase (ATPase) enzyme. The ATPase is also a membrane-bound enzyme located in the inner mitochrondrial membrane, catalyzing reaction (2), where ADP is adenosine diphosphate and P_i

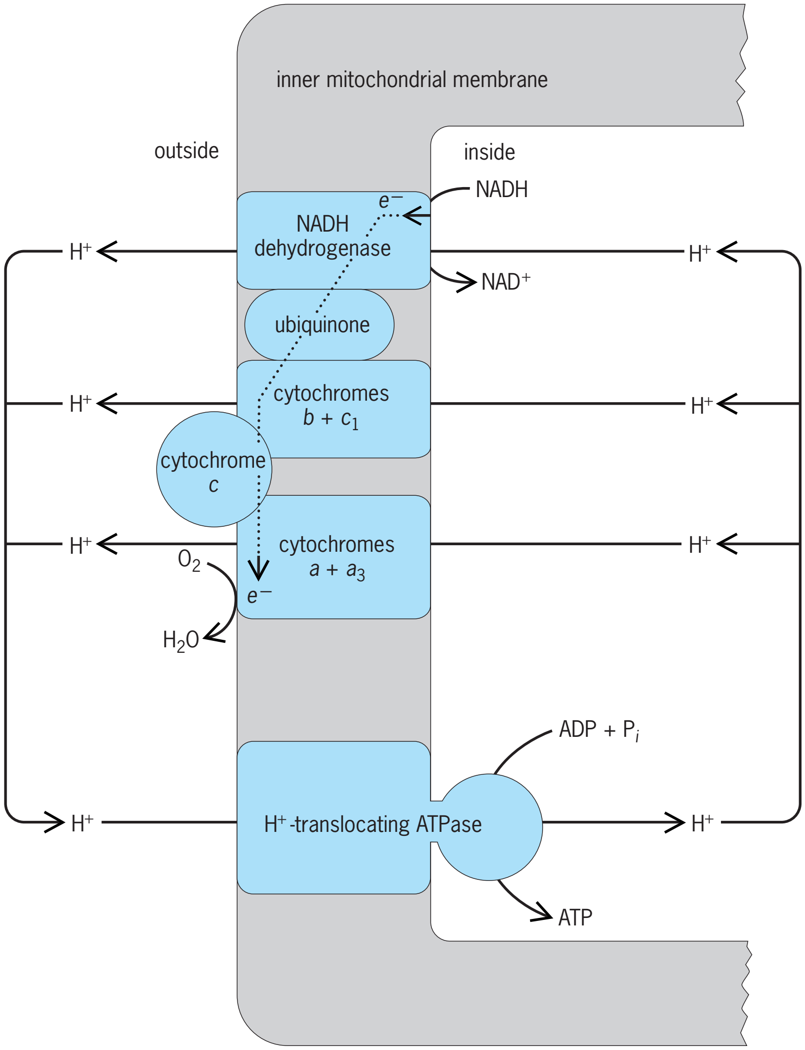
$$\mathrm{ADP} + \mathrm{P}_i + \mathrm{H}^+ \longrightarrow \mathrm{ATP} + \mathrm{H}_2\mathrm{O} \qquad (2)$$

is inorganic phosphate. The reaction occurs with a standard free-energy change, $\Delta G^{\circ\prime}$, of +7.3 kcal/mol. The two processes, oxidation and phosphorylation, are metabolically coupled, so that mitochondria continually synthesize ATP by using energy derived from the respiratory chain. In the case of NADH oxidase, the net reaction is shown as (3). In the overall biological reaction, three ATP's are synthesized for each NADH reduced, even though enough energy was available for six or seven ATP's. This assumes that the actual free-energy change, ΔG, is approximately the same as the standard free-energy change at pH 7, $\Delta G^{\circ\prime}$. Calculations suggest that the free energy of formation of ATP is probably greater than −7.3 kcal/mol, perhaps as much as −10 to −15 kcal/mol, but it is difficult to determine this parameter in a living system. The stoichiometry is a function of the molecular mechanism of coupling.

$$\begin{aligned}&\mathrm{NADH} + {}^1/{}_2\mathrm{O}_2 + 3\mathrm{ADP} + 3\mathrm{P}_i + 4\mathrm{H}^+ \longrightarrow \\ &\qquad\qquad \mathrm{NAD}^+ + 3\mathrm{ATP} + 4\mathrm{H}_2\mathrm{O} \quad (3)\end{aligned}$$

Most early postulates about the mechanism by which the redox energy of NADH is converted into the energy-rich phosphoric anhydride bond of ATP involved the formation of a high-energy chemical intermediate during the flow of electrons down the respiratory chain. This chemical intermediate could then interact with ADP, forming a high-energy nucleotide which could finally interact with P_i, producing ATP. For two decades this chemical intermediate proved elusive. The search culminated in the formulation of the chemiosmotic hypothesis by Peter Mitchell in 1961. For this contribution Mitchell was awarded the Nobel prize in medicine in 1978.

Mitchell postulated that chemical energy, that is, the energy of a chemical bond, can be reversibly converted into electroosmotic energy. The reactions are catalyzed by enzyme complexes which function as primary ion pumps. From the work of Mitchell and of others, the respiratory chain and the ATPase have both been shown to be proton pumps. The respiratory chain transports protons out of the mitochondrion into the cell cytosol, creating an electrochemical gradient of protons. When the ATPase hydrolyzes ATP, it also pumps protons out of the mitochondrion, hence the name H^+-translocating ATPase. Since the free energy produced by respiration is so



Mitochondrial oxidative phosphorylation. The chemiosmotic proton circuit of the inner mitochondrial membrane is depicted. NADH oxidase is composed of three proton-translocating units connected in series to form an electron transport chain. Electrons flow down a redox potential gradient from NADH to oxygen (broken line). Protons are pumped up an electrochemical gradient from inside to outside the mitochondrion, generating a proton motive force. Uptake of protons by the proton-translocating ATPase couples the phosphorylation of ADP to ATP.

much greater than that derived from ATP hydrolysis, proton translocation by the respiratory chain creates a force which drives the uptake of protons by the ATPase and consequently the synthesis of ATP. A diagram of the coupling of oxidation and phosphorylation is shown in the **illustration**.

Mitchell termed the force derived from proton translocation the proton motive force (pmf), by analogy with the electromotive force (emf) of electrochemical cells. Since the pmf is produced by pumping of H^+ ions across the mitochondrial membrane, it has both electrical and chemical components. The electrical or membrane potential ($\Delta\psi$) is due to the separation of positive and negative charges across the mitochondrial membrane. The chemical component results from the separation of H^+ and OH^-. Since $\text{pH} = -\log [H^+]$, $[H^+]$ being the concentration of H^+ ions, the chemical proton gradient is measured as a pH difference, ΔpH. Thus, $\text{pmf} = \Delta\psi - (2.3RT/F) \cdot \Delta\text{pH}$ and $\text{pmf} = \Delta G/F$, where R is the gas constant, T is the temperature, and F is the Faraday constant.

The concept of chemiosmosis is now well accepted, although some still question whether the pmf is the primary source of energy for phosphorylation. Most effort is concentrated on the molecular mechanisms of chemiosmotic coupling. It is clear that respiratory chains pump out protons, but questions such as which components directly transport protons, how many protons are translocated per pair of electrons, and what is the catalytic mechanism of proton translocation are still not adequately answered. It is clear that the ATPase transports protons outward during ATP hydrolysis and inward during synthesis, but the number of protons per ATP is controversial. The protons may directly interact with substrate within an active site, participating directly in catalysis. Conversely, binding of protons may change the shape or conformation of the ATPase enzyme in such a way as to alter its affinity for ATP. These are not trivial distinctions. How these macromolecular complexes work, how chemical energy is transformed into electrochemical and back into chemical energy, cannot be understood without the answers to the more basic questions. *See* ADENOSINE TRIPHOSPHATE (ATP); BIOLOGICAL OXIDATION.

Bacterial oxidative phosphorylation. Bacteria do not contain mitochondria, but many of the functions of the mitochondrial membrane are carried out by the bacterial cytoplasmic membrane. All bacteria contain a H^+-translocating ATPase in their cytoplasmic membrane. This enzyme is nearly identical to that of mitochondria. In fact, the genes for the bacterial and mitochondrial versions are clearly derived from a single evolutionary precursor. Many bacteria also use respiratory chains. Oxygen is not always the terminal electron acceptor of those chains. In some, nitrate or other oxidants can serve this role. But all of the chains are proton pumps. Thus, oxidative phosphorylation in bacteria is also chemiosmotic in nature. This resemblance to mitochondria is more than chance. The evidence, although mostly circumstantial, suggests that mitochondria, chloroplasts, and perhaps other eukaryotic organelles were originally free-living bacteria. These bacteria and larger protoeukaryotic cells became mutually symbiotic, so that neither was complete or viable without the other. The animal and plant kingdoms arose from these endosymbiotic events. *See* BACTERIAL PHYSIOLOGY AND METABOLISM.

Photosynthesis. Photosynthesis is the conversion of light energy into chemical energy. Overall photosynthetic bacteria and the chloroplasts of eukaryotic plants capture sunlight or other light and use that energy to generate both ATP and a reductant for use in biosynthesis. The mechanism of photophosphorylation, that is, the use of light energy to drive the phosphorylation of ADP to ATP, resembles that of oxidative phosphorylation. Chloroplasts use a H^+-translocating ATPase for phosphorylation. Again, the genes for the chloroplast ATPase are derived from the same evolutionary precursor as the mitochondrial and bacterial genes. Electron transport chains are also components of membranes found within chloroplasts. These chains have components similar to those of mitochondria, but the direction of electron flow is reversed. Water is oxidized to produce oxygen. Nicotinamide adenine dinucleotide phosphate ($NADP^+$) is reduced to NADPH, which is used for CO_2 fixation and the synthesis of carbohydrates. The energy to drive these endergonic reactions is derived from light through the absorption of photons by chlorophyll-containing photosystems. The chloroplast electron transport chain comprises a proton pump, generating a pmf which drives the phosphorylation of ADP to ATP by the ATPase. *See* PHOTOSYNTHESIS.

Thermogenesis. Not all of the energy of the proton motive force is coupled productively. It was noted above that enough chemiosmotic energy is generated by respiration to allow for phosphorylation of six or seven ATP. Yet, at best only three are produced. If not coupled to the performance of work, the excess energy may be lost as heat. In some cases, heat production or thermogenesis through the dissipation of the pmf is regulated. Some mammals, for example, cold-adapted animals, hibernating animals, and infants of hairless species (including humans), have a specialized form of adipose tissue called brown fat. The inner membrane of brown-fat mitochondria has unique proton channels which open or close depending on the need for heat. When open, the channels allow for the return of protons extruded by respiration. This cycling of protons uncouples the pmf from ATP synthesis. The energy from proton cycling becomes heat energy. By controlling the rate of the cycle, animals can regulate body temperature. *See* ADIPOSE TISSUE; THERMOREGULATION.

Other chemiosmotic systems. Oxidative phosphorylation and photophosphorylation are but specialized examples of chemiosmotic energy coupling. In the broader sense, the pmf is an ion current analogous to an electric current. Electric generators are machines which convert stored energy into a current of electrons. Among the forms of useful energy are chemical energy, such as that derived from fossil fuels, and light energy in the case of solar cells. Electricity is transmitted to motors, which couple electrical energy to the performance of work. Bacterial cells, mitochondria, and chloroplasts have protonic generators and protonic motors. Respiratory and photosynthetic electron transport chains are generators of proton currents pmf's, which then drive the various motors of the cell or organelle. When the H^+-translocating ATPase is "plugged in," the proton current drives phosphorylation. There are other motors present in the cell. Most membranes contain specific transport systems for small molecules, such as ions, sugars, and amino acids. Many of these transport systems are protonic; that is, they use the energy of the pmf to drive the accumulation or extrusion of their substrate. To give one example, in many bacteria the transport system for the sugar lactose consists of a single membrane protein which catalyzes the simultaneous co-transport of both lactose and a proton. Entry of protons through this carrier protein is driven by the pmf. Since a molecule of lactose enters the cell with each proton, entry and accumulation of lactose is thus coupled to the pmf. *See* BIOPOTENTIALS AND IONIC CURRENTS.

Other metabolic events have been found to use the pmf. Flagellar rotation in bacteria is coupled to the pmf. The flagellum is a motor which uses a flow of protons to do mechanical work, just as a paddle wheel uses a flow of water to turn it. Another example of a membrane event which uses the pmf is the uptake of DNA by bacterial cells. Foreign DNA can enter cells by sexual conjugation, by direct uptake (transformation), or by injection of viral DNA by bacteriophage. Similarly, some proteins destined to be secreted by cells require a pmf to be inserted into, or translocated through, the cytoplasmic membrane. Exactly how the pmf functions in the transport of DNA or protein is not clear. In conclusion, chemiosmosis is a universal phenomenon involved in many membrane and transmembrane events. *See* BACTERIAL GENETICS; BACTERIOPHAGE; CELL MEMBRANES.

Chemistry

The science that embraces the properties, composition, and structure of matter, the changes in structure and composition that matter undergoes, and the accompanying energy changes. It is important to distinguish chemical change, implicit in this definition, and changes in physical form. An example of the latter is the conversion of liquid water to solid or gas by cooling or heating; the water substance is unchanged. In chemical change, such as the rusting of iron, the metal is consumed as it reacts with air in the presence of water to form the new substance, iron oxide.

Modern chemistry grew out of the alchemy of the Middle Ages, and the attempts to transmute base metals into gold. Seminal observations were made in the early eighteenth century on the changes in volume of air during combustion in a closed vessel, and the French chemist Antoine Lavoisier in the 1770s interpreted these phenomena in essentially modern terms.

Atoms and elements. Underlying all of chemistry is the concept of elementary units of matter which cannot be subdivided. This idea was adumbrated in classical Greek writings, and was clearly expressed by the Englishman John Dalton in 1803, who called these units atoms. Different kinds of atoms were recognized, each corresponding to one of the chemical elements such as oxygen, sulfur, tin, iron, and a few other metals. By the mid-nineteenth century, about 80 elements had been characterized, and these were organized on the basis of regularities in behavior and properties, into a periodic table. *See* ELEMENT (CHEMISTRY); PERIODIC TABLE.

In the early twentieth century, observations of radiation from various sources and its impact on solid targets led to the recognition of three fundamental particles that are common to all elements; the electron, with negative charge; the proton, with positive charge; and the neutron, with zero charge. An atom consists of a nucleus containing protons and neutrons, and a diffuse cloud of electrons, equal in number to the number of protons and arranged in orbitals of progressively higher energy levels as the distance from the nucleus increases. The atomic number of an element (Z) is defined as the number of protons in the nucleus; this is the sequence of ordering in the periodic table. The mass number corresponds to the total number of protons and neutrons. *See* ATOMIC NUMBER; ELECTRON; NEUTRON; PROTON.

Isotopes. Most elements exist as isotopes, which have differing numbers of neutrons. All isotopes of an element exhibit the same chemical behavior, although isotopes can be separated on the basis of differences in atomic mass. The known elements as of mid-2000 total 115; of these, 97 have been detected in one or more isotopic forms in the Earth's crust. The other elements, including all but one of those with atomic number above 92, are synthetic isotopes produced in nuclear reactions that take place in nuclear piles or particle accelerators. Most of the isotopes of these heavier elements and also some lighter ones are radioactive; that is, the nuclei are unstable and decay, resulting in the emission of radiation. *See* ISOTOPE; PARTICLE ACCELERATOR; RADIOACTIVITY.

Molecules and chemical reactions. Molecules are combinations of two or more atoms, bonded together in definite proportions and specific geometric arrangements. These entities are chemical compounds; a molecule is the smallest unit. The bonding of atoms in compounds involves the distribution of electrons, and is the central concern of chemistry.

Compounds result from chemical reactions of atoms or molecules. The process involves formation and breaking of bonds, and may be either exothermic, in which the net bond charges lead to a more stable (lower-energy) system and heat is evolved, or endothermic, in which energy must be added to overcome a net loss of bonding energy.

A simple case is the reaction of hydrogen and oxygen to give water, which can be expressed as reaction (1).

$$2H_2 + O_2 \rightarrow 2H_2O \qquad (1)$$
$$\Delta H = 572 \text{ kilojoules}$$

The equation is balanced; no atoms are gained or lost in a chemical reaction. The symbols represent the nature of the initial and final materials and also the relative amounts. Thus H_2O represents a molecule of water or a mole, which is the quantity in grams (or other mass units) equivalent to the molecular weight. The symbol ΔH indicates the energy (enthalpy) change for the process. The reaction of hydrogen and oxygen is highly exothermic, and the sign of the energy charge is therefore negative since the system has lost heat to the surroundings. *See* ENTHALPY; MOLE (CHEMISTRY); STOICHIOMETRY.

Bonds. Bonds can be broadly classified as ionic or covalent. An ion is an atom or molecule which has an electric charge. Ionic compounds can be illustrated by salts such as sodium chloride, NaCl, in which a positive sodium ion, Na^+, and negative chloride ion, Cl^-, are associated by electrostatic attractions in regular locations of a crystal lattice. In solution the ions are solvated by water molecules and can conduct an electric current.

In covalent molecules, bonds are formed by the presence of pairs of electrons in overlapping orbitals between two atoms. Thus when two hydrogen atoms ($H\cdot$) come within bonding distance, a molecule of hydrogen is formed in an exothermic reaction, by formation of a covalent bond. In this case the heat of reaction represents the energy of the H-H bond [reaction (2)].

$$2H\cdot \rightarrow H\text{—}H \qquad (2)$$
$$\Delta H = -435 \text{ kilojoules}$$

See CHEMICAL BONDING.

Chemical compounds. A compound is specified by the elements it contains, the number of atoms of each element, the bonding arrangement, and the characteristic properties. The number of unique compounds that have been isolated from natural sources or prepared by synthesis is enormous; as of 2000, over 15 million substances were registered in the file maintained by Chemical Abstracts (American Chemical Society). Most of these are organic compounds, containing from a few to many hundred carbon atoms. The element carbon, unlike any others, can form long chains of covalently bonded atoms. Moreover, there can be many compounds, called isomers, with the same atomic composition. Thus a molecular formula such as $C_8H_{16}O$ can represent many thousand different compounds. *See* CARBON; MOLECULAR ISOMERISM.

Branches. Traditionally, five main subdivisions are designated for the activities, professional organizations, and literature of chemistry and chemists.

Analytical chemistry. This subdivision is an overarching discipline dealing with determination of the composition of matter and the amount of each component in mixtures of any kind. Analytical measurements are an integral and indispensable part of all chemical endeavor. Originally, analytical chemistry involved detection, separation, and weighing of the substances present in a mixture. Determination of the atomic ratio and thence the molecular formula of a compound is a prerequisite for any other investigation; the development of balances and techniques for doing this on milligram quantities of material had an enormous impact on organic chemistry. Advances since the 1950s have involved increasingly sophisticated instrumentation; mass spectrometers are a notable example. Other important methods include high-resolution chromatography and various applications of electrochemistry. A constant goal in analytical chemistry is the development of methods and instruments of greater sensitivity. It is now possible to detect trace compounds such as environmental pollutants at the picogram level. *See* ANALYTICAL CHEMISTRY.

Biochemistry. Biochemistry is the study of living systems from a chemical viewpoint; thus it is concerned with the compounds and reactions that occur in plant and animal cells. Most of the substances in living tissues, including carbohydrates, lipids, proteins, nucleic acids, and hormones, are well-defined organic substances. However, the metabolic and regulatory processes of these compounds and their biological function are the special province of biochemistry. One of the major areas is the characterization of enzymes and their cofactors, and the mechanism of enzyme catalysis. Other topics of interest include the transport of ions and molecules across cell membranes, and the target sites of neurotransmitters and other regulatory molecules. Biochemical methods and thinking have contributed extensively to the fields of endocrinology, genetics, immunology, and virology. *See* BIOCHEMISTRY.

Inorganic chemistry. This discipline is concerned with any material in which metals and metalloid elements are of primary interest. Inorganic chemistry is therefore concerned with the structure, synthesis, and bonding of a very diverse range of compounds. One of the early interests was the composition of minerals and the discovery of new elements; from this has grown the specialized area of geochemistry. Early synthetic work emphasized compounds of the main group elements, and particularly in this century, complex compounds of the transition metals. These studies have led to soluble transition-metal catalysts, and a greatly increased understanding of catalytic processes and the pivotal role of metal atoms in major biochemical processes, such as oxygen transport in blood, photosynthesis, and biological nitrogen fixation. Other contributions of inorganic chemistry are seen in advanced ceramics, high-performance composite materials, and the growing number of high-temperature superconductors. *See* CATALYSIS; CERAMICS; COMPOSITE MATERIAL; INORGANIC CHEMISTRY; PHOTOSYNTHESIS.

Organic chemistry. This subdivision is centered on compounds of carbon. Originally these were the compounds isolated from plant and animal sources, but the term was early broadened to include all compounds in which a linear or cyclic carbon chain is the main feature. Two of the major thrusts have been the elucidation of new structures and their preparation by synthesis; another long-standing interest has been study of the reaction mechanisms and rearrangments of organic compounds. Structure work on naturally occurring compounds progressed over a 150-year period from simple straight-chain compounds with 2–10 carbon atoms, hydrogen, and 1 or 2 oxygen atoms to antibiotics and toxins with many rings and as many as 100 carbon atoms. In modern work, nuclear magnetic resonance spectroscopy and x-ray diffraction have become indispensable tools. Paralleling structural studies has been the synthesis of increasingly complex target molecules. Synthetic work is directed also to the preparation of large numbers of compounds for screening as potential drugs and agricultural chemicals. Plastics, synthetic fibers, and other high polymers are other products of organic chemistry. *See* NUCLEAR MAGNETIC RESONANCE (NMR); ORGANIC CHEMISTRY; X-RAY DIFFRACTION.

Physical chemistry. This discipline deals with the interpretation of chemical phenomena and the underlying physical processes. One of the classical topics of physical chemistry involves the thermodynamic and kinetic principles that govern chemical reactions. Another is a description of the physical states of matter in molecular terms. Experimentation and theoretical analysis have been directed to the understanding of equilibria, solution behavior, electrolysis, and surface phenomena. One of the major contributions has been quantum chemistry, and the applications and insights that it has provided. The methods and instruments of physical chemistry, including such hardware as spectrometers and magnetic resonance and diffraction instruments, are an integral part of every other area. *See* CHEMICAL THERMODYNAMICS; PHYSICAL CHEMISTRY; QUANTUM CHEMISTRY.

Others. Each broad area of chemistry embraces many specialized topics. There are also a number of hybrid areas, such as bioorganic and bioinorganic chemistry, analytical biochemistry, and physical organic chemistry. Each of these areas has borrowed extensively from and contributed to every other one. It is better to view chemistry as a seamless web, rather than a series of compartments. *See* BIOINORGANIC CHEMISTRY.

James A. Moore

Chemometrics

A chemical discipline that uses mathematical and statistical methods to design or select optimal measurement procedures and experiments and to provide maximum chemical information by analyzing chemical data. Chemometrics is actually a collection of procedures, mathematics, and statistics that can help chemists perform well-designed experiments and proceed rapidly from data, to information, to knowledge of chemical systems and processes.

Medicinal chemists use chemometrics to relate measured or calculated properties of candidate drug molecules to their biological function; this subdiscipline is known as quantitative structure activity relations (QSAR). Environmental chemists use chemometrics to find pollution sources or understand the effect of point pollution sources on regional or global ecosystems by analyzing masses of environmental data. Forensic chemists analyze chemical measurements made on evidence (for example, gasoline in an arson case) or contraband to determine its source. Experimental physical chemists use chemometrics to unravel and identify physical or chemical states from spectral data acquired during the course of an experiment. *See* FORENSIC CHEMISTRY; PHYSICAL CHEMISTRY.

In analytical chemistry, chemometrics has seen rapid growth and widespread application, primarily due to the computerization of analytical instrumentation. Automation provides an opportunity to acquire enormous amounts of data on chemical systems. Virtually every branch of analytical chemistry has been impacted significantly by chemometrics; commercial software implementing chemometrics methods has become commonplace in analytical instruments. *See* ANALYTICAL CHEMISTRY.

Whether the analyst is concerned with a single sample or, as in process analytical chemistry, an entire chemical process (for example, the human body, a manufacturing process, or an ecosystem), chemometrics can assist in the experimental design, instrument response, optimization, standardization, and calibration as well as in the various steps involved in going from measurements (data), to chemical information, to knowledge of the chemical system under study.

Tensorial calibration. Chemical processes are usually controlled by acquiring information on physical properties (such as temperature, pressure, and flow rate) and chemical properties (composition) at one or more locations in a chemical reactor. These data are then fed to process control computers that open or close valves and provide heating or cooling of the process to optimize yield and quality of the product. Sensors that measure product in terms of intermediate or starting material composition are calibrated by using pure standards. One problem often encountered is that the sensor may be sensitive to an unsuspected interferent in the process, causing the reported composition data to be erroneous. Simple sensors generating only one measurement or datum can be classified as zero-order sensors and cannot separate the signal generated by the analyte from the interferent. This is a serious problem in process control.

First order. To solve the problem of separating the signals, chemists have turned to multivariate calibration using first-order instruments. These are instruments capable of producing a vector of measurements, a first-order tensor, per sample and include spectrometers and arrays of nonselective zero-order sensors. For the calibration of such instruments, methods such as classical multilinear regression (MLR), principal components regression (PCR), and partial least-squares regression (PLS) have become popular, especially in infrared and near-infrared spectrophotometry. Besides being able to analyze for multiple analytes in one sample while correcting for interferences, the methods have also been used to predict physical properties from spectral data. While these methods correct for interferences, the interferents must be included in the calibration step according to a good statistical experimental design. If an uncalibrated interferent is present in a sample to be analyzed, these methods can detect its presence but cannot, in general, correct for its effect, and therefore the results are biased.

First-order calibration is used in many areas of process control. The physical properties of polymers, such as tensile strength and the ability to incorporate dyes for color, can be predicted from on-line spectral data acquired during a polymerization process before the process is complete. Another important application involves the use of on-line fiber-optic-based near-infrared spectrometers to predict the octane number of gasoline at various stages of refining and blending. Accurate knowledge of fuel properties during production can save millions of dollars per year at a large refinery. A multivariate calibration method is used to relate the spectral data from calibration samples to one or more known performance properties. If the calibration model passes various statistical tests, it can be used in the refinery. *See* PROCESS CONTROL.

Second order. Quite often the relationship between the analytical measurements and the analyte concentration, or physical property, is nonlinear. Methods are available for calibration and analysis in these cases, for example locally weighted regression, nonlinear partial least squares, and neural networks. *See* LEAST-SQUARES METHOD; NEURAL NETWORK.

A common problem in environmental science is determining the concentrations of pollutants in very complex samples containing completely unknown components. For example, in order to determine the migration of toxic chemicals in the ground near a known or suspected dump site, environmental analytical chemists sample ground and subsurface water from monitoring wells located around the site. Environmental analyzers have been developed that can be lowered down the wells for in-place analysis in order to avoid the time, expense, and other problems associated with taking hundreds of samples to the laboratory. The in-place analyzers must be calibrated, and the calibration models must be capable of accurate determination of the toxic chemicals, even though what may be present in the wells is not fully known. When an unknown interferent is present, it must be physically separated from the analyte by chromatography; or the analyst can move up to second-order calibration using an instrument capable of acquiring a matrix of data, second-order tensor, per sample. These instruments involve all so-called hyphenated methods, for example, gas chromatography–mass spectrometry (GC/MS) and liquid chromatography–ultraviolet, and include as well tandem mass spectrometers (MS/MS), two-dimensional nuclear magnetic resonance spectrometers (2D-NMR), and emission-excitation fluorescence spectrometers. Methods to analyze these data include the generalized rank annihilation method (GRAM) and residual bilinearization; they come in a variety of algorithms according to the mathematical characteristics (for example, bilinearity) of the data. The most important benefit associated with second-order calibration (the second-order advantage) is the possibility to analyze for analytes in the presence of unknown interferents. Also, under certain conditions these methods yield qualitative information about sample components as well as quantitative information. This characteristic is particularly important for environmental or medical applications and assures the analyst that the analyzer is operational. *See* CALIBRATION; CHROMATOGRAPHY.

Standardization. The composition of many agricultural and food products is determined by spectrometers. For example, near-infrared reflectance (NIR) is commonly used to determine the moisture, protein, and fat concentration in wheat or other grains in farm fields. These data are useful for determining harvest time, irrigation, and fertilizer requirements and for setting the value of the product. Either the spectrometers must be calibrated individually or, more desirably, a reference instrument can be calibrated and the calibration model then used with several other similar instruments. Unfortunately, the latter is problematic since no two analytical instruments are exactly alike, even if they come from the same company and have the same model numbers. Also, a single instrument's response to a standard reference sample will change over time because of subtle changes in its components. To circumvent these and similar problems, chemometricians have developed the topic of instrument standardization. This is fundamentally different than calibration, which is used to relate instrument response to the property of interest. The goal of standardization is to correct the response of an instrument to be in accord with another instrument or with itself over the time it is in service.

Standardization can be as simple as using a stable wavelength reference such as a laser line to correct for shifts in wavelength that can invalidate calibration and produce incorrect analyses. There are multivariate instrument standardization methods that use multiple standardization or transfer samples to calculate the parameters of a model that can, for example, correct the response obtained from one instrument so that the response is like that obtained from another instrument. This approach can facilitate the use of a calibration model among several instruments. In process analytical chemistry, this is a major advantage, since a calibration model developed on one instrument, perhaps a high-quality laboratory spectrometer, can be transferred to several process analyzers; thus the need to calibrate each one is avoided, often a very costly process. Also, as the process analyzers change over time (for example, drift), they can be restandardized to generate the same response as when they were first put into service. *See* INSTRUMENT SCIENCE.

Curve resolution. Chromatography is widely used in product testing and quality control, especially in the pharmaceutical industry. As the components of a sample are separated in a chromatogram, it is imperative that the purity of each component be assured in order to avoid having a contaminant in the final product. To help solve this problem, chromatographers employ rapid scanning or diode array spectrometers as detectors so that the spectrum of each component eluting can be checked for purity.

When two analytes coelute near each other during a chromatographic separation of a mixture sample, a single peak in the chromatogram may result. If the analyst has previous knowledge of the shape of a pure analyte elution profile, it may be possible to resolve the mixture peak into the two pure analyte peaks by using, for example, Fourier deconvolution. Fourier deconvolution uses the fast Fourier transform algorithm to mathematically extract a curve with a known shape from a more complex mixture curve, itself composed of a number of curves.

If a spectrometer is used as the detector, multivariate curve resolution methods based on principal components analysis, factor analysis, or singular value decomposition can be used to resolve the mixtures into their component parts, thereby detecting the presence of a product contaminant. *See* CURVE FITTING; FACTOR ANALYSIS.

Pattern recognition. Perhaps the oldest activity in modern chemometrics is the application of data analysis methods developed in computer science and electrical engineering under the heading of pattern recognition to chemical data. As with most of the multivariate methods mentioned above, a pattern recognition application begins when a series of measurements is made on a collection of samples called the training set. For example, the concentrations of a number of trace elements may be measured on several quartzite samples acquired from three known quarries involved in an archeological study. One goal would be to determine if the pattern of trace-element concentrations can be used to distinguish the samples from a given quarry from all of the others. If this training step is successful, the rule or model can be used to classify samples taken from statues or monuments in order to determine their origin. Several studies of this type have been carried out in archeology, where trace-element patterns in antiquities (such as statues or arrowheads) have been traced back to their origins in order to study trade routes or cultural diversity.

Many similar studies have been conducted in forensic chemistry, drug design, screening, taxonomy, and product quality determination. In drug design, structural, chemical, or physical properties are used to classify previously untested drugs as active or inactive in a particular drug screening test. The chemometric methods used are called multivariate classification or supervised learning methods, and they are the same as those used in archeological studies. If the methods are successful, they can be used to predict the activity of untested candidate drug compounds and even to indicate which of the structural, chemical, or physical properties are the most related to biological activity, giving the medicinal chemist information useful for finding more potent drugs.

A medicinal chemist may want to subject a subset of a large set of chemical compounds to a biological screening test. The subset would be selected to represent the structural diversity of the full set as much as possible. Based on structural properties available for each compound, cluster analysis (a type of pattern recognition) might determine that the many compounds can be arranged in, say, 20 groups or clusters, with the compounds belonging to any one group being similar to its class members. The chemist need only test one compound per group, thereby saving considerable expense but getting a good coverage of available compounds.

Other areas. There are several other areas of chemometrics research. Experimental design is a well-developed topic in statistics that chemists use to get the maximum amount of pertinent information from the smallest investment of time, money, or effort. Using one of several multivariate optimization methods, computers can optimally tune complex instruments to get the best possible results. Wherever experiments generating data, particularly large quantities of data, are being conducted, modern chemometrics methods can be applied to make the best measurements possible and move quickly from data to information to knowledge. *See* STATISTICS.

Chemoreception

The ability of organisms to detect changes in the chemical composition of their exterior or interior environment. It is a characteristic of every living cell, from the single-celled bacteria and protozoa to the most complex multicellular organisms. Chemoreception allows organisms to maintain homeostasis, react to stimuli, and communicate with one another. *See* HOMEOSTASIS.

At the single-cell level, bacteria orient toward or avoid certain chemical stimuli (chemotaxis); algal gametes release attractants which allow sperm to find oocytes in a dilute aqueous environment; and unicellular slime molds are drawn together to form colonial fruiting bodies by use of aggregation pheromones. *See* CELLULAR ADHESION; TAXIS.

In multicellular organisms, both single cells and complex multicellular sense organs are used to homeostatically maintain body fluids (interoreceptors) as well as to monitor the external environment (exteroreceptors). The best-studied interoreceptors are perhaps the carotid body chemoreceptors of higher vertebrates, which monitor the levels of oxygen, carbon dioxide, and hydrogen ions in arterial blood. The best-studied exteroreceptors are those associated with taste (gustation) and smell (olfaction). Such receptors may occur anywhere on the bodies of different organisms, from antennae and tongues to legs and fins, and range from single hair cells in some invertebrates to the complex nasal epithelia of higher vertebrates. Internal communication is also effected by chemical means in multicellular organisms. Thus both hormonal and neural control involve the perception, by cells, of control chemicals (hormones and neurotransmitters, respectively). *See* CAROTID BODY; CHEMICAL SENSES; OLFACTION; SENSE ORGAN; TASTE; TONGUE.

Basic mechanism of action. Although tremendous diversity can be seen in the evolution of complex chemosensory structures, chemoreception is ultimately a property of single cells. The basic mechanism underlying chemoreception is the interaction of a chemical stimulus with receptor molecules in the outer membrane of a cell. These molecules are believed to be proteins which, because of their three-dimensional shapes and chemical properties, will have the right spatial and binding "fit" for interaction with only a select group of chemicals (the same basic mechanism by which enzymes are specific for various substrates). The interaction between a chemical stimulus and a receptor molecule ultimately leads to structural changes in membrane channels by mechanisms that are not totally clear. In some instances, the chemical stimulus–receptor complex activates an enzyme (adenylate cyclase) that synthesizes cyclic adenosine monophosphate (cAMP), which acts as a second messenger interacting with membrane channels and changing their conductance. In other instances, the chemical stimulus interacts with the channel protein directly, altering its conductance. In either case, the net result is usually a change in membrane conductance (permeability) to specific ions which changes both the internal chemical composition of the cell and the charge distribution across the cell membrane. In single-celled organisms, this may be sufficient to establish a membrane current which may elicit responses such as an increase or decrease in ciliary movement. In multicellular organisms, it usually results in changes in the rate of release of hormones or the stimulation of neurons. *See* CELL MEMBRANES.

Characteristics of chemoreceptors. The basic characteristics of all chemoreceptors are specificity (the chemicals that they will respond to); sensitivity (the magnitude of the response for a given chemical stimulus); and range of perception (the smallest or largest level of stimulus that the receptor can discriminate). Specificity is a consequence of the types of proteins found in the membrane of a receptor cell. Each cell will have a mosaic of different receptor molecules, and each receptor molecule will show different combinations of excitatory or inhibitory responses to different molecules. In an excitatory response, there is a net flux of positive ions into the cell (depolarization); for an inhibitory response, there is a net flux of negative ions into the cell (hyperpolarization). In single cells, or in primary sensory neurons, the receptor current will spread along the membrane by passive electrotonic means. The stronger the stimulus—that is, the more of the chemical present—the more receptors affected, the greater the change in conductance, and the larger the membrane current.

In animals with nervous systems, these changes in conductance of primary sensory cells can lead to one of two events. In some receptors, if the current is excitatory and sufficient in magnitude (threshold), an action potential will be generated at a spike-initiating zone on the neuron. Other receptors are not able to generate action potentials but respond by releasing a neurotransmitter (the depolarizing current causes a change in membrane conductance of the transmitter substance) that acts on a second-order neuron which is excitable and therefore can generate action potentials. *See* BIOPOTENTIALS AND IONIC CURRENTS.

The sensitivity of a chemoreceptor reflects both the amount of chemical substance required to initiate a change in membrane potential or discharge of the receptor cell, and the change in potential or discharge for any given change in the level of the chemical stimulus. There are real limits as to the extent of change in membrane conductance or firing frequency. Thus, for more sensitive cells, there is a smaller range over which they can provide information about the change in concentration of any given chemical before it has reached its maximum conductance or discharge rate and has saturated.

In most chemoreceptors, this problem is reduced by a variety of mechanisms. To begin with, the relationship between stimulus intensity and neuronal discharge frequency is usually logarithmic. This means that the high-intensity end of the scale is compressed, greatly extending the range of discrimination of the receptor. Although this may seem to decrease the sensitivity of the receptor at higher stimulus intensities in absolute terms, the increment in discharge remains the same for any given percentage change in stimulus intensity. In other words, a doubling of the stimulus intensity will produce the same increase in receptor potential anywhere over the full range of sensitivity of the cell. Receptor adaptation, a decrease in receptor discharge despite a constant chemical stimulus, also extends the dynamic range over which receptors operate. Finally, in chemoreceptive organs of multicellular organisms, the interaction of chemoreceptors with different threshold levels (range fractionation) can also extend the dynamic range of sensory perception.

Chemosensory systems can be extremely sensitive. Humans can detect 1 molecule of mercaptan in 5×10^{10} molecules of air, while marine crabs have been shown to respond to as little as 10^{-17} lb (10^{-15} g) of prey tissue in 0.264 gal (1 liter) of seawater. Perhaps most impressive, however, is the ability of the antennal chemoreceptor cells of the male silkworm (*Bombyx mori*) to detect a single molecule of female pheromone. Only about 90 molecules per second impinging on a single receptor are required to alter the firing rate of a cell, and stimulation of only 40 chemoreceptors out of roughly 20,000 per antenna is sufficient to evoke a behavioral response (excited wing flapping). *See* PHEROMONE.

Chemoreceptor tuning. In animals, the responsiveness of some chemoreceptors can be either enhanced or attenuated by other neural input. These influences come in the form of efferent inputs from the central nervous system, from neighboring receptors, or even from recurrent branches of the chemoreceptor's own sensory axons. The net effect is either (1) to increase the acuity of the receptors (excitatory input brings the membrane potential of the receptor cell closer to threshold, requiring less chemical stimulus to elicit a response); or (2) to extend the range of responsiveness of the receptors (inhibitory input lowers the membrane potential of the receptor cell, requiring more chemical stimulus to bring the cell to threshold). For example, chemical sensitivity is greatly heightened in most animals when they are hungry.

Central integration of input. Any given chemoreceptor cell can have any combination of receptor proteins, each of which may respond to different chemical molecules with either an increase or a decrease in the membrane potential. Thus, chemoreceptor cells do not exhibit a unitary specificity to a single chemical substance, but rather an action spectrum to various groups of chemicals. The ability of animals to distinguish such a large number of different, complex, natural chemical stimuli resides in the ability of higher centers in the nervous system to "recognize" the pattern of discharge of large groups of cells. Sensory quality does not depend on the activation of a particular cell or group of cells but on the interaction of cells with overlapping response spectra.

Structural adaptations. Despite the common, basic mechanism underlying chemoreception in all organisms, there is a great diversity in the design of multicellular chemoreceptive organs, particularly in animals. The complex structures of most of these organs reflect adaptations that serve to filter and amplify chemical signals. Thus, the antennae in many insects, and the irrigated protective chambers, such as the olfactory bulb of fishes and nasal passages of mammals, increase the exposure of chemoreceptor cells to the environment. At the same time, they allow the diffusion distances between chemoreceptive cells and the environment to be reduced, thereby increasing acuity. In terms of filtering, they may serve to convert turbulent or dispersed stimuli into temporal patterns that can be more easily interpreted. The extent to which such structural adaptations are seen in various organisms tends to reflect the relative importance of chemoreception to the organism, which, to a large extend, reflects the habitat in which the organism lives. *See* CHEMICAL ECOLOGY.

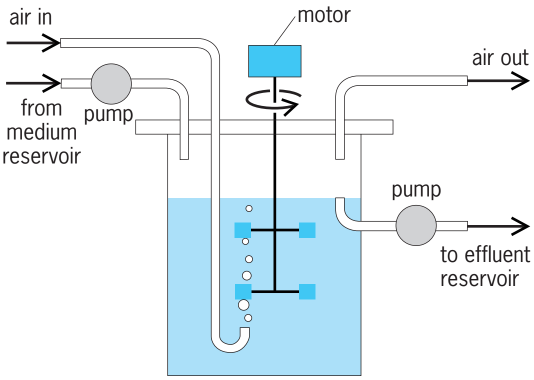
Chemostat

An apparatus (see **illus.**) for the continuous cultivation of microorganisms, such as bacteria, yeasts, molds, and algae, or for the cultivation of plant cells. The nutrients required for cell growth are supplied continuously to the culture vessel by a pump



Schematic representation of chemostat apparatus.

connected to a medium reservoir. The cells in the vessel grow continuously on these nutrients. Residual nutrients and cells are removed from the vessel (fermenter) at the same rate by an overflow, thus maintaining the culture in the fermenter at a constant volume.

Parameters. An important feature of chemostat cultivation is the dilution rate, defined as the volume of nutrient medium supplied per hour divided by the volume of the culture. During chemostat cultivation, an equilibrium is established (steady state) at which the growth rate of the cells equals the dilution rate. The higher the dilution rate, the faster the organisms are allowed to grow. Above a given dilution rate the cells will not be able to grow any faster, and the culture will be washed out of the fermenter. The chemostat thus offers the opportunity to study the properties of organisms at selected growth rates. This is particularly important because in their natural environment microorganisms seldom grow at their maximum rate. Under nutrient limitation, cells may display properties which also are of great importance in a number of applications, such as industrial fermentation and wastewater treatment. *See* FERMENTATION; WATER TREATMENT.

The nutrient medium which is fed to the fermenter contains an excess of all growth factors except one, the growth-limiting nutrient. The concentration of the cells (biomass) in the fermenter is dependent on the concentration of the growth-limiting nutrient in the medium feed. Upon entering the fermenter, the growth-limiting nutrient is consumed almost to completion, and only minute amounts of it may be found in the culture and the effluent. Initially, when few cells have been inoculated in the growth vessel, even the growth-limiting nutrient is in excess. Therefore, the microorganisms can grow at a rate exceeding their rate of removal. This growth of cells causes a fall in the level of the growth-limiting nutrient, gradually leading to a lower specific growth rate of the microorganisms. Once the specific rate of growth balances the removal of cells by dilution, a steady state is established in which both the cell density and the concentration of the growth-limiting nutrient remain constant. Thus the chemostat is a tool for the cultivation of microorganisms almost indefinitely in a constant physiological state.

To achieve a steady state, parameters other than the dilution rate and culture volume must be kept constant (for example, temperature and pH). The fermenter is stirred to provide a homogeneous suspension in which all individual cells in the culture come into contact with the growth-limiting nutrient immediately. Furthermore, stirring is also required to achieve optimal distribution of air (oxygen) in the fermenter when aerobic cultures are in use.

Laboratory chemostats usually contain 0.5 to 10.5 quarts (0.5 to 10 liters) of culture, but industrial chemostat cultivation can involve volumes up to 343,000 gal (1300 m^3) for the continuous production of microbial biomass.

Advantages. The chemostat offers a number of advantages for the cultivation of cells as compared with growth in a batch culture. In the latter, a closed system, organisms grow in excess nutrients at their maximum rate, and the nutrient concentration, products, and biomass change continuously. When a nutrient becomes depleted, a rapid fall in the growth rate takes place. This often leads to the death of cells. In the chemostat, however, the constancy of all parameters allows accurate and reproducible experiments. By varying the dilution rate, within limits, the rate of growth of the organisms can be changed at will. The density of cells in the cultures can be chosen by the appropriate concentration of the growth-limiting nutrient in the medium reservoir. Depending on the question to be answered, the type of growth-limiting nutrient can be selected. Of course, possible choices are limited by the nature and capabilities of the organisms studied.

The chemostat can be used to grow microorganisms on very toxic nutrients since, when kept growth-limiting, the nutrient concentration in the culture is very low. The chemostat can be used to select mutants with a higher affinity to the growth-limiting nutrient or, in the case of a mixed population, to select the species that are optimally adapted to the growth limitation and culture conditions. The chemostat is of great use in such fields of study as physiology, ecology, and genetics of microorganisms. *See* BACTERIAL GENETICS; BACTERIAL PHYSIOLOGY AND METABOLISM; MICROBIOLOGY.

Mathematical description. The operation of a chemostat can also be described in mathematical terms. Growth of a microorganism can be described by the empirical formula of J. Monod (1942) as a function of the growth-limiting substrate, Eq. (1), in

$$\mu = \mu_{\max} \frac{C_s}{K_s + C_s} \qquad (1)$$

which μ is the specific growth rate (h^{-1}), $\mu_{\max}$ is the maximum specific growth rate, C_s is the concentration of the growth-limiting substrate, and K_s is a Monod saturation constant, numerically equal to the substrate concentration at which $\mu = {}^1\!/_2\mu_{\max}$. The relationship between C_s and μ is a typical saturation curve. When an organism is grown in a closed system (batch culture) with, initially, excess substrate, it will grow at $\mu_{\max}$. During growth its environment will constantly change, but if the conditions remain favorable, growth will continue until the growth-limiting compound is depleted. Near the end of growth, μ will fall because of the factors described by Eq. (1), and will finally become zero.

The chemostat can be considered as an open culture system in which fresh (sterilized) medium is introduced at a constant flow rate ϕ, and from which the culture fluid emerges at the same flow rate. At a constant volume υ and an in-flow rate ϕ, the dilution rate D is defined by Eq. (2), in which the dilution rate is expressed in h^{-1}.

$$D = \frac{\phi}{V} \tag{2}$$

Monod demonstrated that over a large range of growth rates a fixed relationship exists between the amount of (growth-limiting) substrate consumed and the amount of biomass produced, Eq. (3), in which C_x

$$\frac{dC_x}{dt} = -Y''_{sx}\frac{dC_s}{dt} \tag{3}$$

is the biomass concentration and t is time. Y''_{sx} is the yield factor and is defined as the amount (weight) of cell material produced per amount (weight, or mole) of substrate consumed. Y''_{sx} is not always a constant.

If the medium in the fermenter is inoculated (for example, with bacteria), the culture will grow at a given rate. At the same time, a quantity of bacteria will be washed out because the culture is continuously fed and diluted with fresh medium. It thus follows that accumulation of biomass in the culture is equal to growth minus washout.

The balance equation is Eq. (4). Hence if μ is

$$\frac{dC_x}{dt} = \mu C_x - DC_x = (\mu - D)C_x \tag{4}$$

greater than D, C_x will increase, while if μ is less than D, C_x will decrease. If μ equals D, Eq. (4) will be zero and an equilibrium will exist.

It can be shown mathematically that, irrespective of the starting conditions, a steady state, with μ equal to D, must inevitably be reached, provided that D does not exceed a critical value.

In order to calculate the steady-state concentrations of biomass and the growth-limiting nutrient in the culture, mass balance equations similar to Eq. (4) for the nutrients entering, being consumed, and leaving the culture must also be made. In Eq. (5), C_s is

$$\frac{dC_s}{dt} = D(C_{si} - C_s) - \frac{\mu C_x}{Y''_{sx}} \tag{5}$$

the substrate concentration in the culture, and C_{si} the concentration of the substrate entering the vessel. The net change in C_{si} per unit of time is equal to the dilution rate multiplied by the difference in substrate concentration entering and leaving the culture, minus the substrate consumed. The substrate consumed is expressed as the growth divided by the yield, Eq. (3). At steady state, both Eqs. (4) and (5) are zero. This, when combined with Eq. (1), will lead to the equilibrium concentrations $\overline{C}_x$ for biomass [Eq. (7)] and $\overline{C}_s$ for the substrate [Eq. (6)]. Here

$$\overline{C}_s = K_s(D/\mu_{\max} - D) \tag{6}$$

$$\begin{aligned}\overline{C}_x &= Y''_{sx}(C_{si} - \overline{C}_s)\\ &= Y''_{sx}\left(C_{si} - \frac{K_s \cdot D}{\mu_{\max} - D}\right)\end{aligned} \tag{7}$$

K_s, $\mu_{\max}$, and Y''_{sx} are constants for a microorganism under the specified conditions of temperature, medium composition, and the nature of the growth-limiting substrate. For C_{si} and D, any realistic constant value can be chosen. From Eq. (6) it appears that $\overline{C}_s$ solely depends on D. Equation (7) shows that $\overline{C}_x$ depends on D and C_{si} and is proportional to C_{si} if $\overline{C}_s \ll C_{si}$, which is usually the case. If K_s, $\mu_{\max}$, and Y''_{sx} are known for a given micrognanism, the relationship between C_x or C_s, and D can be predicted at a chosen C_{si}.

Chemostratigraphy

A subdiscipline of stratigraphy and geochemistry that involves correlation and dating of marine sediments and sedimentary rocks through the use of trace-element concentrations, molecular fossils, and certain isotopic ratios that can be measured on components of the rocks. The isotopes used in chemostratigraphy can be divided into three classes: radiogenic (strontium, neodymium, osmium), radioactive (radiocarbon, uranium, thorium, lead), and stable (oxygen, carbon, sulfur). Trace-element concentrations (that is, metals such as nickel, copper, molybdenum, and vanadium) and certain organic molecules (called biological markers or biomarkers) are also employed in chemostratigraphy. *See* DATING METHODS; ROCK AGE DETERMINATION.

Radiogenic isotope stratigraphy. Radiogenic isotopes are formed by the radioactive decay of a parent isotope to a stable daughter isotope. The application of these isotopes in stratigraphy is based on natural cycles of the isotopic composition of elements dissolved in ocean water, cycles which are recorded in the sedimentary rocks. The element commonly used is strontium, but osmium and neodymium isotopes are used as well. *See* ISOTOPE; RADIOISOTOPE.

Strontium (Sr) has four naturally occurring, stable isotopes, with mass numbers (sum of protons and neutrons) 88, 87, 86, and 84. Strontium-87 is radiogenic, formed by the radioactive decay of rubidium-87. Strontium replaces calcium in calcium carbonate and other calcium-bearing minerals (such as aragonite, apatite, and plagioclase). Calcite typically contains 500–2000 parts per million strontium, and aragonite (another form of calcium carbonate) contains 2000–9000 ppm. Strontium is the major cation in strontianite ($SrCO_3$) and celestite ($SrSO_4$), but its principal occurrence in minerals is as a trace element.

The ocean is a large reservoir of dissolved strontium. The isotopic composition of strontium in the oceans reflects the isotopic composition and relative proportions of strontium entering the ocean. Strontium is delivered to the oceans by dissolution in river water with an average ratio of strontium-87 to strontium-86 ($^{87}Sr/^{86}Sr$) of 0.710 and by dissolution and recrystallization of submarine carbonates. Strontium is removed from the oceans by incorporation into precipitate minerals such as calcium carbonate as well as by inorganic precipitation of evaporites, phosphorites, and ferromanganese oxides. Seawater also exchanges strontium with ocean-floor rocks at mid-ocean ridges. Ocean-floor rocks (basalt) have a relatively low average $^{87}Sr/^{86}Sr$ ratio of 0.703. The variations in the $^{87}Sr/^{86}Sr$ ratio in seawater over millions of years are largely due to the changing inputs of continent-derived strontium delivered by rivers versus strontium derived from exchange of seawater with sea-floor basalt. Comparison of the strontium isotope curve and the geologic record indicate that the $^{87}Sr/^{86}Sr$ ratio in seawater is highest during periods of mountain building and continental collision, when there is a large flux of material from the continents due to increased erosion rates. Conversely, the $^{87}Sr/^{86}Sr$ ratio is lowest in seawater during times when the continents are splitting apart and when sea-floor spreading rates are greatest. *See* SEAWATER.

Measurements of the $^{87}Sr/^{86}Sr$ ratio of calcium-bearing marine precipitates (calcium carbonate, anhydrite, gypsum, and phosphate minerals) show that the $^{87}Sr/^{86}Sr$ ratio of strontium dissolved in seawater has fluctuated over the past 600 million years between the limits of 0.7068 and 0.7092. Because the average strontium atom remains in seawater 3–4 million years before it is removed, which is much longer than the mixing time of the oceans (1000 years), the $^{87}Sr/^{86}Sr$ ratio in seawater is the same throughout the oceans at any given time. Consequently, calcite that forms in the ocean in different places at the same time has the same $^{87}Sr/^{86}Sr$ ratio. When the $^{87}Sr/^{86}Sr$ ratio is changing rapidly with time in seawater, such as between the late Eocene and the present (the past 40 million years), excellent age resolution can be obtained for stratigraphic studies. *See* EOCENE.

An assumption in using strontium isotopes (or any geochemical method) in stratigraphic studies is that the $^{87}Sr/^{86}Sr$ ratio remains unaltered during diagenesis (all the chemical and physical changes that occur in the sediment following its deposition), and hence retains the original strontium isotopic signature. Careful inspection and sample selection prior to analysis are necessary to assess the degree of diagenetic alteration. *See* DIAGENESIS; STRONTIUM.

Stable isotope stratigraphy. The elements hydrogen (H), carbon (C), nitrogen (N), oxygen (O), and sulfur (S) owe their isotopic distributions to physical and biological processes that discriminate between the isotopes because of their different atomic mass. The use of these isotopes in stratigraphy is also facilitated by cycles of the isotopic composition of seawater, but the isotopic ratios in marine minerals are also dependent on water temperature and the mineral-forming processes.

Oxygen isotope stratigraphy. Oxygen isotope stratigraphy has developed since the mid-1950s following the pioneering work of Harold Urey; it has become the most widely used method for dating and correlating marine sediments deposited during the Quaternary (Pleistocene and Holocene). Oxygen isotope stratigraphy is based on the ratio of two isotopes of oxygen (oxygen-18 and oxygen-16) in the calcium carbonate ($CaCO_3$) shells of marine fossils. *See* QUATERNARY.

Detailed measurements of the ratio of oxygen-18 relative to oxygen-16 ($^{18}O/^{16}O$) in planktonic foraminifera from sediments cored in the deep ocean show that the ocean changed periodically over the past 3 million years because of alternating glacial (or ice age) and interglacial conditions. During glacial periods, water depleted in oxygen-18 is transferred to and stored on the continents as glaciers, leaving the oceans enriched in oxygen-18 (higher $^{18}O/^{16}O$ ratio). Although both the water temperature and the $^{18}O/^{16}O$ ratio in the water determine the $^{18}O/^{16}O$ ratio in the carbonate shells, the fluctuations of the $^{18}O/^{16}O$ ratio between interglacial and glacial periods are mainly caused by fluctuating continental ice volume. Each isotopic fluctuation representing a glacial-interglacial cycle has been assigned a stage number, with odd numbers corresponding to interglacial periods and even numbers corresponding to glacial periods (numbered 1 through 23). These stages are globally synchronous and can be intercalibrated with other stratigraphic scales, such as magnetostratigraphy and biostratigraphy. There is much evidence that these climatic fluctuations (called Milankovitch cycles) are a result of changes in the incoming solar radiation reaching the surface of the Earth. The dominant periodicities of these cycles are 100,000, 40,000, and 23,000 years. *See* GLACIAL EPOCH; INSOLATION.

Carbon isotope stratigraphy. Stable carbon (C) isotope stratigraphy involves measurements of the ratio of carbon-13 to carbon-12 ($^{13}C/^{12}C$) in carbonate ($CaCO_3$) fossil shells and organic matter. Organic matter and calcium carbonate are converted to carbon dioxide (CO_2) prior to simultaneous measurement of the ratios $^{13}C/^{12}C$ and $^{18}O/^{16}O$ on a gas-source mass spectrometer.

The carbon isotopic composition in marine organisms (calcite shells or organic tissue) reflects the local and global changes in the cycling of nutrients and CO_2 in the ocean, as well as ocean circulation and ocean-atmosphere interactions. The $^{13}C/^{12}C$ ratio of both organic material and carbonate material can be used as a stratigraphic tool. The $^{13}C/^{12}C$ ratio of a sample depends on the $^{13}C/^{12}C$ ratio of the source [atmospheric CO_2 for land plants, both dissolved CO_2 and bicarbonate (HCO_3^-) for aquatic environments] and the isotopic fractionation produced by equilibrium and kinetic effects (the fractionation of isotopes of the same element in physical or chemical processes occurs because of their slight mass differences). In general, organic carbon is depleted in carbon-13 relative to carbonate carbon in the marine environment. A major focus of carbon isotope studies in stratigraphy is the assessment of detailed variations and excursions of the $^{13}C/^{12}C$ ratio on a stratigraphic level. For example, during periods of increased productivity in the surface layer of the ocean, the carbon-12 is preferentially removed by phytoplankton during photosynthesis, enriching the surface water in carbon-13. Calcium carbonate and organic tissue that form during these periods have an increased $^{13}C/^{12}C$ ratio. Many organic carbon-rich, laminated black shales of Jurassic and Cretaceous age contain organic carbon that is enriched in carbon-13.

Sulfur isotope stratigraphy. The isotopic composition [the ratio of sulfur-34 to sulfur,-32 ($^{34}S/^{32}S$)] of sulfur in the sulfate molecules (SO_4^{2-}) dissolved in seawater has varied systematically through Phanerozoic time (the past 600 million years). Sulfate is a major constituent of the marine evaporite minerals gypsum and anhydrite, which are the materials commonly used as recorders of the ocean isotopic ratios. The $^{34}S/^{32}S$ ratio in seawater reflects a complex balance of the sulfate delivered to the oceans by rivers; it also reflects the relative importance of sulfur removal as reduced sulfur in pyrite, as opposed to oxidized sulfur in gypsum and anhydrite. *See* ANHYDRITE; GYPSUM; PYRITE.

Radioactive isotope stratigraphy. Radiocarbon [the radioactive isotope of carbon (^{14}C)] and the isotopes uranium-234 (^{234}U) and thorium-230 (^{230}Th) are used in radioactive isotope stratigraphy.

Radiocarbon stratigraphy. Carbon-14 is used in dating and stratigraphy of both marine and terrestrial sediments younger than 50,000 years. Radiocarbon is continually produced in the upper atmosphere by the capture of neutrons by nitrogen (^{14}N), forming carbon-14, which is radioactive with a half-life of about 5730 years. The carbon-14 enters the hydrosphere and biosphere as CO_2, and it is incorporated into plant and animal organic tissues and hard parts (such as calcium carbonate). When the plant or animal dies, exchange with the atmosphere ceases; the carbon-14 begins to decay, starting the radioactive clock.

Uranium-thorium stratigraphy. Marine minerals such as calcite incorporate minor amounts of the radioactive isotope uranium-234 (^{234}U), which has a half-life of 2.4 million years and decays to thorium-230, which is also radioactive with a half-life of 70,000 years. Because marine calcite forms almost free of thorium-230, the accumulation of radiogenic thorium-230 can be used to measure the age of marine calcites up to about 300,000 years old. This technique is valuable for measuring the age of coral reefs. *See* THORIUM; URANIUM.

Molecular stratigraphy. Certain organic molecules that can be linked with a particular source (called biomarkers) have become useful in stratigraphy. The sedimentary distributions of biomarkers reflect the biological sources and inputs of organic matter (such as that from algae, bacteria, and vascular higher plants), and the depositional environment. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS.

One method of molecular stratigraphy uses the composition of long-chain alkenones (lipids whose molecules comprise chains of 37–39 carbon atoms). These compounds are produced by certain photosynthetic algae (coccolithophorids) that regulate the fluidity of their membranes in waters of different temperatures by biosynthetically controlling the extent of unsaturation in their alkenones. The degree of unsaturation of alkenones in marine sediments varies as a function of water temperature, which varies from glacial to interglacial times. A molecular stratigraphic record of sea surface temperatures in Quaternary sequences has been developed and intercalibrated with the oxygen isotope record for the past half million years. Alkenones are found in marine sediments throughout the Quaternary and Tertiary.

Trace elements. Certain trace metals, such as nickel, copper, vanadium, magnesium, iron, uranium, and molybdenum, are concentrated in organic-rich sediments in proportion to the amount of organic carbon. Although the processes controlling their enrichment are complex, they generally form in an oxygen-poor environment (such as the Black Sea) or at the time of global oceanic anoxic events, during which entire ocean basins become oxygen poor, resulting in the death of many organisms; hence large amounts of organic carbon are preserved in marine sediments. The trace-metal composition of individual stratigraphic units may be used as a stratigraphic marker (or “fingerprint”), making it possible to correlate, for example, black shales from location to location within a basin. *See* GEOCHEMISTRY; MARINE SEDIMENTS; STRATIGRAPHY.

Chemotherapy and other antineoplastic drugs

Chemotherapy is the use of chemicals to treat any disease, but the term has come to be applied most commonly to the use of drugs to treat cancer and that exhibit cytotoxic activity through inhibition of cell division. Recently, several other classes of drugs (biologicals) started to be used to treat cancer, often in conjunction with conventional chemotherapy. Cancer is an abnormal growth or proliferation of cells that tends to invade locally or spread to distant parts of the body. Several treatment modalities can be used for cancer. Surgery physically removes the abnormal growth, whereas radiation, immunotherapy, hormonal therapy, and chemotherapy are directed at killing or slowing the growth of cancerous cells. *See* CANCER (MEDICINE).

History. In 1865, in an early, well-documented use of chemotherapy, Heinrich Lissauer gave potassium arsenite (Fowler's solution) to treat leukemia. Despite this work, Paul Ehrlich, a German physician and 1908 Nobel Laureate in Medicine, is generally credited with pioneering the field of chemotherapy and coining the word. However, his efforts were directed toward discovering antibiotics for infections rather than cancer drugs. He was an early advocate of understanding biochemically why certain chemicals effectively kill actively growing bacteria. He also coined the term "magic bullet" for drugs that specifically kill bacteria. *See* ANTIBIOTIC.

The first extensively utilized cancer chemotherapeutic agent was nitrogen mustard, which was used in the mid-1940s by Alfred Gilman and Frederick S. Philips for the treatment of lymphomas and chronic leukemias. During World War I it had been noted that mustard gas, used as a toxic irritant, caused destruction of lymph nodes and bone marrow, which are both sites of active cell proliferation. This observation suggested that mustard gas is toxic to actively growing cells and that it might also kill proliferating cancer cells. Nitrogen mustard is still occasionally used for the treatment of some lymphomas, although it has largely been replaced by other chemotherapeutic regimens. *See* LEUKEMIA.

Folic acid antagonists. The second group of useful anticancer drugs developed were folic acid antagonists. All actively growing cells require the chemical metabolite folic acid to grow and divide. The antagonists were designed to inhibit a cancer cell's ability to produce folic acid, and therefore they are toxic. Aminopterin was the first in this group to be employed clinically. A major breakthrough occurred in 1948, when it was reported that over half of children with acute leukemia could obtain temporary remissions by using aminopterin. This began the era of antimetabolite therapy. Methotrexate, a related drug, replaced aminopterin and is still used in acute lymphoblastic leukemia, choriocarcinoma, carcinomas of the head and neck region, and for other tumors. The first documented chemotherapeutic cure was with methotrexate, which was used in 1961 to treat a gestational choriocarcinoma.

Nucleic acid antagonists. The third group of chemotherapeutic agents was designed to have a toxic effect on the cell's DNA. The development of these drugs was based on the hypothesis, conceived by George Hitchings and Gertrude Elion, that tumor growth might be stopped with chemicals that antagonize nucleic acids, which are necessary for cancer cell growth and division. They eventually were awarded the Nobel Prize in Physiology or Medicine for the development of such compounds. The first clinically useful compound, 6-mercaptopurine, was described in 1952 and is still used for the treatment of acute lymphoblastic leukemia. Another drug, with a different site of action, 5-fluorouracil, was synthesized in 1957 by Charles Heidelberger. It is used today in the treatment of colorectal, head and neck, and breast cancer. Cytarabine (cytosine arabinoside) was reported in 1968 to be useful in adult acute leukemia. It is still used for the primary treatment of most patients with acute myeloid leukemia. Fludarabine is a modern member of this group effective in the treatment of chronic lymphocytic leukemia.

Antitumor antibiotics. Antitumor antibiotics became recognized as potential chemotherapeutic agents in 1954, when actinomycin D (dactinomycin) was studied. They differ from antimicrobial antibiotics in that their spectrum of cytotoxicity includes human cells rather than bacteria and fungi. Doxorubicin (Adriamycin) is one of the most widely used anticancer drugs for both solid tumors and blood or bone marrow tumors.

Since the mid-1950s, many new drugs have been developed. This progress was stimulated by the pharmaceutical industry, by the important preclinical work of Howard E. Skipper and Frank M. Schabel, Jr., at the Southern Research Institute, and by the establishment of a special section of the U.S. National Cancer Institute for drug development and testing, which began work in 1955. Chemotherapeutic drugs now total more than 50, many having novel mechanisms (**Table 1**). The availability of the techniques of molecular biology and a greater understanding of the genetic abnormalities of cancer are resulting in more effective therapies, which tend to be more specific for cancer cells. Drugs which inhibit angiogenesis (blood vessel formation) or which target promoting (oncogenes) or suppressing (tumor suppressor) genes are being tested and incorporated into treatment regimens.

Monoclonal antibodies. A new class of drugs involves the use of monoclonal antibodies that target specific cell receptors. Bevacizumab is a recombinant humanized monoclonal antibody against the vascular endothelial growth factor (VEGF). VEGF is found to be overexpressed in many cancers and is in part responsible for the process of intratumoral angiogenesis. Bevacizumab is currently used in metastatic colon cancer.

Cetuximab, which binds the epidermal growth factor receptor (EGFR), and Trastuzumab, which targets Her2-neu receptor in breast cancer cells, are other examples of antibodies currently used in clinical practice (Table 1). Rituximab is an important therapeutic monoclonal antibody to the B-lymphocyte cell-surface molecule designated CD20. It has important activity in inhibiting the growth of lymphomas that express CD20. It is also possible to deliver a chemotherapy agent to a specific target cell type using a monoclonal antibody. For example, gemtuzumab ozogamicin (Mylotarg) is a drug with the monoclonal antibody anti-CD33 attached to a cytotoxic antitumor antibiotic, calicheamicin. This drug is thereby targeted by the antibody to the leukemia cell. Other than a small incidence of allergic reactions during infusion, side effects of monoclonal antibodies are variable and are closely related to the function of the receptor (VEGF, EGFR, CD20) being targeted by the antibody. Monoclonal antibodies also have been combined with

TABLE 1. Groups of drugs and mechanisms of action

Group	Source	Mechanism of action	Examples	Uses
Alkylating agents	Chemical synthesis	Blocking of DNA synthesis by chemical attachment of a reactive part of the drug (alkyl portion) to DNA and other cell components to form damaging cross links	Ifosfamide, cyclophosphamide, busulfan, chlorambucil, melphalan, dacarbazine, carmustine (BCNU), lomustine (CCNU), streptozotocin, procarbazine, hexamethylmelamine, thiotepa, nitrogen mustard (mechlorethamine), estramustine, temozolomide	Many solid tumors and hematologic (blood and bone marrow) malignancies; brain tumors; often used for high-dose chemotherapy prior to bone marrow transplantation
Antifolates	Chemical synthesis	Inhibition of DNA synthesis by inhibiting the enzyme dihydrofolate reductase	Methotrexate, pemetrexed	Head and neck cancer; lung cancer, leukemia; lymphoma; breast cancer; choriocarcinoma; mesothelioma
Antipurines	Chemical synthesis	Variable, for example, incorporation into DNA as a false building block (6-mercaptopurine, cladribine), inhibition of DNA polymerase which is required for synthesis (fludarabine), and inhibition of adenosine deaminase enzyme with the accumulation of deoxyadenosine which kills lymphocytes	Fludarabine, cladribine, azathioprine, 6-mercaptopurine, 6-thioguanine, pentostatin, clofarabine	Chronic lymphocytic leukemia; acute lymphoblastic leukemia; lymphoma; hairy cell leukemia; immunosuppression after transplantation or for aplastic anemia and autoimmune blood disorders
Antipyrimidines	Chemical synthesis	Variable, for example, incorporation into DNA (cytarabine); inhibition of thymidylate synthase (5-fluorouracil), and inhibition of DNA methylation (5-azacitidine)	Cytarabine, 5-fluorouracil, floxuridine, capecitabine, gemcitabine, 5-azacitidine, nelarabine	Acute leukemia; breast, colorectal, pancreas, and head and neck cancer; myelodysplastic syndrome
Anticancer antibiotics	Fungi or bacteria or chemical synthesis	Variable, for example, oxidation of DNA and RNA (bleomycin), inhibition of RNA synthesis (actinomycin D)	Bleomycin, dactinomycin, mitoxantrone, mitomycin C, streptozotocin	Hodgkin's disease; lymphoma; testis, breast, cervix, penis, islet cell pancreas, and head and neck cancer; acute lymphoblastic leukemia
Anticancer antibiotics of the anthracycline group	Bacteria	Several may be important, including intercalation into DNA, oxygen free-radical formation, and inhibition of topoisomerase type II	Idarubicin, doxorubicin, daunorubicin, epirubicin	Acute leukemia; Hodgkin's disease; lymphomas; multiple myeloma; breast, lung, bone, and thyroid cancer
Drugs that interfere with synthesis of cell microtubules	Semisynthesis or natural occurrence	Binding of the protein tubulin and interference with polymerization which is required to form microtubules	Vincristine, vinblastine, vindesine, vinorelbine	Multiple myeloma; lymphoma; lung and testis cancer; acute lymphoblastic leukemia; Hodgkin's disease
Drugs that stabilize microtubules against depolymerization and induce mitotic block	Tree bark, fungi, or semisynthesis	Enhanced microtubule formation, inhibition of mitosis	Paclitaxel, docetaxel	Colorectal, ovarian, breast, lung, germ cell, and head and neck cancer
Cytokines	Recombinant DNA technology	Interference with intracellular signaling	α-Interferon, aldesleukin (interleukin-2)	Chronic myelocytic leukemia; melanoma; kidney cancer; hairy cell leukemia
Topoisomerase inhibitors	Semisynthesis	Inhibition of topoisomerase enzymes I and II resulting in single- or double-strand DNA cleavage	Etoposide, teniposide, topotecan, irinotecan, anthracyclines	Leukemia; lymphoma; lung, colorectal, and ovarian cancer; myelodysplastic syndrome
Platinum drugs	Chemical synthesis	Binding to and inhibiting function of DNA	Cisplatin, carboplatin, oxaliplatin	Lung, ovary, and bladder cancer

(cont.)

TABLE 1. Groups of drugs and mechanisms of action (*cont.*)

Group	Source	Mechanism of action	Examples	Uses
Enzyme therapy	Bacteria	Depletion of asparagine, an essential amino acid	Asparaginase, pegasparaginase	Acute lymphoblastic leukemia
Inhibitors of ribonucleotide reductase	Synthesis	Inhibition of ribonucleotide reduction necessary for DNA synthesis	Hydroxyurea	Myeloproliferative diseases (such as chronic myelocytic leukemia, polycythemia vera, essential thrombocytosis); acute leukemia; melanoma; head and neck cancers; sickle cell anemia
Differentiating agents	Derivative of vitamin A	Binding to receptors on cell nucleus and stimulating differentiation of some cells	Tretinoin (all-*trans*-retinoic acid)	Acute promyelocytic leukemia
Molecular targeted therapy: small-molecule kinase inhibitors	Chemical synthesis	Inhibit dysregulated cancer-related kinases	Imatinib mesylate (targets ABL tyrosine kinases such as BCR/ABL kinase), gefitinib and erlotinib (both target epidermal growth factor receptor kinases), sorafenib (multikinase inhibitor that targets serine/threonine and tyrosine kinases)	Chronic myelocytic leukemia, acute lymphoblastic leukemia with Philadelphia chromosome, gastrointestinal stromal tumors, hypereosinophilic syndrome, non-small-cell lung cancer, kidney cancer
Proteasome inhibitors	Chemical synthesis	Inhibit a large complex that degrades proteins	Bortezomib	Multiple myeloma
Forms of naturally occurring elements	Natural	Not known. Induces apoptosis and differentiation	Arsenic trioxide	Acute promyelocytic leukemia
Monoclonal antibodies	Hybridoma techniques	Monoclonal antibodies against surface proteins	Rituximab (anti-CD20), alemtuzumab (anti-CD52), bevacizumab (antivascular endothelium growth factor), cetuximab (antiepidermal growth factor receptor), trastuzumab	Lymphomas, chronic leukemias, colorectal cancer, breast cancer
Targeted immuno-chemotherapy	Hybridoma techniques and chemical synthesis	Use cancer surface receptors to target chemotherapy	Gemtuzumab ozogamicin	Acute myelocytic leukemia
Targeted immuno-radiotherapy	Hybridoma techniques and chemical synthesis	Use cancer surface receptors to target radioactive compounds	Ibritumomab tiuxetan, tositumomab/iodine I-131	Lymphomas
Immunomodulatory drugs	Chemical synthesis	Multiple (antiangiogenic, T-cell modulation, cytokine secretion modulation)	Thalidomide and lenalidomide	Multiple myeloma, myelodysplastic syndromes
DNA methylation modulators	Chemical synthesis	Reverse abnormal DNA methylation	5-Azacitidine, decitabine	Myelodysplastic syndromes, acute leukemia
Hormonal therapy	Chemical synthesis	Multiple (blocks receptors, inhibits hormones, other)	Goserelin, bicalutamide, ketoconazole, tamoxifen, anastrozole, letrozole, tamoxifen	Prostate and breast cancer

radioisotopes for the treatment of lymphomas.

Tyrosine kinase inhibitors. Another class of anticancer agents that has been recently introduced in oncology clinical practice involves small-molecule tyrosine kinase inhibitors. Among other functions, tyrosine kinase enzymes regulate several of the intracellular processes normally responsible for cell proliferation. In cancers, these processes are often found to be dysregulated. Imatinib mesylate (Gleevec) is one of the most exciting recent drugs. It is a rationally designed ABL (Abelson leukemia oncogene) specific tyrosine kinase inhibitor. It inhibits BCR-ABL, which characterizes chronic myelocytic leukemia cells, and results in hematologic, cytogenetic, and sometimes molecular complete remissions (no abnormality detectable by the most sensitive molecular techniques). Erlotinib inhibits the EGFR-associated tyrosine kinase and has been shown to produce a survival benefit in patients with advanced non-small-cell lung cancer. Special patient populations that may derive greater benefit from erlotinib are being actively studied, including those with other cancers. These tyrosine kinase inhibitors can frequently be given by mouth. A large number of other inhibitors are currently under clinical investigation.

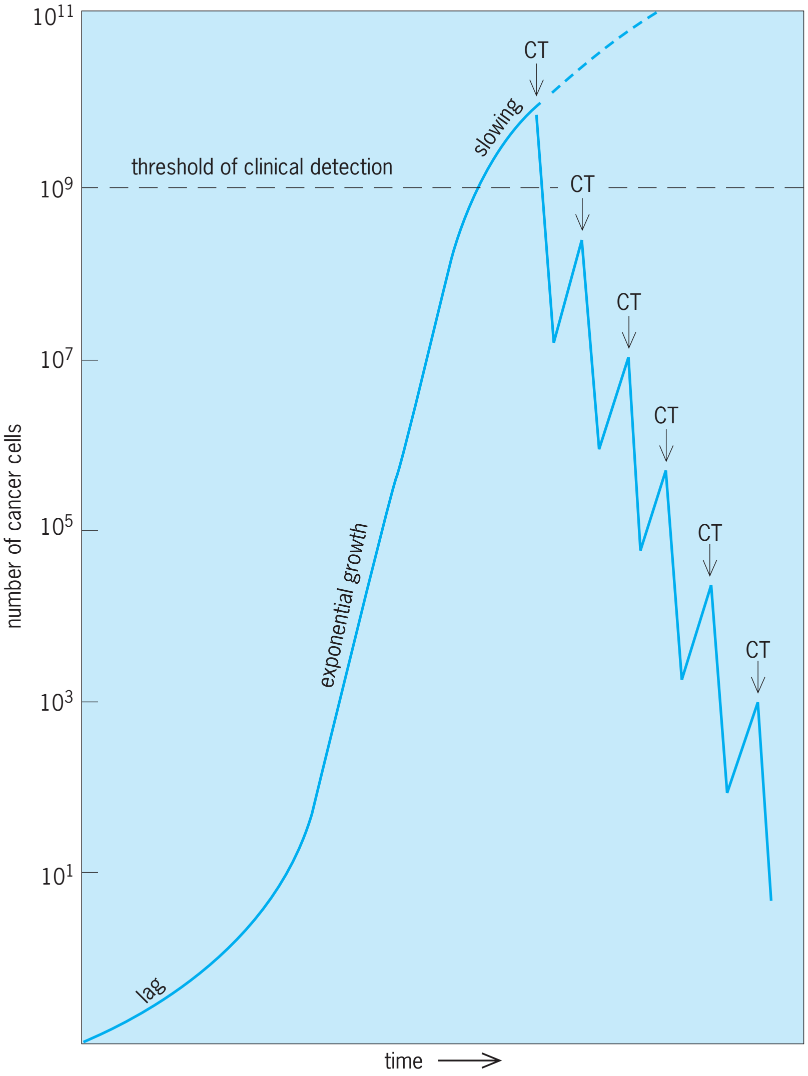
Hormonal agents. Hormonal agents have been used for several decades to inhibit cancer cells, especially in breast cancer, which frequently expresses hormone receptors on the cell surface. Representative hormonal agents include tamoxifen (a selective estrogen receptor modulator that also has partial estrogen agonist activity) and aromatase inhibitors such as anastrozole, among others. Aromatase is the enzyme responsible for conversion of androgens into estrogens and is the predominant source of estrogens in postmenopausal women. Hormonal therapy is also widely employed in metastatic prostate cancer, such as luteinizing hormone-releasing hormone (LHRH) agonists (goserelin, leuprolide), direct antiandrogen (bicalutamide), and blockers of adrenal androgen production (ketoconazole).

Sources. Chemotherapeutic drugs come from various sources. They may be extracted from natural sources—such as from bacteria, fungi, plants, or trees—or they may be chemically synthesized to target a specific protein—such as tyrosine kinase inhibitors. They may also be semisynthetic, meaning that the process starts with a complex natural compound that is then modified chemically. They may also be produced using modern recombinant DNA technology. Monoclonal antibodies may be murine (-monab); chimeric (-ximab), containing mouse variable regions and human constant regions; humanized (-zumab), containing murine binding regions (about 5% of total antibody) in a human framework; or human (-umab), derived using a variety of techniques from immunoglobulin genes with no murine immunoglobulin sequences.

Clinical trials. After basic laboratory studies suggest that a chemical might be effective in killing cancer cells, animal and then human testing begins. These tests are carried out in steps in order to systematically and safely identify those chemicals with the most usefulness. In phase I tests, the toxicity of the drug (or combination of drugs) and the maximum tolerated dose are determined by gradually increasing the dose given to patients until toxic effects are observed. In phase II studies, efficacy (tumor shrinkage) is determined in a single series of patients with a certain type of cancer. Recently, several new phase II design have been developed (for example, one called randomized discontinuation design) to identify preliminary evidence of activity of drugs that may have a greater effect on preventing cancer growth, rather than actual shrinkage. Typically, results of phase II studies are then used to proceed with larger phase III studies. In phase III tests, the drug (or combination) is randomized against the standard drug (or combination) used for that cancer to determine whether the experimental drug is more effective than the standard therapy. Phase III trials have historically been the gold standard to prove clinical efficacy.

Principles. Chemotherapy or immunotherapy is used when a cancer has spread to multiple sites (has metastasized) and cannot be removed surgically or treated with radiation therapy. It can also be used after all detectable tumor has been eradicated (complete remission) to destroy suspected but undetectable residual tumor. This type of treatment is called adjuvant, intensification, or consolidation chemotherapy. Adjuvant therapy is effective in breast and colon cancer, and consolidation in acute leukemia, for example. Neoadjuvant chemotherapy is used to shrink a tumor prior to surgery or radiation. *See* ONCOLOGY.

Fractional cell kill. For classic chemotherapy agents, the results of treatment depend upon how much chemotherapy is given, how many times it is applied, and how effective it is against the tumor. These facts are derived from a basic principle of chemotherapy that a uniform dose of a drug will destroy a constant fraction rather than a constant number of tumor cells regardless of the size of the tumor or number of cells present (fractional cell kill hypothesis). This result can be seen in the **illustration**, where the tumor



Sigmoid-shaped (Gompertzian) cancer growth (prior to first arrow) and fractional cell kill due to chemotherapy (after first arrow). Arrows indicate times of chemotherapy. Vertical axis is a log scale. The threshold for clinical detection of cancer is 10^8–10^9 total body tumor cells; since cancer probably starts from a single abnormal cell, this requires 27–30 doublings.

TABLE 2. Results of chemotherapy for disseminated disease in various cancers*

Cure in a majority of patients	Testicular cancer, childhood acute lymphoblastic leukemia, Hodgkin's disease, selected non-Hodgkin's lymphomas such as adult large B-cell lymphoma, gestational choriocarcinoma, hairy cell leukemia
Cure in a small subset of patients	Acute adult myeloid and lymphoblastic leukemia, ovarian cancer, some intermediate- and high-grade lymphomas, small-cell lung cancer
Induction of long-lasting remission	Follicular lymphoma, chronic myelocytic leukemia, gastrointestinal stromal tumor
Adjuvant† use with increased cure rates	Breast cancer, colorectal cancer, Ewing's sarcoma, Wilms' tumor, osteogenic sarcoma, rhabdomyosarcoma, glioblastoma multiforme, bladder cancer, gastric cancer
Prolongation of life but rare cures when metastatic‡	Multiple myeloma, follicular lymphoma, chronic lymphocytic leukemia, small cell lung cancer, bladder cancer, gastric cancer, colorectal cancer, pancreatic cancer, lung cancer, breast cancer, renal cell carcinoma
Palliation with unclear prolongation of life when metastatic	Head and neck cancer, hepatoma, melanoma, soft-tissue sarcoma, gallbladder cancer, cholangiocarcinoma

*These categories do not apply to cancers that have not metastasized and are treatable with surgery or radiation therapy alone, or to those that can be treated with bone marrow transplantation.

†Adjuvant refers to the use of chemotherapy in a situation where no tumor is detectable but there is a high chance that undetectable tumor cells are still present; the term for this type of therapy in blood or marrow cancers is consolidation therapy.

‡Some patients in this group can be cured by bone marrow transplantation.

number declines linearly on the log scale after the chemotherapy is applied. Drugs which are more effective in killing cancer cells give a greater slope of decline. Regrowth eventually occurs, but each subsequent dose of chemotherapy brings about a further decline in tumor cell number until eventually, in optimal circumstances, the number of tumor cells is low enough for the body to eliminate them by other mechanisms, resulting in a chemotherapy cure.

Mechanisms of cell death. Although the different groups of chemotherapeutic agents have different mechanisms of toxicity for cells, the cellular death response is often thought to be by apoptosis (programmed cell death). In this process a death signal is generated from within the damaged cells. This initiates a series of energy-requiring, choreographed cellular events leading to cellular suicide. Other mechanisms of death are necrosis and clonogenic (reproductive) death.

Goal. The goal of therapy should be determined in all patients before chemotherapy is started. The possibilities include cure, prolongation of life but not a cure, or palliation (alleviating symptoms) without likely prolongation of life (**Table 2**). The choice of chemotherapy depends not only on the type of tumor and the drug efficacy but, most importantly, on the patient. Also, it must be decided whether the chemotherapy will improve the quality of life of the patient and not just shrink the tumor. Age and the general condition of the patient influence the outcome. Those patients who are more active (better performance scores, which estimate degree of physical incapacitation by the tumor) are more likely to have a favorable outcome to chemotherapy. There are questionnaires to aid in measuring quality of life before and after drugs are given.

Dosage. For conventional chemotherapy, dosing has traditionally been based on the amount of body surface in square meters, or occasionally just on body weight. These dose calculations reflect the fact that toxicity often occurs at doses only slightly higher than those needed for therapy. In clinical trials, often the maximum tolerated dose (MTD) is the one taken forward for further testing and eventual routine use. Tyrosine kinase inhibitors, in contrast, are often prescribed at fixed doses expressed in milligrams. Knowledge of pharmacokinetic principles and drug interactions is very important when administering chemotherapy drugs.

Measurement of effect. The response of a cancer to a drug is determined by measuring the size of the cancer directly or the amount of marker substances produced by some tumors. A complete response is defined as disappearance of the tumor. A partial response means a specified decrease in tumor size that does not qualify for a complete response. In many cancers, the ultimate measure of benefit is whether the patients have a prolongation of life, which in clinical trials may require observation over a long period of time. Time to progression, or the time it takes for the cancer to recur after initial treatment, is another commonly used endpoint in cancer studies. Quality of life is another endpoint often applied in clinical studies in cancer.

Adjuvant therapy. This is a concept that is commonly used in medical oncology and accounts for significant use of chemotherapy at present. It translates into using chemotherapy after surgical removal of the cancer (for example, mastectomy for breast cancer). Chemotherapy is used to kill microscopic amounts of cancer cells that were not removed with the surgery or had spread to distant areas before the surgery. Adjuvant chemotherapy has been shown in numerous phase III trials to increase cure rates in selected common cancers. Typically, large numbers of patients need to be treated to demonstrate a benefit in the population.

Minimal residual disease. The detection of cancer cells that remain in submicroscopic numbers after therapy is referred to as minimal residual disease (MRD). Its importance is being evaluated in several malignancies, and MRD has been shown to correlate with recurrent clinical disease, especially in selected leukemias and lymphomas. The availability of improved molecular biology techniques has allowed increasing ability to detect MRD. These techniques include cytogenetics (chromosome analysis) and fluorescent in-situ hybridization (FISH), which uses DNA probes specific to regions of individual chromosomes, and these targeted areas are then identified by a fluorescent marker. Finally, reverse-transcription polymerase chain reaction (RT-PCR) is the most sensitive method currently available for detection of MRD.

Side effects. Chemotherapeutic drugs have side effects that are specific for the agent and may include transient or permanent damage to almost any organ system of the body. They cause side effects because, in addition to destroying the actively dividing cancer cells, they damage actively growing normal cells. Common sites of damage are the bone marrow, resulting in increased risk for infection, anemia, and bleeding; the gastrointestinal tract, resulting in vomiting and diarrhea; the hair follicles, causing hair loss; and the kidneys, resulting in renal failure. Today, cancer specialists have many ways of preventing or diminishing these toxicities, such as red blood cell transfusions for anemia, drugs to prevent nausea and vomiting, and growth factors which may improve anemia (erythropoietin) or shorten the time of low white blood counts (granulocyte-colony stimulating factor).

Drug resistance. Cells can become resistant to drugs of different groups, including anthracyclines, vincristine, etoposide, and paclitaxel. The general mechanism is referred to as multidrug resistance (MDR). This resistance is due to an acquired ability of the cells to pump these drugs out before they can cause irreversible damage. This pumping action is due to a transmembrane glycoprotein referred to as P-glycoprotein. These tumor cells overexpress the gene *MDR1*, which can be a useful marker of the resistance.

There are other ways by which a cancer cell can become resistant to chemotherapy. The cell may increase the amount of an intracellular drug target (for example, increased dihydrofolate reductase, which produces methotrexate resistance), reduce uptake of drugs (for example, alkylating agents), or decrease expression of a drug target (such as topoisomerase II). In some cases, resistance is due to a malfunctioning tumor suppressor gene called *p53*. The *p53* protein is an important initiator of drug-induced apoptosis; therefore, cells lacking *p53* do not commit cellular suicide in response to chemotherapies in the same way that *p53*-positive cells would.

In the case of tyrosine kinase inhibitors, resistance is often correlated with the emergence of a malignant cell clone with a new mutation in the targeted receptor, making the drug ineffective. Resistance can also be due to the presence of alternative molecular pathways that lead to cell proliferation, other than the pathway targeted by the drug.

Tumor growth. After an early lag phase, tumors grow exponentially, meaning that the time for a tumor to double in size is constant. However, as tumors grow, there is a deceleration in growth rate (see illustration), which may be due to outgrowing their blood supply, lack of sufficient nutrients, or changes in growth signals. This slowing means that there is an increase in the number of cells that are not dividing (G0 cell cycle phase), and these cells may be less susceptible to killing by drugs which act only on dividing cells. This phenomenon may compromise effective anticancer chemotherapy.

Selectivity and toxicity. Some tumors fail to respond to chemotherapy because normal tissues of the bone marrow, gut, or other organs are just as sensitive to the drug as the tumor, and unacceptable side effects preclude increasing the dose to therapeutic levels. These side effects may be early and transient such as vomiting, hair loss, or bone marrow suppression, or late and irreversible such as second malignancies, decline in fertility, lung fibrosis, and heart damage. Fortunately, effective drugs have some selectivity for the tumor, often for unknown reasons. Prednisone is an example of a drug that has the ability to destroy malignant lymphocytes with little damage to normal cells, and it is therefore selective.

Tumor heterogeneity. Cancers are not always uniform in their content of abnormal cells. There may be a mixture of cancerous cells with different features and different sensitivities to chemotherapy. Some cells may be sensitive while others are resistant to a specific drug. The use of a drug that destroys only one type of cell within a heterogeneous tumor will lead to eventual failure of therapy.

Strategies to overcome clinical resistance. Most successful modern chemotherapeutic regimens are combinations of drugs. These are usually named as acronyms, for example, CHOP therapy for lymphomas [cyclophosphamide, hydroxydaunorubicin (another name for doxorubicin), oncovin (another name for vincristine), and prednisone]. Response to combination therapy is usually superior to single-drug therapy. The use of more than one drug increases the chance of a cancer being sensitive to treatment since it is possible that a cancer cell resistant to one drug will be sensitive to another. Combinations of drugs with different mechanisms of tumor cell killing are commonly used. Also, in an effort to decrease side effects, drugs with nonoverlapping side effects are used. Drugs can also be combined with other general types of treatment such as immunotherapy. It is known from preclinical testing that chemotherapy and immunotherapy are more effective when the tumor is small. Therefore, surgery or radiation can be used in combination with chemotherapy to shrink the tumor with one modality and subsequently destroy the remaining smaller tumor with the other. Conversely, chemotherapy may be used to decrease tumor size to make surgery or radiation possible. In the case of tumors sensitive to tyrosine kinase inhibitors, resistance due to emergence of new mutations can sometimes be partially overcome by increasing the dose of the drug.

Biochemical modulation. Resistance to chemotherapy can be overcome in some instances by giving a second drug either simultaneously or in sequence. An example is the use of leucovorin (folinic acid) that potentiates 5-fluorouracil therapy administered to treat colorectal cancer by increasing reduced folates, which indirectly leads to a more stable complex of 5-fluorouracil with its target enzyme thymidylate synthetase and eventual cell death. Another example is experimental agents that increase the retention of drugs affected by multidrug-resistant cells.

High-dose chemotherapy. A strategy to kill tumors resistant to conventional doses of chemotherapy involves the use of extrahigh (supralethal) doses of chemotherapy. Because this damages the normal tissues, it is necessary to perform transplantation of hematopoietic stem cells (obtained from blood or bone marrow) afterwards to reconstitute vital bone marrow function.

Cell cycle. There has been a good deal of interest in the specific phase of the cell division cycle that is affected by chemotherapy, in the hope that this information could be used to develop more effective cures for cancer. However, the results have been disappointing overall. Some drugs kill cancer cells only in specific phases of the cell cycle (S-phase: cytarabine, methotrexate; M-phase: paclitaxel); others have no specificity (gemcitabine). Some drugs, such as the alkylating agents, cisplatin, and anthracyclines, can also kill nondividing cells. This type of information, which is usually established in tissue culture or animals, has been of limited practical use in planning human therapy. Recently, there has been renewed interest in control of the cell cycle by genes and growth factors. This may eventually lead to effective cell cycle–based drug strategies. Some of the proteins that control the cell cycle (for example, cyclins) might become targets for drug action. *See* CELL CYCLE; CELL DIVISION.

Differentiation. Tumor cells are often immature compared to normal cells and retain the ability to self-replicate. More differentiated mature cells often lose this ability and are end-stage cells. Therapy designed to induce differentiation often results in the loss of the cells' ability to reproduce. In this way tumor cells can be inactivated without administering toxic drugs, thereby avoiding toxicity to normal cells. An active drug in this group is tretinoin (all-*trans*-retinoic acid), which can lead to remissions in a large percentage of patients with acute promyelocytic leukemia. These remissions are usually of short duration unless cytotoxic drugs are added. Unfortunately, the strategy has not been useful in most cancers.

Drug delivery. Techniques are being developed to ameliorate toxicity so that higher doses of chemotherapeutic agents may be delivered directly to the tumor. One approach involves a lipid carrier to deliver more of the toxic drug to the tumor as compared to normal tissues. Thus far, the technique has some usefulness with the drugs doxorubicin in ovarian cancer and cytarabine in central nervous system lymphoma or leukemia.

Cherry

Sweet or sour fruit of the *Prunus* genus, having cultivated and wild varieties.

Cultivated varieties. The two principal cherries of commerce are the sweet cherry (*Prunus avium*) and the sour cherry (*P. cerasus*). Both are of ancient origin and seem to have come from the region between the Black and Caspian seas. They were probably carried into Europe by birds before humans were there. The cherry was mentioned in 300 B.C. by the Greek botanist Theophrastus. It was taken to America from Europe.

Cherries of minor importance are the dwarf or western sand cherries (*P. besseyi*) of the plains region of North America; the Duke cherries, which are supposedly natural hybrids between the sweet and sour cherry; and the Padus cherries, which bear their small fruits in long clusters or racemes rather than in short fascicles.

Sweet cherries may be divided into two groups, firm-fleshed types known as Bigarreaus, represented by the Napoleon (also called the Royal Anne), and soft-fleshed types known as Hearts, represented by the Black Tartarian. Sour cherries may also be divided into two groups, clear-juice or Amarelle types, represented by the Montmorency, and colored-juice or Morello types, represented by the English Morello.

In North America the principal sweet commercial varieties are the Napoleon (white), Bing, Lambert, Van, Schmidt, and Windsor (dark). The principal commercial variety of sour cherry is the Montmorency.

Trees are propagated by budding into seedlings of the wild sweet (mazzard) cherry or of *P. mahaleb,* commonly called the perfumed cherry of southern Europe. The former is best suited to the sweet cherry, and the latter to the sour cherry. *See* PLANT PROPAGATION; REPRODUCTION (PLANT).

The sweet cherry is somewhat hardier than the peach, and the sour cherry is hardier than the sweet cherry. Cultivated varieties are usually planted 25–30 ft (7.5–9 m) apart and allowed to grow to heights of only about 15–20 ft (4.5–6 m) for ease of culture and harvest. Sour cherry trees may reach 30–40 ft (9–12 m) but are kept at 15–20 ft (4.5–6 m) and planted 18–22 ft (5.4–6.6 m) apart. Cherry trees do best in well-drained sandy loam soils. They will not tolerate wet soil. Sweet varieties require cross-pollination; common sour varieties are self-fruitful (self-pollinated). *See* FRUIT; FRUIT, TREE; ROSALES. R. Paul Larsen

Wild varieties. The wild cherry tree, *P. serotina*, grows to a height of 100 ft (30 m) and may reach an age of 200 years. It belongs to the rose family, and is an important timber species of cherry in the United States. Native in the eastern half of the United States and adjacent Canada, it reaches its largest size in the southern Appalachian Mountains. The deciduous leaves are long-pointed, thickish, and shining above (**Fig. 1**). The edible fruit is a shiny black drupe found in long clusters. The hard, strong wood is a red-brown and is used for furniture, often as an imitation mahogany.

The sweet cherry or mazzard (*P. avium*), which grows to 70 ft (21 m), is naturalized over a large part of the United States. It has fruits borne in umbel-like clusters. It also differs from the wild cherry in having more ovate leaves with rounded teeth (**Fig. 2**).

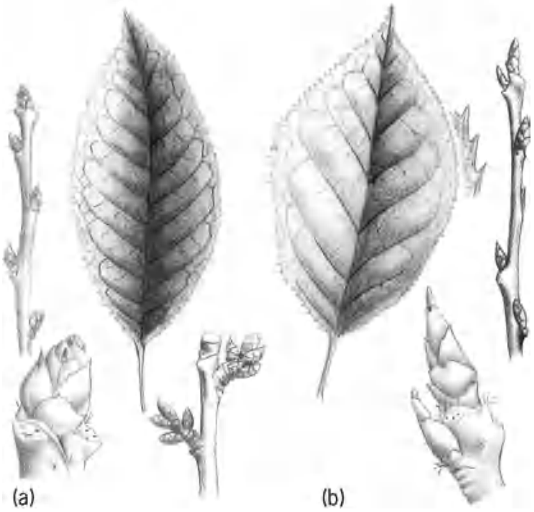

Fig. 1. Leaves, twigs, and buds of (*a*) sweet cherry (*Prunus avium*) and (*b*) choke cherry (*P. virginiana*)

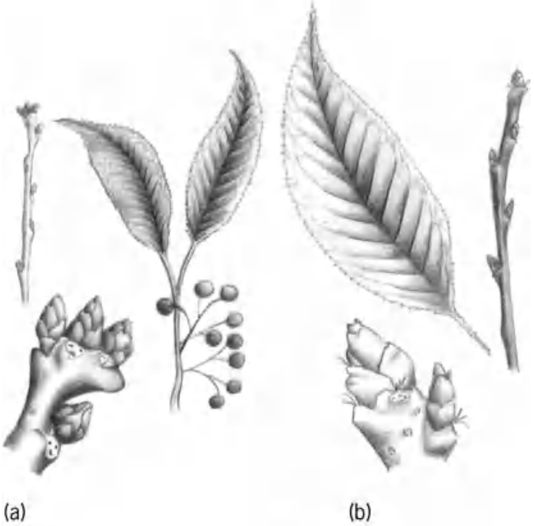

Fig. 2. Leaves, twigs, and buds of (*a*) pin or fire cherry (*Prunus pensylvanica*) and (*b*) wild cherry (*P. serotina*)

The Japanese flowering cherries are varieties of *P. serrulata*, which attract much attention at blossoming time in early May.

Arthur H. Graves; Kenneth P. Davis

Diseases. A destructive disease of cherry in the orchard and after harvest is brown rot, caused by the fungus *Monilinia fructicola*. Infections occur first in blossoms, and later in the maturing fruit, causing rot (**Fig. 3**). Cherry leaf spot, caused by the fungus *Coccomyces hiemalis*, results in leaf spotting, yellowing, and premature defoliation. Without well-functioning leaves, trees lose vigor and decline in productivity. Powdery mildew, caused by the fungus *Podosphaera oxyacanthae,* impairs the ability of leaves to supply sugars and other products needed by the tree for normal development. These three diseases can be effectively controlled with timely sprays of recommended fungicides.

Fig. 3. Brown rot disease of sweet cherry.

The major bacterial diseases of cherry are bacterial canker caused by *Pseudomonas syringae* (affecting leaves, branches, and fruit) and crown gall, due to *Agrobacterium tumefaciens*, which causes a tumorlike growth on the crown and roots.

Important virus (or viruslike) diseases are Prunus ring spot, prune dwarf, little cherry, and X disease ("buckskin"). Virus diseases affect certain tissues (wood, bark, leaves, seeds, pollen) of certain branches or even the entire tree. The symptoms vary with each disease, but usually involve small, mottled, yellow, or missing leaves, and small and poorly colored fruit. Tree growth and yield suffer. Preventive control measures include planting resistant varieties and certified virus-free stock and, where applicable, spraying for the control of insect vectors that transmit the pathogens. *See* PLANT PATHOLOGY; PLANT VIRUSES AND VIROIDS. Chert

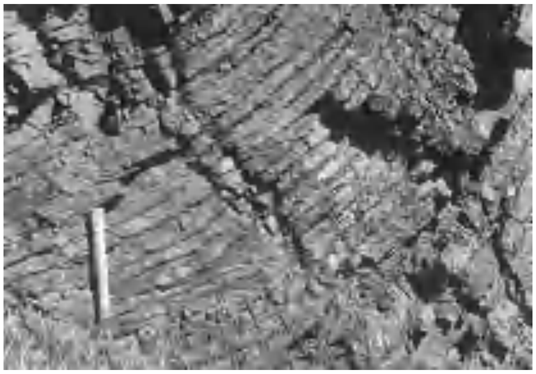
A hard, dense sedimentary rock composed of fine-grained silica (SiO_2). Chert is characterized by a semivitreous to dull luster and a splintery to conchoidal fracture, and is most commonly gray, black, reddish brown, or green. Chert is also used as a field term to describe silica-rich rocks which may be impure; common impurities include carbonates, iron and manganese oxides, and clay minerals. When impurities change the texture of the rock to the extent that it is less dense and hard than chert, and has the appearance of unglazed porcelain, the rock is then called porcellanite or siliceous shale. The term flint is synonymous with chert, but its use has become restricted to archeological artifacts and to nodular chert that occurs in chalk. The term chert, however, is preferred for the nodular deposits. Jasper refers to red or yellow quartz chert associated with iron ore or containing iron oxide. Novaculite is a white chert of great purity and uniform grain size, and is composed chiefly of quartz; the term is mostly restricted to descriptions of Paleozoic cherts in Oklahoma and Arkansas. Chert synonyms that have become obsolete include silexite, petrosilex, phthanite, and hornstone. *See* JASPER.

Composition. The silica that composes chert occurs in four forms: quartz, chalcedony, opal-CT, and opal-A. Chalcedony is a microscopically fibrous form of the mineral quartz with water trapped in void spaces parallel to the fibers. The poorly understood opal-CT phase is probably an interstratified mixture of the silica minerals cristobalite and tridymite, although it has been suggested to be solely disordered tridymite. In chert, the chalcedony, quartz, and opal-CT are secondary forms of silica derived from the dissolution and later precipitation of a primary silica phase, which for most chert is biogenic silica (opal-A). The main rock-forming types of biogenic silica are the tests and frustules of the siliceous plankton diatoms, radiolarians, silicoflagellates, and ebriidians, and the siliceous spicules of sponges. The composition of chert changes with time and temperature, beginning with opal-A, which transforms to opal-CT and finally to quartz or chalcedony. Under special conditions, opal-A can transform directly to quartz. *See* CHALCEDONY; OPAL; QUARTZ.

Diagenesis. Opal-A and opal-CT are metastable phases within the Earth's crust. The diagenetic transformation of opal-A to opal-CT and then to quartz is primarily controlled by temperature and time, but also by surface area, pore-water chemistry, sediment permeability, and host-sediment composition. The mineralogical transformations are commonly, but not invariably, accompanied by textural transformations. For example, diatom or radiolarian ooze (unconsolidated marine sediment composed mostly of diatom frustules or radiolarian tests) or diatomaceous or radiolarian earth (weakly consolidated oozes that have been incorporated into on-land deposits), which are composed of opal-A, transform into porcellanite (most commonly composed of opal-CT), which in turn transforms into chert (most commonly composed of quartz). *See* DIAGENESIS; MARINE SEDIMENTS.



Rhythmically bedded radiolarian chert from the Franciscan Complex, Diablo Range, California; of Late Jurassic age.

Occurrence. Chert occurs mainly in three forms: bedded sequences (see **illus.**), nodular, and massive. Bedded chert (called ribbon chert if beds show pinch-and-swell structure) consists of rhythmically interlayered beds of chert and shale; chert and carbonates; or in some pre-Phanerozoic formations, alternations of chert and siderite or hematite. Bedded sequences can be hundreds of feet thick stratigraphically and cover areas of hundreds of square miles. Individual beds are commonly $^1/_2$–8 in. (1–20 cm) thick. Intercalated shale layers are commonly, but not invariably, thinner than the associated chert layers. In many places individual chert beds are laminated. Chert nodules and lenses occur primarily in chalk, limestone, and dolomite, and are the only types of chert recovered by the Deep Sea Drilling Project from open-ocean sediment. Chert nodules are well known from many places in western Europe, where their dark color contrasts strikingly with the white host chalk. Nodules and lenses vary in size from $^1/_2$ in. to 30 ft (1 cm to 9 m). Fossils and sedimentary structures characteristic of the host rock are preserved within the nodules. Massive cherts occur in the interstices between basalt pillows, and as the basal member of bedded chert that overlies pillow basalts in ophiolites. *See* BASALT; CHALK; DOLOMITE ROCK; LIMESTONE.

Origin. When a supply of silica is available, chert forms in four ways: (1) by replacement of mainly carbonate rock; (2) by deposition from turbidity currents composed primarily of biogenic silica; (3) by increasing the deposition of silica relative to terrigenous input, commonly by increased productivity of biogenic silica; and (4) by precipitation of silica from water under either hydrothermal or low-temperature hypersaline conditions. The replacement of chalk and limestone by silica has been well documented in Deep Sea Drilling Project cores and in some deposits on land. The silica is derived from the dissolution of biogenic silica deposited with the biogenic carbonate. The resultant chert most commonly forms nodules, but the silica may also replace beds of limestone completely, thereby forming bedded chert. Most bedded chert, however, is probably turbidite sequences, although additional work is necessary to confirm this hypothesis. Transient, sediment-laden density currents (turbidity currents) that flowed down the sides of submarine basins carried mostly biogenic silica which settled in layers. The layers later transformed into cherts through diagenetic processes. Pelagic or hemipelagic clays were deposited in the basin between times of turbidite deposition, thus creating the rhythmically bedded chert-shale sequences found in many mountain belts. In some places, the shales may be the turbidites and the cherts the pelagic deposits. The rhythmic bedding can also be produced by productivity cycles of biogenic silica. Of relatively minor volumetric importance in post-Archean rocks is the primary precipitation of silica. Inorganic precipitation of silica takes place in hypersaline lakes and lagoons. Chert also forms by deposition of silica from hydrothermal solutions into the interstices between basalt pillows, and in other localized areas within ophiolite sequences. *See* TURBIDITE; TURBIDITY CURRENT.

Distribution. The distribution of chert is tied to the distribution of siliceous plankton, which in turn depends on oceanographic conditions. After the plankton die, their shells accumulate in great quantities on the sea floor, especially around the polar regions (diatoms) and the equatorial belt of high biological productivity (radiolarians and diatoms). Shells also accumulate in other areas where cold, nutrient-rich subsurface water upwells, such as off the west coasts of continents and in marginal seas such as the Philippine and Japan seas. Marine siliceous deposits, along with the underlying oceanic crust, are incorporated into mountain belts by uplift of oceanic crust or by obduction and thrust faulting at subduction plate margins. Such on-land cherts of every age are found at many locations around the world. *See* BACILLARIOPHYCEAE.

Radiolarians and sponge spicules occur in Phanerozoic chert. Diatoms first evolved during the Mesozoic Era and came into prominence in the Tertiary, when they became the dominant precursor of chert. The source of silica for pre-Phanerozoic cherts, which are commonly associated with banded iron formations, is equivocal. Direct evidence of a biological source is lacking, and inorganic precipitation of silica is generally postulated. Most Archean (before 2.5 billion years ago) cherts likely formed from hydrothermal or other abiotic processes. Future studies may yield information that would indicate additional sources of silica for pre-Phanerozoic cherts. *See* SEDIMENTARY ROCKS. James R. Hein

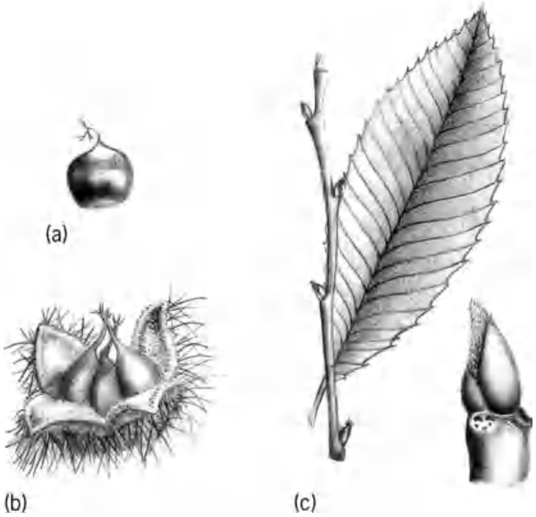
Chestnut

Any of seven species of deciduous, nut-bearing trees of the genus *Castanea* (order Fagales) native to the Northern Hemisphere and introduced throughout the world. The nuts are actually fruits, with the shells enclosing cotyledons. Trees bear both male and female flowers in late spring but must be cross-pollinated for nut production. Nuts are borne in a spiny involucre or bur that opens to release the nuts in late fall. *See* FAGALES.

Varieties. Japanese chestnuts (*C. crenata*) and Chinese chestnuts (*C. mollissima*) are grown in Asia and the United States for their nuts, and many cultivars have been selected. European chestnuts (*C. sativa*) are an important food source, both cooked whole and ground into flour. They are native to the Caucasus mountains, and distributed throughout southern Europe. American chestnuts (*C. dentata*; see **illus.**) have smaller nuts than Asian or European species and are usually sweeter. Only American trees served as an important source of lumber, because of the length of their unbranched trunks; all chestnut species have been used as a source of tannin for the leather-tanning industry. American and Chinese chinquapins (*C. pumila* and *C. henryi*) have very small nuts that are an important source of food for wildlife. All of the species can be crossed, and hybrids have been selected primarily as orchard cultivars.

Diseases. In 1838 a root disease was reported on European chestnut in Portugal, and soon after this "ink disease" was found in several other parts of southern Europe. The pathogen, *Phytophthora cinnamomi*, causes brownish-black lesions on the roots that exude an inky-blue stain. The lesions expand, coalesce, and girdle the root, resulting in tree death.



American chestnut (*Castanea dentata*). (*a*) Nut. (*b*) Bur. (*c*) Leaf, twig, and bud.

Breeding with ink disease–resistant Asian species has produced new cultivars, and careful sanitation and site selection allow European chestnuts to still be grown. In the United States, ink disease probably accounted for the recession of chestnut species from large areas in the Gulf and Atlantic states and inland to the foothills and mountains of Mississippi, Alabama, Georgia, Tennessee, Maryland, Virginia, and the Carolinas. The fungus is assumed to have entered the United States in the mid-1800s.

The second disaster for American and European chestnuts was also a fungus disease. *Cryphonectria* (formerly *Endothia*) *parasitica* was first reported in New York City in 1904 and was found to be widespread throughout the northeast region of the United States. This fungus, causing chestnut blight, had probably entered the United States on imported Japanese chestnuts in the late 1800s. The initial spread was on nursery stock (most major mail-order nurseries sold Japanese chestnuts at the turn of the century), but spores were also carried on the fur, feet, and feathers of the birds, animals, and insects that walked up and down the trees. Wounds in the bark allow access and initial fungal growth, and the resulting canker expands to kill the cambium and eventually the twigs, branches, and trunk. The fungus does not kill the root collar, and the dormant embryos there sprout and grow until wounded, infected, and killed, and the cycle is repeated. In the northern part of the natural range of American chestnut (northern Georgia to southern Maine, and west through Ohio, Kentucky, and Tennessee), sprout clumps have survived well, but farther south repeated chestnut blight cycles kill the sprout clumps. American chinquapins are also very susceptible to chestnut blight, and their sprouting system (relying on the old root system, instead of forming new roots as chestnut does) may make them more liable to be killed by blight.

Chestnut blight was first reported in Europe on chestnuts in Italy in 1938. The epidemic there proceeded as in the United States, but natural virus infection of the fungus now provides a biological control. The fungal strains with viruses are less virulent (hypovirulent), and can be inoculated into natural cankers to transmit the viruses and establish biological control in orchards. Hypovirulent strains have been used in the United States for control of blight fungus populations in orchards and forest stands of American chestnut sprouts. Improved control may result from new genetically engineered strains. In addition, trees are bred for resistance by crossing susceptible trees with resistant Chinese and Japanese chestnuts.

The next potential disaster for chestnut trees in the United States and Europe is infestation with a small wasp native to Asia called the Oriental chestnut gall wasp (*Dryocosmus kuriphilus*). Eggs laid in leaf and flower buds develop into galls and heavy infestations can kill the trees. The insect has been in the United States since 1974 (on Chinese chestnut trees in orchards in Georgia), and is now infesting American chestnut trees at the southern part of the range. Japanese chestnut breeders released cultivars with some resistance to the insect, and American chinquapins also seem to have good resistance. *See* FOREST AND FORESTRY; PLANT PATHOLOGY; TREE.

Sandra L. Anagnostakis

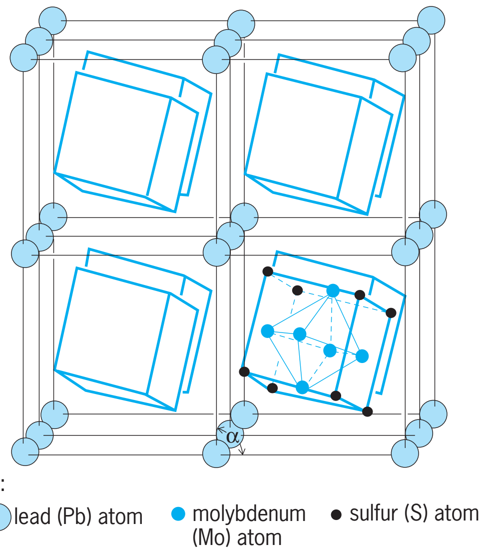
Chevrel phases

A series of ternary molybdenum chalcogenide compounds. They were reported by R. Chevrel, M. Sergent, and J. Prigent in 1971. The compounds have the general formula $M_xMo_6X_8$, where M represents any one of a large number (nearly 40) of metallic elements throughout the periodic table; x has values between 1 and 4, depending on the M element; and X is a chalcogen (sulfur, selenium or tellurium). The Chevrel phases are of great interest, largely because of their striking superconducting properties.

Crystal structure. Most of the ternary molybdenum chalcogenides crystallize in a structure in which the unit cell, that is, the repeating unit of the crystal structure, has the overall shape of a rhombohedron with a rhombohedral angle close to 90°. Some of the ternary molybdenum chalcogenides display a slight distortion of the rhombohedral crystal structure at, or below, room temperature to a triclinic structure in which the three axes of the unit cell, and the three angles between them, are unequal.

The building blocks of the Chevrel-phase crystal structure are the M elements and Mo_6X_8 molecular units or clusters. Each Mo_6X_8 unit is a slightly deformed cube with X atoms at the corners, and Mo atoms at the face centers. One of these structures, that of $PbMo_6S_8$, is shown in the **illustration**. *See* CRYSTAL STRUCTURE; CRYSTALLOGRAPHY.

Superconductivity. Many of the Chevrel-phase compounds exhibit superconductivity, a phenomenon in which a metal, when cooled below its



Crystal structure of $PbMo_6S_8$. Each lead atom is surrounded by eight Mo_6S_8 units, the structure of which is shown in the lower right part of the figure. The rhombohedral angle α is indicated also.

superconducting transition temperature T_c, loses all resistance to flow of an electric current. Several of the Chevrel-phase compounds have relatively high values of T_c, the maximum being about 15 K (−433°F) for $PbMo_6S_8$. Prior to 1986, the highest T_c of any known material was 23 K (−418°F) for the A15 compound Nb_3Ge. *See* A15 PHASES.

Since 1987, superconductivity at temperatures above the boiling point of liquid nitrogen (77 K or −321°F) has been discovered in several families of copper oxide compounds. A value of T_c of approximately 122 K (−240°F) has been observed in a compound comprising the elements thallium, barium, calcium, copper, and oxygen. As in conventional superconductors, the superconductivity is associated with electron pairs, called Cooper pairs; but the attractive mechanism responsible for the formation of the Cooper pairs may be different in the high-T_c superconducting oxides than in conventional superconductors, like the Chevrel phases and the A15 phases, where it involves the interaction between the negatively charged electrons and the positively charged ions of the crystal lattice.

The superconductivity of any superconducting compound can be destroyed with a sufficiently high magnetic field, called the upper critical magnetic field $H_{c2}(T)$, which depends on the temperature T and varies from material to material. As the temperature is lowered, $H_{c2}(T)$ generally increases from zero at T_c to a maximum value, $H_{c2}(0)$, as the temperature approaches absolute zero. The Chevrel-phase $PbMo_6S_8$ has a value of $H_{c2}(0)$ of about 60 teslas (600 kilogauss), the largest value observed for any material prior to 1986. The highest $H_{c2}(0)$ that had been previously reported for a non-Chevrel-phase material was 40 teslas (400 kilogauss) for the A15 compound Nb_3Ge. In comparison, the values of $H_{c2}(0)$ for the highest T_c copper oxide superconductors may reach several hundred teslas, values so large that they cannot readily be measured by using the magnetic fields and techniques that are presently available in the laboratory.

A number of Chevrel-phase compounds of the form RMo_6X_8, where R is a rare-earth element with a partially filled $4f$ electron shell and X is S or Se, display magnetic order at low temperatures in addition to superconductivity. The superconductivity is primarily associated with the mobile $4d$ electrons of Mo, while the magnetic order involves the localized $4f$ electrons of the R atoms which occupy regular positions throughout the lattice. Superconductivity has been found to coexist with antiferromagnetic order, but to be destroyed by the onset of ferromagnetic order. *See* ANTIFERROMAGNETISM; FERROMAGNETISM; SUPERCONDUCTIVITY.

Chevrotain

The name for four species of mammals which constitute the family Tragulidae in the order Artiodactyla. These animals, also known as mouse deer, are the smallest ruminants, growing to a maximum height of 12 in. (30 cm) at the shoulder. The water chevrotain (*Hyemoschus aquaticus*; see **illustration**) is found in west-central Africa along the banks of rivers in Sierra Leone through the Cameroons to the Congo. It feeds principally on aquatic vegetation. The other species are all members of the genus *Tragulus*, and range through the forested areas of Sumatra into Borneo and Java. These are the Indian chevrotain (*T. meminna*), the larger Malay chevrotain (*T. napu*), and the lesser Malay chevrotain (*T. javanicus*). They are differentiated by the pattern of markings (stripes or spots) on their coats. *Tragulus javanicus* has a coat of uniform color. The chevrotain lacks horns or antlers. There are two well-developed toes on the feet, and the upper canines of the male are elongate and protrude from the mouth as small tusks. The chevrotain is a shy animal which leads a solitary life except during the breeding season. After a gestation period of 120 days, one or two young are born. There is a total of 34 teeth with the dental formula I 0/3, C 1/1, Pm 3/3, M 3/3. The Eocene fossil traguloid, *Archaeomeryx*, which was unearthed in Mongolia, shows many general similarities to the modern chevrotains. The main line of evolutionary development of the traguloids occurred in Eurasia. *See* ARTIODACTYLA; DENTITION.

Chickenpox and shingles

Chickenpox (varicella) and shingles (herpes zoster) are two different forms of disease caused by the varicella-zoster virus, which is a deoxyribonucleic acid (DNA) virus closely related to herpes simplex and Epstein-Barr viruses. Initial infection causes varicella, a common childhood infection characterized by fever, malaise, and a rash consisting of dozens to hundreds of small fluid-filled lesions (vesicles) that are individually surrounded by reddened skin. Successive crops of lesions appear that eventually ulcerate and crust over during the two-week course of the disease. The virus is spread from person to person by the highly infectious respiratory secretions and lesion drainage. Varicella is rarely a serious disease in normal children but can be severe in immunocompromised individuals or in the rare adult who escaped childhood infection. Primary infection results in immunity to a new varicella-zoster virus, but the original virus lies dormant in nerve ganglia cells. *See* EPSTEIN-BARR VIRUS; HERPES.

At some time in their life, approximately 10% of the population suffers subsequent reactivation of latent virus, which spreads to the skin overlying the affected nerve and causes a localized eruption of vesicles called herpes zoster. The vesicles are similar in appearance and in infectiousness to varicella lesions. This syndrome is usually well tolerated, although elderly persons may develop chronic pain at the site of reactivation. Herpes zoster in immunocompromised individuals may be prolonged or may disseminate to vital organs.

Varicella or herpes zoster in a normal host is self-limited and does not typically require antiviral therapy. In individuals with underlying immune disorders, treatment with the antiviral drug acyclovir decreases the duration and severity of disease. Previously uninfected immunocompromised individuals or pregnant women recently exposed to varicella-zoster virus can be partially protected from subsequent disease through the administration of varicella-zoster immune globulin. However, antibody tests often indicate preexisting immunity from asymptomatic or forgotten childhood varicella. *See* ANIMAL VIRUS; VIRUS INFECTION, LATENT, PERSISTENT, SLOW.

Frederick P. Heinzel

Chicle

A gummy exudate used in the manufacture of chewing gum. It is contained in the bark of a tall evergreen tree, *Manilkara zapota* (see **illus.**), belonging to the sapodilla family (Sapotaceae). The species is a native of Mexico and Central America. The latex (secretion) is collected and carefully boiled to remove excess moisture. When the water content is reduced to 33%, the chicle is poured off and molded into blocks. Crude chicle contains resin, arabin, gutta, sugar, calcium, and different soluble salts. For refining, it is broken up, washed in strong alkali, neutralized with sodium acid phosphate, rewashed, dried, and powdered. The resulting product is an amorphous, pale-pink powder, insoluble in water, and forming a sticky paste when heated. In the manufacture of chewing gum, the chicle is cleaned, filtered, and sterilized, and various flavoring materials and sugar are added. *See* EBENALES; RUBBER.

Fruit of *Manilkara zapota*. (*After L. H. Bailey, The Standard Cyclopedia of Horticulture, vol. 3, Macmillan, 1937*)

Perry D. Strausbaugh; Earl L. Core

Chicory

A perennial herb, *Cichorium intybus* (Asteraceae), with a long taproot, a coarse branching stem, and a basal rosette of numerous leaves. Although the plant is a native of Europe, it has become a common weed in the United States. It is used as a salad plant or for greens. The roasted root is also used as an adulterant of coffee. *See* CAMPANULALES; SPICE AND FLAVORING.

Perry D. Strausbaugh; Earl L. Core

Child-Langmuir law

A law governing space-charge-limited flow of electron current between two plane parallel electrodes in vacuum when the emission velocities of the electrons can be neglected. It is often called the three-halves power law, and is expressed by the formula below.

$$j(\mathrm{A/cm^2}) = \frac{\epsilon}{9\pi}\left(\frac{2e}{m}\right)^{1/2}\frac{V^{3/2}}{d^2}$$

$$= 2.33 \times 10^{-6}\,\frac{V(\mathrm{volts})^{3/2}}{d(\mathrm{cm})^2}$$

Here ϵ is the dielectric constant of vacuum, $-e$ the charge of the electron, m its mass, V the potential difference between the two electrodes, d their separation, and j the current density at the collector electrode, or anode. The potential difference V is the applied voltage reduced by the difference in work function of the collector and emitter. The Langmuir-Child law applies, to a close approximation, to other electrode geometries as well. Thus for coaxial cylinders with the inner cylinder the cathode, it leads to a deviation from the true value of the current density of 13% at most. *See* SPACE CHARGE.

Edward G. Ramberg

Chilopoda

A class of the Myriapoda commonly known as the centipedes. As are all myriapods, centipedes are ground dwellers whose permeable cuticle largely restricts their distribution to moist sites and habitats. Centipedes are mostly found under stones, in moss cushions, in leaf litter, and beneath loose bark on trees; several species inhabit caves, especially those of temperate regions. All centipedes are carnivorous; their predatory habits are reflected in their great agility and fleetness and especially in the modification of the first trunk appendages into a pair of usually massive raptorial pincers, the poison claws (also called the forcipules or the prehensors). Each poison claw contains a poison gland whose duct opens near the tip of the claw. Exceptionally, the poison gland may be located in the trunk, in which case the duct connecting it to the apical opening can be as long as twenty body segments. The poison immobilizes or kills arthropod prey and even some small vertebrates. The bite of larger species, particularly of the Scolopendromorpha, may be painful to human beings, but no serious consequences have been reported. *See* ARTHROPODA.

Distribution and taxonomy. The class is divided into two subclasses, the Notostigmophora and the Pleurostigmophora. There are five orders: two are basically tropical (Scutigeromorpha, Scolopendromorpha), two are essentially temperate (Lithobiomorpha, Craterostigmomorpha), and the Geophilomorpha is abundant in both zones. Indeed, there are some Lithobiomorpha and Geophilomorpha that occur as far north as the Arctic Circle, and others at elevations as high as 4000 m (13,123 ft) on the Himalayas.

Fragmentary fossils of Scutigeromorpha are known from the Upper Silurian. Fossil Scolopendromorpha that are very similar to modern types are known from a Carboniferous site. The extinct order Devonobiomorpha, only known for the one species *Devonobius delta* from an upper Middle Devonian site near Gilboa, New York, is probably closely related to the living Craterostigmomorpha.

Morphology. Centipedes have a globular or, more often, flattened head that is distinctly articulated in respect to the long trunk. The head bears a pair of unbranched antennae, which are sometimes very long with up to more than 100 articles. The eyes are of the compound type in the Scutigeromorpha, but are simple ocelli in the other groups; however, there are no eyes in the cryptopid Scolopendromorpha, in the Geophilomorpha, and in many cave-dwelling Lithobiomorpha. The mouthparts include one pair of mandibles and two pairs of maxillae. Excluding the first segment (which bears the poison claws) and the last two or three segments (which are devoid of appendages or bear only short genital appendages), each trunk segment bears one pair of legs. In the adult centipedes, the number of leg-bearing segments is always odd: 15 in the Scutigeromorpha, Lithobiomorpha, and Craterostigmomorpha; 21 or 23 in the Scolopendromorpha; and 27 to 191 (odd numbers only) in the Geophilomorpha. Variation in segment number within the same species is the general rule among the Geophilomorpha (most species in the family Mecistocephalidae being the exception) and has also been reported in one representative of the Scolopendromorpha. Although the trunk segments are uniform ventrally, they are often unequal dorsally. This is most conspicuous in the Lithobiomorpha, in which longer and shorter segments alternate quite regularly except close to midbody.

Gas exchange occurs through lateral spiracles or through dorsal stomata (in Scutigeromorpha only). A circulatory system is present; the copper-containing respiratory pigment hemocyanin has been found in the hemolymph of Scutigeromorpha. Excretion is mainly through a pair of Malpighian tubules similar to those of the insects; in addition, Scutigeromorpha and Lithobiomorpha have a pair of maxillary reins. The genital ducts open at the posterior end of the body. *See* RESPIRATORY PIGMENTS (INVERTEBRATE).

Reproduction and development. All centipedes have separate sexes. The females of Scutigeromorpha and Lithobiomorpha have a pair of pincer-shaped appendages used in egg-laying; otherwise sexual dimorphism is usually limited to the shape of the last pair of legs, which are more elaborate in the male. Males and females of most Scolopendromorpha are virtually indistinguishable without dissection.

Fig. 1. European house centipede, *Scutigera coleoptrata* (order Scutigeromorpha); it is now commonly found in many urban sites in America. (*Photo by Marco Uliana*)

Fig. 2. Scolopender, *Scolopendra cingulata* (order Scolopendromorpha), from the Mediterranean region. (*Photo by Lucio Bonato*)

Although a few instances of parthenogenesis have been described, sexual reproduction among centipedes typically involves the transfer of sperm. Sperm transfer occurs through the production of sperm packets (spermatophores) that the male fixes to the ground (Scutigeromorpha) or, more frequently, places on a small silky web, before inviting the female to collect them. The eggs of centipedies are large. In Scutigeromorpha and Lithobiomorpha, the eggs are manipulated by the female through the posterior pincerlike appendages and finally abandoned, individually, in the soil, covered by soil particles. However, in the Craterostigmomorpha, Scolopendromorpha, and Geophilomorpha, the female not only broods her eggs but also guards the young for a time; without the attention of the female, they would succumb to the fungi and bacteria of the forest floor.

Fig. 3. Geophilomorph centipede, *Clinopodes flavidus*, from northern Italy, illustrating the very elongated, wormlike habit that is characteristic of members of order Geophilomorpha. (*Photo by Lucio Bonato*)

Many centipedes (Scutigeromorpha, Lithobiomorpha, and Craterostigmomorpha) are hemianamorphic, the young hatching with less than the adult number of pairs of legs and continue to molt until the final complement is achieved. However, even once the full complement is attained, a few more molts are required before the animal reaches sexual maturity. Postembryonic development is thus divided into a larval phase, during which the animal achieves the complete number of fully developed segments, and a postlarval phase, during which the segments do not increase further but the animal continues to grow until sexual maturity is reached.

The Scolopendromorpha and Geophilomorpha are epimorphic; that is, upon hatching, the young already possess the adult complement of leg-bearing segments, and successive molts merely permit an increase in size. Centipedes rarely reach sexual maturity in less than 1 year. There is evidence to suggest that all centipedes continue to molt even after they reach sexually maturity and perhaps throughout life; in some species this may entail many years. *See* REPRODUCTION (ANIMAL).

Notostigmophora. The subclass Notostigmophora comprises a single order, Scutigeromorpha. These centipedes are peculiar in embodying primitive as well as highly advanced characters. The group is characterized by the presence of dorsal respiratory openings (stomata); compound-type eyes; long flagellate, multisegmented antennae; and long thin legs with multisegmented tarsi. The trunk has 15 leg-bearing segments but only seven terga. The most familiar member of the order is the common house centipede, *Scutigera coleoptrata*, a species native to southern Europe but accidentally introduced to North America and elsewhere (**Fig. 1**).

Pleurostigmophora. In contrast to the Notostigmophora, the subclass Pleurostigmophora have lateral respiratory openings (or spiracles) and long, branching tracheae similar to those of the insects. Four orders are recognized: Lithobiomorpha (about 1075 species described thus far), Craterostigmomorpha (1 species), Scolopendromorpha (about 810 species), and Geophilomorpha (about 1290 species).

Lithobiomorpha and Craterostigmomorpha. The Lithobiomorpha share some primitive traits with the Scutigeromorpha, with which they were allied in some old classifications: both are anamorphic, have 15 leg-bearing trunk segments, and are rapid runners. However, members of Lithobiomorpha differ in having a flattened rather than globular head, ocelli (if present) rather than compound eyes, shorter antennae, and, mostly, two-segmented tarsi. The majority of these centipedes are rather small in size, attaining a length of up to only 4 cm (1.6 in.). Although the order is typically temperate in distribution, there are a few mainly tropical or subtropical groups; only a few species are exclusively tropical.

The order Craterostigmomorpha, represented by a single known species inhabiting Tasmania and New Zealand, resembles the Lithobiomorpha in having 15 leg-bearing segments with associated sternites; they differ, notably, in possessing 21 tergites and large, peculiar poison claws.

Scolopendromorpha. The Scolopendromorpha (**Fig. 2**) are the most abundant centipedes in the tropics, where the order exhibits its greatest diversity. They also include the largest centipedes, some of which reach a length close to 30 cm (128 in.). There are also many species, of smaller size, in the temperate zone. The order is divisible into three families: the Scolopendridae, which possess eyes, and the Cryptopidae and Scolopocryptopidae, which are blind.

Geophilomorpha. The Geophilomorpha (**Fig. 3**) represent the most specialized of all centipedes. All are dorsoventrally flattened, and their bodies are long and pliable, permitting them to squeeze through tight openings. All geophilomorphs are blind. The spiracles occur as an unbroken series from the second through the last or next-to-last leg-bearing segment. Unlike most other chilopods, which are voracious hunters that emerge at night to seek their prey in the open, the geophilomorphs are generally found in crevice-cranny habitats; they are adapted to the special requirements of life in the soil, living in the close confines of leaf litter. Chimaeriformes

The only extant order of the chondrichthyan subclass Holocephali, and the closest living relatives of the Elasmobranchii (sharks and rays). The chimaeriformes (ratfishes) are a distinctive group of marine fishes that mostly inhabit the deeper parts of the world's oceans, especially in the Atlantic and Pacific. Some species move to coastal waters during the winter months, and a few species may be restricted to these environments. Modern ratfishes are divided into three families, distinguished by the shape of the snout: Chimaeridae, Rhinochimaeridae, and Callorhinchidae. *See* CHONDRICHTHYES.

Morphology. Molecular sequence data and anatomical similarities (such as a cartilaginous and superficially calcified internal skeleton, urea retention mechanism, and clasper organs in the male for internal fertilization) show that chimaeriform fishes and elasmobranchs are more closely related to each other than to any other vertebrate groups. Unlike the elasmobranchs, however, chimaeriforms have the upper jaw fused to the braincase (holostylic condition); a hyoid arch that is not involved in jaw suspension; four gill slits opening into a common outer chamber covered by an opercular skinfold, with a single branchial opening on each side of the head and no spiracle in the adult; massive dental plates instead of individual teeth, with special zones of hard tissue (tritors) separated by softer dentine; a persistent and unconstricted notochord; several ringlike centra per body segment instead of a single one (polyspondylous condition); a narrow, tapering tail; and a dorsal fin with a long, barbed spine just behind the head (**Fig. 1**). A special cartilage (synarcual) connects the back of the braincase to the dorsal fin, and muscles are capable of raising the dorsal fin and its spine (Fig. 1 and **Fig. 2**). The clasper organ (Fig. 2) in males is supplemented by an anterior structure called a tenaculum, which is thought to play a role in copulation, display, or courtship. There is also a large hooklike frontal "clasper" on the head, which may play a similar role. *See* ELASMOBRANCHII. John G. Maisey

Fig. 3. Modern chimaeriform *Hydrolagus colliei* (spotted ratfish). (*Photo © by Joseph Dougherty/www.ecology.org*)

Extant forms. About 31 living species of ratfishes are categorized into six genera and three families, which can be readily distinguished as follows:

Callorhynchidae (plownose chimaeras). The four species in one genus of these chimaeras have an elongate, flexible snout with a hooklike process at the end. They occur in the Southern Hemisphere, off the southern shores of South America, Africa, New Zealand, and Australia.

Chimaeridae (shortnose chimaeras or ratfishes). This family consists of two genera and about 21 species that are known from the Atlantic and Pacific oceans. They have a short, rounded snout and long tapering ratlike tail (**Fig. 3**). The sharp dorsal spine has associated with it a poison gland that produces venom painful to humans.

Rhinochimaeridae. The three genera and six species of this family are similar to the shortnose chimaeras but differ in having a long and pointed snout lacking a hooklike process. They are known from the Atlantic and Pacific oceans, as well as the Indian Ocean off southern Africa.

Most chimaeras feed on mollusks and crustaceans and occasionally on smaller fishes. Herbert Boschung

Fossil record. The fossil record of the chimaeriforms shows that essentially modern forms were present in the Middle Jurassic (175–150 million years ago, ma). Even earlier chimaeriform-like fishes from the Devonian, Carboniferous, and Permian periods (375–250 ma) reveal a surprising variety of morphological diversity, suggesting that they occupied a wide range of exclusively marine habitats (there is no evidence of nonmarine forms). Some had rows of blunt teeth arranged across the jaws (as in sharks) instead of dental plates, while others had continuously growing, curved tooth plates (although these lack the complexity of modern chimaeriform dental plates and do not have tritors). In some, the jaws were not fused to the braincase, as in modern chimaeroids. Many were armored with bonelike plates in the skin, especially around the head. For this reason, it was once thought that chimaeriforms were related to some group of placoderms, although their "armor" is very different in form and structure and the similarities between them are probably either convergent, or represent primitive features of jawed vertebrates generally. Importantly, no placoderms are known to possess the unique features of chimaeriforms. *See* CARBONIFEROUS; DEVONIAN; JURASSIC; PERMIAN; PLACODERMI.

Evolution. The main line of chimaeriform evolution apparently began in the Late Devonian (375 ma). Many spectacular discoveries of chimaeriform-like fossils have been made in the Lower Carboniferous Bear Gulch Limestone of Montana (325 ma). These fossils suggest that several distinctive holocephalan lineages radiated during the late Paleozoic, but only one (Chimaeroidei) survived to the present day. *See* PALEOZOIC.

Two Paleozoic holocephalan orders of particular importance are the Cochliodontiformes and Menaspiformes. These are considered to be successive extinct sister groups to the Chimaeriformes, with which they share one to three pairs of tooth plates. Cochliodontiformes (Late Devonian to Late Permian; worldwide) are mostly known from isolated tooth plates, but complete fossils from Bear Gulch show they had a variety of body forms (Fig. 1). Many cochliodontiforms had a dorsoventrally flattened body; paired mandibular and occipital spines; paired, brushlike frontal spines on either side of the mouth; and "bradyodont" teeth with curved or rounded surfaces, usually with grooves or folds, and multiple small anterior tooth plates in the upper jaw plus two larger posterior tooth pairs in the upper and lower jaws. The branchial arches did not always lie beneath the head as in modern chimaeriforms, but were sometimes behind the head as in elasmobranchs. Some cochliodontiforms lacked a synarcual or dorsal fin, although most had both. Menaspiformes (Early Carboniferous to Permian; North America and Europe) had two pairs of large sickle-shaped frontal or cephalic spines anterior to the orbits, several large dermal "plates" (actually fusions of numerous small tesserae) on the top and sides of the head, holostylic jaws set a distinct angle to the body axis, with the lower jaw rami diverging at about 90°; thin tooth plates, a single pair of lower tooth plates plus anterior teeth at the midline; paired and extremely robust "prepectoral" or "mandibular" spines; a two-part synarcual but no dorsal fin or spine; a complex pattern of dermal scutes, often coalescing to form armor plates; and two rows of enlarged scales on the dorsal part of the trunk (**Fig. 4**).

The order Chimaeriformes includes four suborders: Echinochimaeroidae (Early Carboniferous; North America), Squalorajoidei (Early Jurassic; Europe), Myriacanthoidei (Late Triassic–Late Jurassic; Europe), and Chimaeroidei (Jurassic–Recent, worldwide). Until quite recently, no chimaeriforms were known before the Triassic, but the discovery of *Echinochimaera* in the Bear Gulch Limestone of Montana dramatically extended the stratigraphic

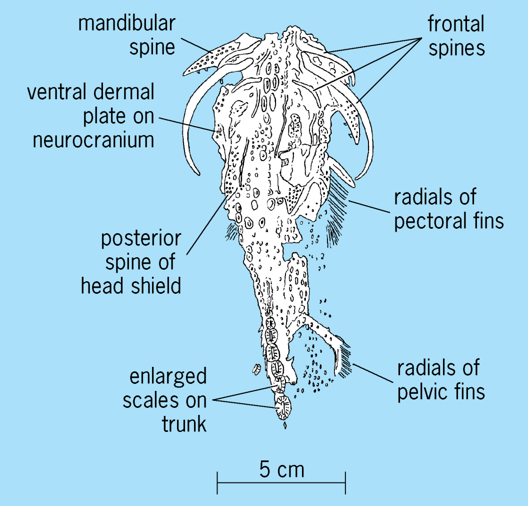

Fig. 4. Permian menaspiform *Menaspis*, dorsal view. (*After C. Patterson, The phylogeny of the chimaeroids, Phil. Trans. Roy. Soc. London, 249:101–219, 1965*)

range of the group (Fig. 2). *Echinochimaera* was remarkably modern in appearance, with a tenaculum and tooth plates (although these lack continuous tritors), but it retained a well-developed second dorsal fin instead of having a narrow, ribbonlike tail. Myriacanthoids resembled modern chimaeriforms in having tritors on at least some tooth plates, polyspondylous ring centra, reduced dermal armor, a single barbed dorsal spine attached to a movable dorsal fin, and a large frontal clasper on the head. Chimaeroids (including modern ratfishes) possess well-developed dental plates, all with specialized tritors; a laterally flattened head; and an ethmoidal canal (an enclosed space in the skull roof above the brain). Apart from the tritors, however, it is unknown whether these characters were also present in other chimaeriforms.

Chimera

An individual animal or plant made up of cells derived from more than one zygote or otherwise genetically distinct.

Animals

Although some chimeras do arise naturally, most are produced experimentally by mixing cells of very early embryos or by tissue grafting in late embryos or adults. Experimental chimeras have been used to study a number of biological questions, including the origin and fate of cell lineages during embryonic development, immunological self-tolerance, tumor susceptibility, and the nature of malignancy. *See* CELL LINEAGE.

Mixing embryo cells. Two techniques used to form chimeras by mixing embryo cells are aggregation and injection.

Aggregation chimeras. The first experimental mammalian chimeras were produced from mouse embryos in the early 1960s, first by Andrei Tarkowski and later by Beatrice Mintz. The technique involves removing the zonae pellucidae from around 8–16 cell embryos of different strains of mice and pushing the morulae together so that the cells can aggregate. After a short period of laboratory culture, during which the aggregate develops into a single large blastocyst, the embryo is returned to a hormone-primed foster mother (**Fig. 1**). Chimeric offspring are recognized in several ways. If derived from embryos of pigmented and albino strains, they may have strips of pigmented skin and patches of pigment in the eye. Internal chimerism can be detected by use of chromosomal markers or genetically determined enzyme variants. Chimeras accept skin grafts from the two component strains but reject grafts from third-party strains. Aggregation chimeras formed from embryos of strains A and B are denoted A ↔ B, and chimeras developing from two embryos are often known as tetraparental animals. Up to 15 mouse embryos have been aggregated to form a single giant blastocyst. However, the offspring from such experiments are always normal, so that size regulation must occur after implantation. On average, 50% of aggregation

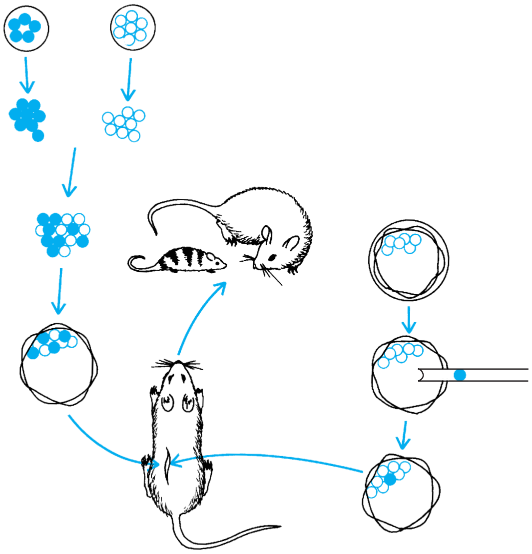

Fig. 1. Techniques for making aggregation chimeras (left) and injection chimeras (right) from early mouse embryos.

chimeras will be XX ↔ XY. Sex determination seems to depend on the relative number of XX and XY cells in the fetal gonads, and in mice most of these animals develop into phenotypic males.

Injection chimeras. This technique was first described for mouse embryos by Richard Gardner in 1968. A blastocyst of the host mouse strain is removed from its zona pellucida and held on a suction pipette. Cells of the donor strain are injected through a fine glass needle, either into the blastocoele cavity or into the center of the inner cell mass (the group of cells from which the fetus is derived). After a short period of culture, the blastocyst is returned to a foster mother. By analogy with aggregation chimeras, injection chimeras are denoted A ↔ B and are recognized by similar, genetically determined markers (pigment formation, and enzyme, serum, and urinary protein variants). A variety of cells have been injected into blastocysts in this way. Cells from adults fail to either grow or become incorporated into the fetus. Early-cleavage-stage embryos injected into the cavity of giant blastocysts (formed by aggregating several embryos in culture as described above) develop inside their zonae into "blastocysts within blastocysts." In contrast, individual cells or groups of cells isolated from embryos of about the same age as the host become incorporated into the host embryo and grow and differentiate along with it. By taking appropriately marked cells from different positions in the donor embryo, placing them in different positions in the host blastocyst, and following their contribution to the late-gestation embryo or adult, important information was obtained about cell interactions and lineages in mouse development.

Another kind of cell—the pluripotent stem cell of mouse teratocarcinomas—was found to give rise to normal tissues in adult chimeras after injection into the mouse blastocyst. Teratocarcinomas are tumors consisting of a disorganized mixture of adult and embryonic tissues. They develop spontaneously from germ cells in the gonads of certain mouse strains, or from cells in early embryos transplanted to ectopic sites. All the differentiated tissues in the tumor arise from pluripotent stem cells known as embryonal carcinoma (EC) cells. When embryonal carcinoma cells are injected into a genetically marked host blastocyst, they continue to divide and participate in normal development, and give rise to fully differentiated cells in all tissues of the adult, including skin, muscle, nerve, kidney, and blood.

Embryonal carcinoma cells from several sources, including spontaneous and embryo-derived tumors and cultured lines selected to carry specific mutations or even human chromosomes, have contributed to normal chimeras. However, embryonal carcinoma cells from some other sources fail to integrate, but produce teratocarcinomas in the newborn animal or adult. The factors controlling successful integration are not yet fully understood, but must include such things as the relative division rate of the embryonal carcinoma cells, their biochemical similarity to cells of the inner cell mass, and their chromosomal constitution. On general grounds, embryonal carcinoma cells should be expected to give rise also to fully functional germ cells, so that EC → blastocyst chimeras might be used to generate nonchimeric mice carrying specific mutations. The fact that certain embryonal carcinoma cells give rise to tumors when injected under the skin or into the body cavity but behave normally in the blastocyst has been used to support the idea that cancers can develop not only as a result of gene mutations but also as a result of disturbances in environmental factors controlling normal cell differentiation (epigenetic theory of cancer). *See* ONCOLOGY.

Interspecies chimeras. A number of interspecies chimeras have been produced by aggregating sheep and goat embryos and reimplanting them in sheep. The offspring have tissues containing a mixture of both sheep and goat cells. The goat, for example, may have patches of both wool and hair. Interspecies chimeras have also been made between rat and mouse, but these do not develop in the uterus, presumably because of immunological rejection by the foster mother. This rejection does not occur in sheep for unknown reasons.

Tissue grafting. Animals that have accepted skin or organ grafts are technically chimeras. Radiation chimeras are produced when an animal is exposed to x-rays, so that blood-forming stem cells in the bone marrow are killed and then replaced by a bone marrow transplant from a genetically different animal. Lymphoid cells in the process of differentiating from stem cells in the donor marrow recognize the recipient as "self" and do not initiate an immune response against the host cells. By removing the thymus from the irradiated host and replacing it with a thymus from another animal prior to the bone marrow transplant, it has been shown that this organ plays an important role in the generation of immunological self-tolerance. *See* TRANSPLANTATION BIOLOGY.

Natural occurrence. Naturally occurring chimeras in humans are rare and are most easily recognized when some cells are XX and others XY. Such individuals are usually hermaphrodite and probably result from fertilization of the egg by one sperm and the second polar body by another, with both diploid cells then contributing to the embryo (the small polar bodies normally degenerate). Blood chimeras are somewhat more common in animals such as cattle where the blood vessels in placentas of twins fuse, so that blood cells can pass from one developing fetus to the other. The female sibling of male and female cattle twins is sterile (a freemartin), because sex hormones from the male fetus interfere with sexual differentiation in the female. Blood chimerism always occurs in marmosets, which produce twins at most pregnancies, but no abnormalities in sexual function are found.

Brigid Hogan

Plants

In modern botanical usage a chimera is a plant consisting of two or more genetically distinct kinds of cells. Chimeras can arise either by a mutation in a cell in some part of the plant where cells divide or by bringing together two different plants so that their cells multiply side by side to produce a single individual. They are studied not only because they are interesting or ornamental but also because they help in understanding many developmental features of plants that would otherwise be difficult to investigate.

Grafting. The first type of chimera to be used in this way resulted from grafting. Occasionally a bud forms at the junction of the scion and stock, incorporating cells from both; sometimes the cells arrange themselves so that shoots derived from the bud will contain cells from both plants. A plant of this kind is *Laburnocytisus adami*, formed in 1825 by grafting *Cytisus purpureus* onto *Laburnum anagyroides*. The flowers are brown instead of the purple or yellow of the scion and stock. It has the treelike habit of *Laburnum*; its leaves resemble those of *Laburnum* except for the surfaces, which are like those of *Cytisu*; and its seeds always grow into *Laburnum* trees. Occasionally a branch grows out wholly like *Laburnum* or, more rarely, wholly like *Cytisus*. *See* PLANT PROPAGATION.

At first people thought that *Laburnocytisus* and other similar plants derived from grafting must have been nonsexual hybrids, the result of fusing two somatic cells, but there was no evidence that this could occur and result in viable hybrid cells. The occasional reversion to pure *Laburnum* or *Cytisus* branches and the fate of their seeds militated against this theory.

Further investigation showed that the plant consists of a skin of *Cytisus* cells overlying a core of *Laburnum* cells (**Fig. 2**). The skin is only one cell deep, and the flowers appear brown because a purple epidermis covers yellow cells inside the petals. The germ cells which go on to form the embryos in the seeds are always formed from the second layer of the shoot and so always produce *Laburnum* plants. Reversions are due to some buds being formed wholly from the *Cytisus* skin or by the *Laburnum* tissue bursting through the skin in bud formation.

Apical meristem. *Laburnocytisus adami* has been synthesized only once, and all the specimens in existence have been propagated vegetatively from the original. This implies great stability in the constitution of the chimera, and for a long while after the plant's origin, no one knew any mechanism whereby a shoot could maintain such a stable arrangement of genetically diverse cells. In attempts to solve this problem, it was discovered that flowering plants have growing points (apical meristems) where the outer cells are arranged in layers parallel to the surface, and that this periclinal layering is due to the fact that the outer cells divide only anticlinally, that is, by walls perpendicular to the surface of the growing point (**Fig. 3**). In many plants there are two outer (or tunica) layers and, because cell divisions are confined to the anticlinal planes, each layer remains discrete from the other and from the underlying nonlayered tissue called the corpus (Fig. 3). The epidermis of leaves, stems, and petals is derived from the outer layer of the growing point, and the discreteness of this layer accounts for the stability of the *Laburnocytisus* chimera. *See* APICAL MERISTEM.

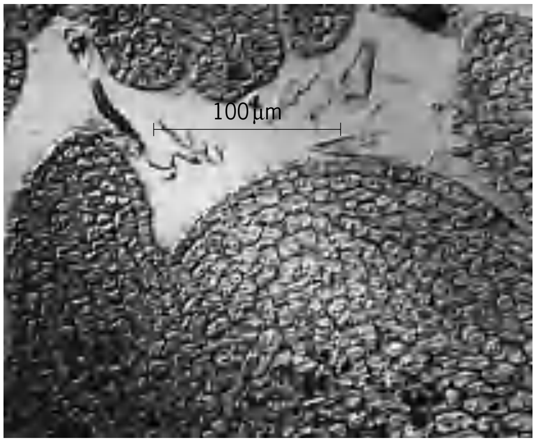

Fig. 2. Section through growing point of *Laburnocytisus adami*.

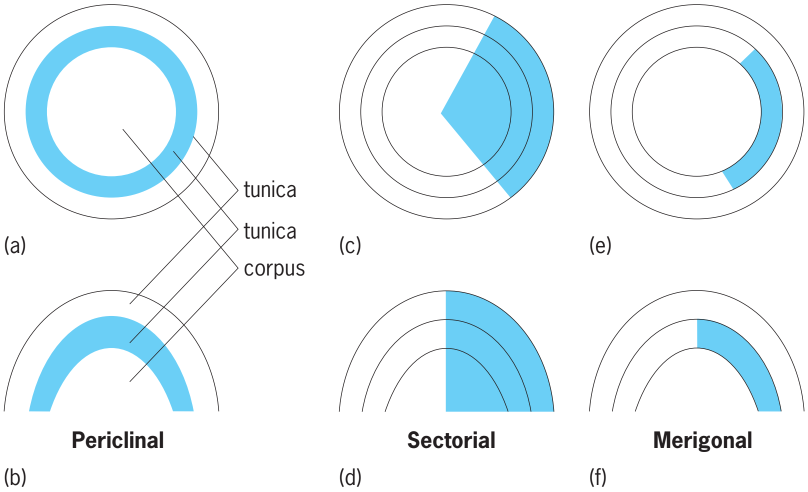

Fig. 3. The two tunica layers and one corpus layer with the three types of chimeras, (*a, b*) periclinal (*c, d*) sectorial, and (*e, f*) merigonal.

An elegant proof of the existence of these self-perpetuating layers in apical meristems came with the synthesis of polyploid chimeras in *Datura* and *Vaccinium*. This was done by treating the embryos or buds with colchicine, a drug that causes nuclei which divide in its presence to double their chromosome number. Since these tetraploid cells and their progeny are larger than ordinary diploid cells, they can be identified in sections cut through the growing point. After the treated meristems had been allowed to grow and produce lateral buds, the buds were sectioned and each tunica layer was seen to contain only cells with the same ploidy; but one layer often consisted of cells of a different ploidy from the other tunica layers and from the corpus. The exclusively anticlinal divisions of the tunica layers clearly prevent the mixing of cells of different ploidy and prevent the chimera from becoming unstable from competition between the cells of different ploidy.

Periclinal chimera. A periclinal chimera has genetically different layers (Fig. 3*a* and *b*). With this type

Fig. 4. Variegated *Pelargonium*, a periclinal chimera whose second tunica layer is genetically white and whose corpus is genetically green.

of chimera, in which the different cells can be identified under the microscope by their relative sizes, it is possible to follow into stems, leaves, and flowers which tissues are derived from each layer in the growing point. For leaves, this can also be done with variegated chimeras, a type of periclinal chimera in which the genetic difference between the cells resides in the plastids due to a mutation that prevents the synthesis of chlorophyll. Tracts of cells whose plastids lack this pigment appear white or yellow instead of green.

A common form of variegated chimera has leaves with white margins and a green center (**Fig. 4**). The white margin is derived from the second layer of the tunica, and the green center from inner cells of the growing point. (The outer tunica layer contributes no color to the leaves of most plants, because it gives rise only to the epidermis, whose cells usually do not develop chloroplasts.) The white leaf tissue overlies the green in the center of the leaf but does not mask the green color. Chimeras with green leaf margins and white centers are usually the result of a genetically green tunica proliferating abnormally at the leaf margin in an otherwise white leaf (**Fig. 5**).

Periclinal chimeras can be used to study the fate of different regions of the growing point, and how the leaves and so forth are constructed; but chimerical plants sometimes do not behave exactly like nonchimerical plants. Nevertheless, they have supplied valuable evidence, sometimes the only evidence, on which to base a view on some developmental problems. Chimeras show, for example, that there is considerable diversity in the number of layers that go to make each kind of organ, and this affects ideas about the homology of different organs.

Sectorial chimera. Since the somatic mutation that initiates most variegated and polyploid chimeras would normally occur in a single cell of a growing point or embryo, it often happens that it is propagated into a tract of mutant cells to form a sector of the plant (Fig. 3*c* and *d*). If the mutation resulted in a failure to form green pigment, the tract would be seen as a white stripe. Such chimeras are called sectorial, but they are normally unstable because there is no mechanism to isolate the mutant sector and, in the flux that occurs in a meristem of growing and dividing cells, one or other of the two sorts of cells takes over its self-perpetuating layer in the growing point. The sectorial chimera therefore becomes nonchimerical or else a periclinal chimera.

Mericlinal chimera. However, in one class of chimeras an isolating mechanism can stabilize the sectorial arrangement (Fig. 3*e* and *f*). This propagates stripes of mutant tissue into the shoot, but because the tunica and corpus are discrete from each other, the plant is not fully sectored and is called a mericlinal chimera.

Many chimeras of this type have a single tunica layer; those with green and white stripes in the leaves have the mutant cells in sectors of the corpus. It was not until C. Thielke tried to find the reason why these chimeras are stable that attention was directed to the fact that they are always plants with leaves in two

Fig. 5. Variegated *Chlorophytum*, a periclinal chimera whose outer cell layer is genetically green and proliferates at the leaf margins to give green tissue in an otherwise genetically white plant.

ranks, and consequently the lateral growth of the growing point occurs by cell expansion only in the plane connecting alternate leaves. This results in the longitudinal divisions of the corpus cells being confined to planes at right angles to the plane containing the leaves. A mutation in one cell therefore can result in a vertical sheet of mutant cells which, in the case of a plastid defect, manifests itself as a white stripe in every future leaf. Transverse sections through the bud confirm that the cells behave as predicted.

Eversports. The eversport is a special type of chimera mainly found in gymnosperms, in which a shoot becomes partially green and partially yellow at a high frequency of about 1 in every 25 nodes. It comes from a periclinal chimera with a single yellow tunica and a green corpus that becomes yellow. This change was explained by H. Derman as coming from a "replacement" periclinal cell division of the topmost cell of the tunica, with one yellow daughter cell remaining in the tunica and the lower yellow daughter cell becoming part of the corpus. This new yellow corpus cell and preexisting green corpus cells proliferate into a partially yellow and partially green corpus, thus seen as a green-yellow chimera (**Fig. 6**).

Recent studies have shown that most eversporting green-yellow chimeras in gymnosperms and dicots eventually become all yellow, leading to the conclusion that the apical meristem has a single apical cell in the top tunica layer similar to what is found in mosses and ferns. Eversports have also been used to understand which regions of a stem give rise to a node and which cells of this nodal region give rise to a leaf.

Roots. The growing points of roots may also become chimerical, but in roots there is no mechanism to isolate genetically different tissues as there is in shoots, and so chimeras are unstable. However, there can be sufficient stability to do experiments with induced root chimeras on the destiny of cells.

Cultivated plants. Since the general acceptance of the existence of organisms with genetically diverse cells, many cultivated plants have been found to be chimeras. This knowledge has explained several phenomena hitherto puzzling. In carnations, for example, white flowers have arisen from red varieties due to the red variety being a periclinal white-red chimera whose normal stability was upset. Flecks of color often indicate the chimerical nature of such plants. Color changes in potato tubers occur similarly because the plants are periclinal chimeras. *See* SOMATIC CELL GENETICS. F. A. L. Clowes; Robert W. Korn

Fig. 6. Eversporting false sawara cypress. Numerous mutant (arrows) green-yellow chimeras are present, most of which become stable mutant shoots.

Tilney-Bassett, *Plant Chimeras*, 1986.

Chimney

A vertical hollow structure of masonry, steel, or reinforced concrete, built to convey gaseous products of combustion from a building or process facility. A chimney should be high enough to furnish adequate draft and to discharge the products of combustion without causing local air pollution. The height and diameter of a chimney determine the draft.

Construction specifications. For adequate draft, small industrial boilers and home heating systems depend entirely upon the enclosed column of hot gas. A draft is produced because the density of the hot gas inside is lower than that of the air outside. In contrast, stacks, which are chimneys for large power plants and process facilities, usually depend upon force-draft fans and induced-draft fans to produce the draft necessary for operation, and the chimney is used only for removal of the flue gas. Some stacks burn off the gases at the top and are known as flarestacks. *See* FAN.

For fire safety, chimneys for residential construction and for small buildings must extend at least 3 ft (0.9 m) above the level where they pass through the roof and at least 2 ft (0.6 m) higher than any ridge within 10 ft (3 m) of them. Some stacks extend as high as 500 ft (150 m) above ground level, thus providing supplementary natural draft.

A chimney or stack must be designed to withstand lateral loads from wind pressure or seismic forces (earthquakes), as well as vertical loads from its own weight. Wind pressure on a cylindrical surface is about two-thirds that on a plane surface. Thus with a wind pressure of 30 lb/ft^2 (1440 newtons/m^2), the pressure per foot of chimney height is 20 times the diameter, in feet, of the chimney (the pressure in newtons per meter of height is 960 times the diameter in meters). Depending upon geographical location, horizontal inertia loads due to an earthquake can be as high as 35% of the weight of the chimney and can result in greater overturning moments and bending stresses than wind loading. *See* LOADS, DYNAMIC.

Construction materials. Small chimneys used in residential construction are commonly made of brick or unreinforced masonry, while stacks are usually made of steel. In the early 1900s it was generally more economical to construct tall chimneys from masonry or reinforced concrete. However, modern construction costs for tall chimneys favor the use of steel since it allows for more rapid fabrication and erection compared with masonry or reinforced concrete. Where flue gases are particularly corrosive to steel, castable or masonry linings or corrosion-resistant steels (stainless) are often used; or the stack is designed with a corrosion allowance. Sometimes a steel stack has a double steel shell, consisting of concentric cylinders with an air space between the two. The inner shell serves mainly to convect the gases, while the outer shell withstands the wind or seismic loads. *See* REINFORCED CONCRETE; STAINLESS STEEL; STEEL.

Tall steel chimneys of small diameter cannot economically be made self-supporting and must be guyed. Where land costs are at a premium or where land is not available for guying, such as at congested process facilities, it is often more economical to support slender steel stacks with a derrick-type structure of steel latticed or trussed construction as opposed to constructing a self-supported stack. Modern steel stacks are usually shop welded into sections, which are then assembled in the field by flange bolting or welding. *See* JOINT (STRUCTURES); TRUSS.

Concrete chimneys may be plain or reinforced. If the bending moment due to wind or seismic forces on concrete chimneys does not produce excessive tension on the leeward side, reinforcing is unnecessary. To prevent temperature cracking, some plain concrete stacks have a fire-clay lining with an air space between the lining and the outer shell. Masonry or concrete linings are often used in construction of concrete chimneys, resulting in a chimney within a concrete chimney. The outer chimney withstands the lateral loads from wind or earthquake, and the inner one withstands the thermal loads and the acid attacks.

Except for rectangular flues and chimneys commonly used in residential construction, masonry chimneys are usually constructed of perforated radial brick molded to suit the diameter of the chimney. Because the compressive strength of the brick is much greater than that of the mortar, the design strength is determined by the tensile strength of the mortar. Unlike its steel or reinforced counterpart, a brick chimney cannot resist high tensile stresses. *See* BRICK; MASONRY; MORTAR.

Accessory structures. Tall chimneys and stacks, particularly flarestacks, are usually provided with a ladder and rest platforms to allow for inspection and maintenance. Safety regulations require either a cage around the ladder, which increases wind loading, or a safety climb device attached to the ladder to prevent a fall.

Tall stacks are usually fitted with some form of lightning protection and are always grounded at the base. Depending upon the lightning activity in a particular area, a tall stack may be fitted with a lightning dissipator at the top with a special copper line to ground to prevent static buildup and lightning strikes. *See* LIGHTNING AND SURGE PROTECTION.

Cylindrical stacks are subject to a phenomenon known as Kármán vortex oscillations due to the alternating vortices that are shed from opposite sides of the cylinder during gentle winds. Masonry (or gunite-lined stacks) and guyed stacks are generally not susceptible to this phenomenon, because the stack damping ratio is raised in the presence of an internal lining or guying, which tends to abate the buildup of oscillations from the Kármán vortex street. For unlined, self-supported, steel stacks, vortex oscillations are usually controlled by adding strakes or fins to the top third of the stack to spoil the airflow. *See* KÁRMÁN VORTEX STREET.

Foundations. Foundations for tall stacks and chimneys are made from reinforced concrete and are usually octagonal. For very soft soils, the foundation strength is augmented by piles. The design of the foundation is controlled almost entirely by the overturning moment from wind or seismic forces. *See* FOUNDATIONS; PILE FOUNDATION.

Joseph Vellozzi

Chinchilla

The name given to two species of rodents which, together with four species of viscachas, make up the family Chinchillidae. These animals are native to several areas of South America and are widely bred on farms in North America and Europe for their fur, which is long, fine, and expensive. The wild population is protected in Chile since the killing of wild stocks in the early 1900s almost led to extinction.

Species. The two species of chinchilla are *Chinchilla brevicaudata* and *C. lanigar*. These animals resemble the squirrel in size and shape and are characterized by long, muscular hindlimbs, with elongate feet bearing four toes, and short forelimbs (see **illus.**). Blunt claws occur on the flexible fingers. These animals have 20 teeth with a dental formula of I 1/1 C 0/0 Pm 1/1 M 3/3. *See* DENTITION.

Chinchillas are gregarious, nocturnally active animals and are found in arid, mountainous regions where they feed principally on vegetation. They often seek shelter in burrows or rock crevices, so

The chinchilla, with more hair per square inch than any other animal, is valued for its fur.

that their capture is difficult. The female, which is larger than the male, bears one to six offspring twice each year after a gestation period of 105–111 days.

Viscacha. There are four species of viscacha belonging to two genera, *Lagidium* (three species) and *Lagostomus*. The mountain viscacha (*Lagidium viscaccia*) lives in burrows near rocks in the foothills of the Andes. It is larger than the chinchilla and has a poor-quality fur, which is woven with wool into cloth. The plains viscacha (*Lagostomus maximus*) inhabits burrows in the pampas region of Argentina. It has coarse fur and is exclusively herbivorous. *See* RODENTIA.

Charles B. Curtin

Chinook

Amild, dry, extremely turbulent westerly wind on the eastern slopes of the Rocky Mountains and closely adjoining plains. The term is an Indian word which means “snow-eater,” appropriately applied because of the great effectiveness with which this wind reduces a snow cover by melting or by sublimation. The chinook is a particular instance of a type of wind known as a foehn wind. Foehn winds, initially studied in the Alps, refer to relatively warm, rather dry currents descending the lee slope of any substantial mountain barrier. The dryness is an indirect result of the condensation and precipitation of water from the air during its previous ascent of the windward slope of the mountain range. The warmth is attributable to adiabatic compression, turbulent mixing with potentially warmer air, and the previous release of latent heat of condensation in the air mass and to the turbulent mixing of the surface air with the air of greater heat content aloft.

In winterthe chinook wind sometimes impinges upon much colder stagnant polar air along a sharp front located in the foothills of the Rocky Mountains or on the adjacent plain. Small horizontal oscillations of this front have been known to produce several abrupt temperature rises and falls of as much as 45–54°F (25–30°C) at a given location over a period of a few hours. Damaging winds sometimes occur as gravity waves, which are triggered along the interface between the two air masses.

In the Alpine regions adverse psychological and physiological effects have been noted in humans during prolonged periods of foehn wind. These phenomena have been referred to as foehn sickness. *See* FRONT; ISENTROPIC SURFACES; PRECIPITATION (METEOROLOGY); WIND; WIND STRESS.

Frederick Sanders; Howard B. Bluestein

Chipmunk

The common name for any of 25 species of rodents in the genus *Tamias* of the mammalian family Sciuridae. Chipmunks have bright and dark stripes, large cheek pouches, and live mainly on the ground (see **illustration**). They are found primarily in forested areas in many regions of North America, south to west-central Mexico, as well as in Siberia, Mongolia, and northern and central China. The two species with the widest distribution in North America are the eastern chipmunk (*Tamias striatus*) and the least chipmunk (*T. minimus*). For the most part, the appearance and ecology of all 25 species is similar. *See* MAMMALIA; RODENTIA.

Eastern chipmunk. The eastern chipmunk is a small, fairly stout-bodied, terrestrial squirrel with five conspicuous dark dorsal stripes, a flattened and hairy tail, and large, well-developed cheek pouches. Overall dorsal coloration is tawny or reddish-brown. On each side, a broad whitish longitudinal stripe is bordered by two dark stripes. Two buff stripes are present above and below each eye. The ears are prominent and rounded. Adults are usually 200–255 mm (8.5–10 in.) in total length, including a 75–100-mm (3–4-in.) long tail, and weigh 70–140 g (2.5–5 oz).

Eastern chipmunks live in deciduous forests and brushy areas, especially near broken rocky ground, stone fences, and fallen logs. Although they spend most of their time on the ground, they occasionally climb up stumps or trees to feed or to escape an enemy. (Predators include snakes, weasels, mink, hawks, and domestic cats.) Hearing, sight, and smell are well developed in these solitary and diurnal mammals.

Habitat and hibernation. Chipmunks dig their own burrows, which provide living chambers (including a nest) and a place to store food. They become less active during the hotter summer months and hibernate during the colder winter months. Even though they hibernate, they do not store fat (as do other

Representative species of chipmunk (*Tamias*).

hibernators), so they must awaken periodically to eat. Home ranges are 0.10 to over 1.2 ha (0.04–0.5 acre), depending upon the quality of the habitat and population density. They prefer open-understory and closed-overstory habitats. Home ranges overlap broadly.

Diet. Chipmunks are chiefly vegetarians, feeding mainly on the seeds (including nuts) of woody plants. Corn, wheat, berries, and mushrooms are also eaten along with an occasional earthworm, snail, insect, frog, small snake, bird, and mouse. The large internal cheek pouches greatly assist in transporting food to underground storage chambers or to other cache sites in hollow logs or beneath rocks.

Reproduction and development. Two breeding periods may occur annually in eastern chipmunks, whereas western species have only one breeding season per year. Litters of three to five young are born after a gestation of 31 days. Young chipmunks leave the burrow for the first time at 5 to 6 weeks of age and are probably weaned before they are 40 days old. They are sexually mature at about 3 months, but most do not breed for the first time until they are one year old. Life span in the wild is usually between 2 and 4 years.

Donald W. Linzey

Bibliography. D. W. Linzey, *The Mammals of Virginia*, McDonald & Woodward, 1998; R. M. Nowak, *Walker's Mammals of the World*, 6th ed., Johns Hopkins University Press, 1999; D. E. Wilson and S. Ruff (eds.), *The Smithsonian Book of North American Mammals*, Smithsonian Institution Press, 1999.

Chiroptera

An order of mammals, commonly known as bats, in which the front limbs are modified as wings, thus making the chiropterans the only truly flying mammals. Bats form the second largest order of living mammals (18 families, 202 genera, 1116 species). They range from the limit of trees in the Northern Hemisphere to the southern tips of Africa, New Zealand, and South America, but most species are confined to the tropics. On many oceanic islands they are the only native land mammals. *See* MAMMALIA.

General characteristics. The wing is formed by webs of skin running from the neck to the wrist (propatagium, or antebrachial membrane), between the greatly elongated second, third, fourth, and fifth fingers (chiropatagium), and from the arm and hand to the body (usually the side) and hindlegs (plagiopatagium). There is also usually a web between the hindlegs (uropatagium, or interfemoral membrane) in which the tail, if present, is usually embedded for at least part of its length (**Figs. 1** and **2**).

Size in bats varies greatly and is well characterized by the length of the forearm (Fig. 1). As familiar reference points, the forearm of *Myotis lucifugus* is about 38 mm long (1.5 in.) and of *Eptesicus fuscus* (**Fig. 3**), about 45 mm (1.8 in.).

Most bats have one young per year, a few have two, and still fewer have three or more. This low reproductive rate is possible because of a long lifespan (up to 34 years in one species) and low predation. Bats have very few natural predators. Most predation is by chance encounters, although some predators may learn to wait at the entrance to a roost and capture bats as they emerge.

Bats are useful as pollinators, as distributors of seeds of tropical plants, and as predators of nocturnal insects. Their prey includes, many agricultural pest insects. Also, they help to maintain the balance of nature, as there are very few other nocturnal insect predators. Although the majority of bats are relatively small and feed on insects, there is great variation in their food habits. Bats can be fruit-eating (there are numerous fruit-eating bats—ranging in size up to the flying fox, with a wingspan reaching nearly 1.5 m or 5 ft); blood-feeding (the vampires); carnivorous (feeding on other small vertebrates—birds, mammals, lizards and frogs); and fish-eating.

Most bats (except pteropids) use echolocation to navigate and to capture insects or other food. Echolocation is similar to radar in that a series of clicks is produced. These clicks bounce off objects, including food items, and return as an echo to the bat, indicating the size, speed, and distance of the object. Most insects are captured by bats in flight using echolocation. Bats catch insects in the air with their mouth, wings, or tail membrane. *See* ECHOLOCATION.

Roost types vary greatly, bats may roost in buildings, in cracks or hollows of trees, under sloughing bark, under bridges, in caves or mines, solitary among foliage, in clusters of leaves, in rolled-up leaves, and in other protected places.

Most temperate bats hibernate during winter; they waken about every 2 weeks for a few hours and then reenter hibernation. About 75% of the fat energy stored for hibernation is used during arousals, leaving only about 25% to support bats throughout hibernation.

The 18 living families of bats may be briefly characterized as follows.

Pteropodidae (Old World fruit bats). These are in general the most primitive of living bats, characterized by more primitive ears and shoulder joints, and are the only family placed in the suborder Megachiroptera. The family, with 42 genera and 186 species, is widely distributed in the tropics and subtropics of the Old World, east to Australia and the Caroline and Cook islands. While some species are quite small, the family includes the largest of all bats, with wingspreads up to 5.5 ft (1.5 m) [Fig. 2]. The external ear of Old World fruit bats is elongate and oval, and there is no tragus. Most still retain a claw on the second digit (absent in all other bats, which constitute the suborder Microchiroptera), as well as the claw on the thumb. The teeth, however, are highly modified for eating fruit or nectar. The tail is short and rudimentary, or absent.

Few have developed the echolocation (radar) mechanism found in all Microchiroptera. One genus emits ultrasonic sounds, but most do not. These bats navigate visually. Many make long flights between feeding and roosting areas. They are slow but strong flyers. Many of the larger fruit bats congregate in large groups, whereas the smaller ones are usually solitary. Most Old World fruit bats find their food by smell. Most feed on ripe fruit, crushing the pulp in their teeth and spitting out the seeds. These bats may get food by hovering, or they may hold onto a branch with their feet and press the fruit to their chest with a foot to extract it. They sometimes eat flowers. Although some appear to breed at variable times, most breed at well-defined times. Most produce only one young. Some individuals in captivity have lived up to 20 years.

Rhinopomatidae (mouse or long-tailed bats). This insect-eating family, with one genus and four species, is found chiefly in arid regions of northern Africa and southern Asia and is characterized by long wirelike tails and rudimentary nose leaves (dermal outgrowths of unknown function above the nostrils). The tails of rhinopomatids are nearly as long as the head and body combined, and the tail membrane is very short and narrow. Rhinopomatids have large ears connected by skin across the forehead. The tragus (cartilaginous flap at the notch of the ear, Fig. 1) is well developed but rather small. These bats roost in caves, houses, and rock clefts, and are also found in pyramids of Africa. Some roost in very large colonies.

Emballonuridae (sac-winged bats). This insectivorous family includes 13 genera with 51 species and is found in the tropics of both the Old and New worlds. Like the Pteropodidae, but unlike other families of bats, members of Emballonuridae have well-developed bony processes behind the eye sockets. The tail extends only partly across the uropatagium. There is a great deal of variation in this family, with adults varying in weight from 5 to 105 g (0.18 to 3.7 oz). Members lack a nose leaf, but a tragus is present. The tail goes through the tail membrane and appears on the upper surface.

Members of Emballonuridae are commonly known as sac-winged bats because of their glandular wing sacs that open on the upper surface of the wing near the shoulder. These glands secrete a pungent red substance. The sacs are best developed in males and thus may function as a sexual attractant. If present, the sacs are located in the antebranchial membrane (the skin ahead of the upper arm and forearm) and can be seen by partially extending the wing against a light.

Roosting may occur in caves, buildings, ruins, trees, curled leaves, hollow logs, and rock crevices. Although many species form large colonies, some form smaller colonies, and some species are solitary.

Noctilionidae (bulldog or fish-eating bats). This tropical American family, represented by two species in one genus (*Noctilio*), includes a highly specialized fish-eating species. Fish are detected by echolocation and gaffed by the bats' long-clawed feet. The nostrils open forward and down, and the tubular nose extends slightly beyond the lips. There is no nose leaf. The ears are large and pointed, are separate, and a tragus is present. The tail, as in the Emballonuridae, is present but extends only to about the middle of the tail membrane and then perforates the membrane, with the tip being free. The fish-eating bat *Noctilio leporinus* has long hindlegs and large hindfeet with well-developed claws that are useful for catching fish. The other species in the family, *N. albiventris*, is not as well modified for fishing. *Noctilio* is one

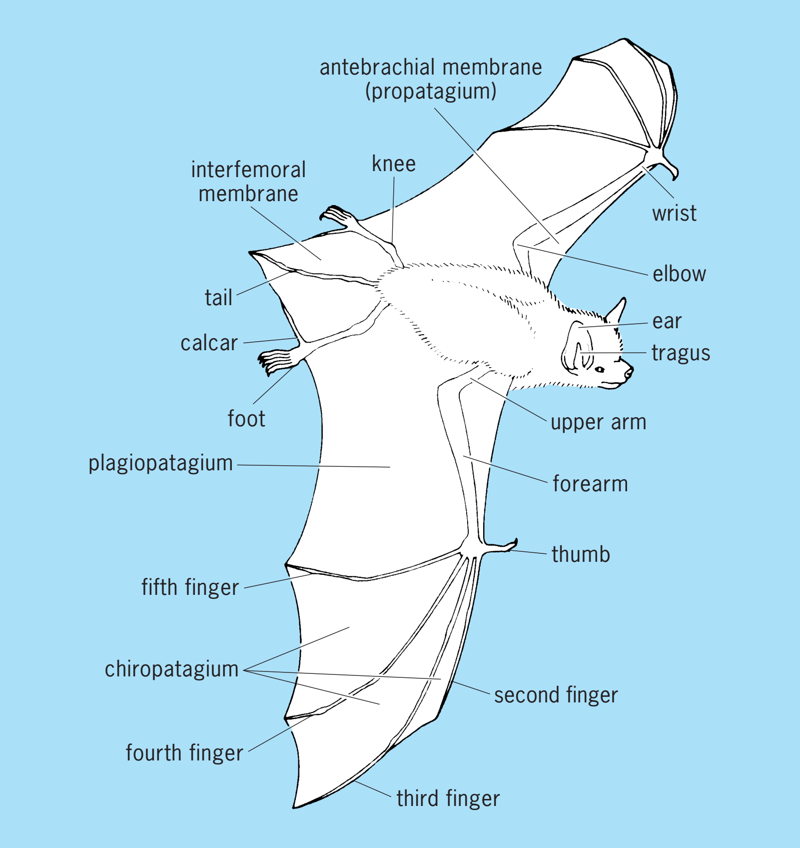

Fig. 1. Anatomical features of bat. (*After R. Peterson, Silently by Night, McGraw-Hill, 1964*)

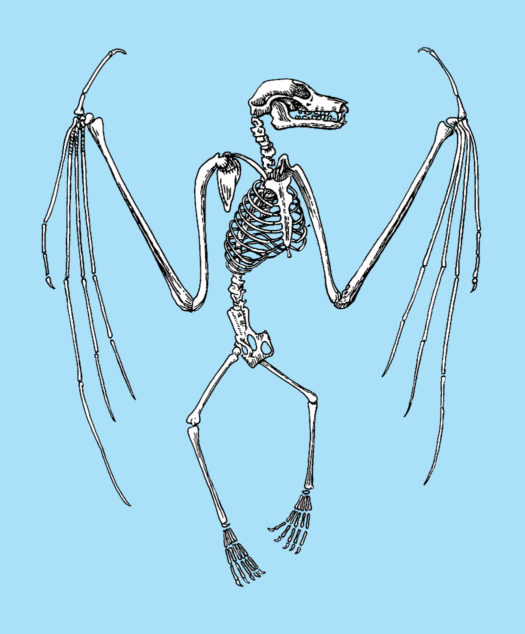

Fig. 2. Skeleton of *Pteropus*, giant fruit bat (lacking tail). (*After R. Peterson, Silently by Night, McGraw-Hill, 1964*)

Fig. 3. *Eptesicus fuscus* (family Vespertilionidae), big brown bat, from Huntington Lake, California. (*Photo by Dr. Lloyd Glenn Ingles; © 1999 California Academy of Sciences*)

of only three genera of bats that feed on fish. The others are *Myotis* (*M. vivesi* and *M. adversus*) and *Megaderma*. *Noctilio leporinus* apparently uses its echolocation to find fishes and then uses its claws to capture them. Besides fish, it will eat aquatic crustaceans, ants, crickets, scarab beetles, and stinkbugs. *Noctilio albiventris* will also eat fish, although this species has been observed using echolocation to capture insects from the surface of the water.

Nycteridae (slit-faced bats). This family of insect eaters, with one genus and 16 species, is found in Africa and southern Asia. These bats have an extensive basin behind the nose, which is partly bridged over by flaps of skin, leaving a mere slit between them. Slit-faced bats have large ears united at the base. They have a small tragus. They feed mainly on insects, spiders, and sun spiders, but some have been known to eat vertebrates, including fish, frogs, birds, and other bats.

Megadermatidae (false vampire and yellow-winged bats). The four genera (with five species) of this family occur in tropical Africa, southeastern Asia and adjoining islands, and northern Australia. The nose leaf is well developed and simple; the ears are very large and are joined across the forehead. An external tail is lacking. There are no upper incisors. Some species are insect-eating; others feed on small vertebrates, including other bats. The name "false vampire" is from earlier times when these bats were thought to feed on blood.

Rhinolophidae (horseshoe bats). The 77 species (in one genus) of these insect-eating bats are widely distributed in the temperate and tropical areas of the Old World. Horseshoe bats are remarkable for their extremely complex nose leaf expansion of the skin surrounding the nostrils. The lower part is horseshoe-shaped and covers the upper lips, surrounds the nostrils, and has a notch on the lower edge. Above the nostrils is an erect structure (the lancet), connected only at the base and pointed upward. The ears are large but lack a tragus. A tail is present. There are two thoracic teats, but females also have two "dummy teats" on the abdomen that the young grasp as they are being transported. Horseshoe bats roost in many different types of locations, including caves, buildings, trees, and foliage. They feed on insects and spiders. Those in temperate areas hibernate. Some species have delayed fertilization.

Phyllostomidae (New World leaf-nose bats). While most of the 160 species (in 55 genera) of this tropical and subtropical American family possess simple nose leaves (less complex than in Old World leaf-nosed bats), there is tremendous variety in structure, reflecting an equal diversity in food habits. Primitively insect-eating, many have become fruit- or nectar-feeders, and a few are predators on small vertebrates, including other bats. The nose leaf structure is usually present and can be very large, but it may be reduced or absent. The tail may be present or absent. A tragus is present. Phyllostomid bats vary greatly in size, from small species to a false vampire bat, *Vampyrum spectrum*, which is the largest New World bat; its head and body length is about 5 in. (130 cm) and the wingspread can be up to about 3 ft (0.9 m). *Vampyrum spectrum* does not feed on blood. It is carnivorous, feeding on birds, bats, and rodents, and (possibly) on fruit and insects.

The true vampire bats (three species) were previously placed in their own family but are now included among the Phyllostomidae, subfamily Desmodontinae. The vampires are essentially confined to the mainland of tropical America. *Desmodus rotundus* is the best-known species. The vampire bats feed only on fresh blood; *D. rotundus* often feeds on cattle. Vampire bats feed by using the very sharp front incisor teeth (not the canines, as commonly believed) to scratch the surface of the skin so that blood oozes out. There is no sucking of blood; the blood is lapped up with the tongue, but the saliva of the bat contains an anticoagulant which helps keep the blood flowing.

Natalidae (funnel-eared bats). These bats (three genera and eight species) are tropical American insect-eating species with large funnellike ears with glandular papillae on the inside. These are relatively small bats, with the forearm ranging up to about 41 mm (1.7 in.) and the adults weighing 7–10 g (0.25–0.35 oz). The eyes and tragus are small. The tail reaches to the end of the membrane. There is no nose leaf, and the thumb claw is prominent. There is a large "natalid organ" on the face of males which bears a resemblance to sensory cells; it is not always noticeable, and appears to be unique to natalids. These bats often roost in caves, but some have been found in trees. Natalids are often found in large groups.

Furipteridae (smoky or thumbless bats). This insect-eating family, confined to tropical Central and South America, is represented by two species in two genera. Bats of this family are small (with forearm lengths of only 30–40 mm or 1.2–1.6 in.). The thumb is present but is enclosed in the wing membrane and is so small it appears to be absent. The ears are funnel-shaped and not connected at the base, and the tragus is small. The eyes are close together and point downward. There is no nose leaf, and the tail is long. The third and fourth toes are joined.

Thyropteridae (disk-winged or New World sucker-footed bats). The three species (in one genus) of this insectivorous family are confined to the tropical American mainland. These are small bats, with a forearm length ranging up to 38 mm (1.5 in.). The average weight of *Thyroptera tricolor* is only about 4.2 g (0.15 oz). The large suction disks on short stalks on the thumbs and hindfeet enable them to roost on the smooth inner surfaces of large rolled-up leaves. Unlike the Old World sucker-footed bats, they have a well-developed thumb claw. The tail extends slightly beyond the tail membrane. The third and fourth toes are joined. These bats differ from most others in that they usually hang with the head upward. These bats cling to surfaces, even smooth surfaces, by the suckers.

Myzopodidae (Old World sucker-footed bat). The single species of this family is unique among bats in that it is confined to Madagascar. It eats insects and has suckers on the thumbs and feet rather like those of the Thyropteridae. However, the suckers on this bat are sessile, whereas those of thyropterids are on a short stalk.

Mystacinidae (New Zealand short-tailed bats). The two insect-eating species of this family (both in the genus *Mystacina*) are confined to New Zealand; one (*M. robusta*) is probably extinct, and the other (*M. tuberculata*) is considered vulnerable to extinction. Their body and hindlegs are stout, and they have short tails that do not reach the edge of the uropatagium. The male has a large claw with a projection from it, and the toes also have extra projections. The tail goes through the tail membrane and appears on the upper surface. These bats are very agile, running on the ground and up sloping branches.

Molossidae (free-tailed and mastiff bats). This family includes 100 species in 16 genera and is widely distributed in the tropics and subtropics. They have long tails that extend beyond their uropatagia, and the body and hindlegs are stoutly built. These bats show great size variation, with forearm measuring 27–85 mm (1.1–3.3 in.) in length. The body hair is short and velvetlike in texture.

One genus, *Cheiromeles*, is referred to as the naked or hairless bat. The naked bats are large (with forearm lengths of 70–86 mm or 2.8–3.4 in.), and the hair is so short that the bats appear to be naked. The eyes are small. The ears are leathery and united across the forehead and possess a tragus. There is no nose leaf. The wings are long and thin, and these bats are rapid fliers.

Free-tailed bats feed on insects, and they roost in caves, buildings, tunnels, trees, foliage, and crevices, that is, almost anywhere that bats can roost. They have a strong musky odor and often occur in huge numbers. For example, *Tadarida brasiliensis* number about 20 million in Bracken Cave, Texas, constituting one of the largest vertebrate congregations in the world. They do not hibernate and apparently are generally active throughout the year. They usually have one young per year.

Craseonycteridae (bumblebee bat). Bumblebee bats were described in 1974 as a new species, genus, and family. This family includes only one species. It is from Thailand and is of special interest because it is the smallest bat, and may be the smallest mammal, in the world. Bumblebee bats weigh about 2 g (0.07 oz), or about the same weight as the other two contenders for "world's smallest mammal," the Eurasian pygmy shrew (*Suncus etruscus*) and southern Indiana populations of the American pygmy shrew (*Sorex hoyi*). It apparently feeds on insects and spiders.

Mormoopidae (ghost-face bats). This family includes two genera and 10 species of insectivorous bats, all in the New World. It was formerly placed in the family Phyllostomidae. They occur in tropical lowland habitats from southern Arizona and Texas, south through Mexico, Central America, and northern South America. The largest of these bats, *Pteronotus parnellii*, has a forearm measuring 54–65 mm (2.1–2.6 in.). Mormoopids differ from phyllostomids in lacking the nose leaf. They do, however, have flaps that form a funnel when the mouth is open. The nostrils are in the upper lip, and there are bristles on the outside of the lip flaps that further push air toward the mouth. The eyes of mormoopids are smaller than those of phyllostomids. Members of this family form large colonies in caves.

Hipposideridae (Old World leaf-nosed bats). The hipposiderids include nine genera and 81 species found in the tropics of Asia and Africa, the Philippines, Solomons, and Australia; they were previously considered a subfamily of the Rhinolophidae, but they are currently are recognized as a full family. Old World leaf-nosed bats, like horseshoe bats, have a nose leaf, although the structure differs between the two families. (Members of the genera *Trianops* and *Cloetis* have three leaf points on the nose.) The tail may be absent, but varies greatly in length and may be up to 60 mm (2.4 in.) long. These bats may live in caves, buildings, or hollow trees.

Vespertilionidae (mouse-eared or vespertilionid bats). This nearly cosmopolitan family, with 404 species in 48 genera, occurs almost everywhere that bats occur. All members have a long tail that extends to the edge of the uropatagium. In spite of its many species, the family shows little structural diversity. Most vespertilionids have no special facial modifications. A few have very large ears or small simple nose leaves. Echolocation, present in all families of bats except the Pteropodidae, is perhaps most highly developed in vespertilionids and is used for catching insects as well as avoiding obstacles. Most species are relatively small, with forearm lengths ranging 22–75 mm (0.9–2.9 in.), and with adults weighing up to 50 g (1.8 oz). Most species have two mammary glands, except for the genus *Lasiurus*, which has four. The many species of this family roost in a very wide variety of locations. Most species appear to have delayed fertilization; however, in a few tropical species, fertilization immediately follows mating. Gestation is usually 40–70 days, but sometimes can last more than 100 days. Almost all are insect-eating, but at least three species of *Myotis* will catch fish. The pallid bat, *Antrozous pallidus*, often comes to the ground to feed on spiders, beetles, and scorpions, and perhaps occasionally even on small vertebrates. This family includes many of the common North American bats, such as *Myotis, Eptesicus* (Fig. 3), *Pipistrellus, Nycticeius*, and *Corynorhinus*.

Fossil record. Bats have a poor fossil record but have been distinct at least since the Eocene, some 50 million years ago. One unusually well-preserved early form, *Icaronycteris*, combined a primitive insect-eating dentition and a retained claw on the second digit with the advanced type of shoulder joint seen in the Vespertilionidae.

Chlamydia

A genus of bacteria with a growth cycle differing from that of all other microorganisms. Chlamydiae grow only in living cells and cannot be cultured on artificial media. Although capable of synthesizing macromolecules, they have no system for generating energy; the host cell's energy system fuels the chlamydial metabolic processes. The genome is relatively small; the genomes of *C. pneumoniae* and *C. trachomatis* have been completely sequenced.

Infectious particle. The chlamydial infectious particle, called the elementary body, is round and about 350–450 nanometers in diameter. It enters a susceptible host cell and changes to a metabolically active and larger (approximately 800–1000 nm in diameter) reticulate body that divides by binary fission. The entire growth cycle occurs within a vacuole that segregates the chlamydia from the cytoplasm of the host cell. The reticulate bodies change back to elementary bodies, and then the cell lyses and the infectious particles are released. The growth cycle takes about 48 h.

Chlamydial diseases. Human diseases are caused by three species of *Chlamydia*. *Chlamydia trachomatis*, occurring in humans, is susceptible to sulfonamides and produces inclusions that stain with iodine because they contain glycogen. *Chlamydia psittaci*, occurring in birds, lower animals, and humans, is sulfa-resistant and the inclusions do not stain with iodine. The so-called TWAR strains have been given their own species category, *C. pneumoniae*. The TWAR elementary body is pear-shaped rather than round, and there is little deoxyribonucleic acid (DNA) relatedness. The species *Chlamydia pecorum* is not an important cause of human disease, but infects domestic mammals.

Chlamydia trachomatis. *Chlamydia trachomatis* is almost exclusively a human pathogen, and one of the most common. Those strains infecting humans have no known animal reservoir. Infections occur in two distinct epidemiologic patterns. In many developing countries, *C. trachomatis* causes trachoma, a chronic follicular keratoconjunctivitis. It is the world's leading cause of preventable blindness, affecting approximately 500 million people, with millions losing their sight. In areas where this condition is highly endemic, virtually the entire population is infected within the first few years of life. Most active infections are found in childhood. Scarring can develop as a result of severe inflammation of the conjunctiva. Over a period of years, the scars shrink and distort the upper eyelid, causing an in-turning of the eyelashes which damages the cornea and causes blindness. By age 60, more than 20% of a population can be blinded as a result of trachoma. *See* EYE DISORDERS.

Chlamydia trachomatis is the most common sexually transmitted bacterial pathogen; an estimated 3–4 million cases occur each year in the United States, and there are close to 90 million worldwide. The most common manifestation is nongonococcal urethritis in males. The cervix is the most commonly infected site in women. Ascending infections can occur in either sex, resulting in epididymitis in males or endometritis and salpingitis in females. Chlamydial infection of the fallopian tube can cause late consequences such as infertility and ectopic pregnancy, even though the earlier infection is asymptomatic. For some women, their first knowledge of having had a chlamydial infection occurs when they are being evaluated for infertility or are hospitalized with an ectopic pregnancy. Thus, chlamydial infection in the female can be particularly insidious and dangerous. *See* SEXUALLY TRANSMITTED DISEASES.

The infant passing through the infected birth canal can acquire the infection and may develop either conjunctivitis (called inclusion conjunctivitis of the newborn, or inclusion blennorrhea) or pneumonia. In the United States, *C. trachomatis* is the leading cause of conjunctivitis in the first month of life, and of pneumonia in the first 6 months.

All of the diseases mentioned above involve mucous membranes. There is a more invasive form of *C. trachomatis* that causes a systemic sexually transmitted disease called lymphogranuloma venereum. Lymphogranuloma venereum has a worldwide distribution, although it is more common in some tropical countries. This disease has a predilection for lymphoid tissue involvement. It occurs in stages: the primary stage involves small, superficial, usually painless genital lesions; in the secondary stage, inguinal buboes (infected lymph nodes) are the common finding. If untreated, the disease may progress to stages involving widespread tissue destruction of genital and intestinal tracts.

Chlamydia psittaci. *Chlamydia psittaci* is virtually ubiquitous among avian species and is a common pathogen among lower mammals. It is economically important in many countries as a cause of abortion in sheep, cattle, and goats. It causes considerable morbidity and mortality in poultry, particularly turkeys and ducks. *Chlamydia psittaci* can infect humans, causing the disease psittacosis. Psittacosis can occur as pneumonia or a febrile toxic disease without respiratory symptoms. Apparently, the chlamydiae that infect turkeys, ducks, and psittacine birds are most infectious for humans. Psittacosis is a potential threat to the health of pet-bird owners and is an occupational hazard in the poultry industry. *Chlamydia psittaci* derived from mammals can also infect humans.

Chlamydia pneumoniae (TWAR). *Chlamydia pneumoniae* appears to be a human pathogen with no animal reservoir. It is of worldwide distribution and may be the most common human chlamydial infection. It appears to be an important cause of respiratory disease, being found in association with sporadic cases of community-acquired pneumonia and epidemics of mild pneumonia. Some evidence has been generated to associate *C. pneumoniae* infections with acute and chronic asthma. In addition, *C. pneumoniae* infection has been linked to coronary artery disease. *Chlamydia pneumoniae* infections start early in life, usually about school age. Infections are likely acquired by the respiratory route. Seroprevalence increases rapidly up to the ages of 30 or 40, where a plateau is approached. Age-specific seroprevalence ultimately reaches 60–70% in many populations. It is believed that asymptomatic, chronic infections are common.

Treatment. Azithromycin is the drug of choice for uncomplicated chlamydial infection of the genital tract. With an antimicrobial spectrum similar to that of erythromycin, it concentrates in cells where the organism grows, and it is effective as a single dose. Two therapeutic agents require longer treatment regimens: doxycycline, a tetracycline antibiotic, is the first alternate treatment; erythromycin may be used for those who are tetracycline-intolerant, as well as for pregnant women or young children. *See* MEDICAL BACTERIOLOGY.

Chlorine

A chemical element, Cl, atomic number 17 and atomic weight 35.453. Chlorine exists as a greenish-yellow gas at ordinary temperatures and pressures. It is second in reactivity only to fluorine among the halogen elements, and hence is never found free in nature, except at the elevated temperatures of volcanic gases. It is estimated that 0.045% of the Earth's crust is chlorine. It combines with metals, nonmetals, and organic materials to form hundreds of chlorine compounds, the most important of which are discussed here. *See* PERIODIC TABLE.

Chlorine and its common acid derivative, hydrochloric (or muriatic) acid, were probably noted by experimental investigators as early as the thirteenth century. C. W. Scheele identified chlorine as "dephlogisticated muriatic acid" in 1774, and H. Davy proved that a new element had been found in 1810. Extensive production started 100 years later. During the twentieth century, the amount of chlorine used has been considered a measure of industrial growth.

Physical properties. The atomic weight of naturally occurring chlorine is 35.453 (based on carbon at

12). It is formed of stable isotopes of mass 35 and 37; radioactive isotopes have been made artificially. The diatomic gas has a molecular weight of 70.906. The boiling point of liquid chlorine (golden-yellow in color) is −33.97°C (−29.15°F) at 760 mm Hg (10^2 kilopascals) and the melting point of solid chlorine (tetragonal crystals) is −100.98°C (−149.76°F). The critical temperature is 144°C (292°F); the critical pressure is 78.7 atm; the critical volume is 1.745 ml/g; and density at the critical point is 0.573 g/ml. Thermodynamic properties include heat of sublimation at 7370 ± 10 cal/mole at 0 K, heat of evaporation at 4882 cal/mole at −33.97°C, heat of fusion at 1531 cal/mole, vapor heat capacity at a constant pressure of 1 atm of 8.32 cal/(mole °C) at 0°C (32°F) and 8.46 cal/(mole °C) at 100°C (212°F). Chlorine forms solid hydrates, $Cl_2 \cdot 6H_2O$ (pale-green crystals) and $Cl_2 \cdot 8H_2O$. It hydrolyzes in water as shown in reaction (1).

$$Cl_2 + H_2O \rightarrow HClO + HCl \qquad (1)$$

Chemical properties. Chlorine is one of four closely related chemical elements which have been called the halogen elements. Fluorine is more active chemically, and bromine and iodine are less active. Chlorine replaces iodine and bromine from their salts. It enters into substitution and addition reactions with both organic and inorganic materials. Dry chlorine is somewhat inert, but moist chlorine unites directly with most of the elements. *See* HALOGEN ELEMENTS.

Compounds. Sodium chloride, NaCl, is used directly as mined (rock salt), or as found on the surface, or as brine. It may also be dissolved, purified, and reprecipitated for use in foods or when chemical purity is required. Its main uses are in the production of soda ash and chlorine products. Farm use, refrigeration, dust and ice control, water treatment, food processing, and food preservation are other uses. Calcium chloride, $CaCl_2$, is usually obtained from brines or as a by-product of chemical processing. Its main uses are in road treatment, coal treatment, concrete conditioning, and refrigeration. *See* HALITE.

Wet chlorine reacts with metals to form chlorides, most of which are soluble in water. It also reacts with sulfur and phosphorus and with other halogens as in reactions (2).

$$\begin{aligned} H_2 + Cl_2 &\rightarrow 2HCl \\ 2Fe + 3Cl_2 &\rightarrow 2FeCl_3 \\ 2S + Cl_2 &\rightarrow S_2Cl_2 \\ S + Cl_2 &\rightarrow SCl_2 \\ S + 2Cl_2 &\rightarrow SCl_4 \qquad (2) \\ P_4 + 6Cl_2 &\rightarrow 4PCl_3 \\ P_4 + 10Cl_2 &\rightarrow 4PCl_5 \\ Br_2 + Cl_2 &\rightarrow 2BrCl \\ 2F_2 + Cl_2 &\rightarrow ClF + ClF_3 \end{aligned}$$

The oxides of chlorine, dichlorine monoxide, Cl_2O, chlorine monoxide, ClO, chlorine dioxide, ClO_2, chlorine hexoxide, Cl_2O_6, and chlorine heptoxide, Cl_2O_7, are all made indirectly. Cl_2O is commonly called chlorine monoxide also. Chlorine dioxide, a green gas, has become increasingly important in commercial bleaching of cellulose, water treatment, and waste treatment.

Hydrogen chloride, HCl, is a colorless, pungent, poisonous gas which liquefies at 82 atm at 51°C (124°F). It boils at −85°C (−121°F) at 1 atm (10^2 kPa). Its major production is as the by-product of many organic chlorinations. It can be made by direct reaction of chlorine and hydrogen in an open combustion chamber submerged in cooled, aqueous hydrochloric acid solution. It is used as a strong acid and as a reducing agent.

Aluminum chloride, $AlCl_3$, is an anhydrous, white, deliquescent, hexagonal crystalline substance. Either scrap aluminum or the oxide (bauxite) may be chlorinated. Aluminum chloride is a catalyst for production of cumene, styrene, and isomerized butane. Of the aluminum chloride uses in anhydrous form, ethylbenzene production uses 25%, dyes 30%, detergents 15%, ethyl chloride 10%, drugs 8%, and miscellaneous production 12%. Hydrated and liquid forms are also available, 50% of which are used in drug and cosmetic production.

Ferric chloride, $FeCl_3$, is a solid composed of dark, hexagonal crystals. Much chlorine from chemical processes is converted to ferric chloride, which is then used for the manufacture of salts, pigments, pharmaceuticals, and dyes and for photoengraving, preparation of catalysts, and waste and sewage treatment.

Natural occurrence. Because many inorganic chlorides are quite soluble in water, they are leached out of land areas by rain and ground water to accumulate in the sea or in lakes that have no outlets. Seawater contains 18.97 g of chloride ion per kilogram (3% sodium chloride). Solar evaporation produces large deposits of salts in landlocked areas. Similar evaporation in the past is responsible for vast underground deposits of rock salt and brines in Michigan, central New York, the Gulf Coast of Texas, Stassfurt in Germany, and elsewhere. These deposits are mainly of sodium chloride, the supply of which is unlimited for practical purposes. Other rocks and minerals in the Earth's surface average slightly over 0.03% chloride. *See* HALOGEN MINERALS; SALINE EVAPORITE.

Manufacture. The first electrolytic process was patented in 1851 by Charles Watt in Great Britain. In 1868 Henry Deacon produced chlorine from hydrochloric acid and oxygen at 400°C (750°F) with copper chloride absorbed in pumice stone as a catalyst. The electrolytic cells now used may be classified for the most part as diaphragm and mercury types. Both make caustic (NaOH or KOH), chlorine, and hydrogen. The economics of the chlor-alkali industry mainly involve the balanced marketing or internal use of caustic and chlorine in the same proportions as obtained from the electrolytic cell process.

Uses. Chlorine is an excellent oxidizing agent. Historically, the use of chlorine as a bleaching agent in the paper, pulp, and textile industries and as a germicide for drinking water preparation, swimming pool purification, and hospital sanitation has made community living possible. Chlorine is used to produce bromine from bromides found in brines and seawater. The automotive age increased the production of bromine tremendously for the manufacture of ethylene dibromide for use in gasoline. Compounds of chlorine are used as bleaching agents, oxidizing agents, solvents, and intermediates in the manufacture of other substances. *See* HERBICIDE.

Chlorite

One of a group of layer silicate minerals, usually green in color, characterized by a perfect cleavage parallel to (001). The cleavage flakes are flexible but inelastic, with a luster varying from pearly or vitreous to dull and earthy. The hardness on the cleavage is about 2.5. The specific gravity varies between 2.6 and 3.3 as a function of composition.

Chlorite is a common accessary mineral in low- to medium-grade regional metamorphic rocks and is the dominant mineral in chlorite schist. It can form by alteration of ferromagnesian minerals in igneous rocks and is found occasionally in pegmatites and vein deposits. It is a common constituent of altered basic rocks and of alteration zones around metallic ore bodies. Chlorite also can form by diagenetic processes in sedimentary rocks. *See* DIAGENESIS.

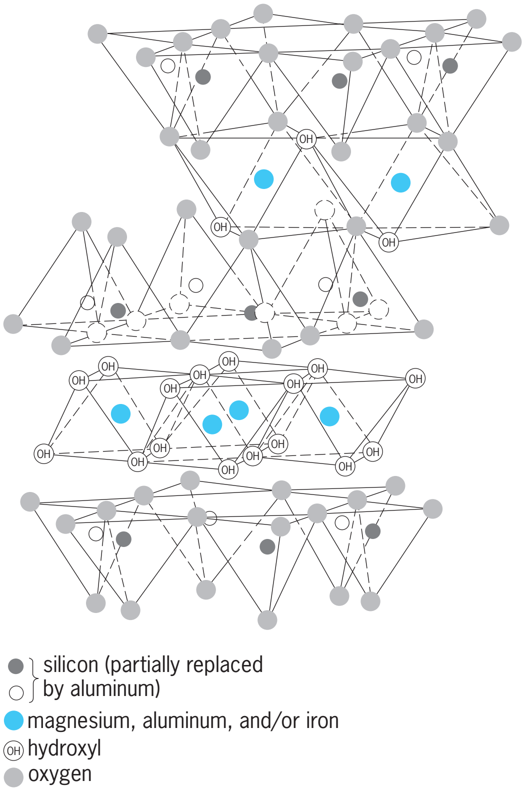

Diagram of the structure of chlorite. (*After R. E. Grim, Clay Mineralogy, McGraw-Hill, 1953*)

The crystal structure of chlorite consists of a 2:1 layer, similar to that in mica, with octahedrally coordinated cations sandwiched between two tetrahedral sheets that are inverted relative to one another. Substitution of Al or Fe^{3+} for Si in the tetrahedral sheets gives a net negative charge to the 2:1 layers, which must be balanced by a positively charged octahedral sheet in the interlayer space. The composition of the 2:1 layer can be expressed as

$$\left(\mathrm{R}^{2+}_{3-a-b-c}\mathrm{R}^{1+}_{a}\mathrm{R}^{3+}_{b}\square_{c}\right)\left(\mathrm{Si}_{4-x}\mathrm{R}^{3+}_{x}\right)\mathrm{R}_{10}(\mathrm{OH})_{2}$$

and that of the interlayer as

$$\left(\mathrm{R}^{2+}_{3-d-e-f}\mathrm{R}^{1+}_{d}\mathrm{R}^{3+}_{e}\square_{f}\right)(\mathrm{OH})_{6}$$

with $\square$ = vacancy. Enough R^{3+} cations must be present in the interlayer to create a net positive charge on that sheet. Long hydrogen bonds link basal oxygens of each tetrahedral sheet with surface hydroxyl groups of the interlayer sheet (see **illus.**). Different stacking arrangements of the layers and interlayers are possible. *See* MICA.

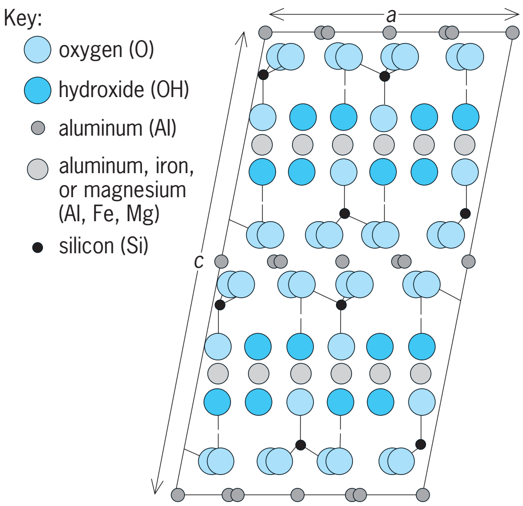
Most chlorites are trioctahedral with close to 3.0 octahedral cations present in both the 2:1 layer and the interlayer. The main octahedral cations present in these sheets are Mg, Fe^{2+}, Fe^{3+}, and Al, but with important substitutions of Cr, Mn, Ni, V, Cu, or Li in certain species. Species names are given according to the dominant divalent octahedral cation present: clinochlore for Mg dominant, chamosite for Fe^{2+} dominant, nimite for Ni dominant, and pennatite for Mn^{2+} dominant. A few dioctahedral chlorites are known also. *See* AUTHIGENIC MINERALS; CLAY MINERALS.

S. W. Bailey

Chloritoid

A hydrous iron aluminum silicate mineral with an ideal formula of $Fe_2^{2+}Al_4O_2(SiO_4)_2(OH)_4$. Chloritoid occurs as platy, black or dark green crystals, rarely more than a few millimeters in size. Its density ranges from 3.46 to 3.80 g/cm^3, and its hardness on the Mohs scale is 6.5.

Crystal form. Chloritoid most commonly forms monoclinic crystals, having a single twofold rotation axis perpendicular to a mirror plane. This is the symmetry of the prismatic crystal class, symbolized as $2/m$. The atomic structure of chloritoid is characterized by silicon atoms surrounded by four oxygen atoms in a tetrahedral arrangement. These tetrahedral clusters form layers that alternate with layers of ferrous iron (Fe^{+2}) and aluminum (Al; see **illus.**) The iron and aluminum are surrounded by six oxygen (O) and hydroxide (OH) ions in an octahedral arrangement in the ratio $[Fe_2^{2+}AlO_2(OH)_4]^-$ and are sandwiched between layers of $(SiO_4)^{4-}$ tetrahedra. The sandwiches of silica tetrahedra–iron and aluminum octahedra–silica tetrahedra are stacked alternately with layers of aluminum. Other structural forms of chloritoid, called polytypes, are created by variations in the stacking of the



Crystal structure of chloritoid, projected on (010). The unit cell for one structural type of chloritoid, $2M_2$, is shown. The unit cell parameters are $a = 0.9482$ nanometers, $b = 0.5485$ nm, $c = 1.8180$ nm, $\beta = 101.8°$. (*After P. H. Ribbe, ed., Orthosilicates, Reviews in Mineralogy, vol. 5, Mineralogical Society of America, 1980*)

tetrahedral-octahedral-tetrahedral sandwiches. *See* CRYSTAL STRUCTURE; CRYSTALLOGRAPHY.

In thin section under the polarizing microscope, chloritoid can appear to be rectangular, with a length two or three times the width. It is observed to be pleochroic, having a color of bluish or greenish gray if the long dimension of the crystal is parallel to the polarizing direction, and pale gray to colorless if the long dimension of the crystal is perpendicular to the polarizing direction. Crystals are commonly twinned across planes parallel to the long dimension. The indices of refraction range from 1.713 to 1.740, with a birefringence (δ) of about 0.010. The mineral has a higher-than-average index of refraction and tends, therefore, to stand out from the other minerals in thin section. Chloritoid exhibits anomalous interference colors in cross-polarized light. *See* BIREFRINGENCE; PLEOCHROISM.

Composition. The composition of chloritoid typically deviates from the ideal formula. Magnesium (Mg) substitutes for as much as 40% of the iron, although the ratio Mg/(Mg + Fe) is generally 0.15 to 0.20. Manganese has been found to substitute for 17% of the iron, but manganese contents are generally less than 1% of the iron. A variety of chloritoid, called ottrelite, contains manganese in substitution for iron in amounts of about 60%. Ferric iron (Fe^{3+}) substitutes for less than 14% of the aluminum, and titanium occurs in trace amounts.

Occurrence. Chloritoid is typically found in low-grade, metamorphosed shales, which are commonly called pelitic schists. It occurs as a comparatively large mineral set in a matrix composed of quartz and fine-grained muscovite. It first appears in most metamorphic terrains near the biotite isograd, that is, near the first appearance of biotite; however, the first appearance of chloritoid depends on many factors, including pressure, oxidation state, and availability of proper rock compositions in the metamorphic terrain. In low-grade rocks, chloritoid is found in association with chlorite, muscovite, and, in some rocks, paragonite. At medium grades of metamorphism, chloritoid can be found with garnet or staurolite in a muscovite and quartz matrix.

The reaction responsible for the synthesis of chloritoid in pelitic schists is not well documented but may occur as in reaction (1), where H_2O may be water or a supercritical fluid phase.

$$\text{12 pyrophyllite} + \text{4 chlorite} \rightarrow \text{9 chloritoid} + \text{49 quartz} + 10\,H_2O \quad (1)$$

Chloritoid breaks down during metamorphism by either reaction (2) or (3).

$$\text{Chloritoid} + \text{quartz} \rightarrow \text{garnet} + \text{staurolite} + \text{chlorite} + H_2O \quad (2)$$

$$\text{Chloritoid} + \text{muscovite} + \text{quartz} \rightarrow \text{garnet} + \text{staurolite} + \text{biotite} + H_2O \quad (3)$$

The stoichiometric coefficients in these two reactions depend on the Fe/Mg ratios in the minerals, which in turn depend on the pressure and temperature of the reaction. Reaction (2) is found to occur in medium- to high-pressure terrains, whereas reaction (3) occurs in low-pressure terrains.

Experimental studies of the stability of chloritoid have been conducted over a limited range in temperature and pressure and in the possible compositions of chloritoid. The low-temperature stability limit of chloritoid has not been well determined. Calculations indicate that reaction (1) proceeds at a temperature near 400°C (750°F) at 500 megapascals (5 kilobars). The high-temperature stability limit of chloritoid has been studied experimentally under conditions appropriate for reaction (2). The results indicate that chloritoid is stable up to temperatures near 550°C (1020°F) at 500 MPa (5 kbar) and 575°C (1070°F) at 1000 MPa (10 kbar), although the precise temperature and pressure conditions of reaction (2) have not been determined. Reactions at low pressures, including reaction (3), have not been investigated.

Chloritoid is increasingly being recognized as a constituent in rocks that formed under high-pressure conditions. It is found in association with glaucophane in blueschist-facies metamorphic rocks, and with amphibole and pyroxene in eclogite-facies metamorphic rocks. These are rocks that formed under conditions thought to prevail at the base of the Earth's crust or in the mantle. Experimental studies of metamorphism of basalt under these conditions indicate the formation of chloritoid at pressures exceeding 2300 MPa (23 kbar) and at a temperature of 650°C (1200°F). In these high-pressure occurrences of chloritoid, the chloritoid is rich in magnesium, having a value of Mg/(Mg + Fe) ranging from 0.38 to 0.40. *See* METAMORPHIC ROCKS. Theodore C. Labotka

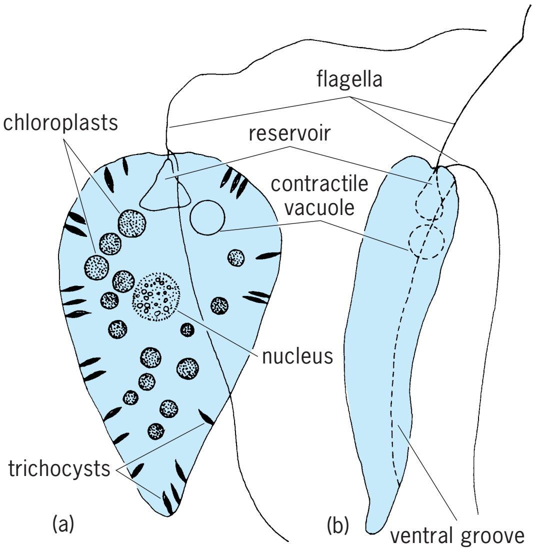
Minerals, 1992; C. Klein and C. S. Hurlbut, Jr., *Manual of Mineralogy*, 21st ed., 1993.

Chloromonadida

An order of the class Phytamastigophorea, also known as the Chloromonadina. These poorly known flagellates are grass-green or colorless, somewhat flattened, and have two equal flagella, one anterior, the other trailing. All known genera are free-swimming, although *Reckertia* and *Thaumatomastix* form pseudopodia. They vary in size from 30 to 100 micrometers. Chromatophores are small disks, stigmas are lacking, and fat is the storage product. Trichocysts are found in three genera. The nucleus is large, with nucleoli and chromosomes visible during interphase. One or two anterior vacuoles are present and a reservoir seems to be present in *Trentonia* and *Gonyostomum* (see **illus.**). Life cycles are unknown, but longitudinal division occurs. *Gonyostomum* sometimes occurs as bloom in cedar swamps, and *Vacuolaria* is sometimes common there. The taxonomic position of the class is poorly defined. *See* CILIA AND FLAGELLA; PHYTAMASTIGOPHOREA; PROTOZOA. James B. Lackey



***Gonyostomum semen*. (*a*) Dorsal view. (*b*) Side view.**

Chlorophyceae

A large and diverse class of plants, commonly called green algae, in the chlorophyll *a-b* phyletic line (Chlorophycota). Estimated number of taxa varies widely; 560 genera and 8600 species are conservative estimates. *See* CHLOROPHYCOTA.

Characteristics. The green algae exhibit great morphological diversity while sharing fundamental biochemical and ultrastructural features. Their photosynthetic pigments are similar to those in higher plants and include chlorophyll *a* and *b*, α-, β-, and γ-carotene, and various xanthophylls, especially lutein, violaxanthin, zeaxanthin, antheraxanthin, and neoxanthin. Chloroplasts vary in number and shape, but always have two membranes, two to five thylakoids per lamella, and usually one or more pyrenoids. A cell wall, which may be calcified, is usually present, and often contains cellulose, hydroxyproline glycosides, xylan, and mannan. The chief food reserve is starch, stored in the chloroplast as granules which often sheathe a pyrenoid. Motile cells usually have two or four apically inserted smooth flagella of approximately equal length. In a few genera, motile cells have more than four apical flagella, one or two pairs of subapical flagella, or a subapical crown of numerous flagella. Flagellar scales and hairs are rare. There is sometimes an eyespot, which lies within the chloroplast. *See* CELL PLASTIDS; CHLOROPHYLL.

Phylogeny. Almost all somatic cell types known for algae occur among the Chlorophyceae, the exceptions being rhizopodial unicells and complex multicellular thalli differentiated into macroscopic organs. In the traditional view of phylogeny within the green algae, the progenitor is a motile unicell (monad) with a wall and a pair of equal, smooth, apical flagella, similar to present-day *Chlamydomonas*. In one line of evolution (volvocine), monads joined to form motile colonies. In a different evolutionary line, monads lost their flagella, forming nonmotile solitary cells and colonies (tetrasporine line), which then underwent specialization and elaboration (chlorococcine line). Multicellular thalli (ulotrichine line) were made possibly by the evolution of desmoschisis, a type of cell division in which the wall of the progeny and that of the parent become an integral structure. Traditionally, the ulotrichine line has been considered to lead from unbranched filaments (Ulotrichales) through forms with both prostrate and erect branched systems (Chaetophorales) to the higher plants, with two very distinctive groups (Zygnematales and Oedogoniales) as early offshoots and a third equally distinctive group (charophytes) diverging from a more advanced position. Siphonous and vesicular green algae (siphonine line) were believed to have evolved prior to the origin of desmoschisis.

Ultrastructural studies, however, have revealed differences in details of nuclear and cell division, cell coverings, plasmodesmata, pyrenoids, and flagellar structure that are correlated among themselves and with certain traditional characters to a degree that strongly suggests that the ulotrichine line is polyphyletic, with desmoschisis having evolved at least four times. Moreover, these studies suggest that the ultimate ancestral green flagellate was prasinophycean (asymmetrical and covered with scales) rather than *Chlamydomonas*-like. Integration of these studies and inferences suggests four phyletic lines: chlorophycean, ulvophycean, charophycean, and pleurastrophycean.

Chlorophycean phyletic line. This phyletic group has motile cells that are usually walled and with two or more apically arising flagella, their basal bodies associated with four or more relatively narrow bands of microtubules in a cruciate arrangement. The group includes the volvocine, tetrasporine, and chlorococcine lines, as well as the Chlorosarcinales, Microsporales, Sphaeropleales, Oedogoniales, and Chaetophorales. It is believed to be the most derived of the four phyletic lines and the only one with a chlamydomonad ancestor.

Volvocales and Chlorococcales. The order Volvocales includes all Chlorophyceae that normally are flagellate and motile. The cells are solitary or united into colonies of definite structure, called coenobia. Some taxonomists place the unicellular forms in a separate order, Chlamydomonadales, and interpret the coenobial forms as being multicellular. *Chlamydomonas*, presumably similar to the volvocalean archetype, has two smooth flagella, a chloroplast that commonly is cup-shaped or H-shaped, a pyrenoid, a nucleus, an eyespot, and contractile vacuoles. The protoplast is enclosed in a wall (theca). Within the Volvocales there are notable evolutionary trends: isogamy through anisogamy to oogamy; increase in number of cells; and increase in polarity, resulting in morphological and functional differentiation of component cells. *Volvox*, terminating these trends, has a spherical coenobium composed of as many as 50,000 cells. The Tetrasporales, regarded by some taxonomists as a suborder of the Volvocales, are essentially unicellular Volvocales that have lost their flagella and become nonmotile in their vegetative phase. The cells generally have an internal organization similar to that of *Chlamydomonas*. They are usually massed in gelatinous colonies of indefinite shape, but in some genera the thallus is saccate, dendroid, or reticulate. *See* VOLVOCALES.

The order Chlorococcales comprises a large and diverse assemblage of nonmotile algae that appear to follow the Tetrasporales phylogenetically, sharing their inability to form multicellular thalli, but differing cytologically in that vegetative cells lack eyespots and contractile vacuoles and tend to be nonpolar. Most Chlorococcales are solitary cells of various shapes (spherical, ellipsoid, reniform, lunate, acicular, polygonal) and sizes (to 200 micrometers maximum dimension). Cells are free or attached by a gelatinous stalk. The wall is plain or ornamented (spines, bristles, knobs, horns) and uniformly or asymmetrically thickened. In many genera, however, the cells are joined into colonies of indefinite or definite structure. Colonies of indefinite structure result from coalescence of gelatinous envelopes (Coccomyxaceae) or joining of successive progenies by persistent remnants of parental walls (Dictyosphaeriaceae, **Fig. 1***f*). Colonies of definite structure (coenobia) result from coherence of the cells of a progeny, whether the cells are nonmotile (Scenedesmaceae, Fig. 1*i*) or initially motile (Hydrodictyaceae, Fig. 1*d*, *e*, *g*). Asexual reproduction is by cleavage of a protoplast to form autospores or autocolonies (cells or colonies having the same shape as the parent) or zoospores. After being released from the parental wall, autospores and autocolonies enlarge to adult size. Zoospores either metamorphose individually into nonmotile cells or settle collectively to form an autocolony. Sexual reproduction is usually isogamous.

The Chlorococcales constitute an important component of fresh-water plankton and soil microflora, but occupy other aquatic and subaerial habitats, including snow and ice. Some are the algal component (phycobiont) of lichens, while others occur in the tissues of aquatic and terrestrial plants and aquatic animals. *Oophila*, for example, lives in the mucilage of salamander eggs. *Prototheca* is an intestinal pathogen of various domestic animals and humans. *Chlorella*, commonly found in a wide variety of aquatic habitats, is used extensively in physiological research and is grown in mass cultures as a protein source for poultry, livestock, and humans.

(*a*) *Chlorococcum* (Chlorococcaceae), vegetative cell; (*b*) cell with zoospores; (*c*) zoospores; (*d*) *Hydrodictyon* (Hydrodictyaceae), portion of coenobium; (*e*) portion enlarged; (*f*) *Dictyosphaerium* (Dictyosphaeriaceae), colony in gelatinous matrix; (*g*) *Pediastrum* (Scenedesmaceae), coenobium; (*h*) *Oocystis* (Oocystaceae), colony (*from G. M. Smith*, *Fresh-water Algae of the United States*, *2d ed.*, *McGraw-Hill*, *1950*); (*i*) *Scenedesmus* (Scenedesmaceae), coenobium (*from G. M. Smith*, *Cryptogamic Botany*, *vol. 1*, *2d ed.*, *McGraw-Hill*, *1955*).

Nearly 200 genera of Chlorococcales are recognized, distributed among 15 or 16 families. They are almost exclusively freshwater.

In the orders Volvocales, Tetrasporales, and Chlorococcales, cell division is of the type termed eleutheroschisis, in which the daughter protoplasts either remain naked or secrete new walls separate from the parental wall, which ruptures or gelatinizes to release the progeny (zoospores, autospores, or gametes). In theory, multicellularity was made possible by the evolution of desmoschisis, a process by which daughter cells make permanent contributions to the parental wall. In multicellular algae with uninucleate cells, there is a regular sequence of karyokinesis, cytokinesis, and cell-wall deposition. The relationship between daughter and parental walls is not always clear, however; numerous intermediate situations have been demonstrated. A relatively small group of green algae (mainly in soil) exhibit desmoschisis but lack intercellular connections (plasmodesmata) and thus form only cuboidal (sarcinoid) or irregular packets. Both chlorophycean and charophycean phyletic lines are represented, with members of the former assigned to the order Chlorosarcinales and those of the latter to the order Chlorokybales. In a few genera, rudimentary filaments result from end-to-end coherence of daughter cells that do not contribute to the parental wall and thus are equivalent to autospores. Such genera can be assigned to the Chlorococcales. Long but unbranched filaments can also be produced in the absence of desmoschisis of which there are two well-known freshwater examples. In *Microspora* (**Fig. 2*a***), each daughter cell forms a partial wall, so that the filament wall is composed of segments that are H-shaped in optical section, each segment covering the lower half of one cell and the upper half of the subtending cell. The cells are quadrate, each with a reticulate chloroplast lacking pyrenoids. The nucleus lies in a bridge of cytoplasm that crosses the middle of the central vacuole. In *Sphaeroplea* (Fig. 2*b*), daughter cells secrete an entire wall, but the parental wall soon breaks apart. Mature cells are 15–16 times longer than wide and have a curious coenocytic organization, in which a linear series of vacuoles is separated by transverse cytoplasmic bands, each containing several nuclei and a parietal girdle-shaped chloroplast with several pyrenoids or numerous discoid chloroplasts, certain of which contain pyrenoids. Sexual reproduction involves oogamy or an advanced form of anisogamy. *Microspora* and *Sphaeroplea* are traditionally assigned to their own families and, in the present classification, to their own orders.

Oedogoniales. The order Oedogoniales and the coextensive family Oedogoniaceae comprise three genera of filamentous fresh-water algae with several unique features, including (1) an elaborate method of cell division that results in the accumulation of apical caps; (2) zoospores and antherozoids with a subapical crown of numerous flagella; and (3) a highly specialized type of oogamy. *Oedogonium*, with simple filaments, comprises several hundred species that grow attached to various substrates, including stones, wood, and aquatic angiosperms. In *Bulbochaete* and *Oedocladium*, which have fewer species, the filaments are branched. *See* OEDOGONIALES.

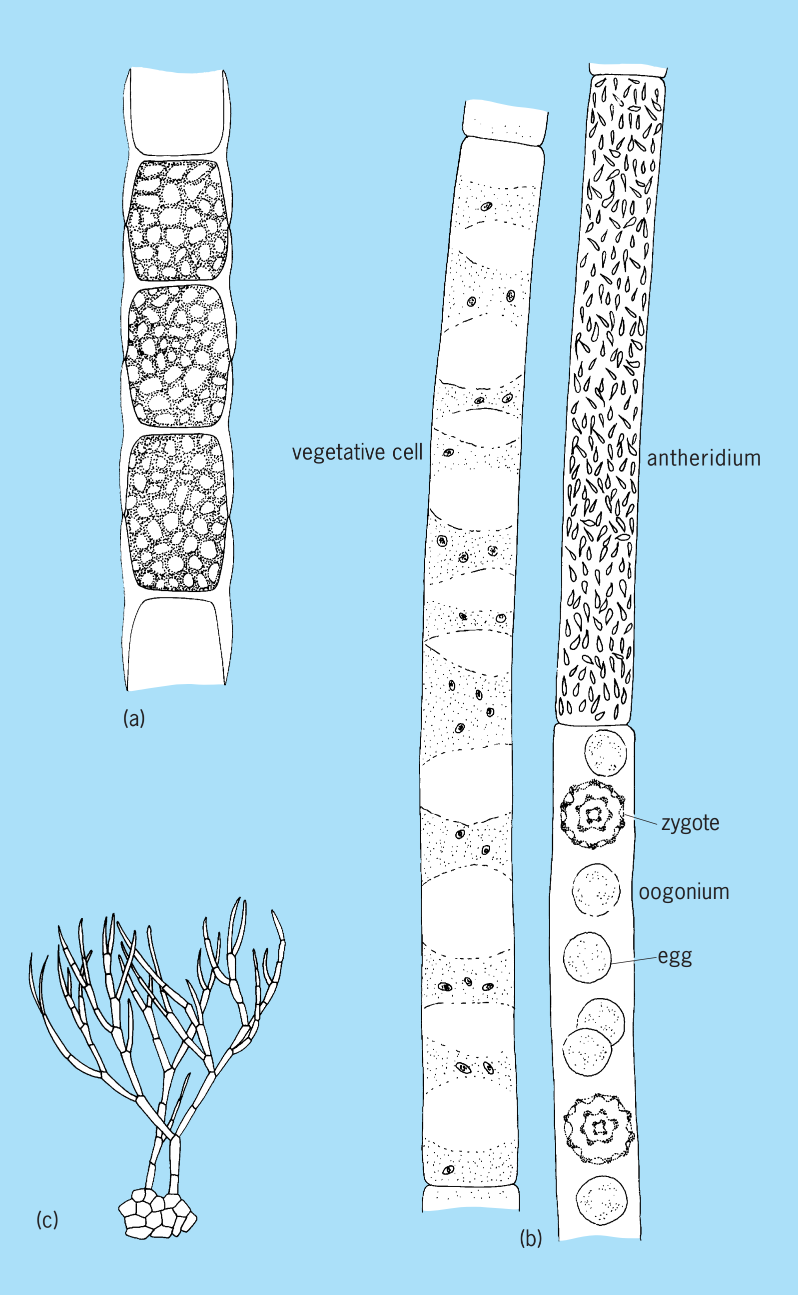


Fig. 2. Filamentous green algae with chlorophycean ultrastructure. (*a*) *Microspora* (Microsporales), showing H-shaped wall segments; (*b*) *Sphaeroplea* (Sphaeropleales); (*c*) *Chaetophora* (Chaetophorales), heterotrichous thallus (erect and prostrate systems).

Chaetophorales. Traditionally, the ulotrichine line was considered to begin with the unbranched filaments of *Ulothrix* and continue through various genera with branched filaments composed of uninucleate cells, each containing a parietal laminate chloroplast. If more than one order (Ulotrichales) was recognized, the branched forms were separated as the Chaetophorales. Modern studies have shown, however, that this morphological spectrum encompasses four phyletic lines as defined by ultrastructural features. *Ulothrix* is ulvophycean, as are *Trentepohlia* and probably all marine genera previously assigned to the Chaetophorales. *Microthamnion* is pleurastrophycean, while *Coleochaete* is charophycean. Residual chlorophycean forms, which include *Uronema* (unbranched) and *Chaetophora* (branched), constitute the order Chaetophorales *sensu stricto* with about 28 genera distributed among three families. Except for *Uronema*, members of the family Chaetophoraceae typically have a thallus differentiated into a prostrate portion composed of loose or pseudoparenchymatous filaments and an erect, freely branched portion (heterotrichous thallus, Fig. 2*c*). Ultimate branches are usually attenuate, often terminating in a long multicellular hyaline hair. In the Aphanochaetaceae, many cells bear unsheathed unicellular hairs, often with a bulbous base. In *Schizomeris*, the only member of the family Schizomeridaceae, the juvenile is similar to *Ulothrix*, but during maturation all cells in the upper portion of a filament undergo repeated division in various planes, resulting in a parenchymatous cylinder indistinctly marked into bands by the persistent transverse walls of the uniseriate cells.

Ulvophycean phyletic line. Ulvophyceae have motile cells that are scaly or naked, are radially symmetrical, and have two or more flagella arising apically from a cruciate root system, but the distal ends of the basal bodies lie in counterclockwise rotation rather than the clockwise rotation seen in Chlorophyceae. Cytokinesis is effected by a precocious cleavage furrow that impinges on microtubules of the persistent spindle. This phyletic line, which is predominantly marine, includes the Ulotrichales, Ctenocladales, Ulvales, Trentepohliales, Acrosiphoniales, Cladophorales, Siphonocladales, Bryopsidales, Dasycladales, and possibly Cylindrocapsales and Prasiolales.

Ulotrichales. The simplest thallus in the ulvophycean phyletic line is the unbranched filament of *Ulothrix* (**Fig. 3**), the only certain member of the family Ulotrichaceae and the order Ulotrichales. Other genera previously aligned with *Ulothrix* have been shown to be chlorophycean (such as *Uronema*, now in the Chaetophorales) or charophycean (such as *Klebsormidium, Stichococcus*, and *Raphidonema*, now in the Klebsormidiales) or to be reinterpreted as filamentous Chlorococcales (such as *Binuclearia*). Each cell of the *Ulothrix* filament has a nucleus and a parietal laminate or cylindrical chloroplast with one or more pyrenoids. Filaments attach (at least initially) by a modified basal cell to stones or wood, forming extensive stands in various aquatic habitats, such as the shores of lakes and harbors. The life history of fresh-water species involves only one somatic phase, a haploid gametophyte, with meiosis occurring in the production of zoospores during germination of the zygospore. Alternation of a filamentous gametophyte with a filamentous sporophyte has been reported for a marine species.

Ctenocladales. Small green algae with branched filaments are widespread in marine habitats, and have traditionally been assigned to the Chaetophorales, but all prove to have ulvophycean rather than chlorophycean ultrastructure. The order Ctenocladales has been proposed to receive them, but some workers refer them to the Ulvales, an order usually restricted to algae with parenchymatous thalli. In these marine forms, which constitute the family Ulvellaceae, the thallus usually consists solely of prostrate filaments that are free or coherent and pseudoparenchymatous. It is affixed to, or immersed in, a solid substrate, usually an aquatic organism. Free erect filaments, if produced, are short, the cells moniliform or irregularly swollen. Colorless anucleate setalike projections of the cell wall are produced in many genera. Sporangia and gametangia are often

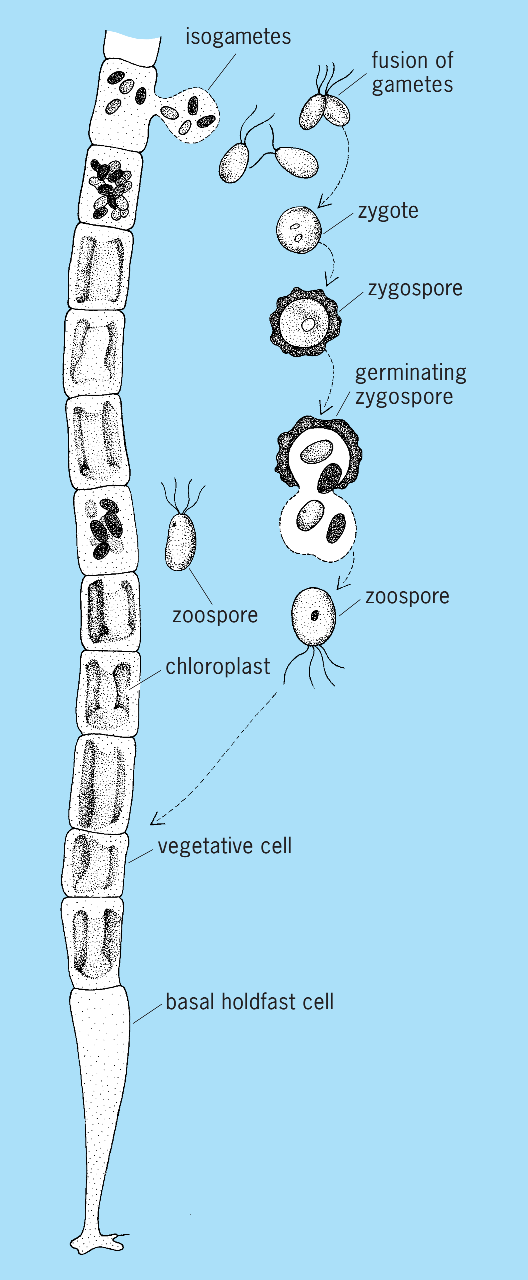

Fig. 3. *Ulothrix* (Ulotrichales).

conspicuously larger than vegetative cells and undergo sequential cleavage. Swarmers are released by the abrupt rupture of an elongate exit papilla. Various ulvophycean genera that previously were assigned to the Chaetophorales but that lack the special features of the Ulvelaceae are tentatively placed in the Ctenocladaceae.

Ulvales. The order Ulvales comprises green algae with thalli in the form of biseriate filaments, monostromatic blades, tubes, or sacs, and distromatic blades. Cytologically, they are similar to *Ulothrix*, and some workers do not segregate them from the Ulotrichales. Various life histories have been demonstrated. *Ulva* (sea lettuce) and its close relative *Enteromorpha* occur abundantly in the intertidal zone, especially in harbors and estuaries. As treated here, the order comprises five families (Capsosiphonaceae, Percursariaceae, Ulvaceae, Monostromataceae, and Gomontiaceae) with about 12 genera.

Trentepohliales. The order Trentepohliales, with the single family Trentepohliaceae, comprises a small, specialized group of subaerial algae. The thallus is composed of branched uniseriate filaments loosely arranged in an erect tuft or cohering laterally to form a prostrate disk. Sporangia and gametangia are clearly differentiated from vegetative cells. Starch is lacking. Carotenoid pigments are abundant, coloring the thallus yellow-green, yellow, orange, or red, and often imparting the odor of violets. *Trentepohlia*, which has both prostrate and erect systems, grows on rocks, tree trunks, leaves, and wooden structures. *Cephaleuros* grows within the leaves and twigs of various plants in tropical and subtropical regions, including those of commercial plantings of tea and coffee. It is parasitic, inducing a massive wound response in many hosts.

Acrosiphoniales. Thalli in the order Acrosiphoniales are composed of unbranched or branched filaments, each cell usually containing many nuclei and a perforate cylindrical chloroplast with numerous pyrenoids. The life history often includes a vesicular sporophyte derived from the zygote. The vesicle produces haploid quadriflagellate zoospores that give rise to filamentous gametophytes. Gametes and zoospores are liberated through a distinct pore, which is operculate in one family. The order includes two families, Codiolaceae with unbranched filaments and Acrosiphoniaceae with profusely branched filaments, comprising three or four genera restricted to cold marine and brackish waters.

Cladophorales. In the order Cladophorales, the simple or branched filaments have multinucleate cells, as in most Acrosiphoniales, but the characteristic life history is an alternation of isomorphic somatic phases. The cell wall is thick and lamellate. The chloroplast is a parietal network with numerous pyrenoids. *Cladophora* is one of the most common algae in all parts of the world and in all aquatic habitats. Certain species form spherical masses (*Cladophora* balls) that roll to and fro on the bottom of shallow lakes.

Siphonocladales. In the Siphonocladales, an order of tropical marine algae closely related to the Cladophorales, the multinucleate cells are often vesicular rather than cylindrical, and when cylindrical may anastomose in one or more planes. The chief feature of the order supposedly is the occurrence of a unique process of cell division, called segregative division. The protoplast cleaves into multinucleate portions of varying size, which round up, secrete a wall, and expand until they are in complete mutual contact. In some genera the daughter vesicles expand outward and upward, forming branches. The enormous size of the primary vesicle of certain species of *Valonia* has made this genus a favorite subject of biophysical studies, especially in the fields of permeability and solute absorption. In the few species of Siphonocladales in which sexual reproduction has been observed, the thalli are diploid gametophytes, with meiosis occurring during the production of biflagellate isogametes. The failure to observe segregative division in more than a few members of the Siphonocladales and the paucity of information on life histories obscure the border between this order and the Cladophorales. Some authors combine the two orders.

Bryopsidales. Many green algae (almost entirely marine) have thalli composed of nonseptate multinucleate filaments or tubes. These forms, which constitute the order Bryopsidales, are abundant and diverse in most tropical waters. *Halimeda*, which has a calcified thallus, is a major contributor to the buildup of coral reefs and infilling of atoll lagoons. *See* BRYOPSIDALES; HALIMEDA.

Dasycladales. In another group of tropical, essentially marine green algae, the thalli are noncellular, but unlike those in the Bryopsidales, they exhibit radial symmetry, with whorls of loosely arranged or densely aggregated branches arising from the primary axis. These forms constitute the order Dasycladales. Most members have calcified thalli, and there is a rich fossil record extending at least to the Cambrian and including more than a hundred extinct genera. Some genera have a unique life history, involving the fragmentation of an enormous primary nucleus to form numerous small secondary nuclei, which migrate into gametangia. The gametangia cleave into uninucleate units, which develop into operculate cysts containing biflagellate isogametes. Meiosis is believed to occur prior to or during fragmentation of the primary nucleus. *Acetabularia* (mermaid's wine glass) is frequently used in morphogenetic experimentation, since its large and readily accessible nucleus is quite amenable to manipulation. *See* DASYCLADALES.

Charophycean phyletic line. This phyletic group has motile cells that are scaly or naked, asymmetrical, devoid of eyespots, and with two laterally or subapically arising flagella, their basal bodies associated with a broad band of microtubules (multilayered structure) and usually an additional, smaller microtubular root. The distal ends of the basal bodies show counterclockwise rotation. Cytokinesis is effected either by centripetal growth of a furrow that impinges on microtubules of the persistent spindle or by means of a cell plate in the presence of a phragmoplast, the microtubules of which proliferate from the persistent spindle. This group includes the Chlorokybales, Klebsormidiales, Zygnematales, and Coleochaetales, as well as the charophytes (treated here as the class Charophyceae).

Chlorokybales. Packet-forming algae with charophycean ultrastructure have been segregated from the Chlorosarcinales as the order Chlorokybales. So far only one genus, *Chlorokybus*, is known.

Klebsormidiales. Rudimentary filaments that dissociate easily and lack holdfast cells are formed by members of the order Klebsormidiales. Plasmodesmata are absent. Each cell contains a nucleus and a parietal laminate chloroplast. Zoospores, which lack eyespots, are formed singly in unspecialized cells. Two families (Klebsormidiaceae and Elakatotrichaceae) with at least seven genera are tentatively recognized.

Zygnematales. The order Zygnematales is a large and well-known group of freshwater and subaerial green algae exhibiting two somatic types, unicells (desmids) and unbranched uniseriate filaments. The cell wall is composed of inner fibrillar cellulose layers and an outer slippery pectic layer. Plasmodesmata are absent. Each cell has a nucleus and one or more distinctly shaped chloroplasts. The most distinctive feature of the order is sexual reproduction by conjugation of ameboid or passive gametes (hence the alternate name, Conjugales). Flagellate cells are unknown. The zygote secretes a thick wall and undergoes a period of dormancy. Meiosis occurs at some point (variable, depending upon the species) between conjugation and germination.

Members of the Zygnemataceae (especially *Spirogyra* and *Zygnema*) form the slippery skeins common in stagnant water. Mesotaeniaceae, often called saccoderm desmids, are essentially unicellular Zygnemataceae. The Desmidiaceae and Peniaceae together constitute the placoderm desmids. The cells vary in shape, but are always composed of mirror-image semicells often demarcated by a median constriction. The cell wall has pores and is frequently ornamented. Placoderm desmids are abundant in slightly acidic fresh water. *See* ZYGNEMATALES.

Coleochaetales. Members of the order Coleochaetales are aquatic epiphytes or endophytes. The thallus consists of cells that are clustered or united into filaments. In *Coleochaete*, the only genus in the family Coleochaetaceae, the thallus may be filamentous, pseudoparenchymatous, or rudimentarily parenchymatous. Most or all cells bear one or more cytoplasmic setae, each with a basal gelatinous sheath. Each cell contains a nucleus and usually a parietal laminate chloroplast with a pyrenoid traversed by one or more thylakoids. Asexual reproduction is by scaly biflagellate zoospores, lacking eyespots and formed within ordinary cells. Sexual reproduction is oogamous, with minute colorless antherozoids being formed singly in conical antheridia, and eggs singly in spherical or flask-shaped oogonia. Fertilization occurs in place. The zygote enlarges greatly and secretes a thick wall. Neighboring branches produce a pseudoparenchymatous or parenchymatous sheath around the zygote, suggesting the possibility of the transfer of substances. After a period of dormancy (winter), the zygote germinates meiotically to form 8–32 biflagellate zoospores. Although exhibiting features conducive to the development of a terrestrial life, *Coleochaete* probably is not in the direct line of evolution of any extant embryophyte.

Pleurastrophycean phyletic line. Pleurastrophyceae have motile cells that are thecate or naked and more or less flattened. The flagella have a cruciate microtubular root system showing counterclockwise rotation of the basal bodies. The ancestral flagellate is believed to resemble *Tetraselmis*, a marine genus usually aligned with Prasinophyceae. The Pleurastrophyceae, while apparently a distinct group, is small. The few genera that have been assigned to it have been taken from several orders, including Chlorococcales, Chlorosarcinales, and Chaetophorales.

Micromonadophyceae. In addition to the four phyletic lines described here, each of which includes monads as well as multicellular algae, there is a residual group of primitive green flagellates for which the name Micromonadophyceae has been proposed. These monads are scaly or secondarily naked and have one to four flagella arising from an apical pit or lateral depression. The interzonal mitotic spindle persists during cytokinesis. This group corresponds to the class Prasinophyceae in the present classification.

The ultrastructural classification described in this article could be incorporated in the traditional scheme with minimal difficulty by according the rank of subclass to each major group, a treatment in keeping with the presumed monophyletic origin of green algae. For the sake of consistency, however, Prasinophyceae and Charophyceae are treated elsewhere in this work as separate classes. *See* ALGAE; CHAROPHYCEAE; PRASINOPHYCEAE.

Chlorophycota

A division of the plant kingdom (also known as Chlorophyta or Chlorophycophyta) comprising all algae that have chlorophyll *a* and *b* except the Euglenophyceae, and that in all other respects are so different as to suggest a separate origin of their photosynthetic pigments. Three classes, Charophyceae (charophytes), Chlorophyceae (green algae), and Prasinophyceae, are recognized. *See* ALGAE; CHAROPHYCEAE; CHLOROPHYCEAE; PRASINOPHYCEAE.

Paul C. Silva; Richard L. Moe

Chlorophyll

The generic name for the intensely green, blue, or purple tetrapyrrolic pigments found in higher plants, algae, and photosynthetic bacteria that serve as photoreceptors and transducers of light energy to chemical energy in photosynthesis. *See* PHOTOSYNTHESIS.

Occurrence and Distribution of Major Cholorophylls

Although only about 20 chlorophylls are discussed here, new chlorophylls are found every year, especially in marine microalgae and photosynthetic bacteria of lakes and tidal flats. Chlorophylls *a*, *b*, and *d* are found in oxygenic photosynthetic organisms. All members of the chlorophyll *c* group are found in oxygenic, marine microalgae. Bacteriochlorophylls *c*, *d*, *e*, and *g* are found in anoxygenic (non-oxygen-producing) photosynthetic bacteria. All members of the chlorophyll *c* group are found in oxygenic, marine microalgae.

Chlorophylls a and b. The principal chlorophylls of higher plants and green algae are chlorophylls *a* and *b*. Chlorophyll *a* is found in the light-harvesting pigment-protein complexes (also called antennae) and reaction-center complexes (where the chemistry takes place) of all oxygen-evolving organisms, while chlorophyll *b* is found only in the antennae.

In higher plants, chlorophylls *a* and *b* are contained in the chloroplast (a type of cell plastid). At the highest magnification of the light microscope, one may just see tiny grana in the plastids of higher plants. A granum is made up of 10–100 discs (known as thylakoids), which are the basic photosynthetic apparatus. Chlorophylls *a* and *b* are attached to specific proteins located in the thylakoid membrane. In addition to the outer light-harvesting antennae complexes, two functionally and structurally distinguishable groups of chlorophyll-protein complexes exist: photosystem I and photosystem II. Each photosystem, with the associated antenna, contains about 300 chlorophyll molecules (and a few carotenoid molecules). The majority of these chlorophylls serve as light-harvesting antennae and funnel the energy they absorb to the special reaction-center chlorophylls of photosystem I and II. These reaction-center chlorophylls are special as they are two chlorophyll *a* molecules held in close juxtaposition by a unique protein environment. *See* CAROTENOID; CELL PLASTIDS; PLANT CELL.

Chlorophyll c. The chlorophyll *c* group is a rapidly expanding group of at least eight antenna chlorophylls. All members of the chlorophyll *c* group are found in oxygenic marine microalgae and brown algae. *See* ALGAE.

Chlorophyll d. Chlorophyll *d* has been shown to be the major chlorophyll in the cyanobacterium *Acaryochloris marina* which is a free-living epiphytic bacterium growing in association with red algae. *See* CYANOBACTERIA.

Bacteriochlorophylls. Photoheterotrophic bacteria, which do not evolve O_2, contain bacteriochlorophyll *a* as their reaction-center pigment but may contain bacteriochlorophylls *a, b, c, d, e*, and *g* as antenna pigments. Purple photosynthetic bacteria contain bacteriochlorophylls *a, b*, and *g*, and the green bacteria contain bacteriochlorophylls *a, c, d*, and *e*. *See* BACTERIA; BACTERIAL PHYSIOLOGY AND METABOLISM.

Function

Chlorophyll molecules have three functions: (1) They serve as antennae to absorb light quanta. (2) They transfer this energy from one chlorophyll to another over distances usually of 1.5–2 nm by a process of resonance transfer, so that the energy finally comes to reside in the special chlorophyll molecules P700 or P680 (the number after P represents their long-wavelength absorption maxima) in the reaction centers of photosystem I or II. (3) The special reaction-center chlorophyll molecules P680 and P700, having in their excited states (symbolized as $P680^*$ and $P700^*$) the energy of the photon, undergo chemical oxidation by transferring one of their electrons to a neighboring acceptor molecule. Specifically, $P680^*$ transfers one electron to a pheophytin molecule (in case of photosystem II) and $P700^*$ to another chlorophyll molecule (in the case of photosystem I). In this way the energy of the fleeting light quanta is converted into stable chemical energy.

Light-induced oxidation of reaction-center chlorophyll molecules leads to photobleaching, which is detected spectroscopically by an absorbance decrease. Loss of an electron oxidizes the reaction-center chlorophyll molecules. P680 is transformed to $P680^+$ and P700 to $P700^+$. Analogous bacteriochlorophyll species, P840+ or P890+, is produced in nonoxygenic photosynthetic bacteria. These cationic species are detected both optically as well as by the electron spin resonance technique, because each has an unpaired electron. *See* SPECTROSCOPY.

Chemical Structure

Chlorophylls contain up to four pyrrole rings that are joined by four methine (—CH═) bridges at C5, C10, C15, and C20. However, all chlorophylls also contain a fifth cyclopentanone ring, designated E. Chlorophylls with four pyrrole rings are called phytoporphyrins, and the chlorophylls of the *c* group belong to this family, the members of which are emerald green in color. Chlorophyll *a* contains three pyrrole rings (rings A, B, and C) and one dihydropyrrole ring (ring D) with a hydrogen atom at C17 and C18 (**Fig. 1**). Such chlorophylls are called chlorins, and chlorophylls *a*, *b*, and *d*, and bacteriochlorophylls *c*, *d*, and *e* belong to this family: chlorophyll *a* is blue and the other five are green. Some chlorophylls contain two dihydropyrrole rings (rings B and D) with hydrogen atoms at C7, C8, C17 and C18. These chlorophylls are called bacteriochlorins. Bacteriochlorophylls *a*, *b*, and *g* belong to the bacteriochlorin family and they are purple. These different-colored chlorophylls allow the organisms that possess them to efficiently use (as photosynthetically active radiation) those parts of the visible and near-infrared spectrum of solar radiation that permeate their environment.

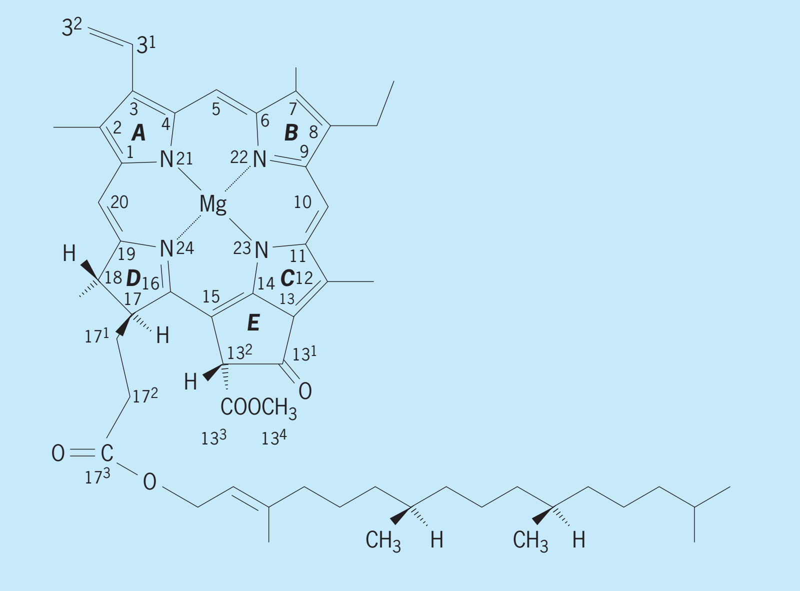

Fig. 1. Structure of chlorophyll *a* ($C_{55}H_{72}O_5N_4Mg$).

Central metal atom. Chlorophyll molcecules contain a central magnesium (Mg) atom that binds extra ligands (besides the four pyrrolic nitrogens) so strongly that it seldom exists only as a four-coordinate metal: one or both of the axial positions are occupied by an electron donor (nucleophile) group so that the Mg is generally a six-coordinate metal, but also sometimes exists as a five-coordinate metal. Axial coordination to the central Mg atom is important for understanding the ligation of chlorophyll to histidine, glutamine, or asparagine residues of chlorophyll apoproteins. Due to the greater than 4 coordination number of Mg, chlorophyll can exist as a monomer, dimer, trimer, tetramer, and as an aggregate of *n* number of chlorophyll molecules. The monomers absorb red light maximally in the 660–670-nm region, whereas the aggregates absorb (darker) red light in the 680–700-nm region. On the other hand, the chlorophyll-H_2O-chlorophyll adduct is suggested to absorb as far as 740 nm; the (chlorophyll·H_2O)$_2$ adduct may absorb around 700 nm.

Chlorins. The structure of chlorophyll *a*, which is a 3-monovinyl compound, is shown in Fig. 1. This molecule has now been synthesized in the laboratory. The characteristic feature of chlorophyll *a* is that it is a Mg-chlorin. Because rings A, B, C, and D are linked through methine bridges at C5, C10, C15, and C20 (Fig. 1), a large resonating 16-membered inner ring of carbon and nitrogen atoms attached to each other through alternating single and double bonds is formed. Closely related derivatives of chlorophyll *a* (the monovinyl pigment shown in Fig. 1) include [3,8-divinyl]-chlorophyll *a* which sometimes has long-chain alcohols other than phytol esterified at C17^3. Some widely dispersed marine phytoplanktonic *Prochlorococcus* strains contain 3,8-divinyl derivatives of chlorophylls *a* and *b*: it has been calculated that these divinyl pigments are responsible for approximately 25% of global photosynthesis.

Other chlorophylls closely related to chlorophyll *a* possess formyl (—CH═O) groups. Chlorophyll *b* is [7-formyl]-chlorophyll *a* and chlorophyll *d* is [3-formyl]-chlorophyll *a*.

Bacteriochlorophylls *c* and *d*, like chlorophyll *a*, belong to the chlorin family. The common features include a hydroxyethyl (—CHOHCH$_3$) group at C3, while the carboxymethyl (—COOCH$_3$) group at C13^2 of chlorophyll *a* is replaced by a H atom and the long-chain alcohol esterified at C17^3 is frequently farnesol ($C_{15}H_{25}OH$) of chlorophyll *a*, which replaces the phytol ($C_{20}H_{39}OH$). Bacteriochlorophylls *c* and *e* in addition have a C20 methyl (—CH$_3$) substituent.

Phytoporphyrins. The chlorophyll *c* group is a diverse group of Mg-phytoporphyrins including [3,8-divinyl]-protochlorophyllide *a*, which is also shown as a biosynthetic intermediate in the biosynthesis of chlorophyll *a* (**Fig. 2**). Most chlorophylls *c* have a free C17^3 carboxyl group, but two recently discovered nonpolar chlorophylls *c* are esterified at C17^3 to the sugar residue of a monogalactosyldiacylglycerol (MGDG) moiety. Frequently, the propionate group at C17 is replaced by an acrylic acid (—CH═CH—COOH) side chain.

Bacteriochlorins. Bacteriochlorophylls *a, b*, and *g* belong to the bacteriochlorin family of chlorophylls. There are several forms of bacteriochlorophyll *a*: one is esterified at C17^3 with phytol and the other is esterified with geranyl-geranol. Both forms have an acetyl (—CO—CH$_3$) group at C3 and an ethyl (—C_2H_5) group at C8. Bacteriochlorophylls *b* and *g* have an ethylidene (═CH—CH$_3$) group at C8 but bacteriochlorophyll *b* has an acetyl group at C3 where bacteriochlorophyll *g* has a vinyl (—CH═CH$_2$) group. In *Acidiphilium rubrum* the central Mg of bacteriochlorophyll *a* is replaced by a zinc (Zn) atom.

Chlorophyll derivatives. Pheophytins are chlorophyll derivatives lacking the central Mg atom; they occur naturally as electron acceptors in photosystem II. Bacteriopheophytin *a* is a derivative of bacteriochlorophyll *a* and serves as an electron acceptor in bacterial reaction centers. Pheophorbides are chlorophyll derivatives that have lost the central Mg atom and the long-chain alcohol ester moiety.

Biosynthesis

The two major plant tetrapyrrole pigments, chlorophylls and hemes, are both synthesized from ALA (5-aminolevulinic acid). ALA is converted to protoporphyrin in a series of enzymatic steps, which are identical in plants and animals. Thereafter, the pathway branches to form hemes text are porphyrins chelated with iron (Fe^{2+}), which are present in many respiratory hemoproteins including cytochromes. In the other branch, porphyrins are chelated with Mg^{2+} to form precursors of chlorophyll (Fig. 2). *See* HEMOGLOBIN; PORPHYRIN.

ALA is formed by the condensation of succinyl coenzyme A and glycine by ALA-synthase in non-plastid-containing eukaryotes (animals, yeasts and fungi) and in the α subgroup of proteobacteria (which includes the well-known genera of photosynthetic bacteria *Rhodopseudomonas,* *Rhodobacter*, and *Rhodospirillum*). However, in plants, algae, Archaea, and most bacteria (excluding the α-proteobacteria), ALA is formed from glutamate, a 5-carbon amino acid, by the C_5 pathway. This is the more ubiquitous pathway of ALA formation in nature. All of the enzymes necessary for converting glutamate to ALA (and further to chlorophyll) are contained in the chloroplasts of higher plants and green algae. The $C13^1$, $C13^2$, and $C13^3$ of ring E (Fig. 1) arise from the propionic acid ($—CH_2—CH_2—COOH$) group of Mg-protoporphyrin. An oxygen is introduced to form a 13^1-oxo-propionic acid ($—CO—CH_2—COOH$) moiety and spontaneous bonding then occurs between $C13^2$ and C15, thus forming ring E with a $C13^3$ carboxymethyl ($CHOOCH_3$) substituent. In higher plants and green algae, the oxygen for the 13^1-oxo-group comes from molecular oxygen (O_2), by activity of an oxygenase-type enzyme; in anaerobic photosynthetic bacteria, it comes from water (H_2O), by a hydratase enzyme activity.

In higher plants, a light-dependent and reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent protochlorophyllide reductase (LPOR) introduces a hydrogen atom at both C17 and C18, thus converting protochlorophyllide to chlorophyllide. Cyanobacteria, green algae, mosses, ferns, and gymnosperms contain both LPOR and a dark (that is, light-independent) DPOR enzyme so that these organisms can synthesize chlorophyllide in light or dark. The esterification of a geranylgeranyl pyrophosphate forms chlorophyll *a* with a geranylgeranyl ester, which is followed by reduction to a phytyl ester: the esterification and reduction are both catalyzed by chlorophyll synthase, thus completing chlorophyll *a* formation. Among additional cofactors required for chlorophyll formation are Fe^{2+}, Mg^{2+}, adenosine triphosphate (ATP), nicotinamide adenine dinucleotide (NAD), and O_2. Concomitant with chlorophyll synthesis, the disk, or thylakoid, membranes are also synthesized. The possible origins of the phycobilin pigments, chlorophylls *b*, *c*, and *d*, and the bacteriochlorophylls are shown in Fig. 2.

Fluorescence

Chlorophylls reemit a fraction of the light energy they absorb as fluorescence. Regardless of the wavelength of the absorbed light, the emitted fluorescence is always on the long-wavelength side of the lowest energy absorption band, in the red or infrared region of the spectrum. The fluorescent properties of a particular chlorophyll are functions of the structure of the molecule and its immediate environment. Thus, the fluorescence spectrum of chlorophyll in the living plant is always shifted to longer wavelengths (peak at 685 nm) relative to the fluorescence spectrum of a solution of the same pigment (peak at approximately 660 nm). This red shift is characteristic of chlorophyll-protein complexes.

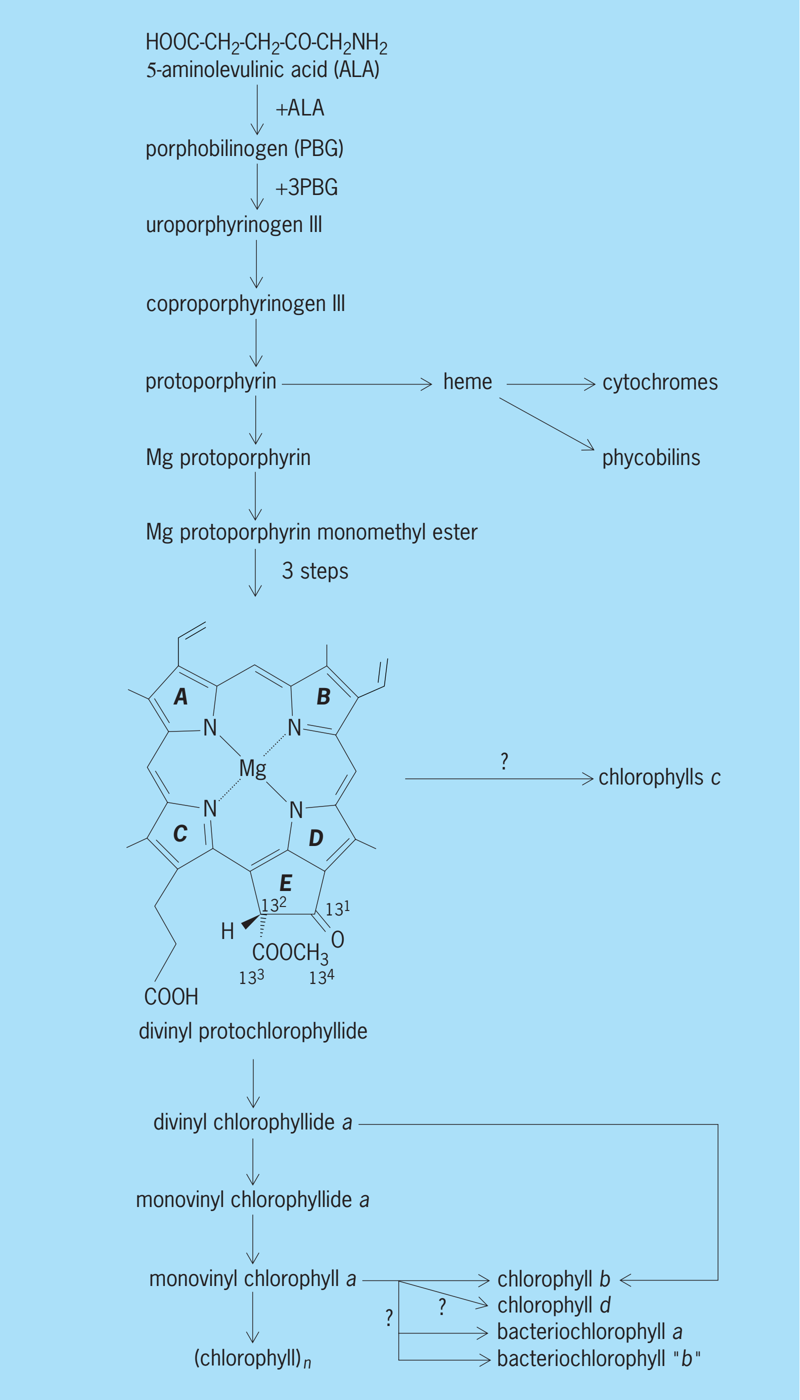

Fig. 2. Simple biosynthetic route for chlorophyll *a* and some related compounds. (In reality most of the pathways are much more complex and are often branched.) The tetrapyrrole structure shown above is Mg 3,8-divinyl protochlorophyllide.

Even in dilute solutions, the capacity of chlorophyll to fluoresce depends on the nature of the solvent. In solvents that can combine with the central Mg atom of chlorophyll by donating a pair of electrons to it, chlorophyll is fluorescent. In solvents that lack this property, chlorophyll is dimeric or polymeric and nonfluorescent at room temperature. The aggregates are formed by combining the carbonyl group of one molecule with the Mg atom of the neighboring molecule.

An excited chlorophyll *a* in diethyl ether has a mean lifetime of 5×10^{-9} s (5 nanoseconds), whereas in the living plant this is reduced to $0.5–2 \times 10^{-9}$ s (0.5–2 ns). A long-lived excited state of chlorophyll *a* (the triplet state) has been observed under special conditions, such as illumination of concentrated solutions in dry hydrocarbon solvents at low temperatures. Under these conditions, chlorophyll *a* emits phosphorescence at a spectral maximum of 750 nm. Weak phosphorescence of chlorophyll *a* has been recently observed in living cells.

The most widespread chlorophylls in nature, chlorophylls *a* and *b*, fluoresce with a quantum efficiency of 0.33 and 0.16, respectively, in dilute solution in diethyl ether. In the living cell the quantum efficiency drops to 0.03 for chlorophyll *a* and to zero for chlorophyll *b*. This is due to the property of chlorophyll *b* to transfer all its excitation energy to chlorophyll *a*, which, in turn, channels most of its excitation to photosynthesis, allowing only a small fraction to escape as fluorescence.

Measurements of chlorophyll *a* fluorescence are of great practical use as these have been shown to be a probe of the efficiency of photosynthesis. Applications of fluorescence are numerous and include measurements of the photosynthetic efficiency of plants under field conditions; advance estimations of the impact of abiotic and biotic environmental stresses on anticipated crop and biomass and yields; and, the assessment of the photosynthetic efficiency and productivity of plant communities in terrestrial, inland water, and marine ecosystems by remote sensing of chlorophyll *a* fluorescence. *See* FLUORESCENCE.

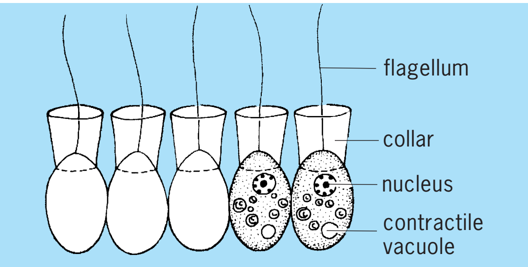
Choanoflagellida

An order of the class Zoomastigophorea, superclass Mastigophora, subphylum Sarcomastigophora, in the phylum Protozoa. They are principally small, single-celled or colonial, structurally simple, colorless flagellates distinguished by having the anterior end surrounded by a thin protoplasmic collar, within which is an ingestive area for particulate matter, for example, bacteria. A single flagellum arises from the center of this collar. The genus *Monosiga* is single, sometimes with a stalk, sometimes free in the plankton. *Desmarella* is a linear colony (see **illus.**), and *Astrosiga* and *Sphaerosiga* are colonies radiating from a center. *Proterospongia* cells arise in a common jelly, the zooids being organically connected. *Diploeca* lives in an attached lorica. *Stelexomonas* and *Aulomonas* inhabit tubular loricae. *Diplosiga* has a double colony. *Sportelloeca* and *Pleurasiga* live in complex loricae. *See* PROTOZOA; SARCOMASTIGOPHORA; ZOOMASTIGOPHOREA.



A linear colony of the choanoflagellate, *Desmarella moniliformis*.

The botanist P. Bourrelly puts these organisms in the order Monosigales. It is generally agreed, however, that the group shows relationships to the sponges. They are widespread in fresh and salt water and are common in inshore waters. James B. Lackey

Choke (electricity)

An inductor that is used to prevent electric signals and energy from being transmitted along undesired paths or into inappropriate parts of an electric circuit or system. Power-supply chokes prevent alternating-current components, inherent to a power supply, from entering the electronic equipment. Radio-frequency chokes (RFCs) prevent radio-frequency signals from entering audio-frequency circuits. The printed circuit boards used in virtually all electronic equipment such as computers, television sets, and high-fidelity audio systems typically have one or more chokes. The purposes of these chokes are the (1) attenuation of spurious signals generated in the equipment itself so that these signals will not be transmitted to other parts of the circuit or beyond the overall system to other electronic devices; (2) prevention of undesired signals or electrical noise generated in other parts of the system from adversely affecting circuit performance; and (3) prevention of ripple from the power supply from degrading system behavior. Waveguide chokes keep microwave energy from being transmitted to the wrong part of a waveguide system. *See* ELECTRICAL

NOISE; ELECTRONIC POWER SUPPLY; PRINTED CIRCUIT; RIPPLE VOLTAGE; WAVEGUIDE.

In its simplest form, a choke or an inductor is a coil of wire (usually copper) wound around and insulated from a core, which may or may not be ferromagnetic. Ferromagnetic cores tend to increase inductance, reduce physical size, and reduce electromagnetic coupling between circuit elements, and they may increase power loss and resultant heating. Such cores often lead to nonlinear or swinging chokes, commonly found in power supplies, where the nonlinearity may be an advantage. The basic principle of operation derives from the fact that it is impossible to change instantaneously the energy stored in a magnetic field. The various configurations are designed to control the magnetic field in an appropriate manner. The graphic symbols used to represent the various types of chokes or inductors in electric circuits are shown in the **illustration**.

Chokes come in a wide variety of inductance ranges, power-handling capabilities, fabrication technologies, and intended applications. In many cases they are specially designed for a particular situation. Chokes are available in inductance sizes ranging from a fraction of a microhenry to tens of henrys or higher. The frequency range of intended use is a major consideration. *See* INDUCTANCE; INDUCTOR.

Choked flow

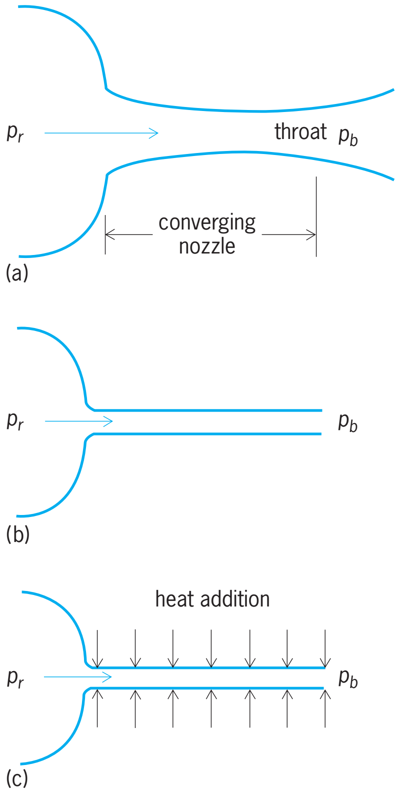
Fluid flow through a restricted area whose volume flow rate reaches a maximum when the fluid velocity at the minimum area reaches sonic speed. The phenomenon of choking exists only in compressible flow and can occur in several flow situations. *See* COMPRESSIBLE FLOW.

Flow through varying-area duct. Choked flow can occur through a convergent flow area or nozzle attached to a huge reservoir (**illus.** *a*). Flow exits the reservoir through the nozzle if the back pressure is less than the reservoir pressure. In all cases considered here, the reservoir pressure is assumed to be a constant. When the back pressure is decreased slightly below the reservoir pressure, a signal from beyond the nozzle exit is transmitted at sonic speed to the reservoir. The reservoir responds by sending fluid through the nozzle. Further, the maximum velocity of the fluid exists at the nozzle throat where the area is smallest.

When the back pressure is further decreased, fluid exits the reservoir more rapidly. Eventually, however, the velocity at the throat reaches the sonic velocity. Then the fluid velocity at the throat is sonic, and the velocity of the signal is also sonic. Therefore, further decreases in back pressure are not sensed by the reservoir, and correspondingly will not induce any greater flow to exit the reservoir. The nozzle is thus said to be choked, and the mass flow of fluid is a maximum for a given reservoir pressure. Thus, choking in a converging nozzle occurs when the Mach number (defined as the ratio of fluid velocity to the sonic velocity) at the throat equals 1. *See* MACH NUMBER; NOZZLE; SOUND; SUPERSONIC DIFFUSER.

Flow with friction. Choked flow can also occur through a long constant-area duct attached to a reservoir (illus. *b*). As before, flow from the reservoir through this duct is induced when the back pressure is decreased below the reservoir pressure, and a signal is transmitted through the duct to the reservoir.

As fluid flows through the duct, friction between the fluid and the duct wall reduces the pressure acting on the fluid. As pressure is reduced, other fluid properties are affected, such as sonic velocity, density, and temperature. The maximum Mach number occurs at the duct exit. As the back pressure is decreased, flow exits more rapidly through the duct,



Examples of choked flow. (*a*) Flow through a varying-area duct or nozzle. (*b*) Flow through a constant-area duct. (*c*) Frictionless flow through a constant-area duct with heat addition. P_b = back pressure; P_r = reservoir pressure.

but eventually the Mach number at the exit reaches 1. Any further decrease in back pressure is not sensed by the reservoir and so causes no increase in flow rate. Thus, when the Mach number is 1 at the duct exit, the flow is said to be choked, and the mass flow rate through the duct is a maximum.

Frictionless flow with heat addition. A reservoir with a constant-area duct attached may also be considered in the case that the flow through the duct is assumed to be frictionless, but heat is added to the system along the duct wall (illus. *c*). As fluid receives energy in the form of heat, fluid properties again change. The maximum Mach number occurs at the duct exit. As the total amount of heat increases, the Mach number at the duct exit increases, and eventually reaches 1. At this point, the mass flow through the duct is a maximum and the flow is said to be choked. Any further heat addition results in a decrease in mass flow through the duct. *See* FLUID FLOW; GAS DYNAMICS.

Cholera

A severe diarrheal disease caused by infection of the small bowel of humans with *Vibrio cholerae*. This facultatively anaerobic, curved, gram-negative, rod-shaped bacterium is rapidly motile by means of a single sheathed polar flagellum. Cholera is transmitted by the fecal-oral route. From its ancestral home in the Indo-Pakistani subcontinent, through movement of people by ships and other means of transportation, cholera has swept the world in seven pandemic waves. These involved the Western Hemisphere several times in the 1800s, and again in Peru in 1991. Whereas previous cholera outbreaks were associated with high mortality rates, through understanding of its pathophysiology it can now be said that no one should die of cholera who receives appropriate treatment soon enough.

Cholera produces a secretory diarrhea caused by the protein cholera enterotoxin (CTX), which is composed of two kinds of subunits: five B subunits responsible for binding to a glycolipid, the GM1 ganglioside, on host membranes; and a single A subunit, which is an enzyme. The latter, an adenosine ribosyl transferase, transfers adenosine diphosphate P–ribose from nicotinamide adenine dinucleotide to a host cell regulatory protein, G_s. This causes permanent activation of adenylate cyclase and a consequent increase in cyclic adenosine monophosphate. The result is hypersecretion of chloride and bicarbonate and inhibition of sodium absorption, leading to the secretion of the large volumes of isotonic fluid which constitute the diarrhea of severe cholera. The B subunit also activates arachidonic acid metabolism, leading to the production of eicosanoids, which may contribute to the diarrhea as well as to the immune response. The treatment consists of replacing the fluids and electrolytes lost in the voluminous cholera stool. This can be done intravenously, which may be essential initially in comatose patients, or perorally using oral rehydration salt solutions containing a utilizable carbon (energy) source (glucose, rice powder). The oral rehydration solutions are a relatively recent development, can also be used in the treatment of other diarrheal diseases, and have been responsible for saving millions of lives. Appropriate antibiotics can also be used adjunctively to decrease the excretion of the vibrios and the duration of the disease. The incubation period may be less than one day or up to several days; properly treated, the patient should recover in 4 or 5 days. The disease produces immunization, and convalescents rarely get cholera again. *See* DIARRHEA.

Despite the fact that the cholera vibrios were first discovered by Robert Koch in 1883 and a cholera vaccine was introduced 3 years later, there is still no effective, economical, and nonreactogenic vaccine. Use of a killed whole-cell vaccine administered parenterally was eliminated because of expense, reactogenicity, and lack of efficacy. Experimental vaccines currently being evaluated include genetically engineered living attentuated preparations administered perorally (or intranasally), killed whole-cell vaccines administered perorally, and conjugated vaccines (polysaccharide and toxin antigens) administered parenterally. Efforts are also being made to include cholera antigens transgenically in edible plants. A recently developed candidate attenuated vaccine has a deletion in the CTXφ (which carries the genes for CTX) and is also defective in its hemagglutinin/protease. The latter is a zinc metalloprotease which apparently causes detachment of the vibrios (to find another host) and may contribute significantly to the diarrhea which is still produced by CTX$^-$ strains.

A complicating feature is the fact that of approximately 150 recognized serogroups of *V. cholerae*, until 1992 only the two biotypes, classical (first described by Koch) and El Tor (recognized later), of serogroup O1 have been responsible for all epidemic cholera (El Tor first emerged in pandemic form in 1961). In 1992 a recently recognized serogroup, O139, caused epidemic cholera in India and Bangladesh and, for a time, replaced the resident El Tor vibrios. O139 resembles El Tor except for the distinctive O139 (instead of O1) polysaccharide somatic antigen and the possession of a capsule. They are antigenically distinct, so a new vaccine will be required for O139. The emergence of O139 raises the specter that other serogroups of *V. cholerae* may acquire virulence and epidemicity by some means of horizontal genetic transmission. It has recently been recognized that CTX is genetically encoded by a bacteriophage, CTXφ, which has become integrated in the *V. cholerae* chromosome. Virulent cholera vibrios also produce toxin-coregulated pili, surface fibrils, which are essential for colonization and also serve as receptors for CTXφ. Other non-O1/O139 vibrios carry CTXφ but apparently do not have other essential attributes of virulence, including the ability to adhere and colonize the small bowel and to spread epidemically. Another pilus, the mannose-sensitive hemagglutinin, serves as the receptor for another temperate filamentous choleraphage, 493, which may play a role in horizontal genetic transmission and cholera vibrio territoriality.

The best ways to avoid cholera are by chlorination of water, sanitary disposal of sewage, and avoidance of raw or improperly cooked seafood, which may have become infected by ingesting infected plankton in epidemic areas.

Cholesterol

A cyclic hydrocarbon alcohol commonly classified as a lipid because it is insoluble in water but soluble in a number of organic solvents. It is the major sterol in vertebrate cells and the most common sterol of eukaryotes, but it is absent from most prokaryotes. In vertebrates, the highest concentration of cholesterol is in the myelin sheath that surrounds nerves and in the plasma membrane that surrounds all cells. Insects and most invertebrates cannot synthesize cholesterol; therefore, they rely on dietary cholesterol for use in their membranes and as a precursor of ecdysone, a molting hormone required during growth and development. *See* ECDYSONE; LIPID.

Function. All vertebrate cells require cholesterol in their membranes to function normally. Cholesterol helps maintain normal cell membrane function by associating with the phospholipid acyl chains within the membrane, thereby adjusting up or down the degree of molecular motion or fluidity within the membrane that allows proteins to carry out their tasks. Cholesterol is also the required precursor molecule for the formation of steroid hormones, bile acids, and vitamin D, which are required in the execution of various essential bodily processes.

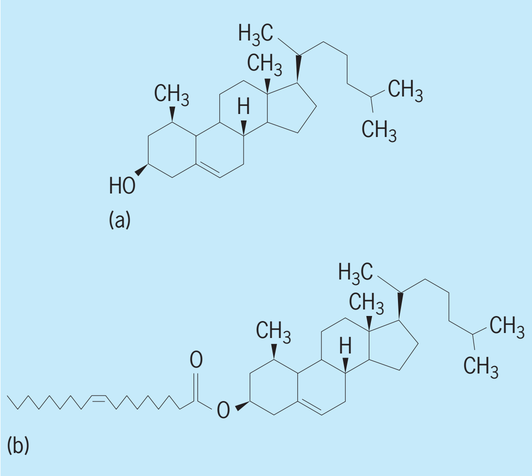

Fig. 1. Cholesterol. (*a*) Structure of unesterified, or free, cholesterol with the hydroxyl group in the 3β, position. (*b*) Structure of a cholesteryl ester molecule with a fatty acid (oleate in this case) attached to the 3β-hydroxy position via an ester bond.

Free and esterified forms. Cholesterol can exist either in the free (unesterified) form, in which the hydroxyl group (OH) at carbon-3 exists in the beta (β) configuration (**Fig. 1***a*), or as a cholesteryl ester to which a fatty acid is attached through an ester bond to the 3β-hydroxyl group (Fig. 1*b*). The free form is found in cell membranes and on the surface of plasma lipoproteins (lipid-protein emulsion-like complexes that transport cholesterol among tissues via the blood), with the hydroxyl group at the membrane aqueous environment interphase and the hydrocarbon tail buried among the fatty acyl chains of the phospholipids forming the membrane or surface layer. The cholesteryl ester molecule is usually found within lipid droplets in the cytoplasm of cells or within the neutral lipid core of plasma lipoproteins.

Cholesterol can be esterified by tissue enzymes termed acyl-coenzyme A (CoA):cholesterol *O*-acyltransferases 1 and 2 (ACAT1 and ACAT2) and by the plasma enzyme lecithin-cholesterol acyltransferase or LCAT. ACAT1 catalyzes the esterification of cholesterol for storage within cells in steroidogenic (steroid-producing) tissues. In the liver, the organ that serves as the central clearinghouse for cholesterol in the body, cholesterol esterification via ACAT2, leads to its storage or its secretion in the form of lipoproteins. Esterification via ACAT1 also occurs in macrophages (phagocytic immune cells) in the arterial wall, forming the lipid-filled foam cells of atherosclerosis in a process apparently designed to protect the cell membrane from becoming overly enriched in free cholesterol. In steroidogenic tissues, cholesteryl ester can be hydrolyzed via catalysis by cholesterol ester hydrolase (CEH), and the resulting cholesterol is then converted into steroid hormones. In macrophage foam cells, hydrolysis via CEH allows for cholesterol mobilization and removal from the cell; and in the liver, hydrolysis via CEH permits the cholesterol molecule to be used for any of the multiple pathways within the liver, including those resulting in the formation of bile and plasma lipoproteins and those involved in membrane function. *See* CELL MEMBRANE; LIPOPROTEIN; PHOSPHOLIPID.

Sources. Cellular cholesterol is obtained both from the diet, following its absorption in the intestine, and from synthesis within all cells of the body.

Intestinal cholesterol absorption. Much of the cholesterol in the body can be obtained in the diet. Foods that contain cholesterol come from animal sources, and those highest in cholesterol include eggs, dairy products, and organ meats such as liver and brain. The cholesterol from the human diet, typically about 250 mg per day, becomes mixed with endogenous (originating from within the body) cholesterol (about 750 mg per day), secreted into the intestine in bile. Through the processes of digestion, dietary cholesterol is solubilized by bile acids (detergents that facilitate fat and cholesterol absorption) into micelles (water-soluble particles) and transferred through a protein called Niemann-Pick C1-like 1 into enterocytes (cells lining the intestine), whereupon it is esterified by ACAT2, incorporated into absorptive lipoproteins called chylomicrons, and brought into the circulation and deposited in the liver. This process is only about 50% efficient, and about half of the cholesterol in the intestine is excreted each day.

While all cell types have the enzymatic machinery to synthesize cholesterol, only the liver has enzymes to degrade the cholesterol molecule in significant amounts by converting it into bile acids. Assembly of bile acids and cholesterol into bile micelles in the liver with subsequent secretion into the intestine, followed by absorption and return of the absorbed cholesterol to the liver constitutes the process termed enterohepatic recirculation. In a normal day, the bulk of the removal of cholesterol from the body occurs through fecal excretion of approximately equal amounts ($\sim$1 g combined) of cholesterol and bile acid. *See* ABSORPTION (BIOLOGY); LIVER.

Biosynthesis and feedback regulation. Cholesterol synthesis occurs in all vertebrate cells, with perhaps the highest rates occurring in the liver, skin, intestine, and in the brain at the time of myelination. The process involves the conversion of two-carbon acetate molecules into isoprenoid units continuing on to produce a 30-carbon precursor known as lanosterol. This molecule is then rapidly converted into the 27-carbon cholesterol molecule. The whole process requires over 40 enzymes and is highly regulated by the cholesterol status of the cell through the process of feedback regulation. The key rate-limiting enzyme in the biosynthetic process is 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase). This is the target enzyme for the statin drugs that are used clinically to reduce blood cholesterol concentrations. These drugs work in part by binding to and inactivating HMG-CoA reductase, resulting in a decrease in the rate of cholesterol synthesis. *See* COENZYME; ENZYME.

Although the presence of feedback regulation of cholesterol synthesis was identified some 70 years ago, only recently have we come to understand the complexity of the process. The systematic identification of the many individual steps in this process has provided new fundamental information about the structure and function of cell membranes. A whole series of protein molecules has been evaluated, and the identification of the processes that govern the behavior of these proteins has provided unique insights into how membranes function as molecular sensors responding to changes in the cholesterol availability within the cell.

In the 1950s, the liver was shown to be the site of much of the feedback regulation; nevertheless, many of the details about the feedback mechanism have been identified in skin fibroblasts and in other cells in culture that can be manipulated to induce mutations in individual steps in the regulatory process (**Fig. 2**). Initially, cholesteryl ester-rich low-density lipoproteins (LDL) bind to receptors on the cell surface termed LDL receptors. These receptors localize in regions within the membrane, termed clathrin-coated pits in cell types other than liver cells. These structures bud off the membrane and move into the cell. The bound LDL is delivered to lysosomes (cellular organelles containing digestive enzymes), whereupon the cholesteryl esters are hydrolyzed, making the cholesterol available to the cell. In liver hepatocytes, where most of the LDL clearance from plasma occurs, the LDL receptors do not cluster in coated pits. Rather, the receptor appears to interact with an as yet unidentified protein molecule for internalization of bound LDL particles.

Within cells, the amount of the LDL receptor produced is regulated through transcriptional mechanisms. The cholesterol molecules brought into the cell as a result of receptor activity will eventually transmit the signal for downregulation (a decrease) of receptor-mediated uptake of LDL. This occurs by shutting down the transcriptional activation of the LDL receptor gene in an analogous fashion to the regulation of the genes that participate in cholesterol biosynthesis.

The transcription factor responsible for stimulating transcription of the enzymes of the biosynthetic pathway as well as the LDL receptor is termed the sterol regulatory element-binding protein (SREBP). This protein controls gene transcription by binding to a nucleotide sequence (typically 5′-TCACNCCAC-3′, where N can be any base) within the promoter region of genes. There appear to be a family of three SREBPs (SREBP1a, SREBP1c, and SREBP2), each of which may be involved in regulation of different aspects of lipid metabolism. These proteins are initially integral membrane proteins within the endoplasmic reticulum. As such, they have no access to the nucleus without protein processing. To gain access to the nucleus, the SREBPs must move within vesicles

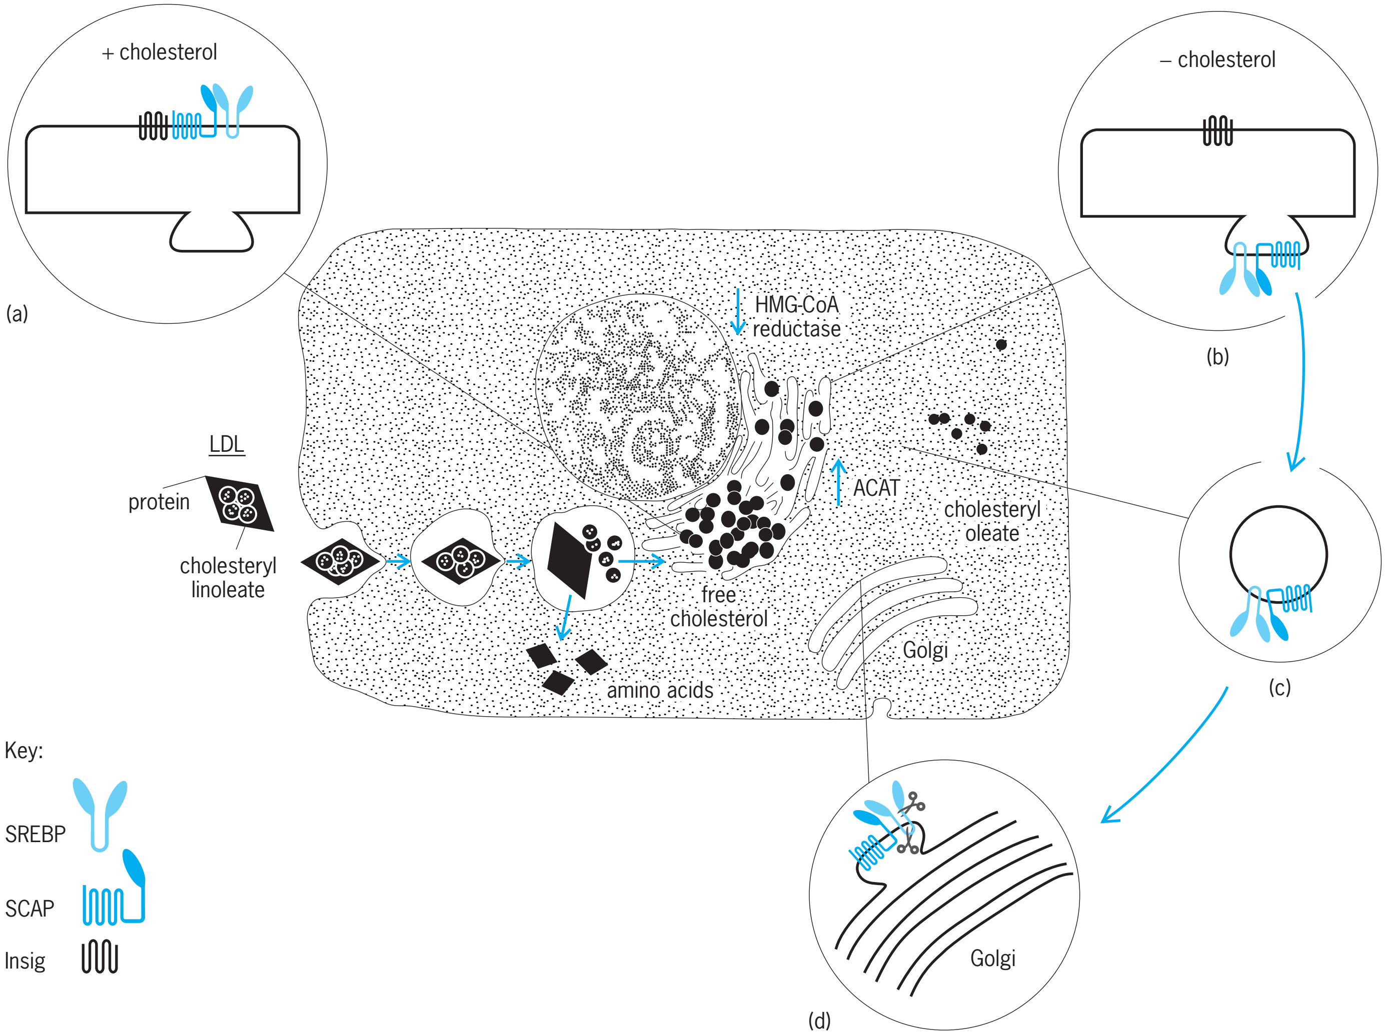

Fig. 2. Insights into the low-density lipoprotein (LDL) receptor internalization pathway, including the uptake of LDL, disassembly in the lysosome, and conversion of the LDL cholesteryl esters into cholesterol, which becomes a part of the regulatory pool of cholesterol inside the cell. (*a*) When cellular cholesterol levels are normal, sterol-regulatory element-binding protein (SREBP), SREBP cleavage-activating protein (SCAP), and Insig-1 form a macromolecular complex in the endoplasmic reticulum (ER). (*b*) Lowering the cholesterol level in the ER stimulates the release of Insig-1 from the complex, which allows SCAP to escort SREBP to vesicles. (*c*) These vesicles bud off and are targeted to carry the SCAP-SREBP complex to the Golgi apparatus. (*d*) In the Golgi, SREBP is cleaved at two sites by proteases, and the sterol-regulatory element-binding fragment is released into the cytoplasm from where it migrates into the nucleus. (*Reprinted from R. G. W. Anderson, J. Goldstein, and M. Brown, From cholesterol homeostasis to new paradigms in membrane biology, Trends Cell Biol., 13:534–539, © 2003, with permission from Elsevier*)

to the Golgi complex inside cells, where the SREBP protein undergoes proteolytic cleavage at two sites by two different proteases, the so-called site 1 and site 2 proteases (Fig. 2*d*). The result is the release of a 480-amino-acid N-terminal portion of the protein that is a transcription factor that travels to the nucleus, where it can bind to the sterol-regulatory element within genes and participate in signaling for their transcription. The SREBP1 transcription factors bind to numerous genes that are involved in fatty acid metabolism, whereas SREBP2 is more involved in promoting the transcription of genes in cholesterol metabolism.

Initially, it appeared that regulation of the release of the processed transcription factor via proteolytic cleavage would be the key regulatory step responsive to cholesterol, but in reality it turned out to be a protein termed SREBP cleavage activating protein, or SCAP (Fig. 2*b*). This protein contains an amino acid sequence termed the sterol-sensing domain (SSD), which is made up of eight membrane-spanning regions that define a signature sequence that is shared with other proteins known to be sensitive to regulation by cholesterol. Several amino acid mutations that abolish cholesterol-mediated regulation occur in the SSD of SCAP. Identification of this fact signaled that it was SCAP that actually detected the level of cholesterol in the membrane. When SCAP binds cholesterol, a conformational change occurs in SCAP that allows the protein to bind to proteins called insigs, which serve as endoplasmic reticulum membrane anchors. When SCAP is bound to insigs, the SCAP–SREBP complex is retained in the endoplasmic reticulum and cannot participate in vesicular traffic to the Golgi compartment (Fig. 2*a*). The result is that SREBP cannot be processed and the transcriptional component of SREBP cannot be generated and travel to the nucleus and activate cholesterol biosynthetic enzymes. The decrease in nuclear content of processed SREBPs results in a decrease in cholesterol biosynthesis. *See* ENDOPLASMIC RETICULUM; GENE; GENE ACTION; GOLGI APPARATUS.

Metabolism. Steroid hormones are derived from cholesterol and are required for the control of many different cell functions. The conversion of cholesterol to the steroid hormones including cortisol, aldosterone, and androgens occurs in the adrenal glands. Conversion of cholesterol to estrogen, progesterone, or testosterone occurs in the ovary, placenta, or testes. *See* HORMONE; STEROID.

Cholesterol is also a precursor of the bile acids that are synthesized in the liver. Bile acids together with cholesterol and phospholipids are secreted into the bile canaliculi (minute ducts or channels) in the liver. The detergent property of bile acids permits these lipids to become micelles. When the fat in food enters the intestine after a meal, the gallbladder contracts and the liver is stimulated to produce more bile that is secreted into the small intestine, where the bile acids participate in the emulsification (solubilization) of the fat in the diet. The emulsification process allows digestion of the fat to take place efficiently, and the products of digestion, including cholesterol, are absorbed into the intestinal cells. Sometimes, cholesterol in the gall bladder crystallizes and becomes gallstones. The size of the gallstones can vary widely from about the size of a grain of gravel to a lima bean. *See* GALLBLADDER; GALLBLADDER DISORDERS.

A cholesterol biosynthetic precursor, 7-dehydro cholesterol is also the precursor of vitamin D, a hormone that is required for control of normal calcium metabolism. The initial step in the conversion of 7-dehydro cholesterol to vitamin D occurs in the skin in response to ultraviolet light; however, further modifications are required in the liver and kidney in order to form the biologically active form of the vitamin. *See* CALCIUM METABOLISM; LIPID METABOLISM; VITAMIN D.

Plasma lipoproteins and atherosclerosis. Cholesterol and cholesteryl esters are essentially insoluble in water so that, in order to transport these molecules among tissues in the blood, the liver and intestine produce lipid–protein complexes termed lipoproteins. These particles solubilize cholesterol and other lipids, including triglycerides (fats) and phospholipids, so that they can move between tissues to satisfy their metabolic needs. Triglyceride-rich lipoproteins are the largest particles and include the chylomicrons and very low density lipoproteins (VLDL). The LDLs are the major lipoprotein class in human blood, and these particles are enriched in cholesteryl esters, while the smallest particles are the high-density lipoproteins (HDLs).

All of the cholesterol in the blood plasma (after blood cells are removed) is present in the lipoproteins. The relative amounts of the lipoprotein classes are often measured in terms of their cholesterol concentrations as risk factors for the development of atherosclerosis, or hardening of the arteries. The best profile is to have low concentrations of LDL cholesterol (preferably below 100 mg/dl) and to have higher concentrations of HDL cholesterol (above 50 mg/dl). When the concentrations of LDL cholesterol get too high, deposition of cholesterol within the arteries occurs that, over years, can result in accumulations that lead to lesions or plaques in the arterial wall. Higher levels of HDL appear to protect against this deposition. The instability or tendency of plaques to rupture can lead to complications of coronary heart disease, such as myocardial infarction (heart attack). Diets high in cholesterol and saturated fat often result in higher LDL cholesterol concentrations and increased risk for the development of atherosclerosis. *See* ARTERIOSCLEROSIS; HEART DISORDERS.

Choline

A compound used by the animal organism as a precursor of acetylcholine and as a source of methyl groups. It is a strongly basic hygroscopic substance with the formula below. It is questionable whether

$$(CH_3)_3{\equiv}N^+{-}CH_2{-}CH_2OH$$

this very necessary metabolite should be considered a vitamin. Choline is determined microbiologically by using a mutant of the mold *Neurospora crassa*.

A choline deficiency has been produced in a number of animal species. The degree of deficiency achieved depends on the amount of choline precursors, particularly methyl donors such as methionine, present in the diet. Choline deficiency is associated with fatty livers, poor growth, and renal lesions. It is a lipotropic agent. There is no direct evidence of disease in humans due to choline deficiency, although there have been suggestions that some of the liver, kidney, or pancreas pathology seen in various nutritional deficiency states may be related to choline insufficiency. Choline is found in acetylcholine, which is necessary for nerve impulse propagation, and in phospholipids.

There is no evidence that choline acts as a coenzyme. Choline functions as a donor of methyl groups to quaternary nitrogen and sulfonium compounds.

Human beings eat 50–600 mg of choline per day, but only excrete 2–4 mg. Consequently, conventional load tests are of no value in studying choline requirements, and no knowledge of human requirements exists. *See* ACETYLCHOLINE; VITAMIN.

Stanley N. Gershoff

Choline, trimethyl-β-hydroxyethylammonium hydroxide, is a quaternary compound which is made by the reaction of trimethylamine and ethylene oxide in either an aqueous or an alcoholic solvent. If choline salts are desired, the reaction can be carried out with the corresponding trimethylamine salt, or the base can be neutralized with the corresponding acid. The salts in common use are choline chloride, choline bitartrate, choline dihydrogen citrate, and tricholine citrate.

Choline salts are sold as liquids and solids. The liquids, such as a 65% solution of tricholine citrate, are prepared by the aqueous quaternization procedure, decolorized with charcoal, and then evaporated to the desired strength. The solid types are prepared in either aqueous or alcoholic media and are crystallized by cooling concentrated solutions.

Richard J. Turner

Chondrichthyes

A class of fishes characterized by well-developed jaws and bony teeth; pectoral and pelvic girdles, each supporting paired fins; a cartilaginous skeleton that lacks true bone; toothlike scales of ectodermal and mesodermal origin; paired nostrils with blind olfactory sacs (not opening into the mouth); a vertebral column having either a straight or heterocercal posterior end; absence of a swim bladder; cranium without sutures; and internal fertilization.

Chondrichthyes has traditionally included the subclasses Holocephali (chimaeras) and Elasmobranchii (sharks, rays, and skates). A group of Devonian armored fishes, the Placodermi, has been regarded as ancestral to the Chondrichthyes, but this derivation is not certain. Another group of primitive jawed fishes called acanthodians, considered by many as ancestral to the higher bony fishes, exhibit certain primitive elasmobranch-like features. In any case, it is probable that the elasmobranchs and chimaeras arose independently of each other some time during the Silurian or Early Devonian. Because even calcified cartilage is rarely preserved, the fossil record of the Chondrichthyes is represented mainly by teeth and spines, with only occasional associated skeletons. *See* ACANTHODII; PLACODERMI.

Holocephali. The Holocephali differ from the Elasmobranchii in having only four pairs of gill arches and gills that open to the exterior from a single pair of apertures; in the erectile dorsal fin and spine; in the naked skin in adults; and in the absence of a cloaca and ribs. Males of some species are equipped with a frontal clasper on the head. The teeth are consolidated into six pairs of plates, and the upper jaw is immovably fused with the brain case; these adaptations function in grinding mollusks, their chief food. Chimaeras date from the Early Mesozoic. *See* CHIMAERIFORMES.

Elasmobranchii. The elasmobranchs have five to seven pairs of gill clefts, all opening separately; one or two dorsal fins; rigid spines preceding the fins of some taxa; spiracles either present or absent; placoid scales; numerous teeth that are not set in sockets and arranged in several rows; the inner margin of the pelvic fins of males modified to form a copulating organ called claspers; and oviparous, ovoviviparous, or viviparous development. *See* BATOIDEA; ELASMOBRANCHII; SELACHII.

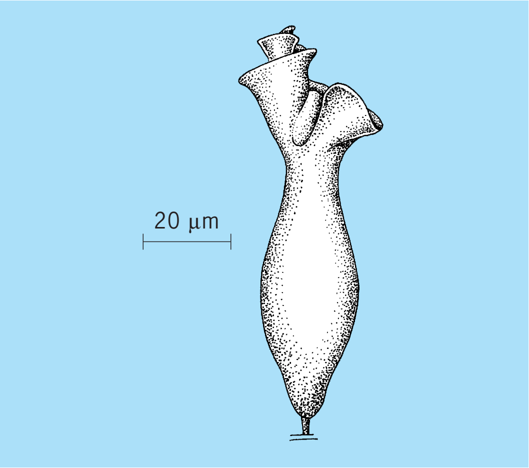
Chonotrichida

An order of the Holotrichia. This is a small group of curious, vase-shaped ciliates, commonly found as ecotocommensals on marine crustaceans. They attach to their hosts by a short, secreted stalk, and their bodies are practically devoid of ciliature.



***Spirochona*, an example of a chonotrichid.**

Spirochona (see **illus.**) is a common example of this order. *See* CILIOPHORA; HOLOTRICHIA; PROTOZOA.

John O. Corliss

Chopping

The act of interrupting an electric current, beam of light, or beam of infrared radiation at regular intervals. This can be accomplished mechanically by rotating a vibrating mirror in the path of the beam to deflect it away from its intended source at regular intervals. A current can be chopped with an electromagnetic vibrator having contacts on its moving armature. A current can also be chopped electronically by passing it through a multivibrator or other switching circuit. Chopping is generally used to change a direct-current signal into an alternating-current signal that can more readily be amplified. Control systems for guided missiles make extensive use of chopping. *See* MULTIVIBRATOR.

Chopping has been increasingly used inside analog integrated circuits. Solid-state switches and capacitors are used to chop operational amplifiers, greatly improving their offset voltages. Chopping is also used in analog large-scale-integrated switched-capacitor filters as a means for reducing their undesirable $1/f$ (inverse-frequency) noise. *See* AMPLIFIER; INTEGRATED CIRCUITS; OPERATIONAL AMPLIFIER; SWITCHED CAPACITOR.

Chordata

The phylum of animals characterized by possession of a notochord, which includes the Cephalochordata (lancelets), Urochordata (tunicates), and Craniata (vertebrates and hagfishes). The phylum also may include the extinct Yunnanozoons and Vetulicolians. Members of the first two groups are small and strictly marine. The vertebrates include the fishes, amphibians, reptiles, birds, and mammals; they are usually free-living and are found in many environments from marine to freshwater and in almost all terrestrial biomes. Some workers include the acorn worms, pterobranchs, and graptolites (Hemichordata) as a subphylum within Chordata, but here it is considered as a separate phylum, because recent morphological and molecular data indicate these organisms are closely related to echinoderms and do not possess a notochord. However, the phylogenetic position of these animals is still controversial. *See* CEPHALOCHORDATA; HEMICHORDATA; TUNICATA; VERTEBRATA.

Characteristics. The typical chordate characteristics include a notochord, a dorsal hollow nerve cord, pharyngeal slits, and a postanal tail. All chordates are deuterostomes, and most chordates also have bilateral symmetry and a somatic arrangement that includes a head, trunk, and tail region, which they share with their common ancestor. *See* DEUTEROSTOMIA.

Notochord. The notochord arises in the chordate embryo as a slender, flexible rod filled with gelatinous cells and surrounded by a tough fibrous sheath. It contains, at least in some chordates, transverse striated muscle fibers and lies above the developing gut. The notochord persists as the axial support for the body throughout the animal's life in cephalochordates and some urochordates, but it is surrounded and gradually replaced by segmental vertebrae in the Vertebrata, starting with the early fishes.

Nerve cord. The dorsal hollow nerve cord grows from a specialized band of neurectoderm along the middorsal surface of the embryo by folding together two parallel ridges. The anterior end enlarges slightly in larval tunicates and somewhat more in lancelets, but enlarges greatly in the vertebrates to form the brain. Vertebral evolution is characterized by continual enlargement of the brain. Moreover, the amount of neurectoderm in the vertebrates is larger than that in the other two groups, and the lateral rims form the neural crests, the cells of which migrate to all parts of the embryo and develop into a number of diverse structures in the body. In the vertebrates or craniates, the brain is enclosed in the braincase or cranium, and the spinal cord is enclosed by the neural arches. *See* NERVOUS SYSTEM (VERTEBRATE).

Pharyngeal slits. Pharyngeal slits are paired slits that develop as outpocketings from the sides of the embryonic pharynx and connect the lumen of the digestive system to the external environment; they are retained as gills in all aquatic chordates. Pharyngeal slits originated as adaptatations for filter feeding but soon became the primary respiratory organ, as blood vessels line the fine filaments on the margins of each slit. Internal gills were lost with the origin of tetrapods. Larval and some adult amphibians possess external gills that are different in structure from the earliest internal gill slits. In embryonic tetrapods, the pharyngeal slits close early in ontogeny, with the pharyngeal pouches becoming the site for development of glands, such as the parathyroids, thymus, and tonsils in mammals. *See* RESPIRATORY SYSTEM.

Postanal tail. The chordate tail is part of the skeletal, muscular, and nervous system of the animal and continues posterior to the anus. It is a feature not found in any other animal group and serves to increase the force available to the organism for locomotion.

Affinities. Much controversy still exists about the origin and affinities of the chordates, although there is no question that the Hemichordata (acorn worms and pterobranchs) are closely related and part of the pharyngeal-slit filter-feeding radiation. Almost all workers agree that the Echinodermata are allied to the Chordata because of evidence ranging from embryonic development (they are both deuterostomes) to biochemical similarities, but early chordate affinities are just now coming to light. *See* ECHINODERMATA.

Evolutionary origins. With the discovery of *Yunnanozoon lividum* in China, the earliest fossil record of putative chordates now dates back to the Early Cambrian (525 million years ago). *Myllokunmingia*, from the early Cambrian Chengjiang fossil site in southwestern China, and *Pikaia*, from the Middle Cambrian Burgess Shale in Canada, are also considered to be the earliest chordates. These organisms appear to have chordate characteristics (though they are still being debated), including an impression of a notochord, segmented muscles, and what appear to be pharyngeal slits. *Pikaia* resembles the present-day lancelet or amphioxus (Cephalochordata), which burrows in shifting sands. Presumably all other chordates developed from this ancestral type, with their differing characteristics evolving because of differing habitat conditions.

There are a number of hypotheses for how chordates evolved. One theory postulates that chordates arose from an echinoderm ancestor, because they share similar embryonic developmental patterns (for example, they are both deuterostomes and exhibit similar cleavage and coelomic formation). Another hypothesis suggests that chordates have evolved from tunicate larval form; however, it is far more likely that the vertebrates descended directly from an amphioxus-like form.

What is known is that the first chordate evolved the notochord, which provided a stronger skeleton and permitted the reduction of the transverse and circular muscles. A notochord resulted in a fixed body length and the loss of peristaltic locomotion. Having a notochord for support permitted the appearance of pharyngeal slits through the lateral walls of the anterior parts of the body, which served for increased filter feeding and subsequently for respiration. The presence of the notochord also permitted the appearance of a postanal tail and increased force for locomotion. The dorsal longitudinal muscles enlarged, and with this modification came the evolution of the dorsal hollow nerve cord (dorsal because of closer proximity with the major muscle masses).

Tunicates (Urochordata) are either sessile organisms that live on hard substrates (Class Ascidiacea) or are planktonic (Class Thaliacea and Class Larvacea). Ascidians and thaliaceans have lost the notochord feature in the metamorphosed adult but retain the pharyngeal gill slits and an endostyle (a glandular ciliated groove along the ventral side of the pharynx). Larvae of all tunicate groups (and adult larvacians) have retained the ancestral chordate features (gill slits and notochord).

The most recently evolved group was the Vertebrata, which are presumed to have left the oceans to invade freshwaters and then the land. They retained the full set of chordate features but had to evolve several additional ones. Size and swimming ability increased to swim upstream against the currents. Because of an increased inward flow of water across the body surface, the problem of water balance was solved when the kidneys, with the nephron as the basic unit, evolved to rid the body of excess water. Finally, dermal bone evolved as armored protection against predators. Embryological development of the nerve cord also changed with the appearance of the neural crest, a unique vertebrate feature that is involved in the development of bony scales, teeth, gill bars, pigment cells, and several parts of the nervous system. *See* AMPHIBIANS; ANIMAL KINGDOM; AVES; MAMMALIA; REPTILIA. Chorion

The outermost of the several extraembryonic membranes in amniotes (reptiles, birds, and mammals) enclosing the embryo and all of its other membranes. The chorion, or serosa, is composed of an outer layer of ectodermal cells and an inner layer of mesodermal cells, collectively the somatopleure. Both layers are continuous with the corresponding tissue of the embryo. The chorion arises in conjunction with the amnion, another membrane that forms the outer limb of the somatopleure which folds up over the embryo in reptiles, birds, and some mammals. The chorion is separated from the amnion and yolk sac by a fluid-filled space, the extraembryonic coelom, or body cavity. In those mammals in which the amnion forms by a process of cavitation in a mass of cells, instead of by folding, the chorion forms directly from the trophoblastic capsule, the extraembryonic ectoderm, which becomes gradually underlain by extraembryonic mesoderm.

In reptiles and birds the chorion fuses with another extraembryonic membrane, the allantois, to form the chorioallantois, which lies directly below the shell membranes. An extensive system of blood vessels develops in the mesoderm of this compound membrane which serves as the primary respiratory and excretory organ for gaseous interchanges. In all mammals above the marsupials, the chorion develops special fingerlike processes (chorionic villi) extending outward from its surface. To a varying degree in different species of mammals, the villous regions of the chorion come into more or less intimate contact with the uterine mucosa, or uterine lining, of the mother, thereby forming the various placental types. *See* ALLANTOIS; AMNIOTA; FETAL MEMBRANE; GERM LAYERS. Nelson T. Spratt, Jr.

Chromadorida

An order of nematodes in which the amphid manifestation is variable but within superfamilies some constancy is apparent. The various amphids are reniform, transverse elongate loops, simple spirals, or multiple spirals not seen in any other orders or subclasses. The cephalic sensilla are in one or two whorls at the extreme anterior. In all taxa the cuticle shows some form of ornamentation, usually punctations that are apparent whether the cuticle is smooth or annulated. When developed, the stoma is primarily esophastome and is usually armed with a dorsal tooth, jaws, or protrusible rugae. The corpus of the esophagus is cylindrical; the isthmus is not seen; and the postcorpus, in which the heavily cuticularized lumen forms the cresentic valve, is distinctly expanded. The esophagointestinal valve is triradiate or flattened. The females usually have paired reflexed ovaries.

There are four chromadorid superfamilies: Choanolaimoidea, Chromadoroidea, Comesomatoidea, and Cyatholaimoidea. Choanolaimoidea is distinguished by a complex stoma in two parts. The group occupies marine habitats; some species are predaceous, but for many the feeding habits are unknown. Chromadoroidea comprises small to moderate-sized free-living forms that are mainly marine but are also found in fresh water and soil. Known species either are associated with algal substrates or are nonselective deposit feeders in soft-bottom sediments. Comesomatoidea, containing only one family, the Comesomatidae, is found in marine habitats, but the feeding habits are unknown. Cyatholaimoidea is found in marine, terrestrial, and fresh-water environments. *See* NEMATA.

Armand R. Maggenti

Chromatic aberration

The type of error in an optical system in which the formation of a series of colored images occurs, even though only white light enters the system. Chromatic aberrations are caused by the fact that the refraction law determining the path of light through an optical system contains the refractive index n, which is a function of wavelength λ. Thus the image position and the magnification of an optical system are not necessarily the same for all wavelengths, nor are the aberrations the same for all wavelengths.

In this article the chromatic aberrations of a lens system are discussed. For information on other types of aberration *see* ABERRATION (OPTICS); REFRACTION OF WAVES.

Dispersion formula. When the refractive index of glass or other transparent material is plotted as a function of the square of the wavelength, the result is a set of dispersion curves which appear to have an asymptote in the near-ultraviolet region and a straight portion in the near-infrared (up to 1 micrometer). In the glass catalogs the indices are given for selected wavelengths between 0.365 and 1.01 μm, which are the absorption (emission) bands of certain chemical elements. For an extended discussion of dispersion *see* ABSORPTION OF ELECTROMAGNETIC RADIATION; DISPERSION (RADIATION); OPTICAL MATERIALS.

For the visible region, the Hartmann formula, Eq. (1), where a and b are constants for a given glass,

$$n = a/(\lambda - b) \tag{1}$$

has been much used. However, if an attempt is made to apply it to the near-ultraviolet or the near-infrared, it proves to be insufficient. Over this more extended range, n can be given as a function of the wavelength by Eq. (2).

$$n = a + b\lambda^2 + \frac{c}{\lambda^2 - 0.028} + \frac{d}{(\lambda^2 - 0.028)^2} \tag{2}$$

Values of the four universal functions $a(\lambda)$ for various wavelengths

λ	a_1	a_2	a_3	a_4
1.0140	0.000000	0.000000	0.000000	+1.000000
0.7682	+0.031555	−0.276197	+1.051955	+0.192687
0.6563	0.000000	0.000000	+1.000000	0.000000
0.6438	−0.004774	+0.051075	+0.966511	−0.012813
0.5893	−0.024952	+0.326272	+0.744598	−0.045919
0.5876	−0.025492	+0.336338	+0.735480	−0.046326
0.5461	−0.033080	+0.597795	+0.479049	−0.043764
0.4861	0.000000	+1.000000	0.000000	0.000000
0.4800	+0.009340	+1.036699	−0.052699	+0.006659
0.4358	+0.143980	+1.193553	−0.394569	+0.057036
0.4047	+0.366779	+1.045064	−0.487634	+0.075791
0.3650	+1.000000	0.000000	0.000000	0.000000

This formula, in which c and d are additional constants, enables one to compute n for any wavelength if it is given for four. An equivalent formula is shown by Eq. (3), where $a_1(\lambda)$, $a_2(\lambda)$, ... are functions of

$$n = n_1 a_1(\lambda) + n_2 a_2(\lambda) + n_3 a_3(\lambda) + n_4 a_4(\lambda) \tag{3}$$

the form of Eq. (2), which assume for $\lambda_1, \lambda_2, \ldots$ the values 1, 0, 0, 0; 0, 1, 0, 0; 0, 0, 1, 0; and 0, 0, 0, 1, respectively. Choosing $\lambda_1 = 0.365 = \lambda^{**}$, $\lambda_2 = 0.4861 = \lambda_F$, $\lambda_3 = 0.6563 = \lambda_C$, $\lambda_4 = 1.014 = \lambda^*$, one finds in the **table** the four universal functions $a(\lambda)$ tabulated for different values of λ. Note that for any wavelength Eq. (4) holds.

$$a_1 + a_2 + a_3 + a_4 = 1 \tag{4}$$

Instead of giving the indices of a glass for the wavelengths specified, one can specify the glass by the refractive index n_F at one wavelength F, the dispersion $\delta = n_F - n_C$, and the partial dispersions in the ultraviolet and infrared, defined respectively by Eqs. (5).

$$P^{**} = \frac{n^{**} - n_F}{n_F - n_C} \qquad P^{*} = \frac{n_F - n^{*}}{n_F - n_C} \tag{5}$$

The partial dispersion for an arbitrary wavelength λ is then given by Eq. (6).

$$P = P^{**} a_1(\lambda) + a_2(\lambda) + P^{*} a_4(\lambda) \tag{6}$$

In the literature the Abbe number, defined by Eq. (7), where n_D is the mean index for the D lines of

$$\nu = (n_D - 1)/(n_F - n_C) \tag{7}$$

sodium, is frequently used to designate optical glass.

In **Fig. 1**, $(n_F - 1)$ is shown plotted against $(n_F - n_C)$ for various optical materials. One sees that in this kind of plot glasses of the same type lie on a straight line, while on the ordinary plot of n_D versus ν they lie on hyperbolas.

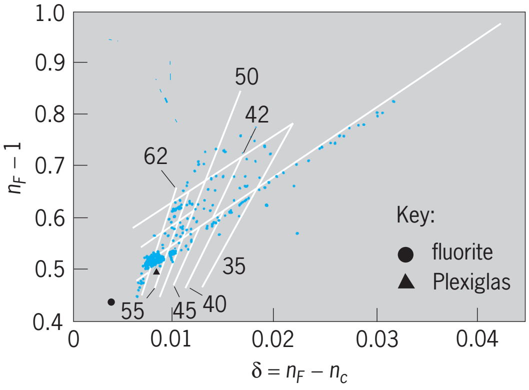

Fig. 1. Plot of (n_F − 1) versus δ for selected glasses and for fluorite and Plexiglas. The numbers on the lines dividing the glasses into groups represent ν values.

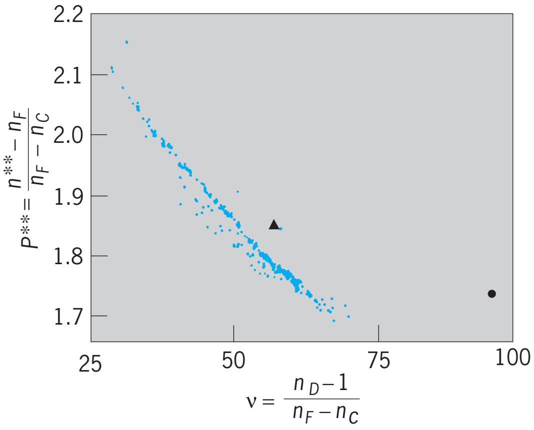

Fig. 2. Plot of P^{**} versus ν for materials of Fig. 1.

Color correction. A system of thin lenses in contact is corrected for two wavelengths λ_A and λ_B if the power of the combination is the same for both wavelengths as in Eq. (8), where the K_κ's are the dif-ference s between the first and last curvatures of the lenses, and the summation is over all the lenses, each with its particular value of n_A, n_B, and K_κ. Two cemented lenses are corrected for wavelengths C and F, for instance, if Eqs. (9) hold.

$$\phi_A = \phi_B = \Sigma(n_A - 1)K_k = \Sigma(n_B - 1)K_k \tag{8}$$

$$\begin{aligned} \phi_1 + \phi_2 &= \phi \\ \phi_1/\nu_1 + \phi_2/\nu_2 &= \phi_C - \phi_F = 0 \end{aligned} \tag{9}$$

See LENS (OPTICS).

The two lenses are also corrected for a third wavelength if and only if, in addition, one has $P_1 = P_2$, where P_1 and P_2 are given by Eq. (6).

A system corrected for three colors is called an apochromat (in microscopy this term traditionally demands freedom from asymmetry in addition). An apochromat for the ultraviolet portion of the spectrum is possible only if the two glasses in **Fig. 2** have the same P^{**} value. For the infrared, the glasses must have the same P^* value (**Fig. 3**). The $\nu - 1$ values for the two glasses should lie as far apart as possible to give low values for the powers.

Three lenses can be corrected for four wavelengths and therefore practically for the whole spectrum if the glasses lie on the straight line on the plot of P^{**} against P^* (**Fig. 4**). Such a system may be called a superachromat.

In lenses with finite thicknesses and distances, there are in gaussian optics two errors to be corrected. One is a longitudinal aberration, which means that the gaussian images do not lie in the same plane, and the other is a lateral aberration, which means that the images in different colors have different magnifications.

In the presence of longitudinal aberration, it is best to balance the lateral aberration so that the apparent sizes of the images as seen from the exit pupil coincide.

A system of two uncorrected lenses, such as a simple ocular, with one finite distance, cannot be corrected for both color errors. Two finite distances are needed to balance both color errors at the same time.

In a general system, all image errors are functions of the wavelength of light. However, in a lens system corrected for color, it is easily possible, with a small adjustment, to balance the correction of the aperture rays (spherical aberration) with respect to

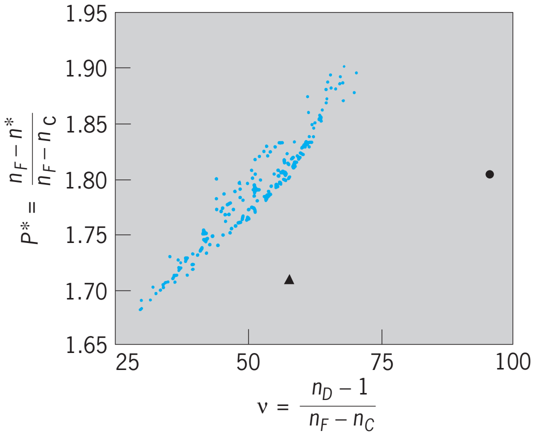

Fig. 3. Plot of P^* versus ν for materials of Fig. 1.

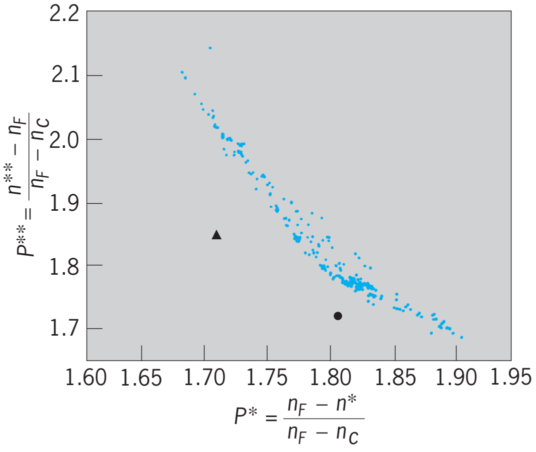

Fig. 4. Plot of P^{**} versus P^* for materials of Fig. 1.

color by introducing a small amount of lateral color aberration.

If only two colors can be corrected, the choice of the colors depends on the wavelength sensitivity of the receiving instrument. For visual correction, the values for *C* and *F* are frequently brought together. Some optical systems contain filters to permit only a narrow spectral band to pass the instrument. This makes correction for color errors easier.

If light of a large band of wavelengths traverses the instrument, it is frequently desirable to use catadioptric systems, such as the Schmidt camera. The mirror or mirrors of these systems are used to obtain the necessary power without introducing color errors, and an afocal lens system can be added to correct monochromatic aberrations. *See* SCHMIDT CAMERA.

Chromatography

A physical method of separation in which the components of a mixture of substances are separated from each other by differences in their distribution between two phases, one (stationary phase) is stationary and the other (mobile phase) moves through the stationary phase in a definite direction. The substances must interact with the stationary phase to be retained and separated by it.

Retention and separation. Retention results from a combination of reversible physical interactions that can be characterized as adsorption at a surface, absorption in an immobilized solvent layer, and electrostatic interactions between ions. When the stationary phase is a porous medium, accessibility to its regions may be restricted and a separation can result from size differences between the sample components. More than one interaction may contribute simultaneously to a separation mechanism. The general requirements are that all interactions must be reversible, and that the two phases can be separated (two immiscible liquids, a gas and a solid, and so forth) in such a way that a distribution of sample components between phases and mass transport by one phase can be established. *See* ABSORPTION; ADSORPTION.

Reversibility of the interactions can be achieved by purely physical means, such as by a change in temperature or by competition; the latter condition is achieved by introducing substances into the mobile phase that have suitable properties to ensure reversibility for the interactions responsible for retention of the sample components. Since this competition with the sample components is itself selective, it provides a general approach to adjusting the outcome of a chromatographic experiment to obtain a desired separation. It is an absolute requirement that a difference in the distribution constants for the sample components in the chromatographic system exist for a separation to be possible.

Methods. A distinction between the principal chromatographic methods can be made in terms of the properties of the mobile phase and configuration of the stationary phase. In gas chromatography the mobile phase is an inert gas, in supercritical fluid chromatography the mobile phase is a fluid (dense gas above its critical pressure and temperature), and in liquid chromatography the mobile phase is a low-viscosity liquid. The stationary phase can be a porous, granular powder with a narrow particle-size distribution packed into a tube (called a column) as a dense homogeneous bed. This configuration is referred to as a packed column and is nearly always used in liquid and supercritical fluid chromatography, and is sometimes used in gas chromatography. Alternatively, the stationary phase can be distributed as a thin film or layer on the wall of an open tube of capillary dimensions, leaving an open space through the center of the column. This configuration is referred to as an open tubular column (or incorrectly as a capillary column); it is commonly used in gas chromatography, but rarely used in supercritical fluid or liquid chromatography.

Thin-layer chromatography is a form of liquid chromatography in which the stationary phase is spread as a thin layer over the surface of a glass or plastic supporting structure. The stationary phase must be immobilized on the support by using a binder to impart the desired mechanical strength and stability to the layer. The samples are applied to the layer as spots or bands near the bottom edge of the plate. The separation is achieved by contacting the bottom edge of the plate below the line of samples with the mobile phase, which proceeds to ascend the layer by capillary action. This process is called development and is performed in a chamber, with the lower edge of the layer in contact with the mobile phase and the remaining portion of the layer in contact with solvent vapors from the mobile phase. The chamber may be a simple device such as a covered jar or beaker or a more elaborate device providing control of the mobile-phase velocity and elimination or control of the vapor phase. Thin-layer chromatography is the most popular form of planar chromatography having virtually replaced paper chromatography in laboratory practice. *See* GAS CHROMATOGRAPHY; GEL PERMEATION CHROMATOGRAPHY; LIQUID CHROMATOGRAPHY; SUPERCRITICAL-FLUID CHROMATOGRAPHY.

Uses. Chromatographic methods provide a means of analyzing samples (to determine component identity and relative amount), isolating significant quantities of purified material for further experimentation or commerce, and determining fundamental physical properties of either the samples or the mobile or stationary phases (for example, diffusion coefficients, partition coefficients, or thermodynamic properties). There are virtually no boundaries to the sample types that can be separated. Examples include organic and inorganic compounds in the form of fixed gases, ions, polymers, as well as other species. Applications are found in all areas of science and technology, making chromatography one of the most widely used laboratory procedures in chemistry. Depending on intent, chromatography can be applied to trace quantities at about the limit of detector response (for example, 10^{-15} g) or to kilogram amounts in preparative separations.

Instrumentation. Modern chromatographic methods are instrumental techniques in which the optimal conditions for the separation are set and varied by electromechanical devices external to the column or layer. Separations are largely automated, with important features of the instrumentation being control of the flow and composition of the mobile phase, introduction of the sample onto the stationary phase, and online detection of the separated components. In column chromatography, the sample components are detected in the presence of the mobile phase after they have exited the stationary phase. In thin-layer chromatography, the sample components are detected in the presence of the stationary phase, resulting in different detection strategies.

Instrument requirements differ by the needs of the method used. Gas chromatography uses a mobile phase of constant composition at a few atmospheres of column inlet pressure and variation in the temperature of the column to effect a separation. Liquid chromatography uses a pump to select or vary the composition of the mobile phase with a high column inlet pressure (typically a few hundred atmospheres) and a constant temperature for the separation. These differences in optimized separation conditions result in different equipment configurations for each chromatographic method.

Interpretation. The results of a chromatographic experiment are summarized in a chromatogram (**Fig. 1**), a two-dimensional record of the detected response to the sample components (*y* axis) plotted against the residence time of the components in column chromatography or migration distance in planar chromatography (*x* axis). Individual compounds or mixtures of unseparated compounds appear as peaks in the chromatogram. These peaks are ideally symmetrical and occur at positions in the chromatogram that are characteristic of their identity, with a distribution around the mean position (apex of the peak) that is characteristic of the kinetic properties of the chromatographic system. The area inscribed by the peak is proportional to the amount of substance separated in the chromatographic system.

Information readily extracted from the chromatogram includes an indication of sample complexity (the number of observed peaks), qualitative substance identification (determined by peak position), relative composition of the sample (peak dimensions; area or height), and a summary of the kinetic characteristics of the chromatographic system (peak shapes).

There is a synergistic relationship between the peak profiles and the properties of the detector. The detector may have an approximately equal response to all substances, in which case the peak sizes are roughly equal to their relative concentration in the sample; or the detector may have a selective response to some property of the sample components, such as a particular chromophore or the presence of a particular element, in which case the peak sizes have to be interpreted with respect to prior knowledge of the way a particular compound responds to the detector. This is also a useful feature, because the information in the chromatogram can be edited to suit an individual application. For example, the determination of organophosphorus pesticides in environmental samples by gas chromatography can be made with a detector that responds selectively to phosphorus, so that the information contained in the chromatogram is limited to the number of phosphorus-containing compounds in the sample and is easier to interpret than a chromatogram in which all compounds present in the sample are revealed by the detector.

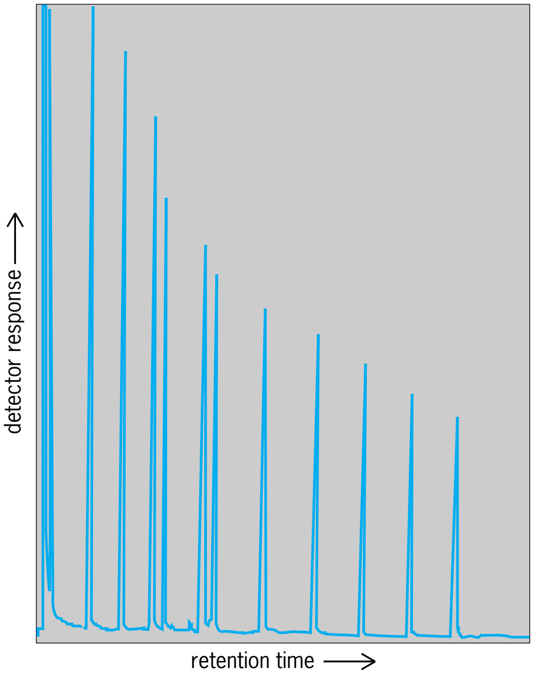

Fig. 1. Typical chromatogram obtained by gas chromatography.

Quality of separation. The object of a chromatographic separation is to obtain a minimum acceptable separation (resolution) between all components of interest in a sample within the shortest possible time. The resolution between two peaks in a chromatogram depends on how well the peak maxima are separated and how wide the two peaks are. This can be expressed numerically, at least for peaks of approximately equal height, by the ratio of the separation of the two peak maxima divided by the average peak widths at their base. When two peaks are separated such that they are just touching at their base, the value calculated for their resolution is 1.5; for difficult-to-separate samples a lower resolution value of 1.0, representing 94% peak separation (6% of the peak areas overlap), is an adequate goal for identification and quantification based on the characteristic shape of the individual peaks. Resolution is also simply related to the properties of the chromatographic system by the equation below,

$$R_s = \frac{N^{1/2}}{4}\,\frac{\alpha - 1}{\alpha}\,\frac{k_2}{1 + k_2}$$

where R_s is the observed resolution, N is the column efficiency measured as the plate number, α is the separation factor (a measure of the relative peak maxima positions; $\alpha = k_2/k_1$), k is the retention factor (the ratio of the time a substance spends in the stationary and mobile phases), and the subscripts 1 and 2 refer to the peak order (peak 2 emerges from the column after peak 1). The equation is derived with the assumption that the average of the two peak widths is identical to the peak width of the second peak, generally a reasonable assumption for peaks that are close to each other in the chromatogram. To a first approximation, the three terms in the equation can be treated as independent variables and optimized separately to obtain a desired separation in the chromatogram.

Efficiency. The efficiency of a chromatographic system is expressed as the plate number. This terminology was adopted from the application of the theory of fractional distillation columns to gas chromatography when this technique was introduced. The term has remained in use, although any analogies between chromatography and fractional distillation are inappropriate and the concept of a theoretical plate has no physical meaning as presently used in chromatography. From a mathematical perspective, efficiency is a characteristic property of the extent of peak dispersion that occurs during the time a compound is resident in the chromatographic system.

Systems with large numerical values for their efficiency are preferred to optimize resolution. Since the resolution is proportional to $N^{1/2}$, unless N can be increased by large increments only small changes in resolution will be obtained. The numerical value for N is governed by kinetic factors that control peak broadening (N affects only peak widths and not peak positions). The chromatographic system should be optimized to minimize peak broadening, leading to better separations. All things being equal, N could never be too large, and chromatographic systems with intrinsically large values of N are desirable. The corollary is also true that systems with intrinsically small values of N are undesirable and diminish the prospects of achieving a desired separation unless other factors in the chromatographic system can be adjusted to compensate for the poor kinetic performance of the column (**Fig. 2***a*).

The rate theory of peak broadening recognizes three processes that contribute to peak widths beyond purely instrumental contributions: (1) resistance to mass transfer between phases prevents instantaneous equilibrium within the chromatographic system; (2) flow anisotropy in packed beds results from variations in the flow characteristics of the bed in regions of unequal packing density; (3) longitudinal diffusion is the natural consequence of molecular diffusion along the axis of migration of the mobile phase. The purpose of column design is to minimize these contributions to peak broadening to achieve the most favorable value of N. The optimum column design is different for each chromatographic method, although it can be easily predicted from the characteristic properties of the chromatographic system and the desired operating conditions (see **table**).

Resistance to mass transfer is often the major cause of peak dispersion in chromatography, and it is related to the absolute magnitude and the relative magnitude of the solute diffusion coefficients in the mobile and stationary phases, and the fact that the relative velocity of the mobile phase is significant on the time scale for these other processes. Resistance to mass transfer, therefore, prevents true equilibrium from being established in the chromatographic system, resulting in additional peak dispersion from that predicted from an equilibrium model.

In gas chromatography, the rate of radial diffusion defines the useful range of column radii for open

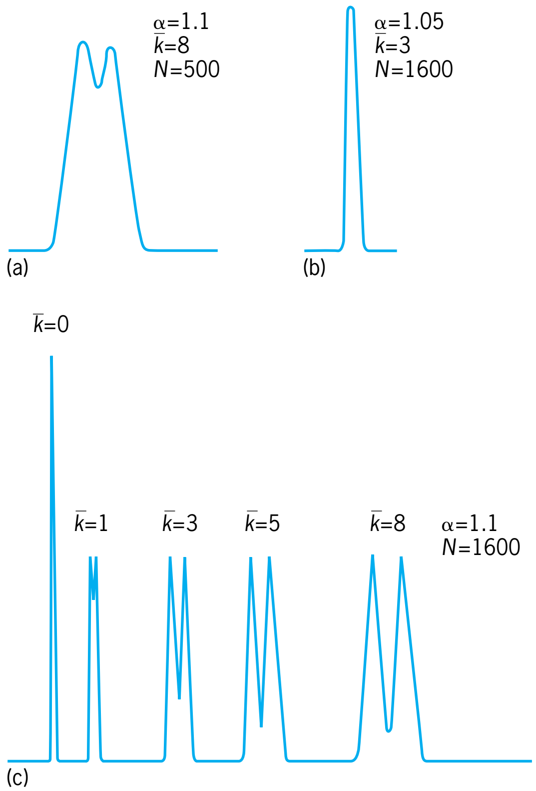

Fig. 2. Observed changes in resolution in a two-component separation for different values of the separation factor, average retention factor, or plate number. (*a*) Viewed vertically, this chromatogram indicates the change in resolution at the same average retention factor and separation factor values when the plate number is varied. (*b*) Viewed vertically, this chromatogram indicates the relationship between resolution and changes in the separation factor with the same plate number and average retention factor value. (*c*) Viewed horizontally, this chromatogram illustrates the change in resolution as the average retention factor is varied with the same value for the separation factor and plate number. (*After P. J. Schoenmakers, Optimization of Chromatographic Selectivity, Elsevier, 1986*)

Approximate values of characteristic parameters in predicting peak broadening

Parameter	Gas	Supercritical fluid	Liquid
Diffusion coefficient (m^2/s)	10^{-1}	10^{-4} to 10^{-3}	10^{-5}
Density (g/cm^3)	10^{-3}	0.3–0.8	1
Viscosity (poise)	10^{-4}	10^{-4} to 10^{-3}	10^{-2}
Column length (m): packed	1–5	0.1–1.0	0.05–1.0
open tubular	10–100	5–25	
Column diameter (mm), open tubular	0.1–0.7	0.02–0.1	
Average particle diameter (μm)	100–200	3–10	3–10
Column inlet pressure (atm)	<10	<600	<400
Efficiency (N): packed	10^3 to 10^4	10^4 to 8×10^4	5×10^3 to 5×10^4
open tubular	10^4–10^6	10^4–10^5	

tubular columns, and the difference in diffusion processes between the mobile and stationary phases dictates that the liquid stationary-phase film should be thin compared to the dimensions of the column radius. High efficiency in gas chromatography can be obtained with open tubular columns of 0.1–0.5 mm diameter, liquid films of 0.1–2.0 micrometer thickness, and column lengths of 5–100 m or more. Open tubular columns of these dimensions offer little flow resistance, and since gases have low viscosities, long columns are practically feasible and compatible with the low operating pressures favored in modern instrument design. Packed columns provide lower efficiencies, since long columns have undesirably high column inlet pressure requirements and the column packing structure results in peak broadening from flow anisotropy, which is unimportant for open tubular columns.

The mobile-phase diffusion coefficients are less favorable in supercritical fluids and liquids than they are for gases. To minimize the contribution of radial mass transfer to peak broadening, the dimensions of an open tube must be reduced proportionately, requiring columns with internal diameters less than 0.10 mm. Small column diameters present significant problems in column preparation and instrument design. These are difficult but possible to achieve for supercritical fluids, but cause exceptional problems in liquid chromatography. Packed columns are invariably used in the practice of supercritical fluid and liquid chromatography. To minimize flow anisotropy and stationary-phase mass-transfer contributions to peak broadening, the columns must have homogeneously packed beds of small particles with a narrow average particle diameter (3–10 μm); the total column length, and therefore the maximum plate number, is limited by the viscosity of the mobile phase and the available column operating pressure (see table). These same restrictions apply to supercritical fluids; however, since their characteristic physical properties are more favorable than those for liquids, supercritical fluids are capable of more efficient separations (larger value for N) than can be obtained in liquid chromatography. Thus, it is generally feasible to optimize resolution through varying N only in gas chromatography and in a more limited way in supercritical fluid chromatography. For liquid chromatography, the largest practical value for N is used for the separation, and the other parameters in the equation are varied to improve resolution. *See* SUPERCRITICAL FLUID.

Selectivity. The separation factor α in the equation is determined by the difference in the distribution coefficients for the two peaks, which is responsible for their relative positions in the chromatogram. Thus, it is the thermodynamic properties of the system that are responsible for the mechanism by which the two components are selectively recognized and therefore retained to different extents. Numerical analysis of the term selectivity reveals its critical importance to obtaining a desired separation. First of all, a separation can result only when α has a value greater than 1.0 ($\alpha = 1$ corresponds to the observed resolution $R_s = 0$), but only a relatively small increase in the value of α close to its minimum value considerably increases the possibility of obtaining a separation (Fig. 2*b*).

In gas chromatography, the mobile phase behaves essentially as an ideal gas and does not contribute to the selectivity of the system. To vary α, a new stationary phase (column) must be selected or the temperature of the system varied. In liquid chromatography, there is a high level of flexibility gained by being able to easily modify the properties of the mobile phase, as well as the possibility of exploiting retention mechanisms that are not available in gas chromatography. These factors account for its widespread use. The properties of the mobile phase are easily varied by changing either the identity or composition of the mobile phase from the wide range of solvents available, or by using additives in the mobile phase to change the properties of individual sample components (for example, buffers, complexing agents, and micelles), as well as by changing the type of stationary phase (column) used for the separation.

In practice, gas chromatography and liquid chromatography should be considered as complementary techniques. Separations by gas chromatography are restricted to thermally stable compounds with significant vapor pressure at the temperatures required for their separation. The upper temperature limit for common stationary phases is in the range 200–400°C (390–750°F). Few compounds with a molecular weight above 1000 have sufficient vapor pressure to be separated in this temperature range, and many low-molecular-weight compounds are known to be labile at temperatures required for their vaporization.

The only requirement for separation by liquid chromatography is that the sample has sufficient solubility in an available solvent whose properties are suitable for the separation. This criterion is much easier to meet in general and results in many of the applications for liquid chromatography as being those for which gas chromatography is unsuitable. Included are applications to high-molecular-weight synthetic polymers, biopolymers, ionic compounds, and many thermally labile polar compounds of chemical interest.

Supercritical fluids have solvating properties that are intermediate between those of gases and liquids. Liquids are virtually incompressible under the conditions used in liquid chromatography, so their capacity for intermolecular interactions is fixed. By contrast, fluids are highly compressible, and their density, which is proportional to their solvating capacity, can be varied over a wide range by simply changing the operating pressure or temperature of the column. This feature is unique to supercritical fluid chromatography, and it is the principal method of varying the separation factor α. The most common mobile phase is carbon dioxide, a relatively nonpolar fluid. More polar fluids, such as water, ammonia, or methanol, tend to have unfavorable critical constants or are highly corrosive to columns and instrument components, limiting their use. Mixed mobile phases, such as carbon dioxide–methanol mixtures, can be used to vary the selectivity but miscibility problems and high critical constants for the mixed mobile phases may restrict the range of properties available for experimentation. Supercritical fluid chromatography can provide faster and more efficient separations than liquid chromatography, but it is more restricted than liquid chromatography in the choice of mobile phases and retention mechanisms to vary the selectivity. However, it finds applications in many areas where the results from gas and liquid chromatography are unsatisfactory. Examples are the separations of low-molecular-weight organic polymers, fats and oils, and enantiomers. *See* CHEMICAL SEPARATION TECHNIQUES.

Separation time. The retention factor k in the equation represents the compromise between the need for retention to achieve resolution and the overall separation time. Numerical evaluation of this term indicates that a minimum value of k is required to obtain close-to-maximum resolution in the chromatographic system, but larger values of k do not increase this resolution significantly and lead to unfavorable separation times (Fig. 2*c*). The most difficult components to separate in a mixture will ideally have k values between 1 and 3, while k values greater than 10–20 have little further influence on resolution. Increasing the residence time of substances in a chromatographic system beyond a certain point does not contribute to their further separation. In practice, larger values than the optimum values may be required to provide sufficient space to fit all the components of a complex mixture into the chromatogram.

Planar chromatography. The separation mechanisms for thin-layer and column liquid chromatography are essentially the same. However, the two processes differ in that in column liquid chromatography all substances migrate the same distance and become separated in time, while in thin-layer chromatography all substances have the same separation time and are separated in space. In column liquid chromatography, the mobile phase moves through the column at a constant velocity, while in thin-layer chromatography its velocity is usually controlled by capillary forces and declines with distance from the solvent entry position. These forces are generally too weak to achieve the optimum velocity required to minimize zone broadening. Compared to a constant mobile-phase velocity, longer separation times and a reduced separation potential result. The useful development distance for a separation is restricted, since eventually the mobile-phase velocity becomes so low that zones begin to broaden faster than their centers are moving apart. The optimum development length depends on properties of the mobile and stationary phases, particularly the average particle size of the layer; and it is typically between 5 and 15 cm for commercially available materials.

A general discussion of zone broadening in thin-layer chromatography is inherently more complex than in column liquid chromatography for reasons which relate to both the practice of the technique and the limitations of subsequent theoretical treatments. Because substances are separated in space, individual zones experience only those theoretical plates through which they travel; and therefore the efficiency N is a function of the migration distance of the substance in the chromatogram. The migration of individual zones occurs across several regions of different local velocity and can be represented only by some average value that is difficult to determine. In practice, when the mobile-phase velocity is controlled by capillary forces, the major contribution to zone broadening is longitudinal diffusion supplemented by a smaller contribution from flow anisotropy. Separations in thin-layer chromatography occur with a plate number of 0–5000, depending on migration distance, and with a capacity for baseline resolved peaks of about 10–14 in the chromatogram.

The general variation of resolution with migration distance is more complex than for column liquid chromatography and is approximately represented by a special curve (**Fig. 3**). The fundamental parameter used to characterize the position of a sample zone in a thin-layer chromatogram is the retardation factor, or R_f value. It represents the ratio of the distance migrated by the sample to the distance traveled by the solvent front in the same time. The boundary conditions for R_f values are $1 \geq R_f \geq 0$ (Fig. 3). There is no separation possible for substances that do not migrate from their origin ($R_f = 0$) or do not interact with the stationary phase and move with the solvent front ($R_f = 1$). A maximum in the resolution of two closely spaced peaks is observed at an R_f of about 0.3, but the resolution does not vary much in the range $R_f = 0.2$–0.5, which is the optimum region in which to obtain a separation. When the difference in R_f values for two substances exceeds 0.1,

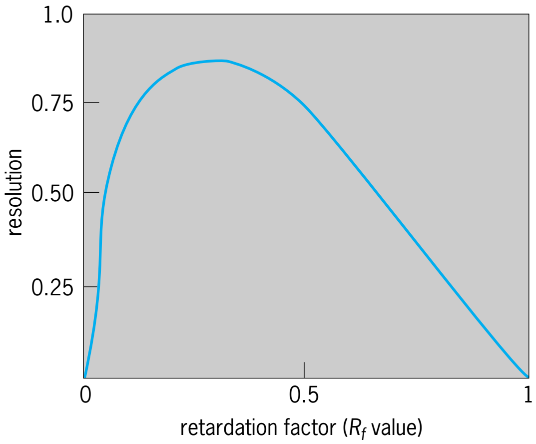

Fig. 3. Variation of resolution of two closely migrating zones as a function of the R_f value of the faster moving zone. (*After C. F. Poole and S. K. Poole, Chromatography Today, Elsevier, 1991*)

separations are easy to achieve; for R_f values less than 0.05, a separation is very difficult or impossible to achieve because of an inadequate range of efficiency values. Therefore, selective separation systems are required.

A common method of improving the separation potential of thin-layer chromatography is to increase the number of development steps used for the separation. This process is known as multiple development. A reduction in zone dimensions is achieved by a refocusing mechanism that is well understood from a phenomenological perspective but is difficult to characterize quantitatively. At the start of each development, the solvent front contacts the bottom portion of the zone first, and this region of the zone starts moving forward before the more distant regions of the zone still ahead of the solvent front. The result is a compression of the sample zone such that its width is reduced in size compared to zones migrated the same distance in a single development. This process can be automated so that a large number of developments can be used in an individual separation, resulting in a peak capacity for baseline resolved peaks of about 25–40, a considerable increase over the separation capacity obtained by using a single development.

The ultimate separation capacity of column liquid chromatography is greater than that of thin-layer chromatography. However, for simple separations where a high sample throughput is required, where crude samples are to be analyzed with minimum sample preparation, and where chemical reactions are to be used for detection, thin-layer chromatography is often preferred to column liquid chromatography. The reasons are that the stationary phase is not reused and multiple samples can be separated in parallel lanes in contrast to the single-sample sequential separations characteristic of column chromatography. After the separation, the components are immobilized on the stationary phase and can be treated with chemical reagents to change their detection properties without time constraints. The types of samples that are suitable for analysis by thin-layer chromatography are the same as those normally separated by column liquid chromatography, and a choice between the two approaches is made on the basis of practical considerations such as those outlined above. *See* ANALYTICAL CHEMISTRY. Chromatophore

A pigmented structure found in many animals, generally in the integument. The term is usually restricted to those structures that bring about changes in color or brightness. A majority of chromatophores are single cells that are highly branched and contain pigment granules that can disperse or aggregate within the cell. However, in coleoid cephalopod mollusks (all mollusks except *Nautilus*), the chromatophores function as miniature organs, and changes in the dispersion of pigment are brought about by muscles. Although the mode of action of the two types of chromatophore is completely different, the effect is the same: pigment either is spread out over a large area of the body or is retracted into a small area.

The movement of pigment takes place in many chromatophores simultaneously, so that the effect is a change in the quality of light reflected from the surface of the animal. The color change functions as a camouflage from predator or prey, but it may also serve for regulating temperature, protecting against harmful radiation, and in some animals, signaling. Light stimulates the responses of chromatophores, and although in some species light may affect the chromatophores directly, light generally acts indirectly via the eyes and central nervous system.

Occurrence. Single-cell chromatophores are found in some annelids, in insects (migratory locusts, some grasshoppers, and stick insects), and in echinoderms (some sea urchins). They are much more conspicuous in crustaceans (shrimps and prawns), in fishes (especially in bony fish and teleosts), in anuran amphibians (frogs and toads), and in a few reptiles.

The chromatophores may be uniformly distributed in the skin (chameleons), or they may occur in patches (flounders) or lines (around the abdomen in shrimps). Chromatophores of various colors may be distributed unevenly across the body, and occur at different depths in the skin. This characteristic can be important for enhancing or suppressing colors produced in the skin by reflecting structures.

Colors produced. Chromatophores produce their colors by reflection after absorption of light. Generally, the light comes from above, but it may come from below after reflection from an underlying structure. The most common type of chromatophore contains melanin (and is, therefore, often called a melanophore), which absorbs all wavelengths so that the chromatophore appears black; other types have red (erythrophores) or yellow (xanthophores) pigments. These pigments generally derive from carotenoids in vertebrates and from ommochromes in invertebrates. It should be noted that although a chromatophore may appear red in the laboratory or in a shallow tidal pool, it will appear black at depths of 165 ft (50 m) or more, and many of the red chromatophores of marine animals may act (like the black ones) as neutral-density filters for matching background brightness rather than for providing color.

Chromatophores do not usually contain green or blue pigments. These colors are often produced structurally, by reflecting or refracting structures (iridophores, also called iridocytes). The skin of many animals contains structures known as leucophores which, being broadband reflectors, can also produce greens and blues. Chromatophores in cephalopods and amphibians often function in conjunction with iridophores and leucophores to produce beautiful and complex color patterns over the whole body.

Crustaceans and vertebrates. Chromatophores contain pigment granules that move within them, giving them an appearance that ranges from spotted to fibrous on the five-stage scale that is widely used to measure the degree of chromatophore expansion. If the pigment within the particular cell is black or brown, the integument takes on a dark appearance when most of the chromatophores are in the last stage of dispersion (stage 5). If the pigment color is yellow or cream, the animal tends to look paler if all the chromatophores are at that stage.

Shrimp or frog chromatophores respond actively to the background illumination (**Fig. 1**). After only an hour or two, changes in the state of the chromatophores become evident with the aid of a microscope. These changes are usually brought about by hormones that are released from a particular site and circulated throughout the body. In shrimp, the hormones acting on the chromatophores originate in organs located in the eyestalk and also in the central nervous system. In the frog, the hormone responsible for color change comes from the pars intermedia of the pituitary organ; it is a peptide, called melanocyte-stimulating hormone, that disperses the pigment granules, thus making the skin darker. In teleosts, the control system is more complicated because there is a second hormone, melanin-concentrating hormone from the hypothalamus, that suppresses melanocyte-stimulating hormone, causing pigment aggregation in all color classes of chromatophores, and hence paling.

In crustaceans, elasmobranch fishes, anurans, and lizards, control of the chromatophores is thought to be exclusively hormonal. Such hormonal control is true also of some teleosts; in others the control is part hormonal and part neural; while in still others control is purely neural, as in the chameleon. Where nerves are involved, the speed of the response is faster, the chromatophores responding in minutes rather than hours. *See* NEUROSECRETION.

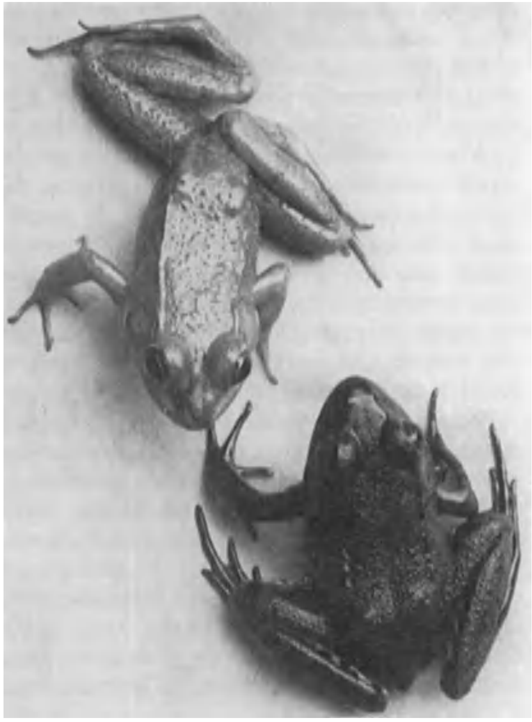

Fig. 1. Light- and dark-adapted frogs. (*After J. Pierce, J. Exp. Zool., 89:293–295, 1942*)

The chromatophores of crustaceans often have pigments of different colors, and they enable the integument to take on the background hue for concealment. When they form patterns, such as lines and bands, they may also serve to conceal the animal disruptively by breaking up the outline of the body. In fish, anurans, and reptiles, camouflage is again a major function, but in terrestrial vertebrates with chromatophores, changes in color may also serve for temperature regulation, at least when the temperature is excessively high or low. In some teleosts, neurally controlled chromatophores permit the rapid color changes that are used for social signaling, for example during sexual or territorial encounters.

Cephalopods. Each cephalopod chromatophore organ comprises an elastic sac containing pigment granules. Attached to the sac is a set of 15–25 radial muscles that are striated and contract rapidly. Associated with the radial muscles are axons from nerve cell bodies that lie within the brain. Active nerve cells cause the radial muscles to contract and the chromatophore sac expands; when the nerves are inactive, energy stored in the elastic sac causes the chromatophore to retract as the muscles relax. The chromatophores receive only nerve impulses, and there is no evidence that they are influenced by hormones.

The chromatophores are ultimately controlled by the optic lobe of the brain under the influence of the eyes. Two consequences follow from the fact that cephalopod chromatophores are under the direct control of the brain. First, color change is

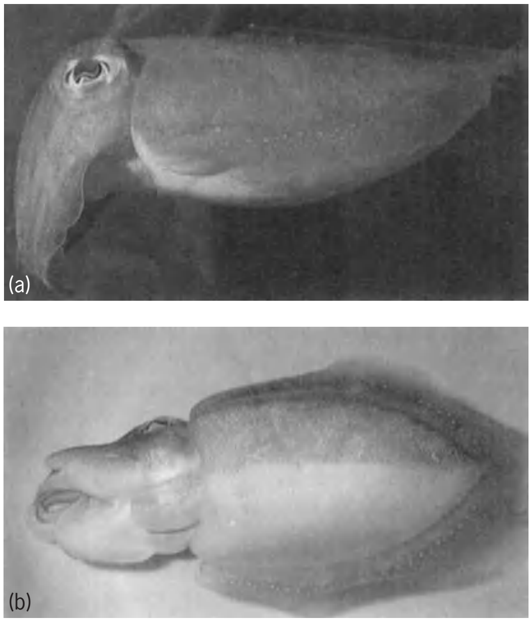

Fig. 2. Orientation of a cuttlefish. (*a*) The animal has a pale underside because all the chromatophores on the ventral mantle are retracted. (*b*) When the cuttlefish is rolled over onto its right side, the chromatophores of the upper (left) half of the ventral mantle expand to maintain the countershading.

instantaneous (an octopus can change from almost white to jet black in less than a second). Such a rapid change may cause a predator to hesitate, permitting escape; also, when the animal reaches the sea floor, it can vanish almost at once. Second, patterns can be generated in the skin in a way impossible in other animals. Thus, cephalopods can use the chromatophores not just to match the background in general color but to break up the body visually (disruptive coloration) so that the predator does not see the whole animal.

Concealment is obviously a major function. It is possible that cephalopod chromatophores evolved for purposes of camouflage after the ancestral cephalopods had abandoned the molluscan shell in the interest of speed and agility. However, because the chromatophores are neurally controlled and patterns can be produced in the skin, they can also be used for signaling. A characteristic of cephalopods is that some species make displays as conspicuous as those of fish or birds. Included are sexual signals destined for members of the same species, and warning signals, such as the large black eyespots used against predators. Signaling is especially well developed in some shallow-water forms, such as the Caribbean reef squid.

Finally, cephalopod chromatophores can be used for countershading and for maintaining countershading after disorientation. Animals that are generally illuminated from above tend to have a dark upper surface and a light lower surface, concealing them from a viewer from the side. This characteristic is true of fish and cephalopods. However, when a fish becomes momentarily disorientated and rolls over on its side, it becomes conspicuous because its countershading is fixed. When a squid rolls over, the chromatophores on the ventral surface of the body expand to maintain the countershading (**Fig. 2**). Such versatility is possible only because the chromatophores are neurally controlled. *See* PIGMENTATION; PROTECTIVE COLORATION.

Chromium

A chemical element, Cr, atomic number 24, and atomic weight 51.996, which is the weighted average for several isotopes weighing 50 (4.31%), 52 (83.76%), 53 (9.55%), and 54 (2.38%). The orbital arrangement of the electrons is $1s^2$, $2s^2$, $2p^6$, $3s^2$, $3p^6$, $3d^5$, $4s^1$. The stability of the half-filled *d* shell doubtless accounts for this rather unusual arrangement. In the crust of the Earth, chromium is the twenty-first element in abundance, which ranks it along with vanadium, zinc, nickel, and copper. Traces of chromium are present in the human body; in fact, it is essential to life. *See* PERIODIC TABLE.

The element was discovered in 1797 and isolated the following year by the French chemist L. N. Vauquelin. It was named chromium because of the many colors of its compounds. It occurs in nature largely as the mineral chromite ($FeO \cdot Cr_2O_3$), which is a spinel, but the ore is usually contaminated with Al^{3+}, Fe^{3+}, Mn^{2+}, and Mg^{2+}. Smaller quantities are found as the yellow mineral crocoite ($PbCrO_4$).

As a transition metal, chromium exists in all oxidation states from 2− to 6+. The chemistry of its aqueous solutions, at least in the 3+ (chromic) state, is complicated by the fact that the compounds exist in many isomeric forms, which have quite different chemical properties.

Pure chromium metal has a bluish-white color, reflects light well, and takes a high polish. When pure, it is ductile, but even small amounts of impurities render it brittle. The metal melts at about 1900°C (3452°F) and boils at 2642°C (4788°F). Chromium shows a wide range of oxidation states; the compounds in which the metal is in a low oxidation state are powerful reducing agents, whereas those in which it shows a high oxidation state are strong oxidizing agents.

The bright color and resistance to corrosion make chromium highly desirable for plating plumbing fixtures, automobile radiators and bumpers, and other decorative pieces. Unfortunately, chrome plating is difficult and expensive. It must be done by electrolytic reduction of dichromate in sulfuric acid solution. This requires the addition of six electrons per chromium ion. This reduction does not take place in one step, but through a series of steps, most of which are not clearly understood. The current efficiency is low (maybe 12%), and the chromium plate contains microscopic cracks and other flaws, and so it does not adequately protect the metal under it from corrosion. It is customary, therefore, to first plate the object with copper, then with nickel, and finally, with chromium.

In alloys with iron, nickel, and other metals, chromium has many desirable properties. Chrome steel is hard and strong and resists corrosion to a marked degree. Stainless steel contains roughly 18% chromium and 8% nickel. Some chrome steels can be hardened by heat treatment and find use in cutlery; still others are used in jet engines. Nichrome and chromel consist largely of nickel and chromium; they have low electrical conductivity and resist corrosion, even at red heat, so they are used for heating coils in space heaters, toasters, and similar devices. Other important alloys are Hastelloy C (Cr, Mo, W, Fe, Ni), used in chemical equipment which is in contact with HCl, oxidizing acids, and hypochlorite. Stellite [Co, Cr, Ni, C, W (or Mo)], noted for its hardness and abrasion resistance at high temperatures, is used for lathes and engine valves, and Inconel (Cr, Fe, Ni) is used in heat treating and in corrosion-resistant equipment in the chemical industry. *See* ALLOY; HEAT TREATMENT (METALLURGY); STAINLESS STEEL.

Several chromium compounds are used as paint pigments—chrome oxide green (Cr_2O_3), chrome yellow ($PbCrO_4$), chrome orange ($PbCrO_4 \cdot PbO$), molybdate orange (a solution of $PbSO_4$, $PbCrO_4$, and $PbMoO_4$), chrome green (a mixture of $PbCrO_4$ and Prussian blue), and zinc yellow (potassium zinc chromate). Several of these, particularly zinc yellow, are used to inhibit corrosion. The gems ruby, emerald, and alexandrite owe their colors to traces of chromium compounds. *See* CORROSION; EMERALD; PAINT; RUBY.

Dichromates are widely used as oxidizing agents, as rust inhibitors on steel, and as wood preservatives. In the last application, they kill fungi, termites, and boring insects. The wood can still be painted and glued, and retains its strength. Other chromium compounds find use as catalysts, as drilling muds, and in photochemical reactions. The last are important in the printing industry. A metal plate is coated with a colloidal material (for example, glue, shellac, or casein) containing a dichromate. On exposure to strong light under a negative image, the dichromate is reduced to Cr^{3+}, which reacts with the colloid, hardening it and making it resistant to removal by washing. The unexposed material is washed off, and the metal plate is etched with acid to give a printing plate. *See* PRINTING.

Chromium is essential to life. A deficiency (in rats and monkeys) has been shown to impair glucose tolerance, decrease glycogen reserve, and inhibit the utilization of amino acids. It has also been found that inclusion of chromium in the diet of humans sometimes, but not always, improves glucose tolerance. Certain chromium(III) compounds enhance the action of insulin.

On the other hand, chromates and dichromates are severe irritants to the skin and mucous membranes, so workers who handle large amounts of these materials must be protected against dusts and mists. Continued breathing of the dusts finally leads to ulceration and perforation of the nasal septum. Contact of cuts or abrasions with chromate may lead to serious ulceration. Even on normal skin, dermatitis frequently results. Cases of lung cancer have been observed in plants where chromates are manufactured.

Chromophycota

A division of the plant kingdom (also known as Chromophyta) comprising nine classes of algae: Bacillariophyceae (diatoms), Chrysophyceae (golden or golden-brown algae), Cryptophyceae, Dinophyceae (dinoflagellates), Eustigmatophyceae, Phaeophyceae (brown algae), Prymnesiophyceae, Raphidophyceae, and Xanthophyceae (yellow-green algae). Some of these classes are closely related, while others stand so far apart that they are sometimes assigned to their own divisions. The chief unifying character is the presence of chlorophyll *c* rather than chlorophyll *b* as a complement to chlorophyll *a* (although only chlorophyll *a* is present in Eustigmatophyceae). The chloroplasts are usually brown or yellowish because of large amounts of β-carotene and various xanthophylls, many of which are restricted to one or more classes. Storage products include lipids, starch, and glucans (glucose polymers with β-1,3 linkages). In all classes except Dinophyceae, the chloroplast is surrounded by chloroplast endoplasmic reticulum that is continuous with the nuclear envelope, and the deoxyribonucleic acid of the chloroplast forms an annular genophore. Except in Cryptophyceae, thylakoids are in groups of three. In most classes, motile cells bear two unequal flagella, one of which may be almost completely reduced and at least one of which bears two rows of hairlike appendages. Algae in this division range in size and complexity from unicellular flagellates to gigantic kelps. *See* ALGAE; BACILLARIOPHYCEAE; CHRYSOPHYCEAE; CRYPTOPHYCEAE; DINOPHYCEAE; EUSTIGMATOPHYCEAE; PHAEOPHYCEAE; PRYMNESIOPHYCEAE; RAPHIDOPHYCEAE; XANTHOPHYCEAE.

Chromosome

A DNA–protein complex in the nucleus of eukaryotic cells. Chromosomes were so named because after staining, nineteenth-century light microscopists saw chromosomes as colored bodies in cells. The combination of DNA and proteins in chromosomes is called chromatin. Collectively the DNA from all the chromosomes in a nucleus is the hereditary blueprint for the species. Eukaryotes (plants, animals, fungi, and protists) usually have one nucleus in each cell. A nucleus is a double membrane-bound compartment in which chromosomes are located in interphase between cell divisions. In contrast, prokaryotes, such as bacteria and their allies (including mitochondria and chloroplasts), do not have true chromosomes or nuclei because prokaryotes do not confine their small, single circle of DNA in a membrane-bound compartment. *See* DEOXYRIBONUCLEIC ACID (DNA).

Interphase chromosomes. Chromosomes are usually described when they are easily observed in a condensed state during mitosis (M phase of the cell cycle). However, chromosomes are not visible during interphase, which comprises the largest part of the cell cycle. Interphase consists of G_1 (the first gap in interphase without DNA synthesis from the end of telophase to the beginning of DNA synthesis), followed by S (the synthesis phase, during which the DNA is replicated so each chromosome has two identical chromatids), and finally G_2 (the second gap phase, beginning after S and lasting until M phase begins). Nuclei in cells that stop dividing usually arrest in G_0, which is a G_1 interphase-like state that may persist indefinitely.

During interphase, chromosomes are decondensed to form an apparently homogenous mass of chromatin that consists of long DNA double helices associated with proteins. Chromosomes are still present as individual units in interphase nuclei, but their boundaries are difficult to distinguish, something like looking at a clear bottle full of cotton balls and trying to tell where one cotton ball ends and another begins. *See* CELL CYCLE; MITOSIS.

Structure and composition of mitotic chromosomes. Each chromatid of a chromosome consists of one long, linear DNA double helix that is associated with proteins to form chromatin. A DNA double helix is composed of two parallel polymeric chains of nucleotides that are twisted around each other. Each strand consists of alternating phosphate and sugar molecules with bases extending from each sugar. There are four bases: adenine (A), which forms hydrogen bonds with thymine (T) in the opposite DNA strand, and guanine (G), which forms hydrogen bonds with cytosine (C) in the opposite DNA strand. As a result, the two single DNA strands of polynucleotides in a double helix are complementary. This relationship is used when DNA is replicated during interphase of the cell cycle and when RNA is transcribed using DNA as a template. The DNA double helix of one chromatid is usually millions of base pairs (bp) long.

When chromosomes condense during mitosis, DNA becomes so highly folded that each double helix is approximately 10,000 times as long as the chromatid in which it is packed. (The necessity of this level of folding is apparent when one considers that diploid human cells contain about 2 m of DNA divided between 46 chromosomes in a nucleus that is about 5 μm in diameter.) In a current model for the structure of an average chromosome, the hierarchy of folding begins with formation of nucleosomes. A nucleosome consists of a core of eight basic proteins called histones (two molecules each of histones H2a, H2b, H3, and H4) and DNA. Histones are positively charged so they are attracted to negatively charged DNA. To form a nucleosome, 146 base pairs (bp) of DNA wraps 1.65 times around the core histone particle. There are about 50 bp of coiled DNA between adjacent nucleosomes. A chain of nucleosomes linked by a continuous DNA double helix forms a fiber with a diameter of about 10 nm and a 6:1 packing ratio of DNA length to 10-nm fiber length. Next, the 10-nm fiber associates with other proteins to coil or fold into a fiber with a diameter of 30 nm and a 42:1 ratio of DNA length to 30-nm fiber length. The 30-nm fiber forms ~1-μm-long loops that are attached to a proteinaceous chromosome core (scaffold). The loops condense against the core under the influence of a protein complex called condensin that is found in the core. The condensed loops and core constitute a strand called the chromonema with a diameter of ~0.2 μm. The chromonema coils, possibly due to contraction of the proteinaceous core, to form a chromatid about 1 μm in diameter with a ratio of DNA length to chromatid length of ~10,000:1. Coiling does not occur at the primary constriction (=centromere), resulting in a narrow part of the chromatid (**Fig. 1**). *See* NUCLEOSOME.

Without resorting to special treatments, chromosomes are visible only when they become condensed into sausage-shaped bodies during division of the nucleus (mitosis and meiosis). Although they are always microscopic, mitotic chromosomes in different species and even within a species can vary enormously in size, for example, from 1 to 40 μm in length and 1 to 2 μm in width. A chromosome can consist of either two identical sister chromatids (during G, prophase, prometaphase, and metaphase of mitosis) or of one chromatid (during G_1, anaphase and telophase of mitosis). Having one or two chromatids per chromosome does not change ploidy (the number of complete chromosome sets in a nucleus).

At a gross morphological level, chromosomes often can be distinguished from one another on the basis of their relative lengths and the positions of their primary constriction. The segments of chromosomes to either side of the primary constriction (centromere) are called arms. If the arms are roughly of equal length, the chromosome is metacentric. If the centromere is near one end, the chromosome is acrocentric, and there is a short (p) arm and a long (q) arm. If the centromere is truly at the end (rare), the chromosome is telocentric.

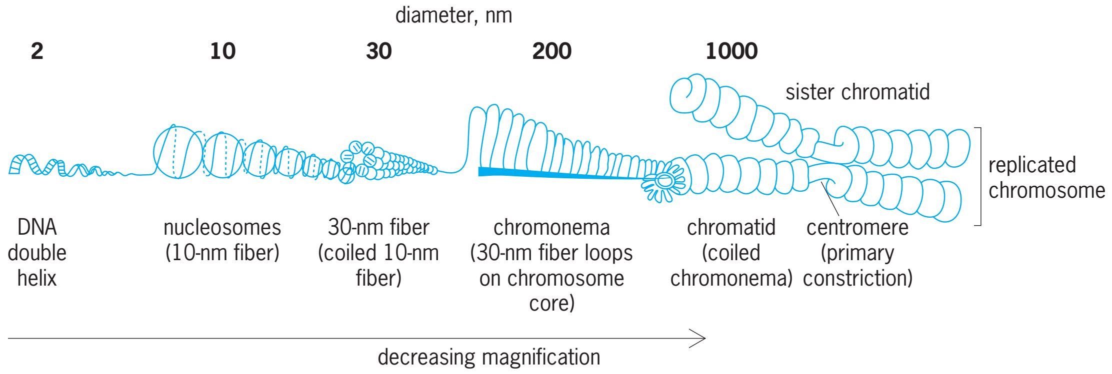

Fig. 1. Model of hierarchy of chromosome structure. Objects on the left are magnified more than those to the right. On the left and progressing to the right, a DNA double helix is associated with nucleosomes to form a 10-nm fiber that is coiled or folded to form a 30-nm fiber that forms loops on the chromosome core to form the chromonema that is coiled to form one chromatid. Note the lack of coiling in the primary constriction (centromere).

Chromosomes with primary constrictions in intermediate positions are described as submetacentric and subacrocentric (**Fig. 2**).

Kinetochores. A kinetochore is a nucleoprotein structure that forms in the centromere on each chromatid. Depending on the species, a kinetochore may appear as an amorphous sphere or a layered disk. The DNA involved in kinetochores often consists of a 150-bp tandem repeat sequence; the exact sequence varies from species to species. [In addition, there are often additional repeated sequences in the centromere and in heterochromatin (chromatin that is tightly coiled even in the nondividing nucleus and stains darkly in interphase). Proteins found in kinetochores are more evolutionarily conserved than the DNA sequences. During mitosis, microtubules grow from the spindle poles and attach to kinetochores. Force is applied through these kinetochore microtubules to move chromosomes to the metaphase plate during prometaphase and then to move sister chromatids (now sister chromosomes) to opposite poles during anaphase.

Telomeres. The ends of chromosomes are called telomeres. Although telomeres usually have no

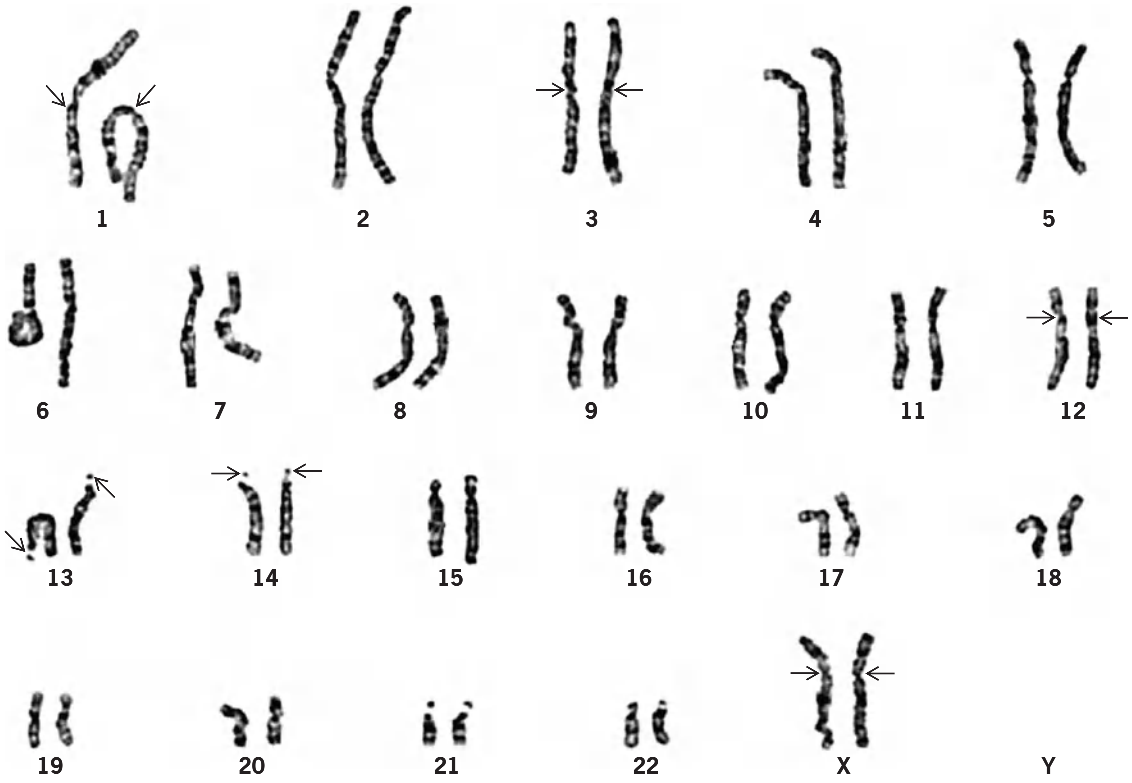

Fig. 2. Diploid set of normal human female chromosomes that have been G-banded for identification. G bands stain more darkly than the lighter R bands, and G bands have more AT-rich DNA than R bands. To construct an idiogram, chromosomes were cut out of a photograph and pasted in a row from longest to shortest with homologs together. Arrows indicate some centromeres. Note metacentric (such as chromosomes 1 and 3), acrocentric (such as chromosomes 13 and 14), submetacentric (such as the X chromosome), and subacrocentric (such as chromosome 12). Since these are chromosomes from a female, there are two X chromosomes and no Y chromosome. (*Courtesy of Genzyme Corporation*)

visibly distinct structure, they are necessary for the survival of chromosomes; without telomeres, chromosomes would be nibbled away slowly from their ends during every round of DNA replication, during which a little of the DNA double helix is lost from both ends of a chromatid. The telomere is the site where an enzyme called telomerase adds expendable DNA, usually in the form of a short repeat sequence such as TTAGGG. Most differentiated animal cells have no telomerase activity, but they inherit telomeres that are thousands of bp long from telomerase activity during meiosis that occurred just before gametes were formed. Telomere lengths are adequate for the normal number of divisions the cells undergo during development. This protects the body from cells that are dividing out of control, because cells that divide too frequently are eventually destroyed when their telomeres are lost. One cost of this protection is aging, and, as one might expect, cancer cells often have telomerase activity that permits them to divide indefinitely.

Euchromatin and heterochromatin. Chromatin is divided into euchromatin and heterochromatin based on its level of condensation during interphase and G_0. Euchromatin is decondensed and available for transcription. However, euchromatin still requires the proper proteins to mark genes (DNA segments) for transcription, that is, genes are not transcribed just because they are in decondensed chromatin, but genes must be in decondensed chromatin to be transcribed. In contrast, heterochromatin generally remains condensed, and its DNA is not used for transcription, if for no other reason than transcription factors and RNA polymerase are sterically hindered from access to the DNA. However, even heterochromatin becomes euchromatic when its DNA is replicated during S phase. There are two types of heterochromatin: constitutive heterochromatin that is always condensed (except during S phase) and facultative heterochromatin that is condensed only in certain cells or in only one sex. Facultative heterochromatin seems to be a way to control gene activity.

During mitosis, euchromatin and heterochromatin are similarly condensed and stained with most dyes. However, heterochromatin in condensed chromosomes can be stained differently from euchromatin after special procedures that typically utilize Giemsa stain. One technique, called C-banding, stains constitutive heterochromatin intensely so that a simple pattern of dark bands is visible on chromosomes. C-bands often occur around centromeres, nucleolus organizers, or at the ends of chromosomes, but they can be anywhere on a chromosome. C-banding has been used successfully on both plant and animal chromosomes. The other technique, called G-banding, stains facultative heterochromatin intensely and results in a relatively complex banding pattern. G-banding works well on mammalian and avian chromosomes and has been important for identifying individual chromosomes in these groups (Fig. 2).

Methyl groups can be added to cytosines in DNA, and this generally causes DNA to become facultatively heterochromatic and unusable for transcription. The pattern of methylation is duplicated during S phase, so methylation is inherited from one cell generation to the next. While spermatozoa and eggs carry genes for the same traits, some genes are differently methylated in spermatozoa compared with eggs. Thus, only the maternal or paternal versions of these genes are active in developing embryos. This is an epigenetic phenomenon (gene activity not determined by DNA sequence, but rather through chemical modification of DNA like methylation) called imprinting.

Chromosome sets, genomes, ploidy, and homologs. Generally, eukaryotes are capable of sexual reproduction that involves fusion of two gametes. Gametes usually carry a haploid set of chromosomes, defined as one copy of each chromosome that is characteristic of the species. An unreplicated haploid set of chromosomes, in which each chromosome consists of one chromatid, contains one genome of DNA called the 1C amount (C standing for "constant" for each species). For example, the human genome (1C amount of DNA) consists of about 3.5 picograms of DNA or 3.4 billion base pairs of DNA or 1 m of DNA. Other species have different genome sizes (1C). Normally each human gamete (spermatozoon or egg) carries a haploid chromosome set (often denoted $1n$) of 23 chromosomes. After fertilization the zygote is usually diploid ($2n$) with 46 chromosomes (Fig. 2 and **Colorplate 1**). If an organism has one or more complete sets of chromosomes with no extra or missing chromosomes, it is euploid. If an organism has more than two sets, it is polyploid. If chromosomes are added or missing from a set, the organism is aneuploid. *See* POLYPLOIDY.

A special class of chromosomes called B chromosomes (or supernumerary chromosomes) occurs sporadically in many organisms. B chromosomes generally have few, if any, active genes, and they are not necessary for the life of the organism. B chromosomes may be thought of as molecular parasites, and their presence or absence does not constitute aneuploidy. Aside from B chromosomes, the numbers of chromosomes in a set vary enormously from one species to another. Generally, haploid numbers above 15 are rare in plants, and haploid numbers above 50 are rare in animals. There are two ways in which chromosomes numbers can change: by breaking one chromosome into two smaller chromosomes or by fusing two chromosomes into one larger chromosome. DNA breaks are usually caused by radiation or chemicals. While breaks usually are repaired without a trace, sometimes repair leads to permanent breaks, fusion of chromosomes, trading segments between chromosomes (translocation), and inversion within a chromosome.

Most eukaryotic organisms are diploid with two sets of chromosomes, so each chromosome is represented twice (one derived from the egg and one from the spermatozoon). These pairs of chromosomes are called homologs or homologous chromosomes. Homologs are the same size and shape, have the same banding pattern, and carry genes for the same traits (but not necessarily the same alleles of those genes) (Fig. 2 and Colorplate 1).

Karyotypes and idiograms. Although the terms karyotype and idiogram have sometimes been used interchangeably, it less confusing to restrict karyotype to a word description of a set of chromosomes (for example, the haploid set of chromosomes is represented by three large metacentric, two large acrocentric, five small acrocentric, and two small metacentric chromosomes), whereas the term idiogram is used for a diagrammatic representation of a chromosome set, in which the chromosomes are arranged in a row from largest to smallest. In general, the longest chromosome is numbered 1, the next longest numbered 2, and so on. The chromosomes can be drawn, but usually they are cut out of a photograph of a chromosome spread and pasted in position. If the cell was diploid, homologs are positioned together in pairs (Fig. 2 and Colorplate 1).

Techniques for spreading and staining chromosomes. To make chromosome preparations suitable for observation by light microscopy, cells are usually fixed (killed and preserved) in a freshly prepared solution of one part acetic acid and three parts ethanol or methanol. The chromosomes are then spread and flattened onto a glass microscope slide, either by squashing cells under a cover glass or by bursting cells that have been hypotonically swollen cells and permitting the chromosomes to dry on the slide. Chromosomes can then be stained for examination by light microscopy.

Many stains have been used for chromosomes. Without special treatments, dyes such as crystal violet, Giemsa stain, orcein, and carmine stain chromosomes homogeneously throughout their length. Historically the Feulgen technique has been important because the intensity of staining is a direct indicator of the amount of DNA present. Some techniques result in the formation of “bands” on chromosomes due to differential staining based on the location of euchromatin and heterochromatin or differences in base composition of DNA along the length of chromosomes. The latter type of banding is observed with fluorescent dyes such as Hoechst 33258, daunomycin, chromomycin A, mithramycin, DAPI, and quinacrine dihydrochloride that either bind better or fluoresce more strongly in AT-rich or GC-rich DNA (Fig. 2).

Fluorescence in-situ hybridization (FISH). Important new tools for cytogenetics have been introduced during the past 30 years. One of these is fluorescence in-situ hybridization (FISH). In this technique, a specific DNA probe is prepared by attaching a small molecule, such as biotin, to a DNA sequence of interest (for example, a gene). A solution containing the DNA probe is placed on a glass microscope slide with chromosome spreads and heated to denature both the probe and the chromosomal DNA, that is, the hydrogen bonds between AT and GC base pairs are broken so that DNA double helices separate into single, complementary DNA strands. When the slide and solution are cooled to a temperature appropriate for renaturation (reformation of double helices by hydrogen bond formation between complementary strands), the probe will renature with any complementary DNA sequence in the chromosomes. Next, an antibody specific for biotin that is itself attached to a small fluorescent dye molecule (such as fluorescein isothiocyanate, FITC) is placed on the slide. This antibody selectively binds to the biotin in the probe and then the slide is examined under a microscope that has an ultraviolet (UV) light source and the appropriate filters for the dye. The dye will fluoresce to show the location of the probe on the chromosome(s) [**Colorplate 2**]. FISH has proven to be a powerful technique for be a powerful technique for locating DNA sequences on chromosomes.

Other forms of FISH include genomic painting, chromosome painting, and multicolor FISH. In genomic painting, the DNA of one species is isolated and labeled with biotin. The labeled DNA is used as a probe to identify chromosomes from that species among the chromosomes from one or more different species in a hybrid. In chromosome painting, one chromosome is isolated and its DNA is amplified by the polymerase chain reaction (a technique for amplifying specific sequences of DNA) involves copying and amplifying the complementary strands of a target DNA) and labeled with biotin; this labeled DNA is then used as a probe to locate a specific chromosome in a group of chromosomes. In multicolor FISH, probes can be prepared for each chromosome in a set, and every chromosome can be identified simultaneously using different dye combinations. *See* GENE AMPLIFICATION.

Immunofluorescence. Immunofluorescence can be used to locate specific proteins on chromosomes. The first step is the preparation of a primary antibody that will specifically bind to the protein of interest in chromosomes on a slide. Next, the primary antibody is bound by a secondary antibody that is labeled with a fluorescent dye that is visualized using fluorescence microscopy. Immunofluorescence is useful for relating proteins to the structure and function of chromosomes (Colorplate 1). *See* IMMUNOFLUORESCENCE.

Function. The nucleus is a molecular library of instructions for building an organism, responding to the environment, and reproducing. Chromosomes are like molecular books, and DNA is the molecular text. In a library, most of the books and the vast majority of the text are stored compactly when not in use, but they must be available when needed. Decondensation of euchromatin in interphase makes the DNA physically available for interaction with proteins called transcription factors that recognize specific base sequences and prepare the DNA for transcription by the enzyme RNA polymerase. During transcription, complementary single-stranded ribonucleic acid is made using one of the DNA strands as a template. Transcribed segments of DNA are called genes. Many RNAs are messages (mRNAs) that are transferred to the cytoplasm, where they associate with ribosomes. There, the base sequence of mRNA is used to determine the amino acid sequence of proteins in a process known as translation of the genetic code. During translation, the linear sequence of bases in mRNA is used to determine the linear sequence of amino acids in a protein. *See* GENE; GENETIC CODE.

Other RNAs are transcribed that are not messages, but instead function as structural components, enzymes, suppressors of gene activity, or signals in the pathway to forming heterochromatin. Four of these other RNAs are components of ribosomes. Most ribosomal RNA is transcribed from nucleolus organizer regions (NORs), where hundreds or thousands of copies of the ribosomal RNA gene are located. Active NORs appear as secondary constrictions on certain chromosomes, that is, chromosome constrictions in addition to centromeres. *See* RIBONUCLEIC ACID (RNA); RIBOSOME.

During mitosis, when the duplicated DNA is being divided equally between the daughter cells, the DNA is so compactly packaged in condensed chromosomes that it is temporarily unavailable for transcription, like books that are crated for shipping to another library. At the end of mitosis (telophase), chromosomes decondense and return to their interphase condition, that is, the books are uncrated, and the library is open for business.

Special chromosomes. Special chromosomes include sex chromosomes, polytene chromosomes, and the chromosomes of meiosis.

Sex chromosomes. Some animals determine whether embryos develop as males or females by the combination of sex chromosomes they carry. Mammals and birds are prominent examples.

In mammals, males normally have only one large X chromosome and one Y chromosome that is usually small and heterochromatic. The Y carries the *SRY* gene, which determines that testes will be formed rather than ovaries. Females have two X chromosomes and no Y chromosome, so they form ovaries by default (Fig. 2 and Colorplate 1). However, because the number of X chromosomes differs in males and females, there is a problem with the dosage of genes on the X chromosome. Either the male with only one X has half enough genes or the female with two X's has twice too many genes. The problem is solved in mammals by converting one of the two X chromosomes in each cell of females into facultative heterochromatin in a process known as lyonization. This involves transcription of a gene on the mostly inactive X to produce RNA molecules that coat and play a role in inactivating the X chromosome. As a result, females, like males, have only one active (euchromatic) X chromosome in each cell. X inactivation occurs early in embryonic development, appears to be random with respect to which X is inactivated, and is inherited in subsequent cell divisions. Thus, the body of female mammals is a patchwork (mosaic) of tissues in which genes from one or the other X is active. During interphase, the inactive X chromosome in the nuclei of female cells stains darkly and is called a Barr body. Male cells seldom show Barr bodies.

In birds, the system is reversed so females have one Z chromosome and one small W chromosome, while males have two Z chromosomes. Presumably the presence of the W chromosome somehow determines that ovaries rather than testes will form in females. Barr bodies are not visible in male birds, indicating that birds deal with dosage compensation differently than mammals. *See* SEX DETERMINATION.

Fig. 3. *Drosophila melanogaster* polytene chromosomes.

Polytene chromosomes. A few insects, plants, and protozoa have cells that undergo endoreduplication, a process involving round after round of DNA synthesis without nuclear division to produce polytene chromosomes. The best-known example of polytene chromosomes occurs in Dipteran (fly) salivary glands. A polytene chromosome often consists of a thousand or more identical DNA double helices lying parallel in a bundle. Polytene chromosomes show intricate patterns of banding, where in some cases a band corresponds to a specific gene. Often euchromatin is selectively replicated, so heterochromatin

Fig. 4. Electron micrograph of a tomato synaptonemal complex. The kinetochore looks like a fuzzy ball, and a single recombination module is indicated by an arrow.

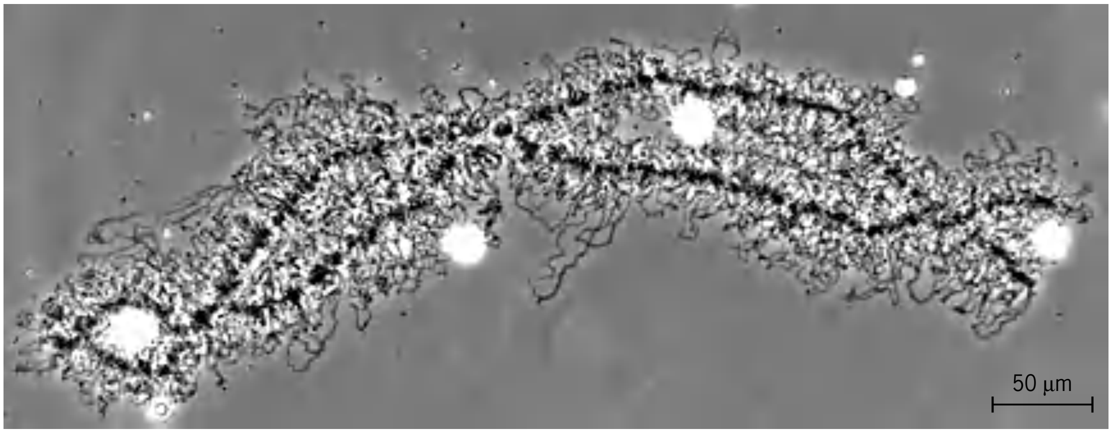

Fig. 5. Lampbrush chromosomes from a salamander (axolotyl) primary oocyte. Chromatin loops extend from the axes of two homologous chromosomes that come together at the chiasmata, where crossing over has occurred. Bright spots are nucleolar material. (*Courtesy of Garry Morgan, University of Nottingham*)

has little representation. Polytene chromosomes are not comparable to mitotic chromosomes; rather they are a special class of interphase chromosomes. Aside from protozoa that produce polytene chromosomes on the way to forming macronuclei, cells with polytene chromosomes are differentiated cells that will never divide again (**Fig. 3**).

Chromosomes of meiosis. Meiosis consists of two special cell divisions referred to as Meiosis I (MI) and Meiosis II (MII). MI is unique among nuclear divisions because crossing over occurs between homologous chromosomes and the chromosome number is reduced from diploid to haploid. For this, elongate homologous chromosomes synapse (come together side-by-side) in a gene-for-gene alignment during prophase I. Synapsed homologs are held together by a proteinaceous structure called the synaptonemal complex (SC) [**Fig. 4**]. The synaptonemal complex looks like a railroad track, with the rails represented by two lateral elements. One lateral element is associated with the two sister chromatids of one chromosome, and the other lateral element is associated with the two sister chromatids of the homologous chromosome. Chromatids in homologs are called nonsister chromatids. Thin transverse filaments span the central region between the lateral elements. It is at this time that new gene combinations are created by crossing over. Pairs of homologous chromosomes held together by synaptonemal complexes or chiasmata are called bivalents. *See* MEIOSIS.

Crossing over involves breakage and repair of DNA in such a way that nonsister chromatids exchange equivalent segments. These events probably occur in recombination nodules, proteinaceous ellipsoids about 100 nm in diameter that reside between the lateral elements of the synaptonemal complex (Fig. 6). The pattern of crossing over (recombination) can be mapped on synaptonemal complexes by examining synaptonemal complexes and recombination nodules using electron microscopy or by locating recombination nodules using immunofluorescent antibodies targeted to a protein in recombination nodules called MLH1 (**Colorplate 3**). Recombination nodule maps show the pattern and frequency of crossing over on chromosomes and thereby link genetic linkage maps to chromosome structure. *See* CROSSING-OVER (GENETICS); RECOMBINATION (GENETICS).

Primary oocytes (immature eggs) of most animals enter a synthetic period right after crossing over is completed and the synaptonemal complex breaks down. During this time, many components that will be needed by the developing embryo are synthesized and stored in the oocyte. Apparently to enhance transcription at this time, the pairs of homologous chromosomes (held together at sites of crossing over called chiasmata) become extremely long to permit rapid RNA synthesis on loops of chromatin extending from the chromosome axes. These bivalents (pairs of homologous chromosomes) are called lampbrush chromosomes because nineteenth-century cytologists thought they looked like the brushes used to clean glass chimneys of oil lamps (**Fig. 5**). Chromosome aberration

Any numerical or structural change in the usual chromosome complement of a cell or organism.

Heteroploidy. Numerical changes (heteroploidy) are of two types, polyploidy and aneuploidy.

Polyploidy is a change in the number of chromosome sets. The polyploid condition has both advantages and disadvantages. For example, tetraploid ($4n$) plants can be fertile because each chromosome can pair in meiosis with a homologous chromosome and segregate properly to form euploid $2n$ gametes or germ cells. These plants are larger than diploid varieties and produce larger fruit making them valuable commercially. Triploid ($3n$) plants, however, are usually sterile because of the inability of every chromosome to find a homologous chromosome to pair with in meiosis. The result is improper segregation (nondisjunction) of chromosomes and aneuploidy in the progeny. Triploidy rarely occurs in animals. Triploid reptiles and frogs are seen only in populations that reproduce parthenogenetically from unfertilized eggs that have not undergone the meiotic divisions that could produce aneuploid ova. Triploidy occurs in about 1% of human pregnancies, but it is almost always an embryonic lethal condition. *See* MEIOSIS; MITOSIS; POLYPLOIDY.

Aneuploidy is a change in the number of chromosomes from the diploid ($2n$) number (usually found in the somatic cells of sexually reproducing organisms, including animals and plants) or the haploid (n) number (usually found in germ cells and the haplophase of some unicellular organisms.) Aneuploidy involves either an increase or a decrease in the number of chromosomes. It usually involves a single chromosome, and any chromosome in the complement can be involved. Aneuploidy is the result of aberrant segregation of one or more chromosomes during meiosis or mitosis. If malsegregation or nondisjunction occurs during meiosis, one daughter cell receives two copies of the chromosome and the other daughter cell receives none. Fertilization of such an aneuploid germ cell by a euploid gamete will produce a zygote that has either three copies (trisomy) or one copy (monosomy) of the chromosome. Malsegregation of a chromosome can also take place during a mitotic division in a somatic cell, producing trisomic or monosomic cells in an otherwise euploid individual. This outcome is important primarily in the origin and progression of some forms of cancer. In humans, nearly 20% of ova and 7% of sperm may be aneuploid, and at least 3% of recognized pregnancies are trisomic and 1% are XO, that is, having a single sex chromosome per cell. Also, nearly half of all miscarriages and 3% of stillbirths are the result of aneuploidy.

Autosomal trisomy. The most common trisomy in human liveborns is trisomy 21, or Down syndrome, which is a major cause of mental retardation and congenital heart disease. Individuals with trisomy 18 and trisomy 13 also occur but are much less common. Most autosomal trisomies are lethal to embryos, leading to spontaneous abortion. The incidence of trisomy for any autosome increases exponentially with maternal age. For trisomy 21, the risk is about 1 in 100 for women over 35 years of age, and much greater for women over age 40. In about 80% of cases, the extra chromosome 21 is inherited from the mother and in 20% from the father, the latter case showing no paternal age effect on incidence. *See* DOWN SYNDROME.

Sex chromosome aneuploidy. In humans, there are more types of aneuploidy involving the sex chromosomes than the autosomes. The most common is XO, occurring in about 1% of pregnancies, with the risk being slightly higher in very young mothers. Although 99% of XO fetuses die early in pregnancy, the other 1% (about 1 in 10,000 liveborn females) survive. The high frequency of deaths of most XO fetuses is somewhat puzzling because the somatic cells in XX females have only a single active X chromosome. It is believed that the cause of death may be the presence of one or more genes on the tiny shared (homologous) segment of X and Y that remain active on both the Y and the otherwise inactive X chromosome. Adults who are XO tend to be short, with some webbing of the neck. They rarely develop secondary sexual characteristics or have children because the germ cells essential for ovarian development are usually absent. These features are characteristic of Turner syndrome. *See* HUMAN GENETICS.

Trisomy for the human X chromosome, commonly called XXX, is not associated with embryonic death or congenital malformations. The reason is that in all mammals, including humans, only a single X chromosome is active in each somatic cell; additional X chromosomes are inactivated, so almost all of their genes fail to be expressed. These are adult individuals with as many as five X chromosomes, and while they are physically normal they do show some degree of mental retardation.

In contrast to autosomal trisomy, sex chromosome aneuploidy increases only slightly with maternal age, and the extra X chromosome comes from the mother in only about 60% of the cases. About 1 of every 1000 liveborn females is XXX, while 1 of every 1000 liveborn males is XXY and 1 is XYY. An additional X chromosome can be present in either egg or sperm; additional Y chromosomes can be present only in sperm. The XXX and XXY individuals display minimal phenotypic manifestations of their increased number of chromosomes, although XXY males are usually sterile and have an increased risk of mild mental retardation. Individuals who are XYY generally are indistinguishable from XY individuals, although they are questionably at a slightly increased risk of antisocial behavior. The presence of a Y chromosome leads to male sex differentiation no matter how many X chromosomes are present, because of the presence of a single, critical gene, called *SRY*, on the Y chromosome. A mutation of this gene has been found in some XY individuals who developed as females.

Structural abnormalities. Structural abnormalities (chromosome mutations) involve the gain, loss, or rearrangement of chromosome segments after the continuity of the deoxyribonucleic acid (DNA) strand in one or more chromosomes is disrupted (**Fig. 1**).

Deletion. A deletion involves the loss of a chromosome segment and the genes it carries. A terminal deletion involves the loss of a segment extending from the point of disruption (breakpoint) to the end

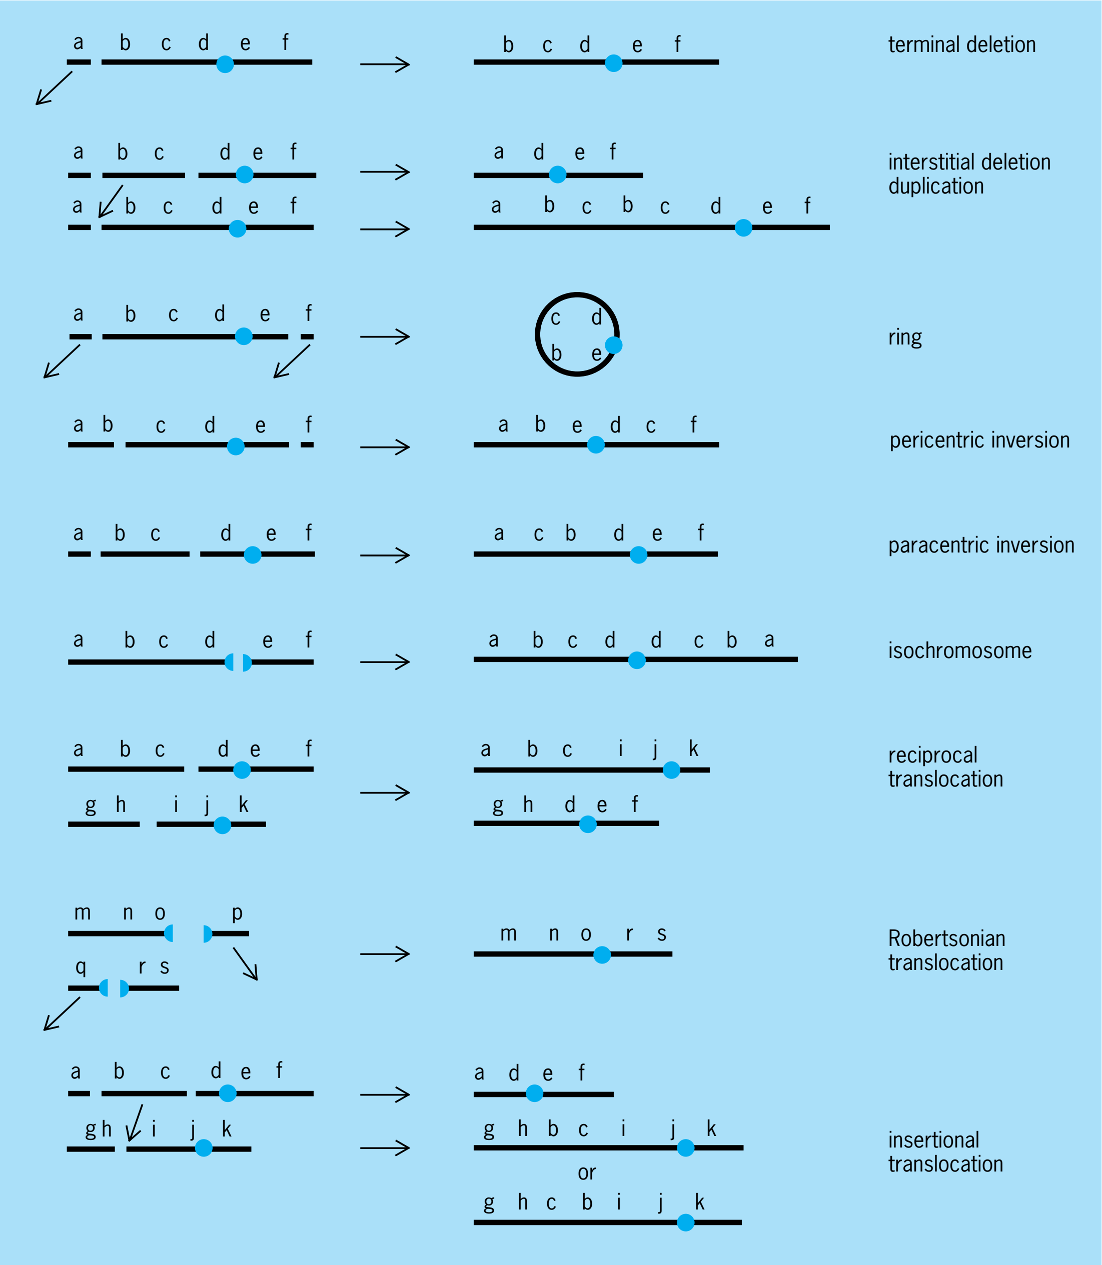

Fig. 1. Diagram of various types of structural abnormalities.

of the same arm of a chromosome. It is relatively uncommon because the broken end of the chromosome is usually repaired during DNA replication, resulting in a dicentric chromosome that is unstable because its two centromeres tend to be pulled toward opposite spindle poles at anaphase of cell division. The result is the breakage and eventual loss of the chromosome. An interstitial deletion involves the loss of the segment between two breakpoints in one arm of a chromosome (**Fig. 2**). The effect of such a loss depends on the genes that are included in the missing segment. If a deletion is associated with a genetic disease, the chromosome breakpoint provides a clue to the location of the gene responsible for the disease. For example, deletions were useful in mapping and isolating the human gene for retinoblastoma.

Fragments and duplication. When one break occurs in each arm of a chromosome, the broken ends of the internal centromeric fragment may join, resulting in the formation of a stable ring chromosome (Fig. 2). Each of the two end segments lacks a centromere, and such acentric fragments are lost during cell division, resulting in deletion of both end segments. Ring chromosomes are subject to reduction in size, as well as doubling. An individual who has a ring chromosome may thus show phenotypic effects not only of deletion but of duplication of part of the chromosome. A duplication more commonly occurs in other ways. For example, a chromosome segment can undergo tandem or inverted duplication at the usual chromosome site, or the second copy of the segment may be carried on another chromosome.

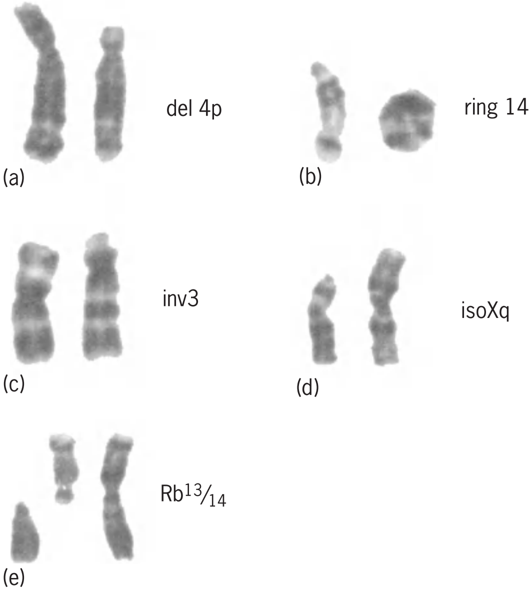

Fig. 2. G-banded human chromosomes illustrating structural chromosome abnormalities present in different individuals. The normal chromosome(s) is on the left in each case. (*a*) Terminal deletion of the short arm of chromosome 4 (4p). (*b*) Ring chromosome 14. (*c*) Pericentric inversion of chromosome 3. (*d*) Isochromosome of the long arm of the X. (*e*) Robertsonian translocation of chromosomes 13 and 14.

Inversion. An inversion is generated by disrupting the DNA strand in a chromosome at two breakpoints and rejoining the broken ends with the interstitial segment in the opposite orientation. This process will invert the order of the genes on the segment (Fig. 2). The centromere is included in the inverted segment in pericentric inversions but not in paracentric inversions. Thus, pericentric inversions can often be identified by an altered position of the centromere, while paracentric inversions can be identified only by an altered banding pattern or altered gene order.

Translocation. A translocation involves the interchange of one or more chromosome segments between two or more chromosomes. A reciprocal translocation involves the reciprocal exchange of the segment produced by a single break in one chromosome for the segment produced by a single break in another chromosome. A Robertsonian translocation (Fig. 2) is produced by the rejoining of the long arms and centromere of two acrocentric or telocentric chromosomes after disruptions in the short arm or at the centromere. It results in the reduction of chromosome number by one, except in the rare case in which the two short arms rejoin and the tiny fragment retains a functional centromere. An insertional translocation is produced when the interstitial segment between two breakpoints in one chromosome is inserted into a breakpoint in another chromosome. A complex translocation involves rearrangement of segments from three or more chromosomes. *See* GENE AMPLIFICATION; MUTATION.

Consequences of translocations and inversions. If a translocation breakpoint disrupts a gene, the gene's function will be blocked or abnormal, and such can have deleterious effects on development or function. Sometimes a normally silent gene is activated by a chromosome rearrangement that places it next to a strong promoter of gene expression, and this change is important as a cause of cancer. If a translocation does not block the function of an essential gene or activate a normally silent gene, the individual carrying the rearrangement will be normal.

In an individual carrying an inversion on one of a pair of homologous chromosomes, pairing leads to the formation of a loop containing the inverted segment. Crossing over within the loop leads either to the formation of gametes with a duplication of one segment of the inversion and a deficiency of the other segment, or to two abnormal chromosomes, one with two centromeres and the other lacking a centromere. *See* CROSSING-OVER (GENETICS).

Causes. Structural aberrations can occur spontaneously or be induced by agents that break chromosomes, such as x-rays, radioactive substances, ultraviolet rays, and certain chemicals. The most frequent cause may be the presence of enormous numbers of a few types of short interspersed elements (SINES), that is, DNA sequences that occur once every few thousand base pairs throughout the genome of most metazoans, including humans. These elements predispose to the occurrence of errors during DNA replication or genetic recombination at meiosis that can lead to the deletion or duplication of the region between two nearby interspersed repeats on one chromosome. They may also play a role in the formation of inversions and, possibly, translocations. *See* MUTAGENS AND CARCINOGENS.

Another cause of structural aberrations is also inherent in the genome: the great abundance of short repeats of a 2-, 3-, or 4-base-pair unit. Some trinucleotide repeats, such as $(CGG)_n$ or $(CAG)_n$, can undergo expansion during meiotic and mitotic cell divisions. This expansion sometimes affects gene function and leads to disease. The most common type of X-linked mental retardation in humans is the result of heritable expansions, in the *FMR-1* gene, of a specific trinucleotide repeat, $(CGG)_n$, where the number of expansions (n) is increased from the normal 8–20 or so to 50–200 or more. For unknown reasons, this expanded region tends to undergo breakage under some conditions, and this particular form of mental retardation is called the fragile X syndrome. There are dozens, if not hundreds, of similar fragile sites in the human and other genomes.

Imprinting. The function of a gene that is inherited from the father may differ from that of the same gene inherited from the mother, a phenomenon known as imprinting. The mechanism for imprinting is not fully understood, but differences in DNA methylation of genes in sperm compared to ova appear to be involved. Imprinting is important in some human diseases, such as Prader-Willi and Angelman syndromes. Although deletions of the same region on chromosome 15 have been observed in some individuals with either of these syndromes, individuals who received the deleted chromosome 15 from the father developed the Prader-Willi syndrome, whereas those

Fig. 3. Q-banded chromosomes of (*a*) normal mouse metaphase cell, arranged according to the standard karyotype, (*b*) and metaphase karyotype of a mouse cancer cell showing numerical and structural changes. Chromosomes 2–18 are structurally normal, but noteworthy are the monosomy 17 and 14 and trisomy 18.

who received the deleted chromosome 15 from the mother developed Angelman syndrome. Thus, although each syndrome is associated with the presence of a single undeleted chromosome 15, the outcome depended on the parental origin.

Abnormal chromosomes in tumor cells. Specific chromosome aberrations play an important role in the development of many, if not all, cancers. For example, most patients with chronic myelogenous leukemia have a translocation between chromosome 9 and 22 which fuses the normally silent *c-abl* oncogene with the expressed *bcr* gene. The result is the production of an abundant *bcr-abl* fusion gene product and tumor development (**Fig. 3***a* and *b*). Tumor cells tend to be chromosomally unstable, and further chromosome aberrations may enhance tumor malignancy. Translocations and trisomies may lead to additional oncogene products, whereas deletions may remove genes that suppress tumor growth.

Some tumor cells have an elongated region on a chromosome arm that contains an increased number of copies (amplification) of an oncogene. Such regions stain uniformly, rather than being banded, and are called homogeneously staining regions (HSRs). The amplified oncogenes are sometimes extrachromosomal, that is, are present on very tiny collections of chromatin resembling small chromosomes that lack centromeres; these are called double minutes (DMs). *See* ONCOGENES; ONCOLOGY.

Evolution. Chromosome complements are remarkably diverse throughout both plant and animal kingdoms, and chromosome aberrations may have played an important role in the reproductive isolation that fosters speciation. For example, polyploidization creates a reproductive barrier that favors the formation of a new, polyploid species. Some species contain very large chromosome numbers, such as a fern with about 1000 chromosomes, a crayfish with over 350 chromosomes, and a butterfly with over 400 chromosomes.

Structural chromosome changes have also been a common occurrence in evolution. As described above, when a translocation or inversion involves one of a pair of homologous chromosomes, abnormal gametes are produced and fertility is reduced. However, in a small, inbreeding population, both male and female parents could receive a copy of the rearranged chromosome or chromosomes, and each parent could pass them on to an offspring, who would thus have a matched set of rearranged chromosomes. The latter would pair normally at meiosis, leading to the production of normal gametes. In this way, the altered chromosome could spread through a small, inbreeding population and might replace the initial chromosome arrangement, becoming fixed in the population. *See* POPULATION GENETICS.

Chromosome rearrangements do not change the banding patterns of the chromosome segments.

Therefore, it is possible to compare the karyotypes of species to determine what changes have been fixed in their evolution. For example, there is a preponderance of Robertsonian translocations in lemurs compared to other primates, and a preponderance of pericentric inversions in the chromosomes of the great apes and humans. The telocentric chromosomes of the European mouse, *Mus musculus domesticus*, undergo frequent Robertsonian translocations and, indeed, one mouse was found in which 18 of the 19 autosomes had undergone such translocations. At this time there is no evidence that chromosome changes alone have led to the creation of a new species, but it is clear that they can lead to sterility in certain outcrosses and to the reproductive isolation that is critical for speciation. *See* CHROMOSOME; RECOMBINATION (GENETICS); SPECIATION.

Chromosphere

A complex structure of warm gas above the visible surface, or photosphere, of the Sun and most stars. The term “chromosphere” was first applied to the red ring and large prominences seen at the edge of the eclipsed Sun with the unaided eye. Emission in the Balmer-alpha line of hydrogen at 653-nanometer wavelength accounts for the red color. The chromosphere is transparent in visible light, but is opaque and bright in the ultraviolet continuum and in strong lines of abundant elements, including hydrogen, helium (first observed during the 1868 solar eclipse), oxygen, calcium, and magnesium. Gas temperatures range from 3500 to 30,000 K (5800 to 54,000°F) and densities are between 10^9 and 10^{12} particles per cubic centimeter.

Structure of solar chromosphere. The solar chromosphere extends from roughly 500 km (300 mi) above the photosphere to where hydrogen becomes fully ionized and the gas temperature rises rapidly to more than 10^6 K (1.8×10^6 °F) in the corona. High-resolution images of the Sun taken in strong emission lines reveal a filamentary structure consisting of many magnetic loops. In the chromospheric network at the edges of 30,000-km-wide (19,000-mi) supergranule cells, the magnetic field is strong, the gas is dense and hot, and the chomosphere may be only 500 km (300 mi) thick. Here the magnetic heating rate is 10 or more times higher than average. Thin gas jets called spicules are clustered in the network. In the center of supergranule cells, where the magnetic field is weak, the chromospheric gas cools to 3500 K (5800°F) and extends upward several thousand kilometers. Here molecular carbon monoxide (CO) is abundant enough to keep this gas cool. *See* SUPERGRANULATION.

Chromospheres of other stars. Stars with effective temperatures less than about 8000 K (14,000°F; the Sun is 5770 K or 9930°F) show the same emission lines as the solar chromosphere and are thus thought to have analogous regions. Slowly rotating old stars show chromospheric emission at minimal levels comparable to those seen in the centers of solar supergranule cells. This weak emission indicates a basal level of chromospheric heating that is probably produced by the damping of nonmagnetic acoustic waves generated by convection in the lower atmosphere. Young, rapidly rotating stars show chromospheric emission at levels 10 or more times higher than is observed in regions of strong magnetic fields on the Sun. The highest levels of this emission correspond to saturated heating by magnetic-field reconnection events (often called microflaring) or the damping of magnetoacoustic waves.

Wilson-Bappu effect. In 1957 Olin C. Wilson and M. K. V. Bappu discovered that the widths of the near-ultraviolet emission lines of singly ionized calcium (Ca^+) increase with stellar luminosity. The Wilson-Bappu effect is now explained by the increased amount of gas in the chromospheres of lower-gravity stars, which have higher luminosities. Wilson began a long-term program to monitor the strength of the stellar Ca^+ emission, which led to the discovery of magnetic cycles on stars analogous to the 11-year solar cycle. Continued monitoring of this emission feature in many stars revealed that some are going through phases of no magnetic cycle, like the Maunder minimum of sunspots observed between 1645 and 1715. The energy budget and dynamics of stellar chromospheres have been studied with the *Hubble Space Telescope* and the *International Ultraviolet Explorer* satellite. *See* SATELLITE (ASTRONOMY); SUN.

Chronic fatigue immune dysfunction syndrome

A condition resulting in massive, debilitating fatigue accompanied by diverse symptoms including memory loss, diminished powers of concentration, sleep disorder, headache, low-grade fever, muscle and joint pains, sore throat, tender lymph nodes, and a postexertional malaise lasting more than 24 hours. This condition is also known as postviral fatigue, chronic fatigue syndrome, and myalgic encephalomyelitis. It is often associated with stress.

The severity of chronic fatigue immune dysfunction syndrome (CFIDS) varies considerably. Some patients are bedridden while others suffer only mildly debilitating symptoms. The cause of the disease is unknown, although there are hypotheses relating it to an abnormal immune response due to concurrent stress and a previous infection, perhaps viral. The Epstein-Barr virus, human herpes virus 6, cytomegaloinclusion virus, Coxsackie virus, various stealth viruses, and a retrovirus have been implicated. All of these viruses are common, and the general population is frequently exposed to them. Nevertheless, the general population does not suffer from the syndrome. One possibility is that exposure to the virus occurs during a period of either physical or emotional stress. Genetic and environmental factors may also be implicated. An abnormal immune response to viral or bacterial activity could explain many symptoms of CFIDS. Among possible sources of immune "dysregulation" in CFIDS are decreased natural killer cell (NK) cytotoxity, increased T and B lymphocyte activation, and elevated cytokine production. *See* EPSTEIN-BARR VIRUS; HERPES; INFECTION.

CFIDS is not life-threatening and is not considered communicable. However, it often occurs within families or within a defined geographical area, which, at least in some cases, suggests the possible involvement of an infectious agent. If a viral cause is proven, there would be an infective phase during or immediately after the incubation of the virus.

There is no definitive diagnostic test for CFIDS; thus it is necessary to first eliminate all other potential symptom etiologies. A diagnosis of the syndrome should be made only after alternative medical and psychiatric causes of chronic fatigue have been excluded. Fatigue can occur in the simplest to the most complex diseases. Conditions that must be excluded include simple iron deficiency anemia, familial or genetically related anemias, hematomachrosis, chronic infections (such as tuberculosis and Lyme disease), inflammatory conditions (such as sarcoidosis and thyroid dysfunction), autoimmune diseases (such as lupus erythematosus, Hashimoto's thyroiditis, and hemolytic anemia), and cancer.

While the majority of individuals with confirmed CFIDS have positive antibodies to one or more of the implicated viruses, the viruses are so common that antibody titers may be suggestive but are not diagnostic. *See* ANTIBODY.

There have been suggestions that CFIDS is a psychiatric state manifesting itself as a primary chronic depressive neurosis. This means that the individual is not physically ill but imagines somatic illness and may be labeled as neurotic or lazy. Despite many similarities in the somatic presentation of CFIDS and depression, various psychological, immunologic, and neurological tests indicate clear differences between the two disorders.

There is no standard method of treatment. However, some believe that treatment based on reversal of the abnormal immune response is helpful. Cognitive behavioral therapy and certain approaches to exercise have also demonstrated efficacy as treatments. Some individuals affected by CFIDS improve with time; when untreated, most remain functionally impaired for several years.

Chronograph

Any device that measures a time interval. The term is usually restricted to measurements that have a small percentage error. Early time measurements used the human pulse rate or counted the number of swings of a pendulum for small time intervals. Astronomers used a regulated rotating drum to measure the time intervals of short changes in objects in the sky. Physicists did the same in the laboratory. The term chronograph seems to have stuck even when the device is digital rather than a graph. The term chronometer is often used interchangeably with chronograph, although again the result may be an electronically produced number rather than a meter reading. *See* CHRONOMETER.

Modern chronographs range from accurate wristwatch chronometers, used to time sporting events, to Doppler or other electronic or atomic means used in the laboratory or everyday living. *See* ATOMIC CLOCK; DOPPLER EFFECT; QUARTZ CLOCK; TIME-INTERVAL MEASUREMENT; WATCH. John L. Safko

Chronometer

A large, strongly built watch especially designed for precise timekeeping on ships at sea. The name is sometimes loosely applied to any fine watch. *See* WATCH.

The features that distinguish a chronometer from a watch are (1) a heavy balance wheel, the axis of which is kept always vertical by mounting the entire instrument within two concentric rings, so pivoted as to permit the chronometer to remain undisturbed despite considerable tilting of the box containing it, as the ship rolls and pitches; (2) a balance spring wound in cylindrical shape, instead of a nearly flat helix; (3) a special escapement; and (4) a fusee, by means of which the power of the mainspring is made to work through a lever arm of continuously changing length, being shortest when the spring is tightly wound and longest when it has run down, thus regulating the transmitted power so that it is approximately constant at all times. *See* ESCAPEMENT; SPRING (MACHINES).

These mechanical chronometers are being replaced by quartz digital chronometers, which operate on the same principle as a quartz watch. *See* QUARTZ CLOCK.

Oceangoing ships formerly relied completely on chronometers keeping Greenwich mean time to determine longitude. The broadcast of radio time signals that became widespread in the 1920s, and subsequently the loran, Omega, and satellite navigation systems, have made Greenwich mean time available to mariners at almost any instant, and chronometers are no longer indispensable for determining longitude at sea. However, they are still a necessary backup, and naval vessels will not leave port without one or more chronometers aboard. *See* CLOCK (MECHANICAL); HOROLOGY; LORAN; SATELLITE NAVIGATION SYSTEMS; TIME. Steven J. Dick

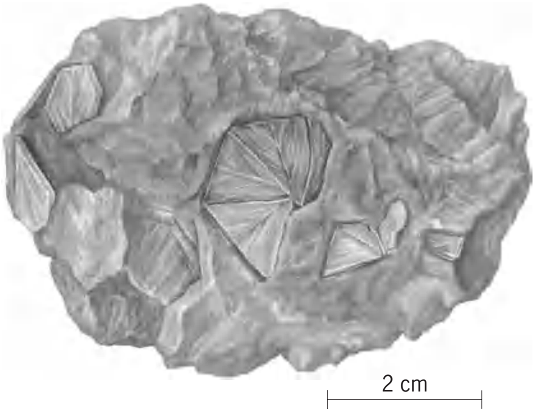
Chrysoberyl

A mineral having composition $BeAl_2O_4$ and crystallizing in the orthorhombic system. Chrysoberyl crystals are usually tabular parallel to the front pinacoid and frequently in pseudohexagonal twins (see **illus.**). There is good prismatic cleavage. The hardness is 8.5 (Mohs scale) and the specific gravity is 3.7–3.8. The luster is vitreous and the color various shades of green, yellow, and brown. There are two gem varieties of chrysoberyl. Alexandrite, one of the most prized of gemstones, is an emerald green but in transmitted or in artificial light is red. Cat's eye, or cymophane, is a green chatoyant variety with an opalescent luster. When cut en cabochon, it is crossed by a narrow beam of light. This property results from minute tabular cavities that are arranged in parallel position.



Chrysoberyl crystals in pegmatite, Greenwood, Maine. (*Specimen from Department of Geology, Bryn Mawr College*)

Chrysoberyl is a rare mineral found most commonly in pegmatite dikes and occasionally in granitic rocks and mica schists. Gem material is found in stream gravels in Ceylon and Brazil. The alexandrite variety is found in the Ural Mountains. In the United States chrysoberyl is found in pegmatites in Maine, Connecticut, and Colorado. *See* BERYLLIUM; GEM. Cornelius S. Hurlbut, Jr.

Chrysocolla

A silicate mineral with composition essentially $(Cu,Al)_2H_2Si_2O_5(OH)_4 \cdot nH_2O$; iron, and more rarely manganese, may substitute for copper. Although acicular monoclinic crystals have been reported, the wide variation in the composition of analyzed specimens suggests that chrysocolla is a hydrogel or gelatinous precipitate rather than a well-crystallized mineral. This suggestion is reinforced by the fact that x-ray diffractions are weak and ill defined. The mineral characteristically occurs in impure amorphous-to-cryptocrystalline crusts and masses with conchoidal fracture.

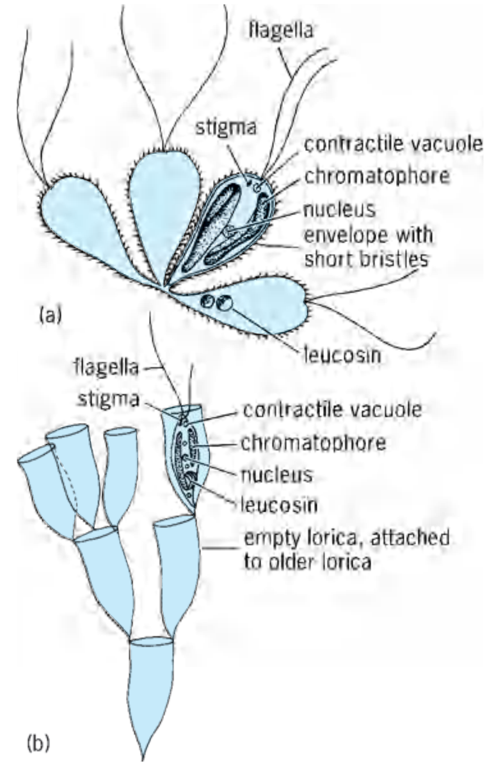
There is a wide variation in physical properties commensurate with the variation in chemical composition. The hardness varies from 2 to 4 on Mohs scale, the specific gravity varies from 2.0 to 4.0, and the refractive index is given variously from 1.40± to 1.60. The luster is vitreous to greasy; and the color is normally green to greenish blue but may be brown or, with manganese present, black.

Chrysocolla is a secondary mineral occurring in the oxidized zones of copper deposits, where it is associated with malachite, azurite, native copper, and cuprite. It is also found in alluvial gravels, indicating that copper is carried in solution far from its primary source. Chrysocolla is a minor ore of copper and a minor gem. Most gem material is essentially chalcedony colored by incorporated chrysocolla. *See* GEM; SILICATE MINERALS. Cornelius S. Hurlbut

Bibliography. C. Klein and C. S. Hurlbut, Jr., *Manual of Mineralogy*, 21st ed., 1993.

Chrysomonadida

An order of the class Phytamastigophorea. Many botanists consider this group a part of the class Chrysophyceae, the golden-brown algae. Chrysomonads, also known as Chrysomonadina, are usually small flagellates, *Mallomonas* being about the largest. They are yellow to brown because of



Chrysomonads. (*a*) Portion of colony of *Synura uvella*. Cell size is 20–40 μm, and colonies 100–400 μm. (*b*) *Dinobryon sertularia* colony. Cells measure 30–44 μm.

phycocrysin in the usual one or two chromatophores, but some lack chromatophores. *Uroglena* colonies may be quite large. Many species form diagnostic siliceous cysts. Palmelloid colonies (*Hydrurus*) consist of a tough, gelatinous matrix holding many nonflagellate cells. Starch is not formed, but fats are, and the refractive carbohydrate leucosin is common. The flagella are usually two, rarely three, and are subequal. Nuclei are small. *See* CILIA AND FLAGELLA.

Synura and *Dinobryon* are colonial types which produce enough oil to be a source of tastes and odors in drinking water (see **illus.**). *Dinobryon* often shows large numbers of cysts in the open ends of empty tests of old colonies. Chrysomonads may ingest food through the area near the flagellar base. Chrysomonadida are common in cooler fresh water, and certain types (Coccolithophora and Silicoflagellata) abound in the ocean. *See* CHRYSOPHYCEAE; COCCOLITHOPHORIDA; PHYTAMASTIGOPHOREA; PROTOZOA; SILICOFLAGELLATA. James B. Lackey

Chrysophyceae

A relatively large and diverse class of algae in the chlorophyll *a–c* phyletic line (Chromophycota). In protozoological classification, these organisms constitute an order, Chrysomonadida, of the class Phytomastigophora. Some workers align Chrysophyceae (golden or golden-brown algae) with Bacillariophyceae (diatoms) and Xanthophyceae (yellow-green algae) in the division Chrysophyta.

Chrysophytes typically are flagellate unicells, either free-living or attached, and solitary or colonial. There are, however, ameboid and plasmodial forms, solitary or colonial nonflagellate cells, filaments, and blades. Fresh-water forms, which are usually found in cold clear water, are more common than marine forms.

Although many unicellular chrysophytes have naked protoplasts, others are covered with organic or siliceous scales, or surrounded by a siliceous, cellulosic-pectic, or (rarely) calcareous lorica. Cells that compose blades and filaments have a polysaccharide wall. The statospore, an internally formed resting stage or cyst, occurs in the life history of most chrysophytes. It is urn-shaped, with a siliceous spiny body and a pectic plug. Similar cysts, assigned to the families Archaeomonadaceae and Chrysostomaceae, are found in the fossil record as far back as the Late Cretaceous.

Motile cells bear two subapically inserted, unequal flagella—a hairy (mastigoneme-bearing) flagellum directed forward, and a shorter, smooth flagellum directed backward. In some genera, the smooth flagellum is greatly reduced and may be represented only by its basal region, which may be transformed into a photoreceptive system, often in combination with an eyespot. Contractile vacuoles may be present in fresh-water forms.

Most chrysophytes are photosynthetic, but some are osmotrophic or phagotrophic. Each cell contains one or two chloroplasts (rarely more), which conform to the biochemical and ultrastructural patterns typical of Chromophycota. The chlorophylls are masked by carotenoids (especially β-carotene and fucoxanthin), producing the characteristic golden-brown color. Chloroplast endoplasmic reticulum is present, thylakoids are in groups of three, and chloroplast deoxyribonucleic acid is distributed in a ring. The chief storage product is chrysolaminaran, which is a glucose polymer with β-1,3 linkages, but lipids are also stored.

Asexual reproduction in unicellular forms is by longitudinal binary fission, autospores (nonflagellate cells that are miniatures of the parent), or zoospores, and in multicellular forms by fragmentation or zoospores. Sexual reproduction, observed rarely and in only a few species, is isogamous.

A satisfactory classification of the approximately 1000 species of chrysophytes has not yet been elaborated. One scheme emphasizes somatic organization, by analogy with green algae (Chlorophyceae), while another scheme emphasizes details of flagellation. Studies using electron microscopy and laboratory culture have led to the removal of certain groups to other classes. The choanoflagellates—collared, colorless flagellate unicells—were formerly aligned with chrysophytes or placed in their own class (Craspedophyceae), but similarity to sponge choanocytes supports their placement among animals, as the order Choanoflagellida of the class Zoomastigophora. Members of the order

Isochrysidales, characterized by having two equal flagella, have been transferred to the class Prymnesiophyceae. The bicosoecids, a small group of colorless unicells with a lorica formed of spiral or annular elements and with one of the two flagella serving as a contractile stalk, are sometimes appended to the Chrysophyceae or, alternatively, assigned to the Zoomastigophora. Finally, silicoflagellates, which are characterized by an elaborate siliceous endoskeleton and a unique protoplast, are placed in the subclass Dictyochophycidae or referred to their own class. They are a relictual group common in the fossil record as far back as the Early Cretaceous but represented in modern seas by only a few taxa. *See* ALGAE; BACILLARIOPHYCEAE; BICOSOECIDA; CHOANOFLAGELLIDA; CHRYSOMONADIDA; XANTHOPHYCEAE. Chrysotile

Chrysotile is a fibrous mineral with a tubular morphology for each fibril (**Fig. 1**). It is a member of the serpentine mineral group, as are antigorite and lizardite. Chrysotile aggregates make up serpentine asbestos, which is the most important type of commercially mined asbestos. Russia and Canada are the main producing countries. Chrysotile displays interesting properties such as being thermally and electrically insulating, sound insulating, chemically inert, fire-resistant, mechanical energy–absorbing, and flexible with enough high tensile strength to be woven. There are hundreds of applications for chrysotile including fire retarder in buildings, roofing tiles, brake pads, weavable material for refractory clothes, filters, and fibers in fibrocement and road surfaces. *See* ASBESTOS; SERPENTINE; SERPENTINITE.

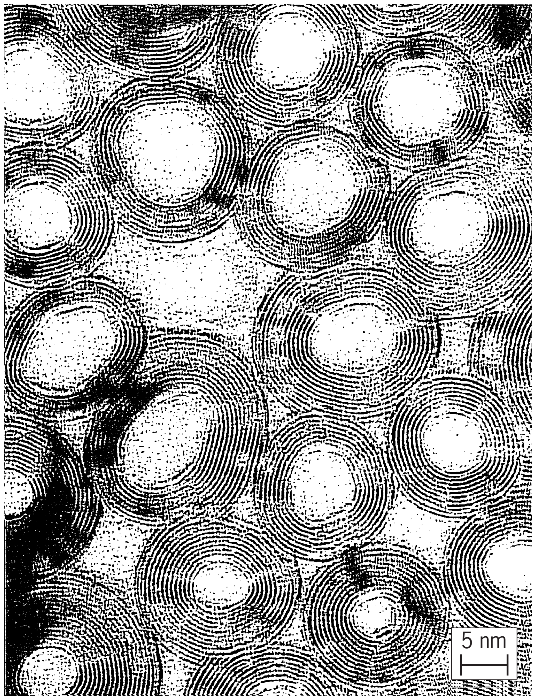

Fig. 1. Cross section of parallel chrysotile fibrils seen with a high-resolution transmission electron microscope (TEM). Black circular fringes image a chrysotile layer containing an octahedral and tetrahedral sheet.

Intensive inhalation of long and thin asbestos fibers over a considerable time period can induce pulmonary diseases such as asbestosis and lung cancers, as well as pleural diseases such as plaques, fibrosis, and mesothelioma. Such health hazards have drastically reduced the use of chrysotile, which is strictly regulated by law in western countries. *See* RESPIRATORY SYSTEM DISORDERS.

Geological occurrence. Chrysotile asbestos shows up mainly as cross-cutting veins in serpentinized green rocks, such as peridotites. It often forms from hydrothermal alteration ($T \leq 350°C$ or 662°F) of magnesium-rich olivines. In general, most serpentines are reacted on and below the sea floor, at slow-spreading mid-ocean ridges, as heated seawater interacts with exposed rocks from the upper mantle of the Earth. Obduction of such rocks accounts for serpentinites in some orogenic belts (for example, the Western Alps). *See* OLIVINE; PERIDOTITE.

Parallel assemblages of chrysotile fibrils in veins are either at a moderate angle (slip fibers) or more commonly normal (cross-fibers) to the vein walls. Progressive shear or opening of the vein by tectonic events seems to be required for massive development of long fibers.

Crystal-chemical properties. The chemical composition of chrysotile expressed as its formula unit is close to $Mg_3Si_2O_5(OH)_4$ [Mg = magnesium, Si = silicon, O = oxygen, OH = hydroxyl], with minor amounts of aluminum (Al) and iron (Fe) and traces of nickel (Ni) and chromium (Cr). This silicate layer is characterized by a tubular shape of each fibril as the basic unit of this material. Each tubule is made of 0.73-nanometer-thick cylindrical layers fitted into each other as telescopic tubes or coils. Most common tubule dimensions are 20 nm outer diameter, 5–7 nm inner diameter, and from 1 micrometer to several centimeters length. Fibrils may aggregate as fibers with a more or less close-packed arrangement of the tubules.

Each curved chrysotile layer is made of two assembled sheet components when viewed at the atomic scale: an outer octahedral sheet (Oc) and an inner tetrahedral sheet (Te). Silicate tetrahedra combine as a honeycomb network to form the tetrahedral sheet. Each silicate tetrahedron consists of a silicon atom surrounded by four close-packed oxygen atoms, and any tetrahedron shares three oxygen atoms with its neighbors whereas the fourth oxygen points toward the octahedral sheet. The octahedral sheet is built up by edge-sharing octahedra all lying on one of the faces, and each is centered by magnesium atoms (**Fig. 2**). All octahedron corners opposed to the tetrahedral sheet are hydroxyl groups. One-third of the inner corners are occupied by hydroxyl groups, whereas the two-thirds left are completed by the above-mentioned nonbridging oxygens of the tetrahedral sheet.

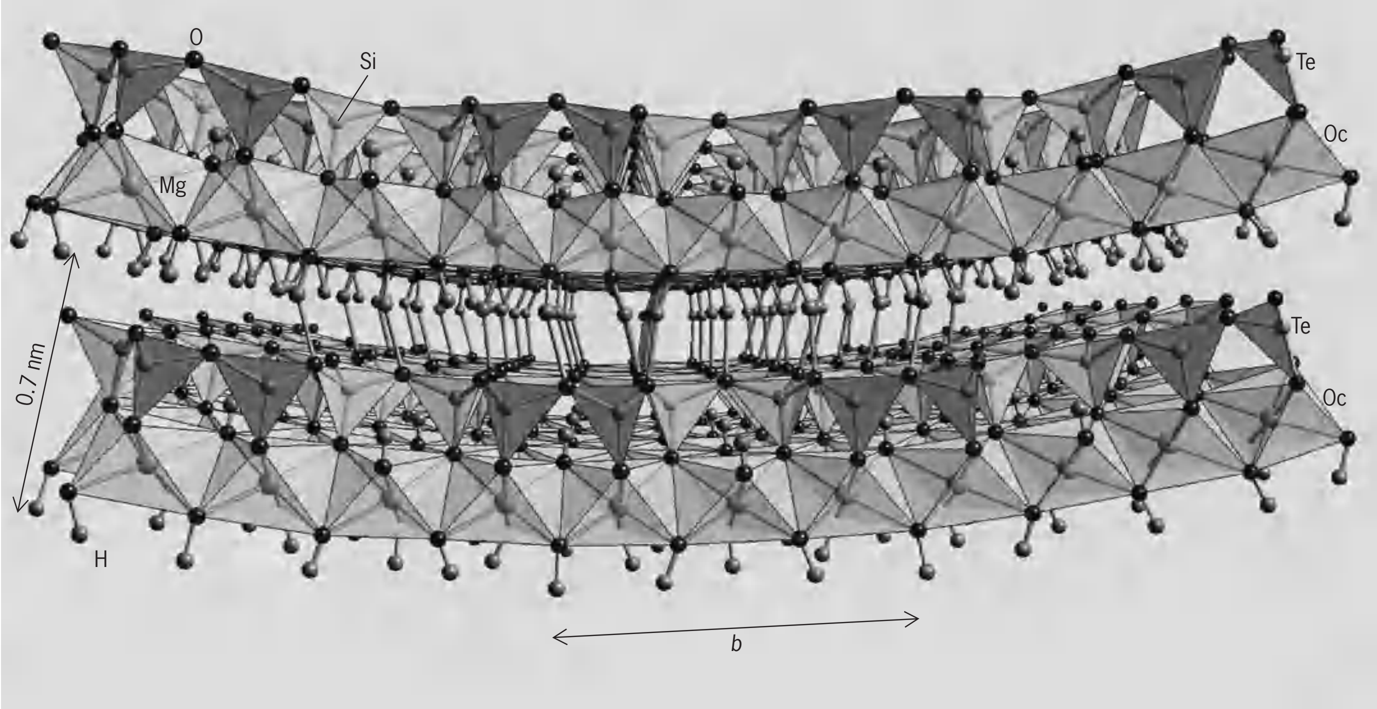

Fig. 2. Atomic structure of a portion of two contiguous chrysotile layers (Oc = octahedral sheet, Te = tetrahedral sheet). Atoms and bonds are seen on and inside translucent coordination polyhedra. Note the progressive deformation and breaking of hydrogen (H) bonds between the layers. This three-dimensional representation was done with CRYSTALMAKER^{TM} software.

The curvature of the serpentine layer of chrysotile is thought to arise from the larger lattice dimensions of the octahedral sheet compared to those of the tetrahedral sheet. Accordingly, curvature is concave toward the tetrahedral sheet, and this partially compensates for any misalignment along with other tetrahedral sheet distortions. Such curvature disturbs the hydrogen (H) bonding between successive layers, that is, the linkage between hydroxyl groups of the octahedral sheet and bridging oxygen of the tetrahedral sheet of the next layer. Due to a progressive structural glide between consecutive layers, a periodic modulation of the hydrogen-bonding strength is observed along the fibril circumference (Fig. 2). This may weaken the average interlayer bonding compared to the case of lizardite, the flat serpentine. *See* HYDROGEN BOND.

Topologies of fibrils. Chrysotile tubules have layers arranged either as pure tube-in-tube cylinders or as spirally wound scrolls. The fibrils elongate either along the x axis (0.53 nm repeat) for normal chrysotile, or along the y axis (0.90 nm repeat) for para-chrysotile. Less frequently, helically wound (chiral) chrysotile tubules are found with curvature axes inside the lattice layer (similar to carbon nanotubes). *See* FULLERENE.

Flat serpentine layers of lizardite are translationally periodic in structure. Once such layers are curved and fitted into each other (as in chrysotile), the tubule loses both radial and circumferential periodicity. Periodicity is maintained along the tubule axis only, thus making chrysotile a kind of a one-dimensional crystal.

Fivefold symmetry. Each time a new cylindrical layer is added on the external surface of a normal chrysotile tubule, five more unit cells of b length are necessary to close up the circumference, because the increment of the perimeter is equal to five times the b length. The uniform distribution of such extra length along a turn implies that any interlayer configuration is recovered regularly five times per turn. Consequently, whatever the stacking sequence of curved unit cells along a tubule radius, the same sequence is recovered at integral multiples of $2\pi/5 = 72^\circ$. Accordingly, fivefold symmetry may be foreseen for the cylindrical lattice of chrysotile tubules as shown by the diffraction pattern of model lattice masks. More direct evidence of fivefold symmetry came from the numerical Fourier transforms of lattice images of tubule cross sections observed by high-resolution transmission electron microscopy (**Fig. 3**). From the above, chrysotile would be the first mineral having a normally forbidden fivefold symmetry axis. This axis would be macroscopic and unique, and in coincidence with the fibril axis. Accordingly, such fivefold symmetry might differ from that of quasicrystals of binary and ternary intermetallic alloys where six distinct fivefold axes are present at both macroscopic and microscopic scales. *See* CRYSTAL STRUCTURE; CRYSTALLOGRAPHY.

Polygonal serpentines. In serpentinite veins of ultrabasic rocks, long and thin chrysotile fibers coexist frequently with shorter but thicker polygonal fibers of serpentine. When observed with the transmission electron microscope, cross sections of polygonal serpentines exhibit either 15 or 30 radially distributed sectors of flat serpentine, each akin to lizardite (**Fig. 4**). *See* ELECTRON MICROSCOPE.

There are geological occurrences where either 15-sectored or 30-sectored fibers are present, others where both types coexist. In the latter case, 30-sectored fibers are statistically larger in diameter (up to several micrometers) than 15-sectored ones. Electron diffraction patterns of single polygonal fibers have fivefold symmetry (Fig. 4). Reasons for such symmetry are the same as those invoked for chrysotile. In polygonal serpentines, flat sectors develop where the interlayer hydrogen bonding is satisfied along the radius of the fiber. Such bonding occurs easily 15 times per turn, or less easily 30 times per turn. *See* ELECTRON DIFFRACTION.

Experimental evidences support a transformation of chrysotile into polygonal serpentines, that is, a polygonization process of cylindrical tubules. Such a transition would take place for growing chrysotile when its diameter overshoots 50–100 nm. Further development of polygonal serpentine to micrometer size would occur by nucleation and further growth of serpentine layers inside and outside the polygonal tube.

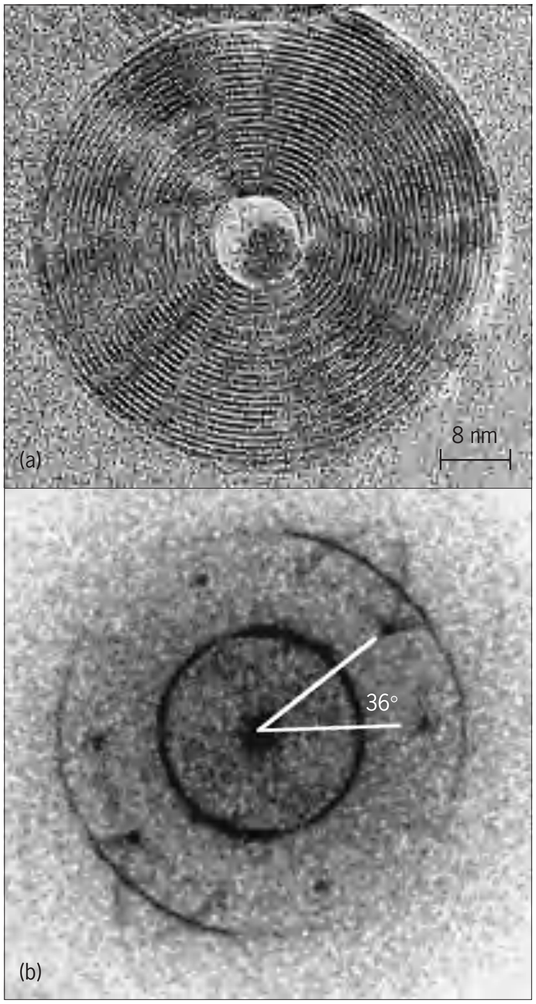

Fig. 3. Chrysotile tube. (*a*) High-resolution TEM image. (*b*) Numerical Fourier transform. The fivefold symmetry of the pattern shows up from the 36° angle between visible spots. (*Courtesy of B. Devouard*)

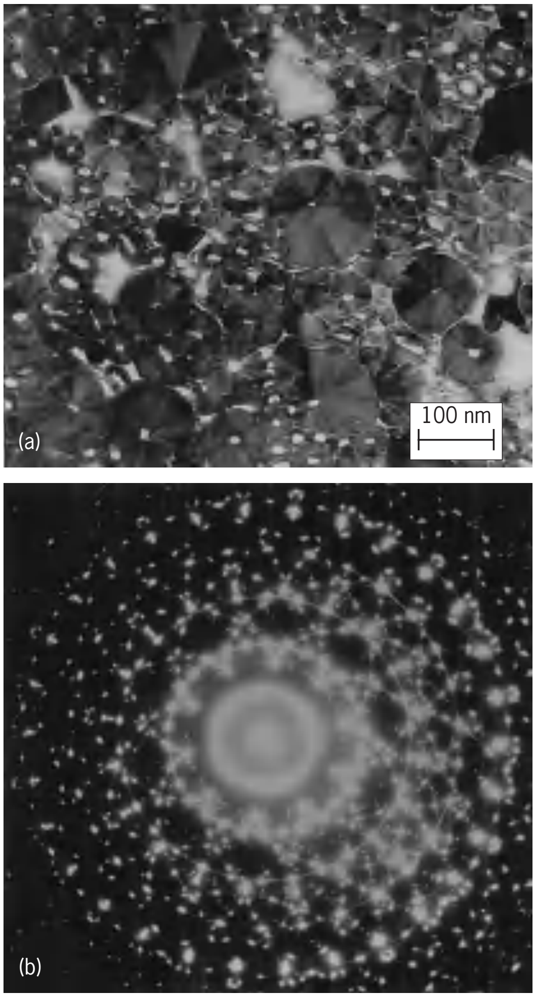

Fig. 4. Polygonal serpentine. (*a*) TEM image of cross-sectioned serpentines, with 15 sectors each. (*b*) Electron diffraction pattern of a serpentine as a rose with fivefold symmetry. (*Courtesy of A. Baronnet and B. Devouard*)

Fiber type and associated hazards. Pure material made of close-packed, poorly coherent chrysotile tubules is finely fibrous and silky. Scratching it with a nail or pouring water droplets on it produces a cottonlike or liquid soap aspect, respectively. Easy separability and thus dispersion of such fibrils in air or in a liquid are likely, so that such material is potentially harmful when inhaled or ingested by humans. Aggregates of polygonal serpentine fibrils that are tightly intergrown and short may be considered less hazardous since they are not able to produce dusts containing long fibers.

Chytridiomycota

A phylum of primitive fungi characterized by production of predominantly aquatic fungi characterized by production of uniflagellate zoospores (asexually produced motile spores). Chytrids are basal in the fungal lineage and are thought to have diverged about 1 billion years ago from an ancestor shared with protistian groups such as the Choanoflagellates and Mesomycetozoa. *See* CHOANOFLAGELLIDA; FUNGI.

Phylogeny. Chytridiomycota includes five orders: Blastocladiales, Chytridiales, Monoblepharidales, Spizellomycetales, and Neocallimastigales. Ultrastructural studies reveal distinct zoospore architecture in each order. Molecular analyses indicate that phylum Chytridiomycota is not monophyletic; rather order Blastocladiales is most basal, evolving among members of the Zygomycota and diverging from the core chytrids. Based on thallus structure, 90 genera and over 1500 species of chytrids have been named. Recent molecular and ultrastructural phylogenetic studies, however, have demonstrated unexpected genetic diversity among chytrid fungi, indicating that the actual species richness of this group is untapped. *See* ZYGOMYCOTA.

Morphology and reproduction. Chytrids exist in a variety of morphological forms, enabling them to adapt to life in diverse habitats. All thallus forms ultimately produce zoospore-generating structures called sporangia (**Fig. 1**). Members of the Blastocladiales and Monoblepharidales commonly form filaments, similar to hyphae of higher fungi. Simpler thallus forms consist of sporangia and rootlike rhizoids, and can vary in structure from a holocarpic thallus, in which the entire thallus has developed into a sporangium, to repeating sporangial units in polycentric rhizomycelia. Sexual recombination is achieved with fusion of motile gametes, fusion of contributing thalli, or fusion of motile gametes with nonmotile gametes. Zoospores function in asexual reproduction, in which stored lipids are used as an energy source through the coordinated interactions of organelles in the microbody–lipid complex. Positioned near the flagellum, the microbody–lipid complex can be viewed as the "battery" of the zoospore (**Fig. 2**). The microbody of the complex contains enzymes that help convert stored lipids to energy with the aid of mitochondria, and the membrane cisterna sequesters calcium, suggesting a role in signal transduction and the regulation of flagellar beating.

Fig. 1. Light micrographs of zoospore discharge. The spherical sporangium (diameter 30 μm) of a chytrid thallus growing on sweet gum pollen (the pollen grain is the sphere at the left) progressively releases a globular mass of zoospores into a vesicle. Zoospores swarm within the vesicle for about 5 min before swimming away as uniflagellate zoospores. (*Micrographs by Peter Letcher*)

Fig. 2. Electron micrograph of a longituditudal section through a chytrid zoospore (length 6 μm) with two visible lipid globules (homogenous gray circles at bottom left and upper right of the zoospore). The single flagellum is at the posterior end of the zoospore. The nucleus is surrounded by a dense, granular mass of ribosomes. Mitochondria cluster near microbodies that encircle the anteriorly located lipid globule. A fenestrated cisterna surrounds the posteriorly located lipid globule.

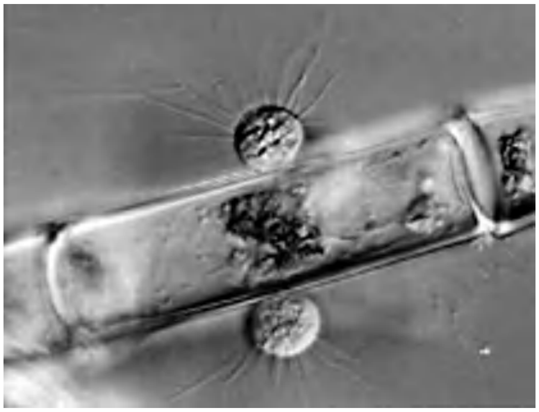

Fig. 3. Light micrograph of two chytrid thalli infecting the filament of a green alga. Hairlike appendages extend from the sporangia (diameter 30 μm) of the chytrid thalli. The contents of the host cell are collapsed.

Ecology. Chytrids are important saprotrophs, feeding on dead and decaying organisms in both aquatic and terrestrial habitats, and have been collected from the Arctic to the tropics. They are biodegraders and nutrient recyclers of resilient materials such as chitin, keratin, cellulose, and pollen. *Rhizophlyctis rosea* is a chytrid resistant to desiccation and a ubiquitous cellulose degrader found in soils. The Neocallimastigales, a group of obligately anaerobic chytrids that live in the digestive tracts of ruminant animals such as cows and sheep, are especially important in improving feed value of cellulosic and hemicellulosic foods. *See* FUNGAL ECOLOGY.

Parasitic activity. Chytrids are also common parasites of algae (**Fig. 3**), other fungi, insects, plants, and animals. Algal parasites are implicated in the natural control of algal blooms. *Coelomomyces* decreases mosquito populations by parasitizing mosquito larvae and inducing adult female mosquitoes to oviposit its sporangia rather than mosquito eggs. *Synchytrium endobioticum* causes black wart of potatoes and makes potato production difficult in infested soils due to the longevity of chytrid resting spores which remain dormant for long periods before germination, withstanding adverse conditions. *Caulochytrium protostelioides* parasitizes hyphal fungi on plant leaves. *Batrachochytrium dendrobatidis*, discovered in the mid-1990s and considered a primary culprit in the global deaths and mass extinctions of frogs and other amphibians, is the first documented chytrid parasite of vertebrate animals. *See* PARASITOLOGY. Martha J. Powell

Ciconiiformes

An order of predominantly long-legged, long-necked wading birds including herons, ibises, spoonbills, storks, and their allies, and also the hawklike New World vultures which were previously placed in the Falconiformes. The flamingos have traditionally been placed in this order; however, they show a number of unique features and differences and so are placed in a separate order, Phoenicopteriformes. Some workers have suggested that the ibises are members of the Charadriiformes and that the herons should be placed in a separate order; however, these suggestions are controversial. *See* CHARADRIIFORMES; FALCONIFORMES; PHOENICOPTERIFORMES.

Classification. The order Ciconiiformes is divided into four suborders and seven families: Ardeae, with the family Ardeidae (herons; 62 species; worldwide); Balaenicipites, with the family Balaenicipitidae (shoe-billed stork; one species; Africa); Ciconiae, with the families Scopidae (hammerhead; one species; Africa); Threskiornithidae (ibises and spoonbills; 33 species; worldwide); Ciconiidae (storks; 17 species; worldwide); and Cathartae, containing the families Teratornithidae (Miocene to Pleistocene of South and North America) and Cathartidae (New World vultures; seven species; New World).

Several of these families are divided into subgroups, the most distinct of which are the ibises (Threskiornithinae) and spoonbills (Plataleinae). The affinities of the New World vultures to the ciconiiforms, and especially to the storks (Ciconiidae), have been demonstrated rather convincingly. For many decades, numerous ornithologists have queried the inclusion of these birds in the Falconiformes, but their true affinities had been obscure.

Great blue heron (*Ardea herodias*), Galápagos Islands, Ecuador. (*Photo by H. Vannoy Davis; © 2001 California Academy of Sciences*)

Fossil record. Except for the Cathartae, the fossil record of the Ciconiiformes is scattered, considering that these are large wading birds, and does not illustrate anything special about the relationships and distribution of these birds. The New World vultures have an extensive fossil record, including in the Old World; the Teratornithidae are found in both North and South America and include the longest winged birds.

Characteristics. The herons (Ardeidae, see **illustration**), shoe-billed stork (Balaenicipitidae), hammerhead (Scopidae), ibises and spoonbills (Threskiornithidae), and storks (Ciconiidae) are mainly wading birds with strong legs, living in marshes and other wet areas. They feed on crustaceans, fish, amphibians, and other animals, which are caught in various ways depending on the structure of the bill. Most are diurnal, but a few are nocturnal. Some of the storks are scavengers. Most species are colonial and nest in mixed, often huge, colonies in trees or on the ground, as well as a few on cliff ledges; the hammerhead builds a huge, domed nest. All are strong fliers, usually having to cover a long distance between the nesting site and feeding areas; some are excellent soarers.

Most species have elaborate courtship displays and form tight pair bonds; many species of herons possess specialized courtship plumes. The young remain in the nest and are cared for by both adults until they are able to fly. They are tropical to cool temperate, with those species breeding in colder areas migrating to warmer regions for the winter. Many species of herons and egrets had been intensively hunted for their courtship plumes; some were almost extinct before fashions of apparel changed and the birds received protection. The numbers of many species have been drastically reduced, and several are threatened mainly because of lack of the needed wetland habitat. The white stork of Europe, which nests readily on human structures and is a symbol of fertility, has been reduced greatly in much of its range because of accidents with wires and loss of wetlands.

Cathartae. The New World vultures appear to be typical hawks and had been placed in the Falconiformes since the beginnings of avian classification but with ever-increasing doubt. It has been shown rather convincingly that they should be placed in the Ciconiiformes and are closest to the storks. They are placed in a separate suborder to emphasize their specialization as scavengers. These vultures are large soaring birds; the Andean condor has the largest wing span of any living land bird. (However, their wings are shorter than the largest members of the fossil teratornithids.) Vultures locate their food from the air either by sight or by smell; these abilities differ in the several species, with the Turkey vulture (*Cathartes aura*) finding its food in forested areas by smell. Vultures may be solitary or hunt in loose flocks; larger concentrations may exist during the winter. They nest solitarily, with the nest placed on the ground or on a cliff ledge. The one to three young remain in the nest until they can fly. Most species are common, but the California condor (*Gymnogyps californianus*) has decreased steadily in numbers and became extinct in the wild. Survival of this species will depend on captive breeding and reintroduction of birds to the wild, which appears to have been successful following releases in California and in the Grand Canyon of Arizona.

The fossil history of the New World vultures is excellent. It suggests that the Cathartidae had their early evolution in the Old World and invaded the New World only in the Neogene. More interesting are the closely related Teratornithidae known from North and South America, which include the birds with the largest wing spans. The relatively small *Teratornis merriami* had a wing spread of up to 3.8 m (12 ft), and the larger *T. incredibilis* had an estimated wing span of up to 5.9 m (19 ft). However, *Argentavis magnificens* from the Late Miocene of Argentina had an estimated wing span of 7–7.6 m (22.5–24 ft) and a weight of about 120 kg (264 lb), making it the largest flying bird known by far. *See* AVES.

Cilia and flagella

Centriole-based, motile cell extensions. These organelles are usually indistinguishable in fine structure as seen with the electron microscope, but quantitatively there are many (several hundred) cilia and few or fewer (usually one or two) flagella, on one cell. Bacterial or prokaryotic flagella are entirely different organelles that are not considered in this article, which concerns only eukaryotic (higher-cell) flagella. *See* BACTERIA.

Characteristics and occurrence. Flagella move with undulatory motion in which successive bending waves progress along the length of the organelle (**Fig. 1**), whereas cilia move with flexural motion consisting of a planar effective stroke, with the organelle extended perpendicular to the cell body, followed by a nonplanar curving recovery stroke, with the organelle pulled parallel to the cell body. Cilia and flagella are low-Reynolds-number systems, which implies that viscous forces are more important to the motion of the organelles than inertial forces are. On a macroscopic scale, this is equivalent to swimming in molasses, and the fluid can be thought of as being clawed forward by the effective stroke of the cilium or as being pushed away by the propagating undulatory wave of the flagellum. Beat frequencies of cilia and flagella in different organisms range from about 2 to more than 50 per second. During a beat, bends usually originate and grow in restricted regions at the base of the organelle in the form of circular arcs. They then propagate toward the tip at rates of several

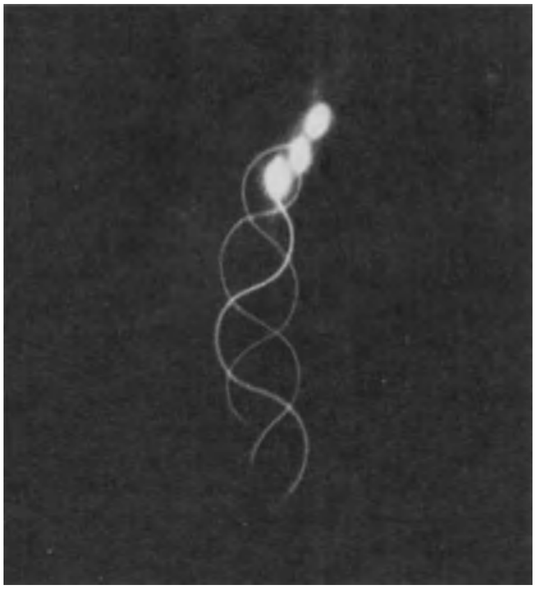

Fig. 1. Sea urchin sperm shown in three positions by dark-field microscopy. Note undulatory waveform as it swims. (*From C. J. Brokaw, Nonsinusoidal bending waves of sperm, J. Exp. Biol., 43:155–169, 1965*)

hundred micrometers per second without changing amplitude or form. On sperm tails, bends of equal magnitude but of opposite direction are separated by straight regions of uniform length to give a symmetrical waveform that is superficially sinusoidal. A similar but asymmetrical waveform on a shorter cilium produces one typical form of flexural motion. Both organelles function to move water past the cell. Their action may bring food and oxygen into an animal, or it may propel the cell to a new environment. Cilia often move sheets of mucus at velocities of about 0.008 in. (0.2 mm) per second, either in water or over surfaces exposed to humid air, as in the human respiratory tract. Particles trapped in such sheets are effectively cleared from the epithelial surface. *See* CELL MOTILITY.

Distribution. Cilia were first described by A. van Leeuwenhoek in 1676. The words cilium (eyelash) and flagellum (whip) are accurate descriptions of the appearance of these cell organelles when they are seen under the light microscope. Cilia are present on protozoa, such as *Paramecium*, and on metazoan cells of many different tissue types. For example, in humans, many cells lining the respiratory and reproductive tracts, the ear and the olfactory epithelium, as well as ependymal cells in the brain, have functioning cilia. A flagellum is present on human sperm; in fact, the sperm of most animals, and the male gametes of many lower plants are flagellated. Even the *Ginkgo* spermatozoon is ciliated. Derivatives that are similar to cilia but nonmotile are found on many sensory structures in a variety of animals and include insect pressure receptors and vertebrate photoreceptors. In addition, many ordinary types of cells of vertebrates, for example, from the thyroid, the kidney, or the pituitary gland, also possess modified nonmotile derivatives that resemble cilia, and other cell lines can be induced to grow them in tissue culture. *See* CILIOPHORA; EPITHELIUM; SPERM CELL; TISSUE CULTURE.

Size. Relative to cell size, both cilia and flagella are very long organelles. Flagella may be more than 50 micrometers long and, in sperm, may be four or more times the cell length. Certain compound cilia, such as the comb plates of ctenophores, are truly macroscopic structures, visible to the naked eye. In these structures, many thousands of individual cilia are joined together laterally, and the length of each cilium runs to a few millimeters. Usually, however, cilia range from 5 to 15 μm in length.

Metachronism. Fields of cilia or flagella such as those in invertebrate flame cells can beat synchronously. Often, however, even on a single cell, cilia beat so that coordinated waves of bending appear to cross the field. Originally, these waves were described as the sort that are seen rippling across a wheat field when the wind is blowing. The phenomenon of beating slightly out of phase is known as metachronism. Several types of metachronism are recognized, since the plane of ciliary beat may be either perpendicular (diaplectic) or parallel (orthoplectic) to the direction of the metachronal wave. Metachronal coordination is usually effected by purely mechanical means; that is, viscoelastic coupling establishes a phase difference between individual cilia so that there is minimal mechanical interference between one beating cilium and its neighbors. In a ciliated epithelium the cells can be functionally linked together so that metachronal waves pass smoothly from cell to cell.

Behavior. Under normal conditions, most cilia and flagella beat continuously, although some cilia (for example, mammalian respiratory cilia and mammalian sperm) require special activation for beating. Many organisms are able to alter properties of ciliary beat, including form, frequency, the direction of the effective stroke, or the direction of bend propagation; sometimes, the ciliary stroke can be arrested. Cells usually alter beat properties by common mechanisms leading to increases in second messengers, including internal calcium ion (Ca^{2+}) or cyclic nucleotide concentrations. For example, in *Paramecium*, depolarization of the cell membrane opens voltage-sensitive calcium channels in the ciliary membrane, which leads to an increase in calcium ion concentration in the cilium above $10^{-7}\,M$. This in turn leads to slowed and then to backward swimming at concentrations above $10^{-6}\,M$. When calcium ion is pumped out of the cilium, the normal beat resumes. Different second messengers may have different effects. Cyclic adenosine monophosphate (cAMP) increases normal beat frequency in *Paramecium* cilia, leading to faster forward swimming. Such processes allow the cell to respond to various stimuli and form the basis of behavioral responses of free-swimming ciliated cells. The same messenger may have different modes of action in different cilia; for example, calcium ion activates and increases beat frequency in mammalian respiratory cilia.

Ultrastructure. The electron microscope reveals that the cilium or flagellum is really an internal organelle since it is bounded by the cell membrane and enclosed at the tip. The main internal structure of the cilium is the axoneme. Under the electron microscope a single axoneme contains a fixed pattern of microtubules. The microtubules are not simple single units; rather, nine doublet microtubules are found on the periphery of the axoneme surrounding two central elements. This is the so-called 9 + 2 pattern (**Fig. 2**).

Microtubule arrangement. Each peripheral doublet is composed of one complete and one partial microtubule. The microtubules are themselves composed of subunits arranged into microfibers or protofilaments. The complete microtubule, labeled subfiber A, consists of a ring of 13 protofilaments. The incomplete microtubule, subfiber B, is a C-shaped structure of 10 or 11 protofilaments. In a transverse section the doublets appear as figure eights, with two short arms and several linkages extending from one end. The doublets form a ring around the central pair. The diameter of this ring is very constant, about 0.2 μm, even in different types of cilia or in cilia of different species.

Microtubule pattern variation. The 9 + 2 pattern is present in all known motile cilia. Motile flagella, especially sperm tails, sometimes possess altered

Fig. 2. Electron micrograph of mussel gill cilia cross sections showing 9 + 2 pattern of axoneme. At the left are cross sections through tips at various levels. (*From P. Satir, Studies on cilia, II: Examination of the distal region of the ciliary shaft and the role of the filaments in motility, J. Cell Biol., 26:805–834, 1965*)

patterns, although these are usually simple variations upon the basic array. Flatworm sperm, for example, show a 9 + 1 pattern (one central element instead of two), although somatic cilia of the same animal are 9 + 2. Insect sperm show even greater divergences. Mammalian sperm have the 9 + 2 pattern, but in addition have a set of thick fibers alongside the axoneme. The most simply organized motile flagella in eukaryotes are the 6 + 0 and 3 + 0 forms present in male gametes of certain gregarine protozoa. In these flagella, the doublet tubules appear to possess normal arms, but the spokes and central pair are lacking. Nonmotile flagellar derivatives usually have 9 + 0 patterns and lack both the arms and the central pair. All these patterns are constant within any one species of animal or plant, with the exception of certain very rare variants that are probably mistakes in assembly.

Symmetry. If the arms are disregarded, there is a plane of bilateral symmetry in the normal cilium which passes between two peripheral doublets, through the central pair, and through one doublet on the side opposite. This doublet is numbered 1, and the plane of bilateral symmetry is also the plane of the effective stroke. By looking from the cell surface and outward along the axoneme, looking clockwise from subfiber B of doublet number 1, the sequence is subfiber B, subfiber A, arms of doublet number 1, subfiber B, subfiber A, arms of doublet number 2, and so on. The arms always extend from subfiber A of any doublet N toward subfiber B of the adjacent doublet. In this manner the doublets can be numbered unequivocally. The two peripheral doublets between which the plane of bilateral symmetry passes are the numbers 5 and 6, and these may be specially distinguished in some cases by being connected by a distinctive bridge.

Axonemal linkages. The axonemal microtubules are interconnected into a functional whole by groups of projections extending in different directions from each subfiber A (**Fig. 3**). These include the two circumferentially oriented rows of dynein arms. The outer arms repeat at spacings of about 24 nanometers. The outer arms are uniform, but the inner arms are sometimes of two or three types with a more complicated spacing. There are also several types of circumferentially oriented links, some of which form elastic connections, some inelastic connections, between doublets. The periodicity of these links is about 96 nm. Radially oriented spoke groups project toward the central sheath with a major period of 96 nm; the spoke groups often comprise three individual spokes, each of which ends in an expanded spoke head. The spokes are spaced at intervals of 32, 24, and 40 nm, with the first spoke of each group in alignment with a set of dynein arms. There are six central sheath projections per spoke group. Such vernier alignments may prove to be important in the regulation of beat form.

Morphogenesis. At the base of the cilium or flagellum there is a basal body, or kinetosome, that is similar to, and sometimes derived from, a centriole. The basal body may have extensions of various sorts attached to it, notably a basal foot that indicates effective stroke direction and prominent striated rootlet fibers in many cilia. Ordinarily, the ciliary axoneme originates and grows in a membrane protrusion which forms just above the basal body, either at the cell surface or deeper inside the cytoplasm. The basal body remains attached to the cell membrane throughout morphogenesis by a structure that extends from the microtubules to the membrane, where it is seen as a ciliary necklace. The necklace forms a barrier that segregates the ciliary membrane from the general cell membrane. As morphogenesis proceeds, from a pool of subunits, axonemal

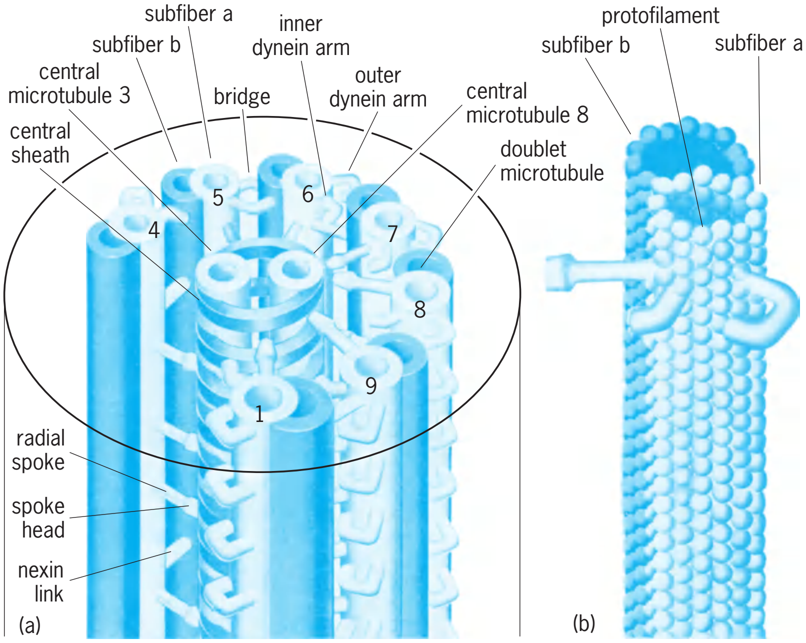

Fig. 3. Ultrastructure of a cilium. (*a*) Three-dimensional reconstruction with doublets 2 and 3 removed to show spoke periodicities more clearly. (*b*) Three-dimensional wall structure of a doublet showing tubulin subunits. (*After P. Satir, How cilia move, Sci. Amer., 231(4):44–52, 1974*)

microtubules polymerize above the basal body. Continuity of the microtubules between axoneme and basal body may be traced through a complex transition zone. Evidently, polymerization of the axonemal microtubules takes place at the growing tip of the cilium. Certain cells such as the ameboflagellate *Naegleria* can grow or resorb the cilia in response to internal programming during the cell cycle, or upon physiological stimulation. *See* CENTRIOLE.

Genetic control. Morphogenesis is under genetic controls, in part by nuclear genes. For example, certain nuclear mutants in *Chlamydomonas* fail to polymerize the central microtubules. Other mutants lack radial spokes or either the outer or the inner row of dynein arms. In these cases, the mutant flagella are partially or completely paralyzed, or the beat form or frequency is altered. Paralyzed and behavioral mutants have also been found in other species, ranging from *Paramecium* to humans. Approximately 1 in 40,000 people suffer from an inherited genetic defect originally known as Kartagener's syndrome, in which the cilia of the bronchial tract and the sperm flagella (in males) are paralyzed, in some instances because dynein arms are completely lacking on the doublet microtubules. People with this syndrome have considerable respiratory difficulty, and males are infertile. These people also have a 50% chance of their heart and other internal organs being on the opposite side of the body compared with normal anatomy, possibly as a result of ciliary immotility during embryonic development.

Growth parameters. The extent of each axonemal component is strictly determined. In mussel gill lateral cilia, all subfiber B's of the peripheral doublets end at the same level. Simultaneously the arms and the spokes also terminate. However, both the central pair and the subfiber A's of the doublets continue, the central pair to the exact end of the ciliary tip, where the elements are topped by a distinctive finial, the central pair cap. Every continuation of subfiber A is unique in length so that subfiber A's of doublets 3 and 8 are overall about 1 μm, or 10%, longer than subfiber A's of doublets 1, 4, and 5. A general reduction in axonemal diameter accompanies microtubule termination and gives the cilium a distinctive conical tip. These growth parameters and the shape of the tip are different for different kinds of cilia and flagella. In certain mammalian cilia the tip is blunt, and the membrane is decorated externally by a cell coat, the ciliary crown.

Chemical composition. Cilia may be isolated en masse from ciliated protozoa, such as *Tetrahymena*, and flagella may be isolated as sperm tails. Such preparations are suitable for chemical analysis, and reasonably pure preparations of axonemes and of membranes can be obtained in quantities adequate for study. The major protein component (70–80%) of the axoneme is tubulin, the structural protein of the microtubules. The second largest component (10–15%) is dynein, the axonemal adenosine triphosphatase protein (ATPase). The remaining 10–15% of the axonemal protein is distributed among approximately 250 distinct polypeptides that can be visualized by two-dimensional electrophoresis. Some of these polypeptides can be assigned to specific axonemal structures, but most have not yet been otherwise characterized. The molecular unit of tubulin is a heterodimer of α and β subunits, each a globular protein about 4 nm long and 5 nm wide. One $\alpha\beta$ tubulin heterodimer (molecular weight 100,000) contains one molecule of bound guanosine triphosphate and one more loosely bound guanosine diphosphate. Axonemal and cytoplasmic microtubules are similar in most properties, but they differ in their stability to depolymerization. In *Chlamydomonas*, axonemal tubulin is acetylated locally after synthesis, while tubulin in most other parts of the cell is not. Another difference is that the midwall of the doublet microtubules is not tubulin, but proteins related to intermediate filament proteins, termed tektins. This may account for the differential stability or other unique properties of the axonemal microtubules.

The axonemal adenosine triphosphatase (ATPase), dynein, consists of a group of related globular proteins of slightly different solubilities with high molecular weights in the range of 1–2 × 10^6. Isolated dynein (**Fig. 4**) resembles a bouquet of two or three globular masses attached to a common base by slender stalks. Analysis after brief protease digestion of the molecule shows that each head contains at least one distinctive heavy polypeptide chain (molecular weight 4–5 × 10^5) that has ATPase activity, and

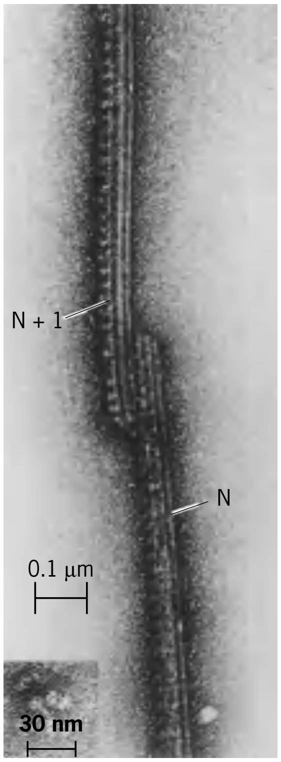

Fig. 4. Sliding of doublet microtubules from an axoneme after destruction of the control system. The dynein arms of the lower doublet (N) have interacted with subfiber B of the upper doublet (N + 1), displacing it toward the ciliary tip. Inset shows an isolated dynein molecule. (*After P. Satir, Structural analysis of the dynein cross bridge cycle, in F. D. Warner et al., eds., Cell Movement, vol. 1, Alan Liss, 1989*; *inset courtesy of K. Barkalow*)

each chain can be cleaved into two distinctive fragments by ultraviolet light in the presence of vanadate ions. In addition, purified dynein contains two or three intermediate-size chains (approximately 1×10^5) and several types of light chains (approximately $1–3 \times 10^4$). Outer and inner arm dyneins of the same axoneme may be different biochemically and structurally. Inner arm dyneins may be closely associated with other axonemal proteins, including small amounts of actin and centrin, in a so-called regulatory complex. The dynein genes of sea urchin and several other organisms have been cloned, and amino acid sequences of the heavy chains have been derived from the deoxyribonucleic acid (DNA) sequences. Each axonemal heavy chain is probably the product of a different gene. The sequences of the ATPase sites of the various dyneins seem highly conserved. Transcription of the axonemal dyneins, of tubulins and, other ciliary proteins, is increased after experimental deciliation of cells.

The membranes of flagella and cilia appear similar in structure, but they differ in composition, from the adjacent cell membranes. Like other membranes, the ciliary membrane is a phospholipid bilayer into which proteins are inserted. Some major membrane components of the cilia and flagella are glycoproteins, including immobilization antigens and other molecules involved in mating or cell recognition. Some ciliary membranes contain specific ion channels, including the voltage-sensitive calcium ion channel responsible for backward swimming in *Paramecium*.

Axonemes sometimes contain target proteins for the second messengers that control their behavior, including calmodulin which binds calcium and loosely or tightly bound protein kinases that may phosphorylate other axonemal proteins in the presence of cyclic nucleotides. A small polypeptide that copurifies with the outer arm dynein is phosphorylated in a cAMP-dependent manner and might act as a regulatory light chain of this dynein.

Mechanism of movement. Cilia and flagella are active structures, and the energy for their motion is provided by the dephosphorylation of adenosine triphosphate (ATP) at the dynein arms distributed along most of the length of the organelle. The membranes of cilia and flagella can be removed selectively by treatment with a nonionic detergent, such as Triton X-100. The motile mechanism in the resulting demembranated cilia and flagella is undamaged, so that when placed in an appropriate saline medium containing added ATP, the organelles regain motility and their pattern of beating closely resembles that of the same organelles in the living organism. An abrupt decrease in ATP concentration causes beating axonemes to set into a rigor state in which the stationary axonemes maintain the bent waveforms that they had at the moment the ATP concentration was lowered. The preservation of these rigor bends results from the dynein arms forming fixed cross-bridges between adjacent doublets in the absence of ATP. Movements between doublets can be regenerated by local addition of ATP; they are the result of a cyclic process in which the binding and hydrolysis of a molecule of ATP at a dynein arm from subfiber A of one doublet (N) causes it to release its cross-bridge attachment to the B subfiber of the adjacent doublet (N+1), change its angle, reattach to a new site closer to the basal end of the B subfiber, and then pull. This paradigm is known as the sliding microtubule model of ciliary motility. Both inner and outer dynein arms operate to produce sliding with the same polarity. Microtubule sliding can be seen in a beating axoneme by attaching gold beads to different parts of the structure and observing their periodic motion in the light microscope.

The outer dynein arms can be quantitatively extracted from certain axonemes. This causes the beat frequency to fall. The beat frequency also decreases in mutants of *Chlamydomonas* where the outer dynein arms or specific portions of them are missing. When corresponding mutants lack a specific type of inner arm, the beat frequency is largely unchanged but the bending pattern of the beat is altered. The suggestion is that sliding produced by the outer dynein arms is a primary determinant of beat frequency, while the inner arms primarily regulate beat form.

Active sliding of the doublet tubules can be demonstrated directly by brief treatment of demembranated axonemes with the protease trypsin. Trypsin rapidly destroys most of the spokes and circumferential links while leaving the arms and doublet tubules relatively intact. When ATP is then added, the treated axonemes no longer generate bending waves, but elongate and grow thinner as the doublets slide apart (Fig. 4). Isolated dynein arms will rebind to axonemal or other microtubules and slide them across glass surfaces in the presence of ATP. Dynein and tubulin are the only proteins necessary to produce sliding. This sliding microtubule mechanism is applicable to other microtubule-based forms of cell motility.

Since all dynein arms operate in the same way, the normal development and propagation of bends in the axoneme requires the presence of a suitable control system to generate appropriately phased localized sliding movements between the axonemal doublets. Trypsin damages this control system that normally limits sliding, leading to an uncoupling of sliding from bending.

The control system permits sliding to be asynchronous; one possibility is that sliding switches back and forth between the two bilaterally symmetrical halves of the axoneme and the other, during each stroke cycle. Inhibitors that act on the switches cause beating to cease abruptly at one particular stroke position. Such arrested cilia can be moved from one position to another by replacing one inhibitor with another, and microtubules from about half of each axoneme prepared from the arrested cilia will slide normally after trypsin treatment. This indicates that arrest is an active state in which the dynein arms producing bending to one side remain potentiated, while those producing bending to the reverse side are inhibited.

The main elements thought to convert the fundamental ATP-powered sliding interaction into local bending are the spokes. The spoke heads appear to be attached to the central sheath at points where bends develop, so as to provide the needed resistance to sliding, while the central tubules and sheath act as a fulcrum around which bending occurs. The presence of spokes affects the behavior of the inner dynein arms. Flagellar mutants of motile *Chlamydomonas* that possess axonemes lacking spokes appear capable of tubule sliding but not of bending. The 3 + 0 flagella in sperm of certain gregarines mentioned above lack both spokes and central tubules, yet generate helical bending waves of low frequency, which indicates that spokes and central tubules are not absolutely required for bending. However, their interactions may play a critical role in generating the asymmetric bending waves characteristic of normal ciliary motion and in the control of heat parameters. *See* ADENOSINE TRIPHOSPHATE (ATP). Peter Satir

Ciliatea

The single class of the subphylum Ciliophora. This group has the characteristics of those defined for the subphylum. This protozoan class is divided into the subclasses Holotrichia, Peritrichia, Suctoria, and Spirotrichia. *See* CILIOPHORA; HOLOTRICHIA; PERITRICHIA; SPIROTRICHIA; SUCTORIA. John O. Corliss

Ciliophora

A subphylum of the Protozoa. The ciliates are a fairly homogeneous group of highly differentiated, unicellular organisms. Over 5000 species have been described, and many more surely exist but remain to be discovered. Typically, ciliates are larger than most other protozoa, ranging from 10 to 3000 micrometers or about 0.004 to 0.12 in. Some larger species are easily visible to the naked eye. The majority of them are free-living forms, found abundantly in a variety of fresh- and salt-water habitats, although a few entire groups live in association with other organisms, generally as harmless ecto- or endocommensals. Their principal value to humans is as experimental animals in a host of investigations concerned with fundamental problems of biology.

Systematics. Classification of ciliates followed here is that published in the "Honigberg Report," which appeared in 1964. That classification scheme, of the entire phylum Protozoa, was determined by an international committee of distinguished protozoologists. It is a reasonable and useful classification. Separate articles appear on each group included in the classification listed below. Subordinal divisions of some orders are commonly recognized by protozoologists, but such taxa are not considered here.

- Subphylum Ciliophora
  - Class Ciliatea
    - Subclass Holotrichia
      - Order: Gymnostomatida
        - Trichostomatida
        - Chonotrichida
        - Apostomatida
        - Astomatida
        - Hymenostomatida
        - Thigmotrichida
    - Subclass Peritrichia
      - Order Peritrichida
    - Subclass Suctoria
      - Order Suctorida
    - Subclass Spirotrichia
      - Order: Heterotrichida
        - Oligotrichida
        - Tintinnida
        - Entodiniomorphida
        - Odontostomatida
        - Hypotrichida

Protociliata or opalinids (**Fig. 1**) are entirely excluded. They are considered members of the subphylum Sarcomastigophora, because they possess only one type of nucleus, a symmetrogenic rather than a homothetogenic type of binary fission, and true syngamy, or sexual reproduction with anisogamous gametes, rather than conjugation. There are four genera of opalinids which are large, mouthless, multiflagellated forms found almost exclusively as saprozoic commensals in the posterior end of the alimentary tract of frogs and toads. *See* SARCOMASTIGOPHORA.

Major subdivisions of the ciliates are reduced to the four subclasses named above. Within the Holotrichia are included the Chonotrichida, a group formerly accorded a high-level, independent taxonomic status. *See* HOLOTRICHIA.

Characteristics. The usual ciliate life cycle is fairly simple. An individual feeds and undergoes binary

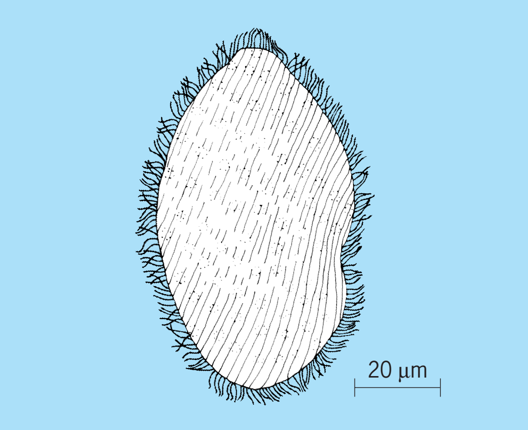

Fig. 1. *Opaline ranarum*, an opalinid; not considered a ciliate by many protozoologists.

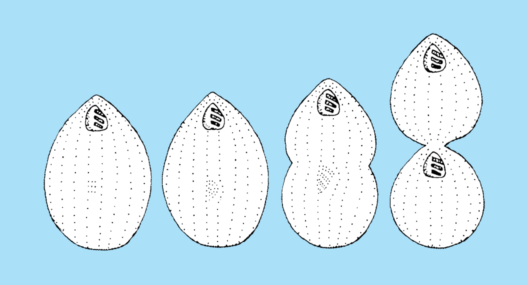

Fig. 2. Binary fission and stomatogenesis in ciliate *Tetrahymena*. Argentophilic basal bodies form part of silverline system and infraciliature.

fission, and the resulting filial products repeat the process. Some commensal or parasitic forms have a more complicated life history, but it is never as involved as the malarial species of the subphylum Sporozoa. Some ciliates, including free-living species, have a cystic stage in their cycle. As in other kinds of Protozoa this stage often serves as a protective phase during adverse environmental conditions, such as desiccation or lack of food. It also may be important in distribution, and thus possibly in preservation, of the species. *See* EUCOCCIDA.

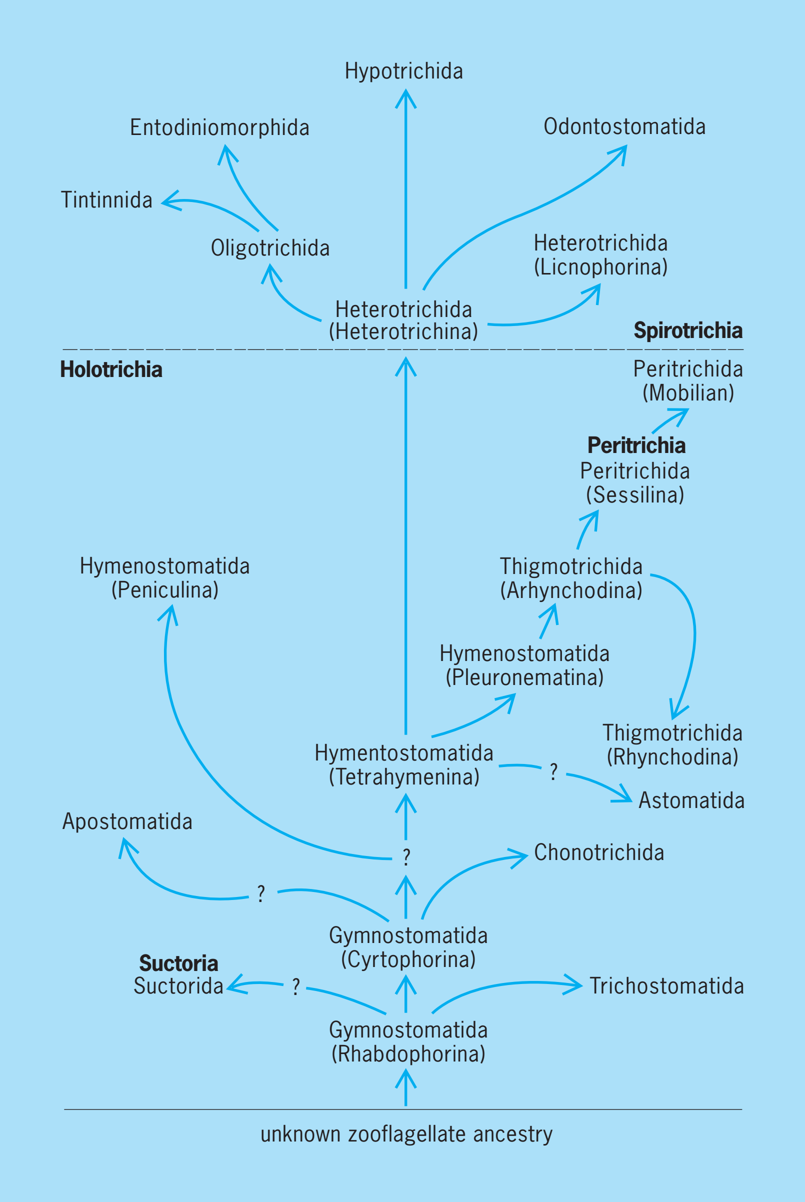

Fig. 3. Phylogenetic tree showing orders of the Ciliophora (names in boldface are of subclasses, and in parentheses of suborders).

Six major characteristics aid in distinguishing the Ciliophora from other protozoan groups. Not all of these are entirely unique, but when taken together they are definitely distinctive of ciliates.

Mouth. Most Ciliophora possess a true mouth or cytostome often associated with a buccal cavity containing compound ciliary organelles. However, some ciliates are completely astomatous, that is, mouthless. Nutrition is heterotrophic in ciliates. Some species are solely or primarily herbivorous since they eat bacteria or algae; some are carnivorous, eating other Protozoa or occasionally small aquatic invertebrate Metazoa; some are omnivorous; and still others live a saprozoic, or saprobic, existence, obtaining all their nutritive needs from materials dissolved in the medium. The process of stomatogenesis, or new mouth formation, which must take place before the completion of binary fission, is a morphogenetic phenomenon of great interest to students of Protozoa. Various modes of stomatogenesis exist in different ciliate groups. Their study helps in postulation of phylogenetic and evolutionary interrelationships within this subphylum of highly differentiated unicellular animals, as well as in throwing light on the important and not yet solved biological process of cell division and its control.

Ciliation. The Ciliophora possess simple cilia or compound ciliary organelles, often in abundance, in at least one stage of their life cycle. Morphologically, cilia are relatively short and slender hairlike structures, whose ultrastructure is known, from electron microscope studies, to be composed of nine peripheral and two central fibrils. Compound ciliary organelles include the undulating membrane, which is essentially a single sheet of fused cilia; the membranelle, a more or less fused block of cilia, typically two to four rows wide and of greater length; and the cirrus, a tuft of closely opposed cilia which is approximately circular in cross section near its base or proximal end but tapered or even fimbriate at its distal end. Functionally, cilia and cirri serve principally as locomotor organelles. Membranes and membranelles are characteristically associated with the mouth or buccal areas and serve to bring food into the oral opening, although they sometimes aid in locomotion as well. Membranelles are typically arranged as an adoral zone. *See* CILIA AND FLAGELLA.

Infraciliature. The presence, without exception, of some sort of infraciliature located at a subpellicular level in the cortex is another characteristic of Ciliophora. The infraciliature consists essentially of basal bodies, or kinetosomes, associated with cilia and ciliary organelles at their bases, plus certain more or less interconnecting fibrils. The basal bodies are argentophilic, that is, they readily stain with silver stains, and are the most important components of the so-called silverline system present in all ciliates (**Fig. 2**). Various argentophilic fibrils, the contractile vacuole pores, and the cell anus (cytoproct or cytopyge) are included in this system. The controversial neuromotor apparatus of ciliates, best known in hypotrichs, is not well understood. Anatomically, it appears to embrace certain parts of the silverline system, although parts of it are definitely not argentophilic. Much remains to be learned of its function.

Nuclear apparatus. Ciliophora possess two kinds of nuclei, and at least one of each is usually present. The smaller, or micronucleus, contains recognizable chromosomes and behaves much as the single nucleus in cells of metazoan organisms. Its mitotic divisions, however, appear to be acentric (without centrioles). The larger, or macronucleus, does not show mitosis but is considered indispensable in controlling metabolic functions, and is recognized as having genic control over all phenotypic characteristics of ciliates. Micronuclei are typically spherical or ovoid and show little variety in shape. Macronuclei vary in different species from compact bodies to C- or E-shaped forms, or from nodulated chains, which look like a string of tiny linked sausages, to bizarre dendritic configurations. Both nuclei divide in fission, but in sexual phenomena new macronuclei arise from what may be considered micronuclear origin. *See* GENETICS.

Fission. Ciliophora exhibit a type of binary fission commonly known as transverse division. In ciliates the splitting results in two filial organisms, the anterior or proter and the posterior or opisthe which, geometrically speaking, show homothety with respect to identical structures possessed by each (Fig. 2). Thus, homothetogenic is both a broader and more exact descriptive term. Indeed, in a number of groups the fission is more nearly longitudinal than transverse. Some ciliates show a budding type of asexual reproduction; some regularly reproduce within a cystic membrane.

Reproduction. Ciliophora lack true sexual reproduction. Ciliates do not show syngamy, with fusion of free gametes. Processes such as conjugation are considered to be sexual phenomena, since meiosis and chromosome recombination are involved, but not sexual reproduction. In addition to conjugation, certain ciliates exhibit forms of sexual phenomena known as autogamy and cytogamy. *See* REPRODUCTION (ANIMAL).

Evolution of ciliates. Ciliated protozoa, by virtue of their universal possession of an infraciliature and relatable patterns of somatic and buccal ciliature, appear to be the most taxonomically compact group in the phylum Protozoa. They also seem to lend themselves most readily to interpretation of their own phylogenetic interrelationships, that is, their own evolutionary history from the conjectured time of the first recognizable ciliate on the phylogenetic tree of the animal kingdom. Handicaps to study include lack of a usable fossil record, the usually microscopic size, and the very unicellularity which places all complexities of organization of necessity at a subcellular level. However, the student of the ciliated protozoa may still recognize, with a certain amount of reasonable, if indirect, supporting evidence, certain evolutionary lines or trends among the several orders. Most fruitful lines of such investigation have involved comparative study of life cycles, infraciliature, mouthparts, and the morphogenetic phenomenon of stomatogenesis. A possible genealogical tree of Ciliophora is given in **Fig. 3**. The change in somatic and buccal ciliature in the evolution of ciliates is emphasized in three present-day forms which, allegedly, are representative of the most primitive, intermediate, and most highly evolved orders (**Fig. 4**). *See* PROTOZOA.

Cinchona

A genus of trees belonging to the madder family (Rubiaceae), occurring indigenously in the cool, cloud forests of the Andes from Colombia to Peru. Many species have been described, most of which may be variants of *Cinchona pubescens* or *C. officinalis*. The bark contains several alkaloids, the most important of which is quinine. This bitter substance is the most specific drug used in the treatment of malaria. The great demand for quinine and the wasteful methods used in collecting the materials threatened extinction of the plants; therefore cultivation was begun. Now there are extensive cinchona plantations in India, Java, Sri Lanka, Australia, and Jamaica. *See* QUININE; RUBIALES.

Cinematography

The process of producing the illusion of a moving picture. Cinematography includes two phases: taking the picture with a camera and showing the picture with a projector. The camera captures the action by taking a series of still pictures at regular intervals; the projector flashes these pictures on a screen at the same frequency, thus producing an image on the screen that appears to move. This illusion is possible because of the persistence of vision of the human eye. The still pictures appear on the screen many times a second, and although the screen is dark equally as long as it is lighted by the projected image, they do not seem to be a series of pictures but appear to the viewer to be one continuous picture.

Traditional Cinematography

This section discusses motion picture cameras, motion picture projectors, and wide-screen processes. For related information *see* CAMERA; MAGNETIC RECORDING; OPTICAL PROJECTION SYSTEMS; OPTICAL RECORDING; PHOTOGRAPHIC MATERIALS; PHOTOGRAPHY; STEREOPHONIC SOUND.

Cameras. Still photographs are taken by motion picture cameras (movie cameras) at the rate of 24 per second, even faster at times. The photographs are sharp and clear, and if they were superimposed on one another would be found to be extremely uniform with respect to position. This last feature is essential in order to have the image appear steady on the screen. A motion picture camera consists of five basic parts: lens, shutter, gate, film chamber, and pull-down mechanism.

Lens. The lens on a motion picture camera collects the light from the scene being photographed and focuses it on the photographic emulsion in the camera aperture. Lenses vary in focal length. The focal lengths most often used on 35mm cameras are between 30 and 50 mm. Other lenses in common use vary from wide-angle (14.5–25 mm), through long-focal-length (60–250 mm), to telephoto (300–1000 mm). Lenses of shorter focal length have a wider angle of view; those of longer focal length give a larger image size on the film. Lenses for the 16mm camera which give the same angle of view and the same relative image size are approximately one-half the focal length of those used on a 35mm camera. Variable-focal-length lenses (zoom lenses) are useful to cinematographers and directors and are used extensively not only for filming sporting events but also in making feature films, documentaries, and television films. *See* FOCAL LENGTH; TELEPHOTO LENS; ZOOM LENS.

To protect the lens from extraneous light and prevent lens flare, a lens shade must be used. On a motion picture camera this shade is called a matte box. It completely surrounds the lens and acts as a lens shade, but it also has slots to hold various types of filters (such as diffusion, fog, color correcting, and polarizing), and optically flat glass for use when needed. These items are used by cinematographers for the many effects required in making a professional motion picture.

Lenses for motion picture cameras have focusing mounts and can be focused on objects as close as 2 or 3 ft (0.6 to 0.9 m). They are fastened to the camera with threaded or bayonet mounts and can be changed when a lens of a different focal length is needed. Although some older cameras have turrets on the front which hold three or four lenses at one time, making it a simple matter to change from one lens to another, all modern professional cameras have solid fronts because of the size and weight of the zoom lens, and because the faster lenses now used require closer tolerances in the positional accuracy of the lens mount relative to the film plane.

The lens has an iris diaphragm which can be opened and closed to control the amount of light reaching the film, thus controlling the exposure. The *f*-number is a ratio of the focal length of the lens to the diameter of the lens opening, and a lens with a given *f*-number will always allow the same amount of light per unit area to strike the film regardless of the focal length of the lens. The *T*-system used in cinematography takes into account all of the light losses encountered in a lens, such as the number of reflecting surfaces inside the lens and the various types of coating on the surfaces. *T*-stops are determined by the amount of light transmitted through the lens, while *f*-stops are determined by a mathematical formula of the focal length of the lens divided by the diameter of the iris diaphragm opening. Since the *T*-stops system is more accurate as far as light transmission is concerned, this is usually used for exposure, while the *f*-number is used to determine the depth of field, that is, a range of subject distances between which all objects will be in sharp focus on the film. *See* LENS (OPTICS).

Shutter. The shutter in a motion picture camera rotates and exposes the film according to its angle of opening. When the shutter is open to its widest angle, the film receives its maximum exposure. Many cameras have variable shutters; that is, the angle of opening can be changed while the camera is running. Such shutter openings usually vary from 180° when the shutter is wide open to 0° when it is closed. The shutter in a motion picture camera is almost always located between the lens and the film.

Gate. The aperture called the gate is the passageway through which the film is channeled while it is being exposed. It consists of the aperture plate, which is in front of the film and masks the frame, or picture; the pressure plate, which is in back of the film and holds it firmly against the aperture plate; and the edge guides, which keep the film stable laterally.

Film chamber. This holds the unexposed film at one end and collects the exposed film at the other. Although some motion picture cameras have an interior film chamber, it is usually a separate piece of equipment called the film magazine. Magazines come in 400-ft (120-m) and 1000-ft (300-m) capacities. One thousand feet of 35mm film, exposed at the normal speed of 24 frames per second, and with a four-perforation pull-down, lasts slightly more than

11 min. The magazines are loaded with film in a darkroom or in a lightproof changing bag and are fitted on the camera as needed, making camera loading easy and rapid.

Pull-down mechanism. The part of the pull-down mechanism called the intermittent movement pulls the film down through the gate of the camera one frame at a time; in a conventional 35mm camera, each frame is four perforations high. Some wide-screen cameras have frames five or six perforations high. The pull-down claw engages the perforations and pulls the film down into place to be exposed. At the bottom of its stroke, the claw remains stationary for a moment to position the film and then disengages itself and returns to the upper portion of the stroke to pull another frame into place. During the time the claw is returning to the top of its stroke, the film is stationary and the shutter opens and exposes the film. Most modern cameras have registration pins which engage the film while the picture is being taken. This ensures that the film is perfectly still and is in exactly the same position as each frame is being exposed. This feature is especially important in special-effects photography where independently photographed images are superimposed.

Mobile cameras. When sound is being recorded, cameras must be absolutely quiet. In the early days of sound, cameras were put in enclosures called blimps. Almost all modern cameras are self-blimped, which enhances their portability. The Mitchell BNC (Blimped News Camera), introduced in 1935, was the first such camera (**Fig. 1**), and remained the worldwide industry standard for 35 years. Although this camera was portable, at approximately 125 lb (55 kg), fully loaded, it was not hand-holdable. In 1968 Arriflex introduced the first hand-held self-blimped camera, the 35 BL. The current model is the 535 (**Fig. 2***a*). In 1972 Panavision introduced the lightweight, silent Panaflex camera, the current version of which is the Millennium (Fig. 2*b*); and in 1979 the silent Moviecam camera was introduced, the current model of which is the lightweight SL (Fig. 2*c*). These later cameras range in weight from 15 to 30 lb (7 to 14 kg), including the lens and a 400-ft (120-m) load of film.

These smaller and lighter cameras have enabled production companies to achieve more mobility and to shoot many pictures on actual locations away from studios, using hotels, cafes, and even private homes in small towns as sets to give the pictures more authenticity. Most feature films, as well as those made for television, are made by independent producers who take advantage of these realistic backgrounds and at the same time save money on stage rentals.

When they go on location, most companies use mobile units which are complete with all the equipment necessary to make a professional motion picture. These vehicles can carry two or three complete camera packages, two or more sound outfits which have been reduced in size even more than the cameras, grip equipment which is used for construction where necessary, camera supports and dollies, and lightweight lamps and cables which feed from a gasoline-powered generator built into the vehicle. Some of these conveyances include space for makeup and wardrobe, although these two departments are usually housed in a separate unit.

Motors. Up until 1970 most sound cameras were driven by 220-VAC (volts alternating current) three-phase synchronous motors, while the sound film, 35mm perforated iron oxide-coated film running over a sprocket, was driven by a similar synchronous motor. After 1970, however, almost all professional

35mm productions in the United States, and many 16mm sound films as well, changed to a new type of motor for driving the camera and a new method of recording synchronous sound, both of which have many advantages over the older system. The motor used on the camera is a direct-current motor, which runs off batteries (12 to 36 V) at a synchronous speed. The speed of the motor is controlled by a crystal oscillator which is so precise that the speed of the motor varies less than one-half a frame of picture in 1000 ft (300 m) of film. All modern cameras (16mm as well as 35mm) use these "crystal motors."

Sound. All sound is recorded on sprocketless 0.25-in. (6-mm) tape. Since tape is an elastic medium, some sort of "sync" pulse must be put on the tape in order to synchronize the recorded sound with the picture when they are put together in a "married" print. The sync pulse is usually an inaudible 1-V, 60-Hz (in Europe, 50-Hz) pulse put on the tape at the time of recording. This pulse can be one generated at the camera and sent to the sound recorder, which is exactly 60 Hz when the camera is running precisely 24 frames/s; or a similar pulse from a crystal oscillator either built into or attached to the tape recorder on which the sound is being recorded. The latter method is the one most commonly used on professional motion picture productions. It is the only system in which there is no physical or electrical connection between sound and camera. Without this connection the camera is completely free; it can be in a separate vehicle, car, boat, or aircraft, while the sound-recording equipment is in another. The only thing required to make a synchronous sound picture with this system is that a sync stick, or clap stick, be used so that sound can have an audible point of reference and the camera can have a visible point of reference.

After the sound is recorded on the 0.25-in. (6-mm) tape, it is put through a resolver, which transfers the sound from the tape to 16mm or 35mm perforated iron oxide–coated film. The resolver corrects for the aforementioned variations in sound-track recording by using the sync pulse as a reference. With the sound on the perforated film it can be precisely synchronized with the picture, using sync-stick marks when the picture is printed for release.

There are two types of sound tracks, optical and magnetic, on release prints, the prints seen by the audience. All 35mm and practically all 16mm release prints have optical sound tracks. A 16mm film may have a magnetic sound track if only one or two prints are to be made, but this is seldom the case. An optical sound track is printed photographically on the film; a magnetic sound track is printed in the same manner as on a tape recorder, after the film is coated with an iron oxide stripe in the area reserved for the sound track. All Super 8 films have magnetic sound tracks.

Until the late 1990s, all 65mm–70mm films, those shot on 65mm film in the camera and printed on 70mm film for release, had magnetic sound tracks. The 70mm prints have six-track sound, one track on each side inside the perforations and two tracks on each side outside the perforations. The space for the tracks outside the perforations is made possible by the additional width of 2.5 mm on each side.

Until the mid-1990s, all sound tracks, both optical and magnetic, were recorded in analog fashion. Developments in the technology, however, have enabled optical sound tracks to be recorded digitally as well, permitting optical sound tracks to provide sound quality comparable to a digital compact disk. For this reason, and for cost savings, the digital-optical sound track has rapidly replaced magnetic-stripe analog sound tracks on 70mm release prints. *See* COMPACT DISK.

Slate. In any motion picture a slate with all pertinent information is of utmost importance (**Fig. 3**). The slate is fastened to the sync stick, and the information is photographed at the beginning of each take. The slate has places for all information relating to the production, such as the name of the picture and its production number for identification at the laboratory, where the film is processed, and the name of the director and the camera operator. In addition, there are spaces for the scene number and the take number, and places to indicate whether the

Fig. 3. Time-code slate. (*Denecke Inc.*)

shot is an interior or exterior, a day or night shot, or sound or MOS (silent); MOS comes from the early European director's pronunciation of "mit-out sound." The term "MOS" is still used extensively throughout the motion picture industry instead of the expression "silent."

Time code. Current practice makes increasing use of some method of coding the film and sound track to facilitate postproduction, especially by permitting transfer to videotape for highly automated editing. Methods have been developed for optically printing time code along the edge of the film beside every frame. The code is machine-readable, and is also human-readable in some systems. A method has also been introduced for printing the human-readable key number, which normally appears as a latent image along the edge of the film, as a machine-readable latent-image bar code. All these schemes facilitate the task of conforming the edit decisions, made in the video domain, back to film for final cutting and assembly. A typical slate (Fig. 3) displays a continuously running time code that is simultaneously recorded as a synchronizing track on the sound recorder. When the clapstick closes, the displayed time stops, providing a visual reference for automatically synchronizing picture and sound in postproduction.

Camera support equipment. A number of devices have been developed to take advantage of the increased mobility of cameras. Their purpose is to give the camera a smooth fluid motion to follow the cinematic action in ever more difficult situations and in ever more ingenious ways. All of these devices are designed to move in such a manner that the film viewer is drawn into the illusion of the scene. A bumpy or jerky camera motion would make the viewer aware of the camera's presence and destroy the illusion.

Crab dolly. One of the first devices developed to permit camera movement was the crab dolly (**Fig. 4**). This dolly can be steered in the usual manner by turning the wheels for curves, and it can be put in a mode where all four wheels turn in the same direction so that it can go forward and backward and also crab across the stage sideways. The camera can be raised or lowered while the dolly is in motion, making it possible to get interesting and creative camera movements.

Cranes and boom arms. A crane (**Fig. 5**) is a larger and more versatile version of the crab dolly. Available in a wide range of sizes, some cranes are slightly larger than a dolly, similar in configuration to a dolly equipped with a boom arm; others extend to 30 ft (9 m) in the air. Cranes are used extensively to achieve large sweeping moves for dramatic effects.

Camera cars. Trucks specially fitted to provide a smooth-moving platform for motion picture cameras (**Fig. 6**) are extremely useful in photographing fast-moving action such as a car chase. These vehicles have become extremely sophisticated. They can support a camera smoothly at highway speeds, in conventional or crab mode, on a boom arm with battery or generator power to satisfy lighting needs.

Steadicam. This is a unique device to support cameras in a mobile situation (**Fig. 7**). It provides a stable platform for a handheld camera supported by the camera operator by means of a vest and supporting spring arm. The mass of the camera and its supporting structure is balanced about a gimbal. The operator guides the camera by gently grasping the system at the gimbal, and is able to walk, run, or go up or down stairs, and still provide totally smooth camera motion.

Film. The film used in the standard motion-picture camera is 35mm (wide) and is perforated along both edges. There are 64 perforations (or sprocket holes) to each foot of film.

Fig. 4. Chapman/PeeWee crab dolly. (*Chapman/Leonard Inc.*)

Fig. 5. Louma crane. (*Panavision Remote Systems*)

Motion-picture film consists of a cellulose acetate base approximately 0.006 in. (0.15 mm) thick and coated with a light-sensitive emulsion. In color film, several layers of emulsion are applied; each of three of the layers is sensitive to one of the three primary colors of light: blue, green, and red. The film is made in large rolls about 54 in. (1.37 m) wide and as long as several thousand feet. It is slit into 35mm strips, perforated, and packed in lightproof bags and cans in rolls 100, 200, 400, and 1000 ft (30, 60, 120, and 300 m) in length.

Smaller widths such as 16 and 8 mm are also made from these wide rolls if they are of the same emulsion type. These sizes are seldom used for feature films but are used extensively by professionals in the audiovisual field and for news and low-budget films for television. The kinds of motion picture film are numerous and varied to meet the needs of a many-faceted industry: black and white, color, high and low speed, fine and coarse grain, high and low contrast, and wide and narrow exposure latitude. These film characteristics describe a particular type of film emulsion.

Fig. 6. Camera car. (*Shotmaker Co.*)

Fig. 7. Steadicam. (*Cinema Products Corp.*)

Film types. There are two different types of film: negative film, from which a print is made in order to see the original subject in its true likeness (for example, Kodacolor, used in amateur photography), and reversal film, in which a negative is first formed in the original film and from this a positive is formed in the same piece of film (for example, Kodachrome, a film familiar to amateurs). In the negative film two pieces of film are necessary to get a picture that can be projected; in the reversal film only one piece of film is required, making it a much less expensive process. In Super 8, as well as regular 8, the reversal film is generally used because of the cost factor. In 16mm and 35mm professional work, the original, that is, the film used in the camera, is never used for projection. A work print is made in order to edit the film and the original negative is assembled to conform to the edited work print. Master positives are then struck from the original negative, and the master positives are used, in turn, to produce duplicate negatives. The release prints are made from the duplicate negatives, and during this process the sound tracks are added. The original film is all-important and is kept in a vault at the laboratory; it is used only for making prints.

Aspect ratio. The picture taken in standard 35mm motion picture cameras is masked by the aperture plate, which varies according to the camera. The silent aperture, that is, the aperture used on cameras that do not leave room on the film for a sound track, is almost the entire width of the film between perforations, slightly less than 1 in. (25 mm) and approximately 0.75 in. (19 mm) high. This gives an aspect ratio (the ratio of its width to its height) of 1.33:1 (4/3). Sound apertures are masked down to a width of 0.868 in. (22 mm), to allow room for the sound track, and a height of 0.631 in. (16 mm), which gives an aspect ratio of 1.37:1.

Projectors. The projector system in a modern motion picture theater has five main assemblies: the optical sound head, which reproduces optical (photographically recorded) sound; the projector head, which projects the image onto the screen; the lamphouse, which furnishes the illumination for the picture; the shutter; and the platter system, which feeds the film through the projector head. On some projectors, there is a second sound head for the reproduction of magnetic (magnetically recorded) sound.

With the development of digital optical sound, most projectors are now equipped with a charge-coupled-device (CCD) line array to read the digital track. The analog optical track, which is still present as a backup system, is now read by a light-emitting diode (LED) array in lieu of the traditional exciter lamp. An alternate dual-system approach has a time-code track on the film that is read to synchronize the picture with the sound track played back from a compact disk machine. *See* CHARGE-COUPLED DEVICES; LIGHT-EMITTING DIODE.

Optical sound head. This consists of an exciter lamp and a photoelectric cell. The optical sound track is 20 frames ahead of the picture on 35mm film (26 frames ahead on 16mm film). If the film has a magnetic sound track in addition to the optical one, it is first threaded over the magnetic sound head, which is above the projector head (**Fig. 8**). The magnetic sound track is 28 frames behind the picture on 35mm film and 23 frames behind on 70mm film (26 frames ahead on 16mm film, the same as optical sound).

Projector head. This consists of the projection lens and the projector intermittent. The projection lens is located in the front of the projector head between the aperture and the screen. The film is put in the projector aperture upside down and with the sound track on the right. The image is inverted by the lens and appears right side up on the screen. The sound track, if it were visible, would appear on the left side of the screen. The focal length of the lens is determined by the size of the image desired on the screen and the distance between projector and screen. The lens usually has a fixed speed of *f*/2 and has no iris diaphragm.

The projector intermittent uses a Geneva movement to pull the film through the gate. This movement drives a 16-toothed sprocket one-quarter of a revolution at a time. With each movement a new frame is pulled into place. The film is wrapped around this sprocket wheel and its perforations on both sides engage four or five teeth on the wheel at all times. This distributes the stress caused by the acceleration and deceleration over many perforations and results in less wear and tear on the film, substantially increasing its life. A framing device is incorporated in the projector head so that the frame can be moved up or down to position the picture correctly and put the frame lines at the top and bottom of the screen.

Lamphouse. All modern projectors employ xenon arc lamps in place of the previously used carbon arc lamps. The xenon arc lamps form a small plasma arc in a sealed glass bulb. A concave reflector behind the lamp collects the light and concentrates it on the film in the projector aperture. Depending on the size of the screen, the lamps generally range from 1 to 7 kW in power input. *See* ARC LAMP.

Platter system. Most modern theaters use a platter system (**Fig. 9**) rather than the conventional 2000-ft (600-m) reels used in older theaters. Conventional reels are labor-intensive and require two projectors to achieve a smooth transition (changeover) between subsequent reels of a motion picture. In the platter system, only one projector is needed. All reels of a motion picture are spliced together and loaded onto one of the platters with the start of the picture at the center of the reel. The film is then threaded from the center of the reel, through the projector, and onto a second platter. When the show is over, it is

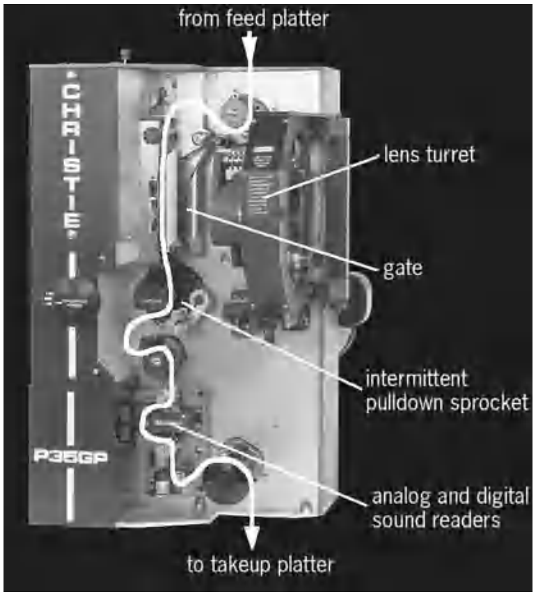

Fig. 8. Motion picture projector. The white ribbon shows the path of film from feed platter down through the projector head gate, over the intermittent pulldown sprocket, over analog and digital sound reader heads, and on the way to the take-up platter. (*Christie Inc.*)

Fig. 9. Nonrewind platter system. (*Kinotone*)

only necessary to rethread the projector, but starting from the second platter.

Shutter. A projector has a two-bladed shutter located between the lamphouse and the gate in the projector head. The shutter cuts off the light to the screen while the film is being moved down from one frame to the next and opens when the new frame has been moved into place. It then closes and opens a second time before another frame has been brought into position. This makes two exposures per frame, or 48 light impulses hitting the screen in 1 s, even though the picture was shot at 24 frames per second. This reduces the flickering effect that would be noticeable if only 24 light impulses per second were flashed on the screen.

Universal types. Universal projectors can show 35mm prints, both normal and anamorphic, with optical sound, four-track magnetic sound, or both. They can also show 70mm normal and anamorphic with six-track magnetic sound. The 35mm sprockets are between and below the 70mm sprockets, and either film can be run by selecting the correct lens and threading the film through the gate and through the appropriate sound head. *See* OPTICAL PROJECTION SYSTEMS.

Wide-screen processes. Until 1952 the motion picture industry as a whole used film and equipment that was well standardized. Film was 35 mm wide, the aspect ratio was 1.33:1, and the camera had a four-perforation pull-down mechanism. These standards had been in effect since early in the twentieth century. With the advent of sound in 1926, standard camera speed became established at 24 frames per second, and most sound tracks were reproduced optically. Beginning in 1952, however, many new processes were introduced which departed from these standards and utilized a multiplicity of film sizes, aspect ratios, and types of sound tracks. Some processes which employ 35mm film use a means of getting more picture on the film. The 1.85:1 ratio has practically become a standard when referring to wide screen. Multitrack digital-optical sound has become fairly common.

Cinerama. The first commercially successful wide-screen process was Cinerama, developed by F. Waller. First shown in 1952, the system employed three separate, matched film strips projected by three separate projectors. The projected image height was equivalent to six perforations, and the width the equivalent of three full 35-mm apertures. The deeply curved screen consisted of 1200 overlapping strips, arranged in such a manner as to minimize lateral reflections. A fourth 35mm film strip carried seven sound tracks for full stereophonic reproduction. The complexities of running these projectors in exact synchronism, in addition to jitter problems between the three panels, caused the system to be simplified some years later to a single 70-mm-wide film with multiple sound tracks and a 1.25:1 anamorphic "squeeze." The first picture made in this manner was *Mad Mad Mad Mad World* (1964).

Cinemascope. The single-film approach was anticipated by Cinemascope, developed by twentieth Century Fox, based on earlier work of the physicist H. Chrétien. Special lens adapters were designed that produced a linear 2:1 anamorphic squeeze when attached to conventional lenses. Integral anamorphic lenses were subsequently developed which were simpler to use. A special projector lens was used to unsqueeze the picture (**Fig. 10**). The first feature

Fig. 10. Action of Cinemascope anamorphic lens. (*a*) Image "squeezed" onto the film by an anamorphic lens. (*b*) "Unsqueezed" image as it appears on the screen. (*Twentieth Century Fox*)

filmed in Cinemascope was *The Robe* (1953). The format continues to be used.

VistaVision. This process, developed by Paramount, utilized an eight-perforation–pull-down, 35mm movement, operating from left to right rather than top to bottom. Conventional spherical lenses were used, and the resulting format was 37.7 mm wide by 25 mm high. *White Christmas* (1954) was the first picture produced by this process. The need for special projection equipment eventually caused VistaVision to be discontinued. It is still used, however, for shooting background plates for process photography since it provides a large format that will not degrade as much as a 35mm format during the duplicating process.

Todd-AO. In the mid-1950s B. O'Brien in cooperation with promoter M. Todd developed the Todd-AO wide-screen process. This process used a 70mm print derived directly from a 65mm negative, five perforations high, with six magnetic sound tracks arrayed as previously noted. A series of special lenses was developed to provide from 37 to 128° of angular coverage. The first picture produced in Todd-AO was *Oklahoma* (1955). As originally presented, Todd-AO used a deeply curved screen, but it was subsequently converted to flat-screen projection. Super Panavision, similar to Todd-AO in format, has been widely used. Mitchell 35mm and 65mm cameras have been used for these processes, as well as cameras specially designed and built for the process.

Screen formats. Films for theatrical release have now been standardized in two basic formats in the United States, as contrasted with the plethora of wide-screen and multiscreen formats that appeared and disappeared during the 1950s and 1960s. With rare exceptions all films for theatrical presentation are now shot either (1) in the 2.35:1 aspect ratio, using the 35mm anamorphic system that was originated by Cinemascope but that now exists largely through the use of Panavision anamorphic lenses and those developed by others, or (2) in the 1.85:1 aspect ratio, which is achieved by cropping the standard 35mm frame top and bottom. In Europe, the popular aspect ratio is 1.66:1.

The 1.85:1 format is extremely wasteful of film, and there have been several attempts to introduce a system involving three-perforation pull-down in the camera as well as in the projector to eliminate this waste.

Techniscope. This was a promising format that has now virtually disappeared in the United States. It was developed in the Technicolor Laboratories in Rome, Italy. The process involves shooting the original camera negative with the camera modified to pull down two perforations, rather than four, in a standard 35mm camera. The taking lenses are the normal complement of spherical lenses. In the laboratory the negative is optically printed through an anamorphic lens which stretches the image vertically by a factor of 2:1 so that the print is identical to one which would have resulted from a negative shot in the Cinemascope anamorphic process. A number of films were shot in this process, but it fell into disfavor in the United States because the increase in granularity and the decrease in resolution due to using a negative area one-half that of the standard 35mm size resulted in a film that was not of acceptable quality when compared with the 1.85:1 format or the anamorphic format. However, in Europe and elsewhere Techniscope is still an acceptable and frequently used process.

Super 16. An alternative means of arriving at current theatrical formats, called Super 16, was pioneered by R. Ericson in Sweden. This process involves photographing with a 16mm camera that is modified so that the full width of the negative is photographed, including that area reserved for sound track in the final release print. The negative is then enlarged, usually through liquid-gate optical printing, to a 35mm format with a 1.65:1 aspect ratio.

70mm presentation. Until the introduction of digital-optical sound, there had been a major move back to theatrical presentation in 70mm film. This was motivated by the ability to provide six magnetic sound tracks on the 70mm print. Original photography was typically on 35mm film and blown up to 70mm. Digital-optical sound technology permits full multichannel surround sound to be recorded on a standard 35mm print, obviating the need to produce very expensive 70mm magnetic-striped prints. However, there has been a growing trend in the use of 70mm prints from 65mm negatives for special-venue presentations such as theme parks, studio tours, dynamic motion simulator rides, and 3D (three-dimensional). To meet this growing need, new 65mm cameras have been developed (**Fig. 11**).

Imax. Epitomizing this trend to larger formats, the Imax process films on a 65mm negative moving

Fig. 11. CP-65 65mm camera system. (*Cinema Products Corp.*)

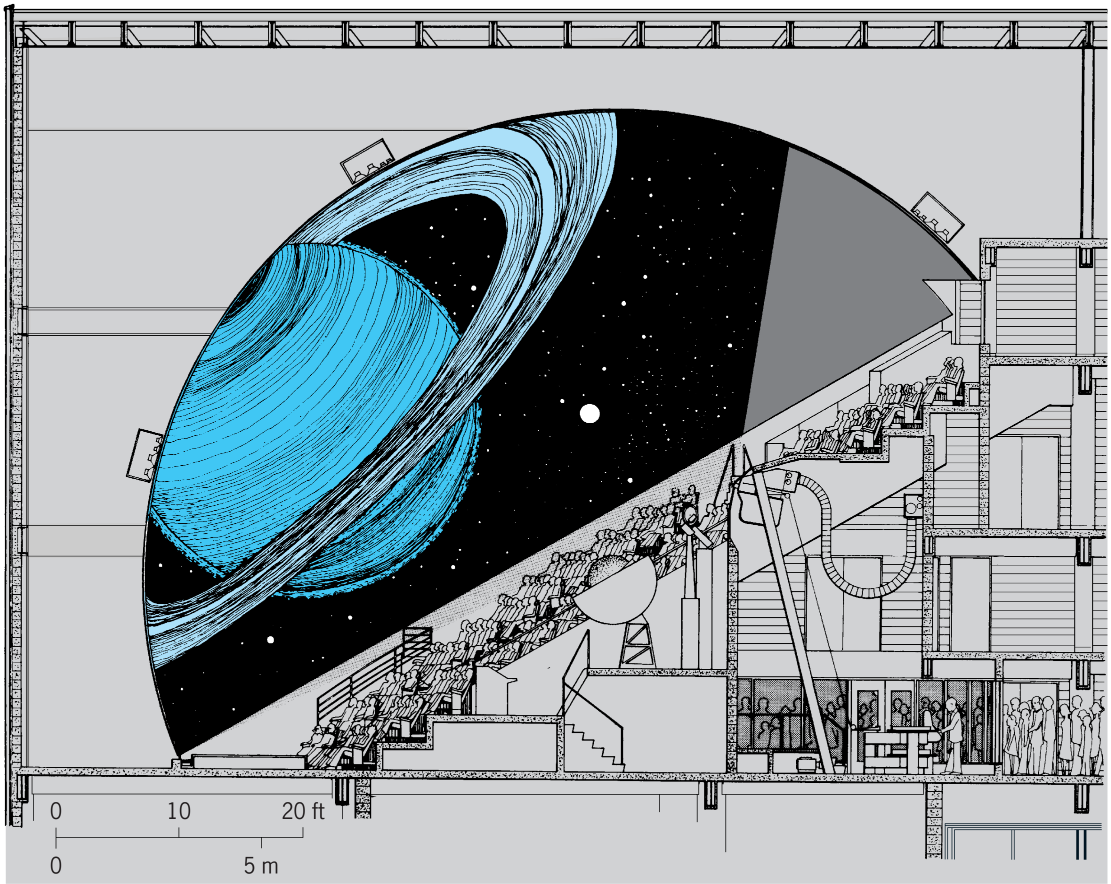

Fig. 12. Cross-sectional view of typical Omnimax theater.

horizontally through the camera, 15 perforations per frame. The resulting aspect ratio is 1.33:1. The 70mm prints are projected on a large flat screen. They can also be photographed and projected with a fisheye lens on a hemispheric dome in a process called Omnimax (**Fig. 12**). The projector is of a unique design that utilizes a rolling loop to rapidly advance the film with no damage and absolute flatness in the film gate. *See* PLANETARIUM.

A less expensive alternative to the Imax format is provided by the Iwerks system of recording eight perforations per frame on 65mm film moving vertically through the camera. This provides essentially the same format, but on a smaller negative area.

Showscan. This process uses the conventional 70mm, five-perforation format, but is filmed and projected at 60 frames per second. This frame rate virtually eliminates all filmic artifacts, such as strobe and flicker, to provide a heightened sense of reality. Edmund M. DiGiulio

Digital Cinematography

Like other forms of media, cinematography is undergoing a transition from photomechanical to digital processes, which offer greater flexibility, consume fewer resources, offer significant time saving, and allow electronic (versus physical) delivery of products. In cinematography, this transition involves three distinct operations: image capture, image editing, and image display. The complete transition will result in an all-digital workflow for the production of motion pictures. Although the implementation of an all-digital workflow is under way, the use of digital methods in the image editing or “postproduction” processes is far more widespread than in image capture or display.

Image capture. The image-capture process involves filming the scenes that will be edited together to make a movie. In this operation, the switch to digital involves capturing the scenes with a high-definition digital camera instead of traditional cinemagraphic 35mm film cameras.

There are several weaknesses in the traditional approach, such as the high cost of the film and the environmental impact of chemical film processing, which are alleviated by digital image capture. In addition, color negative film cannot be evaluated directly (even after processing), so the creative team cannot get immediate feedback on the success of a filming session; film is easily scratched and susceptible to dust; and in order to use digital editing techniques, film images must be scanned to create digital files. Still, cinematographers have been reluctant to give up film cameras because 35mm film captures a higher-resolution image with greater dynamic range than high-definition digital cameras.

Motion pictures in which digital image capture was used include *Sin City* and *Star Wars: Episode III Revenge of the Sith*. In both of these films, digitally generated backgrounds were extensively used. Thus, the limited resolution of the digital camera did not limit the detail that was evident in the background.

For *Sin City*, Sony HDC-F950 digital cameras were used, capturing red, green, and blue images at 1920 × 1080 pixels of resolution with 10-bit color depth at 24 frames per second. Scenes were viewed on a calibrated monitor immediately after shooting, which benefited the production team by avoiding multiple shoots of some scenes.

Star Wars: Episode III Revenge of the Sith used an all-digital workflow, including image capture. The production cost of $100 million is estimated to be half the amount required for a comparable movie shot on film. The savings came from the increased productivity gained by having immediate feedback during shooting and from doing much of the special-effects work before the shooting took place. This enabled the director to make decisions about which angles and perspectives were needed before (rather than after) the filming of a scene.

Over time, digital image capture should replace film because of the creative flexibility and cost savings it offers. Digital cinema cameras are improving steadily, as are data transport, storage, and compression techniques.

Film digitizing. Scanning rolls of film for digital editing has become a lucrative business because an increasing number of films are doing all the post-production processes digitally. The scanners used for rolls of film were initially developed for converting finished films to DVD format. Ideally, each frame would be scanned at 4K (4100 pixels wide by 3000 pixels high) for optimum quality, but the resulting files were too large and it would take days to scan a feature length film. Scanners now are capable of performing 2K scans in real time and 4K scans at 7.5 frames per second, or about 6 h for a feature-length film, with 4K scanning resolution reserved for critical projects and 2K (2048 pixels wide by 1556 pixels high) scanning is used for most applications.

Image editing. Nearly all special effects are achieved through digital means, making image editing the area with the greatest penetration of digital processes. Traditional film-editing methods involved cutting apart scenes from the developed film reels and taping them back together to form the desired sequence. After the taped-together master was made, it was duplicated with color adjustments to form a new master on a continuous piece of film. This process was extremely time-consuming and not easily reversible.

Digital editing offers significant advantages over film editing. It is faster, more precise, and more readily reedited. It also allows the easy integration of digital special effects into the shot sequences and the individual frames of the film.

Digital editing offers color effects that are not obtainable with photomechanical processes. For example, the film *O Brother Where Art Thou* used a restricted color palette for the background scenery that evoked the Dust Bowl era in the American South. This palette could have been achieved on film with the judicious use of lighting and filters, but it could not have been restricted to background elements only.

Image display. In June 1999, the first two films released for display in digital format were *Star Wars Episode I and An Ideal Husband*. There were two competing projectors in use: the Texas Instruments digital light processor (DLP) projector and Hughes/JVC ILA-12K liquid crystal on silicon (LCOS) projector. The DLP projectors were preferred for their larger color gamut and greater contrast range.

DLP projectors use optical semiconductors, called digital micromirror devices (DMD), to modulate the light and form images. Each DMD is an array of 1.3 million microscopic mirrors, which can be individually pivoted in and out of the projector's light path thousands of times per second. The individual mirrors are spaced 1 micrometer apart, so the device exhibits a high fill factor with good brightness and contrast. Cinema projectors are equipped with three DMD arrays (one for each primary color) to produce an image. Early projectors were limited to 1024 × 768 pixel resolution but current equipment offer 2K pixel resolution, 15-bit color depth, and sufficient brightness for a 75-ft-wide screen. In 2004, Sony released the SXRD 4K projector, which uses a variant of LCD technology. Its improved image resolution (4096 × 2160 pixels) offers a more lifelike image to the viewer.

Standards. The digital cinematography industry is developing standards for file format, compression technology, color display, and encryption needed for interoperability for the rapidly developing projector and hardware industries. Several groups are contributing to this effort, including the Motion Picture Association of America (MPAA) and the Digital Cinema Initiatives (DCI) consortium, a group of seven studios. The Society of Motion Picture and Television Engineering (SMPTE) has a technical committee for digital cinema (DC28) that has recommended specifications for file format, compression, and encryption technologies. The American Society of Cinematographers (ASC) has a technical committee to produce standardized evaluation materials for all aspects of digital cinema.

There has been steady development of encryption and digital rights management strategies for digital cinema. Currently, files are encrypted all the way into the projector, where the display files are extracted. This is of great importance to the industry in thwarting the piracy of intellectual property. It reduces the need for high security on the server since it will only receive and distribute encrypted files.

Cinnamon

An evergreen shrub or small tree, *Cinnamomum zeylanicum*, of the laurel family (Lauraceae). A native of Sri Lanka, the plant (see **illus.**) is now in cultivation in southern India, Burma, parts of Malaya, West Indies, and South America. In cultivation the trees are cut back and long, slender suckers grow up from the roots. The bark is removed from these suckers, dried and packaged for shipping. Cinnamon is a very important spice for flavoring foods. It is used in confectionery, gums, incense, dentifrices, and perfumes. Cinnamon oil is used in medicine and as a source of cinnamon extract. *See* MAGNOLIALES; SPICE AND FLAVORING. Perry D. Strausbaugh; Earl L. Core

Cinnamon (*Cinnamomum zeylanicum*). (*USDA*)

Circle

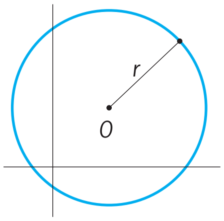

Fig. 1. Circle of radius *r* and center *O*.

The curve that is the locus of points in a plane with equal distance (radius) from a fixed point (center) (**Fig. 1**). In elementary mathematics, circle often refers to the finite portion of the plane bounded by a curve (circumference) all points of which are equidistant from a fixed point of the plane, that is, a circular disk. Circles are conic sections and are defined analytically by certain second-degree equations in cartesian coordinates. They were extensively studied by the ancient Greeks, who formulated the famous problem of "squaring the circle," that is, to construct, with compasses and unmarked straightedge only, a square whose area is equal to that of a given circle. It was not until 1882 that this was shown to be impossible, when F. Lindemann proved that the ratio of the length of a circle to its diameter (denoted by π) is not the root of any algebraic equation with integer coefficients. That π is irrational (that is, not the quotient of two integers) was shown by A. M. Legendre in 1794. Numerous approximations of π appeared quite early; for example, 3 (*Book of Kings*); $3\,{}^1/_7 > \pi > 3\,{}^{10}/_{71}$ (Archimedes); $\sqrt{10}$ (*Ch'ang Höng*, A.D. 78–139); and 3.1416 (Aryabhata, A.D. 476–550). Electronic computers have calculated π to over 10^{12} decimal places. Interesting expressions are

$$\pi = 4(1 - {}^1/_3 + {}^1/_5 - {}^1/_7 + \cdots)$$
$$\pi = 2 \cdot 2(2 \cdot 4/3 \cdot 3)(4 \cdot 6/5 \cdot 5)(6 \cdot 8/7 \cdot 7) \cdots$$

The area of a circle (circular disk) with radius r is πr^2; the length (circumference) is $2\pi r$. The area enclosed by a circle is greater than that bounded by any other curve of the same length. If a circular disk can cover each three points of an arbitrary plane set, then the disk can cover the whole set. It is, moreover, the only disk that has this property. *See* ANALYTIC GEOMETRY; CONIC SECTION. Leonard M. Blumenthal

A great many properties of the circle are in relation to a given triangle. Such, for example, is the nine-point circle theorem. Let the altitudes of any triangle *ABC* intersect each other in the orthocenter *H*, and intersect the opposite sides in *D*, *E*, and *F*, respectively. Then the circle *DEF* passes through the midpoints of each of the six segments *AB*, *BC*, *CA*, *AH*, *BH*, *CH*. It is called the nine-point circle of the triangle *ABC*, and also of each of the triangles *HBC*,

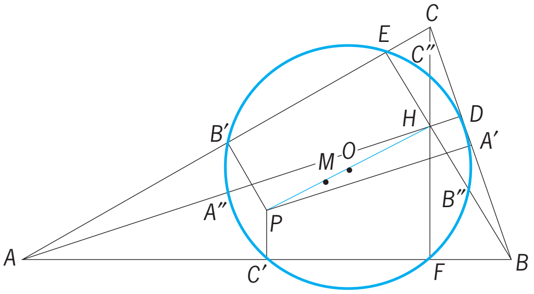

Fig. 2. Nine-point circle and Euler line *PMH*.

HCA, *HAB*, whose orthocenters are *A*, *B*, *C*, respectively. Feuerbach's theorem states that this nine-point circle is tangent both to the inscribed circle and to the three escribed circles of each of these triangles.

The center *O* of the nine-point circle (**Fig. 2**) of any triangle lies midway between the orthocenter *H* and the circumcenter *P* on the so-called Euler line that passes through these points and the centroid *M*. J. Sutherland Frame

Circuit (electricity)

A general term referring to a system or part of a system of conducting parts and their interconnections through which an electric current is intended to flow. A circuit is made up of active and passive elements or parts and their interconnecting conducting paths. The active elements are the sources of electric energy for the circuit; they may be batteries, direct-current generators, or alternating-current generators. The passive elements are resistors, inductors, and capacitors. The electric circuit is described by a circuit diagram or map showing the active and passive elements and their connecting conducting paths.

Devices with an individual physical identity such as amplifiers, transistors, loudspeakers, and generators, are often represented by equivalent circuits for purposes of analysis. These equivalent circuits are made up of the basic passive and active elements listed above.

Electric circuits are used to transmit power as in high-voltage power lines and transformers or in low-voltage distribution circuits in factories and homes; to convert energy from or to its electrical form as in motors, generators, microphones, loudspeakers, and lamps; to communicate information as in telephone, telegraph, radio, and television systems; to process and store data and make logical decisions as in computers; and to form systems for automatic control of equipment.

Electric circuit theory. This includes the study of all aspects of electric circuits, including analysis, design, and application. In electric circuit theory the fundamental quantities are the potential differences (voltages) in volts between various points, the electric currents in amperes flowing in the several paths, and the parameters in ohms or mhos which describe the passive elements. Other important circuit quantities such as power, energy, and time constants may be calculated from the fundamental variables. For a discussion of these parameters *see* ADMITTANCE; CONDUCTANCE; ELECTRICAL IMPEDANCE; ELECTRICAL RESISTANCE; REACTANCE; SUSCEPTANCE; TIME CONSTANT.

Electric circuit theory is an extensive subject and is often divided into special topics. Division into topics may be made on the basis of how the voltages and currents in the circuit vary with time; examples are direct-current, alternating-current, nonsinusoidal, digital, and transient circuit thoery. Another method of classifying circuits is by the arrangement or configuration of the electric current paths; examples are series circuits, parallel circuits, series-parallel circuits, networks, coupled circuits, open circuits, and short circuits. Circuit theory can also be divided into special topics according to the physical devices forming the circuit, or the application and use of the circuit. Examples are power, communication, electronic, solid-state, integrated, computer, and control circuits. *See* CIRCUIT (ELECTRONICS); NEGATIVE-RESISTANCE CIRCUITS.

Direct-current circuits. In dc circuits the voltages and currents are constant in magnitude and do not vary with time (**Fig. 1**). Sources of direct current are batteries, dc generators, and rectifiers. Resistors are the principal passive element. For a discussion of direct-current circuits *see* DIRECT-CURRENT CIRCUIT THEORY

Magnetic circuits. Magnetic circuits are similar to electric circuits in their analysis and are often included in the general topic of circuit theory. Magnetic circuits are used in electromagnets, relays, magnetic brakes and clutches, computer memory devices, and many other devices. For a detailed treatment. *See* MAGNETIC CIRCUITS.

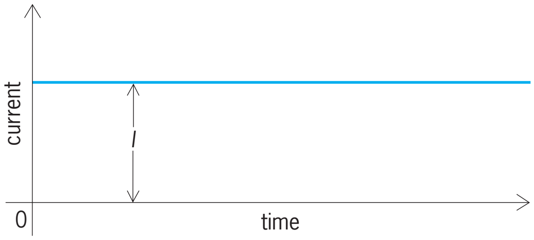

Fig. 1. Direct current, which is constant in magnitude and does not vary with time.

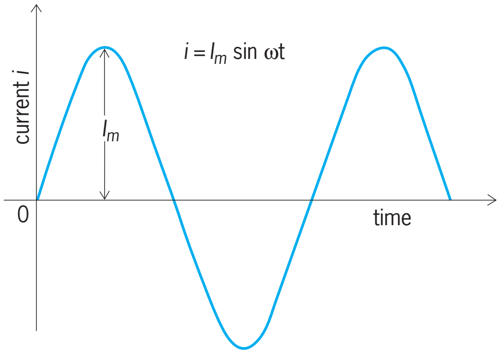

Fig. 2. Alternating current, which periodically reverses direction with time. In this example, the current varies sinusoidally with time.

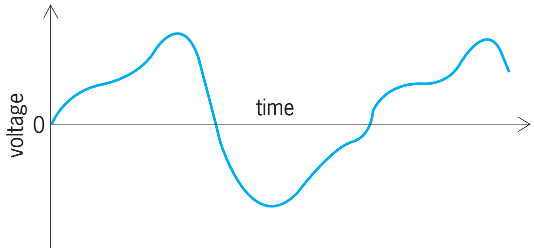

Fig. 3. Nonsinusoidal voltage wave.

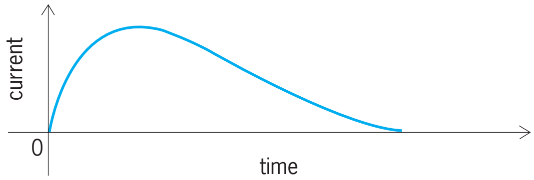

Fig. 4. Transient electric current.

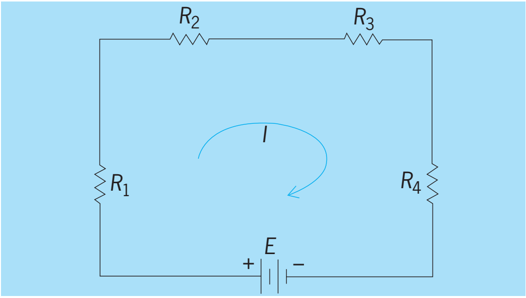

Fig. 5. Series circuit.

Alternating-current circuits. In ac circuits the voltage and current periodically reverse direction with time. The time for one complete variation is known as the period. The number of periods in 1 s is the frequency in cycles per second. A cycle per second was named a hertz (in honor of Heinrich Rudolf Hertz's work on electromagnetic waves).

Most often the term ac circuit refers to sinusoidal variations. For example, the alternating current in **Fig. 2** may be expressed by $i = I_m \sin \omega t$. Sinusoidal sources are ac generators and various types of electronic and solid-state oscillators; passive circuit elements include inductors and capacitors as well as resistors. The analysis of ac circuits requires a study of the phase relations between voltages and currents as well as their magnitudes. Complex numbers are often used for this purpose. For a detailed discussion. *See* ALTERNATING-CURRENT CIRCUIT THEORY.

Nonsinusoidal waveforms. These voltage and current variations vary with time but not sinusoidally (**Fig. 3**). Such nonsinusoidal variations are usually caused by nonlinear devices, such as saturated magnetic circuits, electron tubes, and transistors. Circuits with nonsinusoidal waveforms are analyzed by breaking the waveform into a series ofsinusoidal waves of different frequencies known as a Fourier series. Each frequency component is analyzed by ac circuit techniques. Results are combined by the principle of superposition to give the total response. *See* NONSINUSOIDAL WAVEFORM.

Electric transients. Transient voltage and current variations last for a short length of time and do not repeat continuously (**Fig. 4**). Transients occur when a change is made in the circuit, such as opening or closing a switch, or when a change is made in one of the sources or elements. For a discussion of dc and ac transients. *See* ELECTRIC TRANSIENT.

Series circuits. In a series circuit all the components or elements are connected end to end and carry the same current, as shown in **Fig. 5**. *See* SERIES CIRCUIT.

Parallel circuits. Parallel circuits are connected so that each component of the circuit has the same potential difference (voltage) across its terminals, as shown in **Fig. 6**. *See* PARALLEL CIRCUIT.

Series-parallel circuits. In a series-parallel circuit some of the components or elements are connected in parallel, and one or more of these parallel combinations are in series with other components of the circuit, as shown in **Fig. 7**.

Electric network. This is another term for electric circuit, but it is often reserved for the electric circuit that is more complicated than a simple series or parallel combination. A three-mesh electric network is shown in **Fig. 8**. *See* NETWORK THEORY.

Coupled circuits. A circuit is said to be coupled if two or more parts are related to each other through some common element. The coupling may be by means of a conducting path of resistors or capacitors or by a common magnetic linkage (inductive coupling), as shown in **Fig. 9**. *See* COUPLED CIRCUITS.

Open circuit. An open circuit is a condition in an electric circuit in which there is no path for current flow between two points that are normally connected. *See* OPEN CIRCUIT.

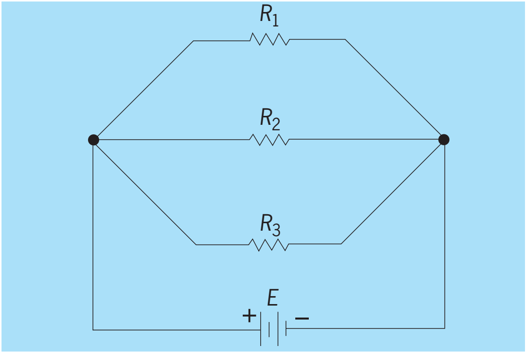

Fig. 6. Parallel circuit.

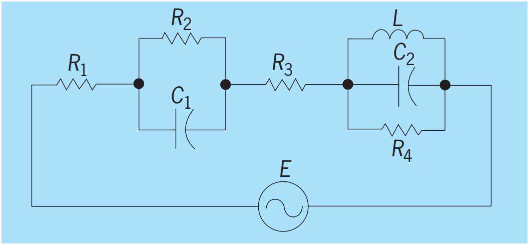

Fig. 7. Series-parallel circuit.

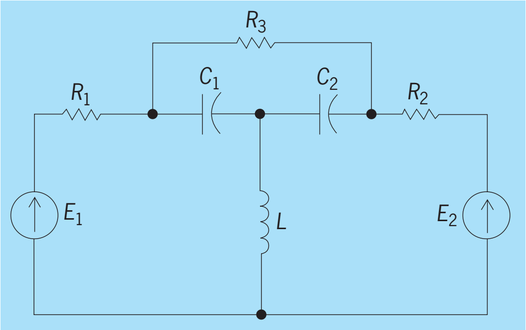

Fig. 8. A three-mesh electric network.

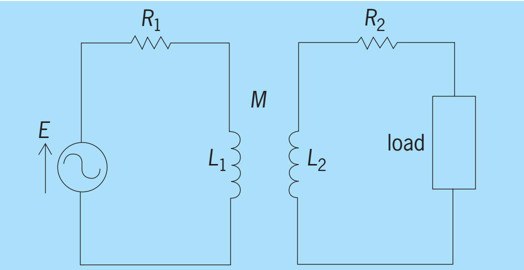

Fig. 9. Inductively coupled circuit.

Short circuit. This term applies to the existence of a zero-impedance or low-impedance path between two points of an electric circuit that are not intended to be connected. *See* SHORT CIRCUIT.

Integrated circuit. In the integrated circuit the entire circuit is contained in a single piece of semiconductor material. Sometimes the term is also applied to circuits made up of deposited thin films on an insulating substrate. *See* INTEGRATED CIRCUITS; SEMICONDUCTOR.

Circuit (electronics)

An interconnection of electronic devices, an electronic device being an entity having terminals which is described at its terminals by electromagnetic laws. Most commonly these are voltage–current laws, but others, such as photovoltaic relationships, may occur.

Basic Concepts

Some typical electronic devices are represented as shown in **Fig. 1**, where a resistor, a capacitor, a diode, transistors, an operational amplifier, an inductor, a transformer, voltage and current sources, and a ground are indicated. Other devices (such as vacuum tubes, switches, and logic gates) exist, in some cases as combinations of the ones mentioned. The interconnection laws are (1) the Kirchhoff voltage law, which states that the sum of voltages around a closed loop is zero, and (2) the Kirchhoff current law, which states that the sum of the currents into a closed surface is zero (where often the surface is shrunk to a point, the node, where device terminals join). **Figure 2** represents an electronic circuit which is the interconnection of resistors (R, R_{B1}, R_{B2}, R_E, R_L), capacitors (C), a battery voltage source (V_{CC}), a current source (i_s), a bipolar transistor (T), and a switch (S). Functionally Fig. 2 represents a high-pass filter when S is open, and an oscillator when S is closed and the current source is removed. *See* AMPLIFIER; BATTERY; CAPACITOR; CURRENT SOURCES AND MIRRORS; DIODE; ELECTRIC FILTER; ELECTRONIC SWITCH; INDUCTOR; KIRCHHOFF'S LAWS OF ELECTRIC CIRCUITS; LOGIC CIRCUITS; OPERATIONAL AMPLIFIER; OSCILLATOR; RESISTOR; TRANSFORMER; TRANSISTOR; VACUUM TUBE.

Active and passive devices. The devices in an electronic circuit are classified as being either passive or active. The passive devices change signal energy, as is done dynamically by capacitors and statically by transformers, or absorb signal energy, as occurs in resistors, which also act to convert voltages to currents and vice versa. The active devices, such as batteries, transistors, operational amplifiers, and vacuum tubes, can supply signal energy to the circuit and in many cases amplify signal energy by transforming power supply energy into signal energy. Often, though, they are used for other purposes, such as to route signals in logic circuits. Transistors can be considered the workhorses of modern electronic circuits, and consequently many types of transistors have been developed, among which the most widely used are the bipolar junction transistor (BJT), the junction field-effect transistor (JFET), and the metal-oxide-silicon field-effect transistor (MOSFET). *See* ELECTRONIC POWER SUPPLY.

Fortunately, most of these transistors occur in pairs, such as the *npn* and the *pnp* bipolar junction transistors, or the *n*-channel and the *p*-channel MOSFETs, allowing designers to work symmetrically with positive and negative signals and sources. This statement may be clarified by noting that transistors can be characterized by graphs of output current i versus output voltage v that are parametrized by an input current (in the case of the bipolar junction transistor) or input voltage (in the MOSFET and JFET cases). Typically, the curves for an *npn* bipolar junction transistor or an *n*-channel field-effect transistor are used in the first quadrant of the output *i-v* plane, while for a *pnp* bipolar junction transistor or a *p*-channel field-effect transistor the same curves show up in the third quadrant. Mathematically, if $i = f(v)$ for an *npn* bipolar junction transistor or *n*-channel field-effect device, then $i = -f(-v)$ for a *pnp* bipolar junction transistor or *p*-channel field-effect device when the controlling parameters are also changed in sign.

Transistor properties. Because the transistors are so basic to the operation of electronic circuits, their performance will be briefly discussed.

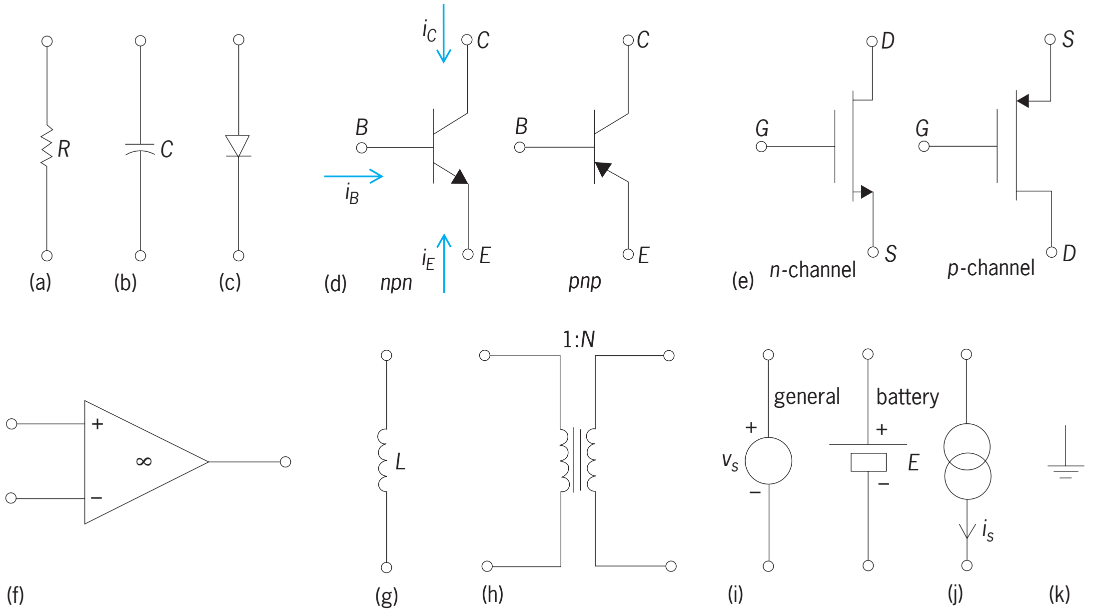

Fig. 1. Representation of some typical electronic devices. (*a*) Resistor. (*b*) Capacitor. (*c*) Diode. (*d*) Bipolar junction transistors (BJTs). (*e*) Metal-oxide-semiconductor field-effect transistors (MOSFETs). (*f*) Operational amplifier. (*g*) Inductor. (*h*) Transformer. (*i*) Voltage sources. (*j*) Current source. (*k*) Ground.

Bipolar transistors. These have three terminals, designated as the base *B*, the collector *C*, and the emitter *E*. These terminals connect to two diode junctions, *B-C* and *B-E*, these forming back-to-back diodes. The *B-E* junction is often forward-biased, in which case its voltage is about 0.7 V, while the *B-C* junction is reverse-biased for linear operation. In the case of linear operation, the bipolar junction transistor is much more than two back-to-back diodes because it has a very thin base which allows almost all of the current i_E entering the emitter to be collected by the collector. Thus, the collector current is nearly equal to the emitter current. This is expressed in Eq. (1), where

$$i_C = -\alpha i_E \tag{1}$$

the transistor parameter α is very close to 1. (The negative sign arises because the positive direction of current is assumed into the terminals, while one current must come out when the other goes in.) By Kirchhoff's current law for a sphere around the transistor ($i_B + i_C + i_E = 0$), the collector current can be expressed in terms of the base current to obtain Eq. (2), where the parameter β, given by Eq. (3), is

$$i_C = \beta i_B \tag{2}$$

$$\beta = \frac{\alpha}{1-\alpha} \tag{3}$$

very large. From this it follows that in linear operation the (bipolar junction) transistor acts like a current-controlled current source which, when used with base current as input and collector current as output, can have a high current gain β (typically 20 to 600). Because a current can be changed into a voltage via resistors, the transistor in its linear mode of operation also can be used to obtain a high voltage gain. For example, if the current source, the three capacitors, the two resistors labeled *R*, and the switch are replaced with a capacitor-coupled voltage source v_s between the point *B* and ground in Fig. 2 the voltage gain is given by Eq. (4), and can be chosen large

$$\frac{v_L}{v_s} = -\alpha \frac{R_L}{R_E} \tag{4}$$

in magnitude by appropriately choosing the ratio of the load resistance R_L to the emitter resistance R_E to be large.

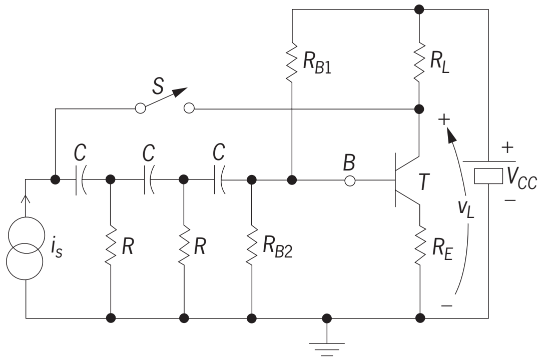

Fig. 2. Diagram of electronic circuit.

Besides biasing of the junctions for linear operation, any state of the two junctions can occur. For example, both junctions might be forward-biased, in which case the transistor is said to be in saturation and acts nearly as a short circuit between *E-C*, while if the junctions are simultaneously back-biased the transistor is said to be cut off and acts as an open circuit between all terminals. The transistor can be controlled between saturation and cutoff to make it act as an electronically controlled switch. This mode of operation is especially useful for binary arithmetic, as used by almost all digital computers, where 0 and 1 logic levels are represented by the saturation and cutoff transistor states.

MOSFET. These also have three regions of operation: cutoff, saturated, and resistive. The MOSFET also has three terminals, the gate *G*, the drain *D*, and the source *S*. A key parameter characterizing the MOSFET is a threshold voltage V_{th}. When the *G-S* voltage is below the threshold voltage, no drain current flows and the transistor is cut off. When the *G-S* voltage is above threshold, then for *D-S* voltages large in magnitude the MOSFET acts as a voltage-controlled current source, with the drain current given by Eq. (5), where *K* can conveniently be controlled by process parameters. Finally, for *D-S* voltages of small magnitude, the drain curent law is given by Eq. (6), in which case the MOSFET acts as a resistor between drain and source which can be varied by the *G-S* voltage v_{GS}. This resistor is nonlinear, because of the square term, but for very small values of v_{DS} can be considered linear [of conductance $K(v_{GS} - V_{th})$].

$$i_D = \frac{K(v_{GS} - V_{th})^2}{2} \tag{5}$$

$$i_D = K\left[(v_{GS} - V_{th})v_{DS} - \frac{v_{DS}^2}{2}\right] \tag{6}$$

The MOSFET is a versatile device, acting as a voltage-controlled current source in the saturation region and approximately as a voltage-controlled resistor in the resistive region. It can also be electronically controlled between cutoff and the resistive region to make it act as a switch, while for small signals around an operating point in the saturation region it acts as a linear amplifier. Another feature of the MOSFET is that, besides the categories of *n*-channel and *p*-channel devices, there are also enhancement- and depletion-mode devices of each category. In practice, for electronic circuit considerations, an *n*-channel device has $V_{th} > 0$ for enhancement-mode devices and $V_{th} < 0$ for depletion-mode devices, while the signs are reversed for *p*-channel devices.

Biasing of circuits. Since active devices usually supply signal energy to an electronic circuit, and since energy can only be transformed and not created, a source of energy is needed when active devices are present. This energy is usually obtained from batteries or through rectification of sinusoidal voltages supplied by power companies. When inserted into an electronic circuit, such a source of energy fixes the quiescent operation of the circuit; that is, it allows the circuit to be biased to a given operating point with no signal applied, so that when a signal is present it will be processed properly. To be useful, an electronic circuit produces one or more outputs; often inputs are applied to produce the outputs. These inputs and outputs are called the signals and, consequently, generally differ fromthe bias quantities, though often it is hard to separate signal and bias variables. For example, i_s in Fig. 2 would be an input signal, while V_{CC} would be a bias supply voltage. The voltage v_L would contain an output signal but would also include a bias component. The resistors R_{B1}, R_{B2}, R_E, and R_L are used to set the bias point of the transistor, but since they also affect the signal-handling capabilities, their choice is important in the design of the circuit. Biasing of electronic circuits is an important, nontrivial, and often overlooked aspect of their operation. *See* BIAS (ELECTRONICS).

Analog versus digital circuits. Electronic circuits are also classified as analog or digital. Analog circuits work with signals that span a full range of values of voltages and currents, while digital circuits work with signals that are at prescribed levels to represent numerical digits. Analog signals generally are used for continuous-time processes, while digital ones most frequently occur where transistions are synchronized via a clock. However, there are situations where it is desirable to transfer between these two classes of signals, that is, where analog signals are needed to excite a digital circuit or where a digital signal is needed to excite an analog circuit. For example, it may be desired to feed a biomedically recorded signal, such as an electrocardiogram into a digital computer, or it may be desired to feed a digital computer output into an analog circuit, such as a temperature controller. For such cases, there are special electronic circuits, called analog-to-digital and digital-to-analog converters. *See* ANALOG-TO-DIGITAL CONVERTER; DIGITAL-TO-ANALOG CONVERTER.

Feedback. An important concept in electronic circuits is that of feedback. Feedback occurs when an output signal is fed around a device to contribute to the input of the device. For example, in Fig. 2, when the switch *S* is closed, the voltage v_L is fed around the transistor *T* back to the input point; removal of i_s then allows v_L to contribute to its own generation, resulting in oscillations if the proper conditions are met. Consequently, when positive feedback occurs, that is, when the output signal returns to reinforce itself upon being fed back, it can lead to the generation of signals which may or may not be wanted. Circuit designers need to be conscious of all possible feedback paths that are present in their circuits so that they can ensure that unwanted oscillations do not occur. In the case of negative feedback, that is, when the output signal returns to weaken itself, then a number of improvements in circuit performance often ensue; for example, the circuit can be made less sensitive to changes in the environment or element variations, and deleterious nonlinear effects can be minimized. *See* CONTROL SYSTEMS; FEEDBACK CIRCUIT.

Specific Circuits

In designing integrated electronic circuits, one of the most useful tools is the current mirror. Two basic current mirrors are that shown in **Fig. 3*a*** for taking current out of a terminal attached to point A, and that shown in Fig. 3*b* for sending current into a terminal attached to point B. In Fig. 3*a*, the base-to-emitter

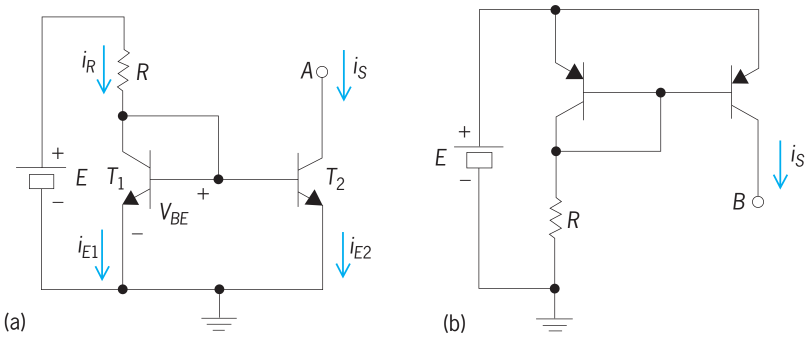

Fig. 3. Basic current mirrors. (*a*) Sink. (*b*) Source.

voltages of both transistors are identical and given by V_{BE}, with typically $V_{BE} = 0.7$ V (since the base-to-emitter junction of T_1 is a forward-biased diode). The current in the resistor i_R is then given by Ohm's law as Eq. (7) since the short circuit between collector

$$i_R = \frac{E - V_{BE}}{R} \tag{7}$$

and base makes T_1 a diode-connected transistor that forces the voltage $E - V_{BE}$ to be across R. From Kirchhoff's current law applied to a sphere encircling T_1, it follows that this current is about equal to the emitter current i_{E1} of T_1 (since the current into the base of transistor T_2 is very small). If the two transistors are identical, then $i_{E2} = i_{E1}$ (because the base-to-emitter voltages are the same). Finally, the collector current i_s of T_2 is about equal to its emitter current [by the construction and characteristics of transistors so that this current is given by Eq. (8)], mirroring the current i_R.

$$i_s = i_R \tag{8}$$

One of the most versatile circuits is the differential pair, since it finds increasing use in both analog and digital circuits. A bipolar-junction-transistor differential pair is shown in **Fig. 4**, where the dc bias current source I_E can be constructed from the output of a current mirror of the type of Fig. 3*a*. If the differential input voltage v_{id} is defined by Eq. (9), then it

$$v_{id} = v_{i1} - v_{i2} \tag{9}$$

can be shown that the differential output voltage v_{od} is given by Eq. (10), where V_T is the thermal voltage

$$v_{od} = \alpha R I_E \tanh \frac{v_{id}}{2V_T} \tag{10}$$

($V_T = 25$ mV at room temperature), α is the parameter alpha (defined above) for the two transistors (which are assumed identical), and tanh[·] is the hyperbolic tangent function. As Eq. (10) shows, the differential pair performs as a differential voltage-controlled voltage source. An MOS differential pair is obtained simply by replacing the bipolar junction transistors in Fig. 4 by MOSFETs, although a somewhat more complicated input-output law results. *See* DIFFERENTIAL AMPLIFIER.

Analog circuits. By replacing the resistive loads of the differential amplifier of Fig. 4 with the current mirror of Fig. 3*b*, a differential voltage-controlled current source (DVCCS) is generated, as shown in **Fig. 5**, where from the above Eq. (11) follows. Since

$$i_o = i_{c2} - i_{c1} = aI_E \tanh \frac{v_{id}}{2V_T} \tag{11}$$

tanh (x) $\simeq x$ when x is very small in magnitude, for small differential inputs the linear law (12) holds.

$$i_0 = \frac{\alpha I_E v_{id}}{2V_T} \tag{12}$$

An application of the differential voltage-controlled current source is seen by connecting its output to a capacitor, in which case an integrator results. Connecting the output of a differential voltage-controlled current source to its input can result in a resistor.

Operational amplifiers. The differential pair forms the input stage to the operational amplifier (op amp), an

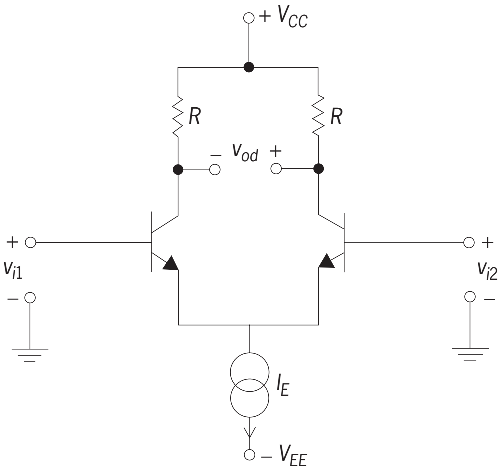

Fig. 4. Differential pair based on bipolar junction transistors.

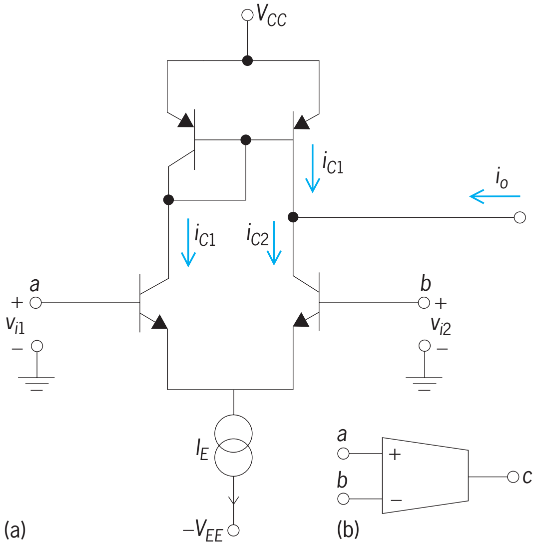

Fig. 5. Differential voltage-to-current converter. (*a*) Circuit. (*b*) Symbol.

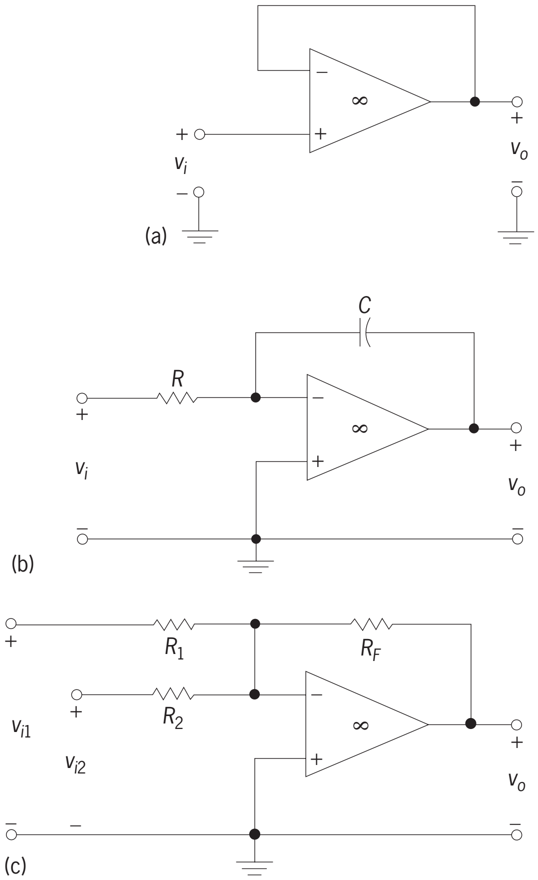

Fig. 6. **Basic operational amplifier circuits. (*a*) Unity-gain (isolation) amplifier. (*b*) Integrator. (*c*) Summer.**

extremely important electronic circuit device. The operational amplifier is typically realized by taking v_{od} of Fig. 4, greatly amplifying it, terminating with an output stage that allows for loading, and improving the input terminals so that miniscule input current is drawn. From this description, it follows that an operational amplifier in the linear region is characterized by the input-output voltage relationship given by Eq. (13), with K tending to infinity. Since v_o is

$$v_o = Kv_{id} \tag{13}$$

finite, this means that either $v_{id} \simeq 0$ or the output is saturated at a bias voltage of the operational amplifier. In either case, for most practical purposes the input current can be assumed to be zero. Therefore, in the linear region the operational amplifier has the very interesting description given by Eq. (14),

$$v_{id} = 0, \quad i_{\text{input}} = 0 \tag{14}$$

in which case its input looks like a simultaneous short and open circuit (while its output can be "anything").

By applying feedback through a direct connection of the output to the negative input, the unity-gain buffer amplifier satisfying Eq. (15) results. The buffer amplifier is shown in **Fig. 6*a***. If the positive input is grounded and negative feedback is applied, then the negative input must be also at ground potential and, since the operational amplifier draws no current, the negative input terminal is said to be a virtual ground. Using the concept of the virtual ground, it is readily seen that the circuit of Fig. 6*b* functions as an integrator, given by Eq. (16), where *s* is the derivative operator (and hence its inverse, 1/*s*, is the integral operator). The circuit of Fig. 6*c* functions as a summer, given by Eq. (17). Using the three circuits of Fig. 6, any set of linear differential equations with constant coefficients can be simulated, and arbitrary transfer functions realized. The operational amplifier is one of the most useful of the electronic circuit devices. *See* ANALOG COMPUTER.

$$v_o = v_i \tag{15}$$

$$v_o = \frac{-v_i}{RCs} \tag{16}$$

$$v_o = -R_F\left(\frac{v_{i1}}{R_1} + \frac{v_{i2}}{R_2}\right) \tag{17}$$

Applying positive feedback in operational amplifier circuits, some interesting results can also be obtained. For example, the circuit of **Fig. 7*a*** is a practical way to obtain a negative resistance; its operation depends on Eq. (18). When the operational amplifier is in its linear region, that is, when notation (19) is valid, Eq. (20) holds, giving the negative resistor equation (21). When the operational amplifier is forced into saturation the behavior of the circuit

$$i = \frac{v - v_o}{R} \tag{18}$$

$$-V_{EE} < v_o < V_{CC} \tag{19}$$

$$v_o = \left(1 + \frac{R_F}{R_1}\right)v \tag{20}$$

$$i = -\left(\frac{R_F}{R_1 R}\right)v \tag{21}$$

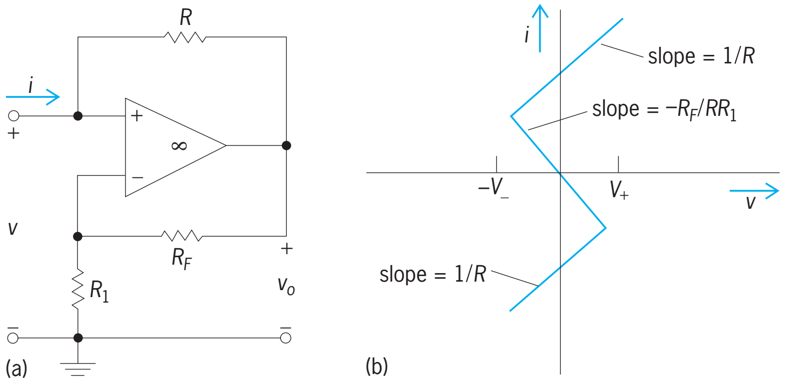

Fig. 7. **Negative resistor circuit. (*a*) Diagram. (*b*) Voltage-current characteristic.**

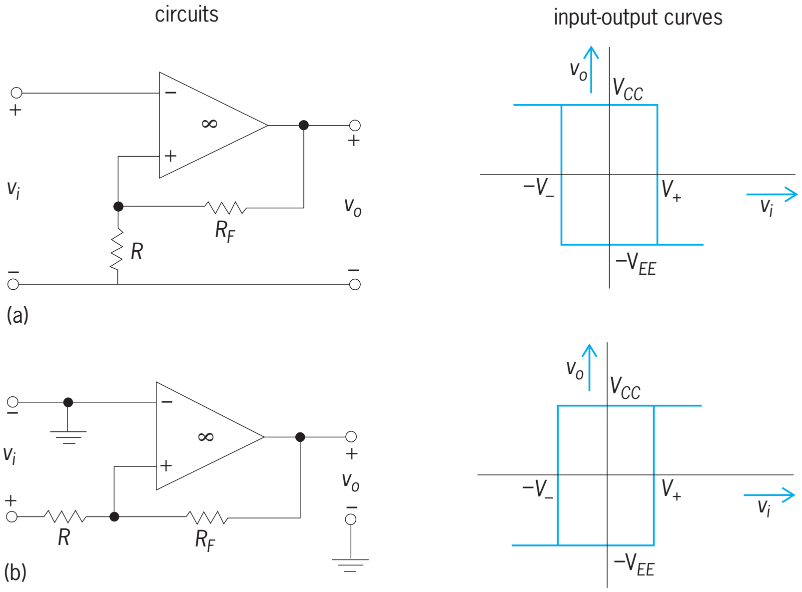

Fig. 8. Schmitt trigger circuits and their input-output curves. (*a*) Circuit with isolated input (negative gain). $V_+ = V_{CC}/[1 + (R_F R)]$; $V_- = V_{EE}/[1 + (R_F R)]$. (*b*) Circuit with coupled input (positive gain). $V_+ = RV_{CC}R_F$; $V_- = RV_{EE}/R_F$.

is given by Eqs. (22) and (23) [Fig. 5]. The resulting

$$i = \frac{v - V_{CC}}{R} \quad \text{when } v < V_+ = \frac{V_{CC}}{1 + (R_F/R_1)} \tag{22}$$

$$i = \frac{v + V_{EE}}{R} \quad \text{when } v > -V_- = -\frac{V_{EE}}{1 + (R_F/R_1)} \tag{23}$$

transfer characteristic is shown in Fig. 7*b*. This negative resistor is multiple-valued when the input voltage v is used as the independent (that is, control) variable. Hence, an attempt to use it as a voltage-controlled device will result in its exhibiting hysteresis, since a switch onto the upper curve occurs at $v = V_+$ whereas a switch off the upper curve occurs at $-V_-$. *See* HYSTERESIS; NEGATIVE-RESISTANCE CIRCUITS; OPERATIONAL AMPLIFIER.

Schmitt triggers. Other circuits exhibiting hysteresis are Schmitt trigger circuits (**Fig. 8**), where positive feedback is again used. In these circuits the output is taken as the operational amplifier output voltage, which saturates at the bias voltages. As shown in the input-output curves of Fig. 8, the Schmitt triggers give binary-valued hysteresis, which makes them useful for storage of binary information or for maintaining a constant output in the presence of noise.

Role of nonlinearity. Since the characteristics of the circuits of Figs. 7 and 8 are very nonlinear, they serve as examples to illustrate that nonlinear theory plays an important role in the area of electronic circuits. There are many other instances where nonlinearities are important, for example, in the construction of analog multipliers where the output is the product of two inputs. (Such a multiplier can be obtained via the differential pair of Fig. 5 if I_E is made to vary with an input. This is achievable by using the current sink of Fig. 3*a* to generate I_E. With this circuit the voltage E becomes the second input.) Likewise, nonlinearities are required in the modern theories of neural networks, where so-called sigmoid-type nonlinearities are used to obtain convergence toward set patterns. (The hyperbolic tangent function realized by the differential pair is a sigmoid-type of nonlinearity.) *See* NEURAL NETWORK.

Filters. One of the most common uses of analog active circuits is in the construction of electrical filters. Electrical filters are circuits whose input-output characteristics allow signals at certain frequencies (called the passband) to pass through unattenuated while signals at unwanted frequencies (called the stopband) are eliminated. By appropriately positioning the passband and the stopband, various filter types such as low-pass, band-pass, and high-pass can be attained. Filter design often concentrates on low-pass filters, since through relatively elementary transformations the band-pass and high-pass responses can be obtained from the low-pass transfer function. The transfer function, $H(s)$, is the ratio of the output v_o to the input v_i as a function of the complex frequency variable s.

Maximally flat filters are common with these resulting from using the Butterworth polynomials, $B_n(s)$, to obtain the low-pass transfer function given by Eq. (24). Here, $B_n(s)$ is given by Eq. (25), where

$$H(s) = 1/B_n(s) \tag{24}$$

$$B_n(s) = (s - s_1) \cdot \ldots \cdot (s - s_n) \tag{25}$$

$s_1, \ldots, s_n$ are the 2nth roots of $(-1)^{n+1}$ with negative real parts. As a function of frequency, f, the magnitude of the transfer function satisfies Eq. (26), so

$$|H(j2\pi f)| = \frac{1}{[1 + (2\pi f)^{2n}]^{1/2}} \tag{26}$$

that it is equal to 1 at dc and to $1/\sqrt{2}$ at $f = 1/2\pi$ [termed the 3-decibel attenuation point]. The substitution of Eq. (27) shifts the 3-dB point to the frequency $\Omega/(2\pi)$; the substitution of Eq. (28) changes

$$s = \frac{S}{\Omega} \tag{27}$$

$$s = \frac{\Omega}{S} \tag{28}$$

the low-pass characteristic to high-pass. The substitution of Eq. (29) leads to a band-pass characteristic

$$s = \Omega_o \left(\frac{S}{\Omega} + \frac{\Omega}{S} \right) \tag{29}$$

(with Ω_o adjusting the bandwidth and Ω adjusting the center frequency).

Since the complex frequency variable s also serves as the derivative operator, a description of the filter in terms of differential equations can be obtained from the transfer function. One way these differential equations can be realized is with the electronic circuits of Fig. 6. Alternatively, the transfer function can be realized by specialized circuits created for the purpose of filtering. Indeed, because of the importance of filters to technology, their theory is extensive, and vast tables of filter transfer functions and circuits to realize them have been compiled. *See* ELECTRIC FILTER.

Digital circuits. The digital computer is based on digital electronic circuits. Although some of the circuits are quite sophisticated, such as the microprocessors integrated on a single chip, the concepts behind most of the circuits involved in digital computers are quite simple compared to the circuits used for analog signal processing. The most basic circuit is the inverter; a simple realization based upon the MOS transistor is shown in **Fig. 9***a*. The upper (depletion-mode) transistor acts as a load "resistor" for the lower (enhancement-mode) transistor, which acts as a switch, turning on (into its resistive region) when the voltage at point *A* is above threshold to lower the voltage at point *B*. Adding the output currents of several of these together into the same load resistor gives a NOR gate, a two-input version of which is shown in Fig. 9*b*; that is, the output is high, with voltage at V_{DD}, if and only if the two inputs are low. Placing the drains of several of the enhancement-mode switches in series yields the NAND gate, a two-input version of which is shown in Fig. 9*c*; that is, the output is low if and only if both inputs are high. From the circuits of Fig. 9, the most commonly used digital logic circuits can be constructed. Because these circuits are so simple, digital circuits and digital computers are usually designed on the basis of negation logic, that is, with NOR and NAND rather than OR and AND circuits. *See* DIGITAL COMPUTER; INTEGRATED CIRCUITS; MICROPROCESSOR.

Conversion. Because most signals in the real world are analog but digital computers work on discretizations, it is necessary to convert between digital and analog signals. As mentioned above, this is done through digital-to-analog and analog-to-digital converters. Most approaches to digital-to-analog conversion use summers of the type shown in Fig. 6*c*, where the voltages representing the digital bits are applied to input resistors, either directly or indirectly through switches gated on by the digital bits which change the input resistance fed by a dc source (as is the case in the R-to-2R type of analog-to-digital converters).

One means of doing analog-to-digital conversion is to use a clocked counter that feeds a digital-to-analog converter, whose output is compared with the analog signal to stop the count when the digital-to-analog output exceeds the analog signal. The counter output is then the analog-to-digital output. The comparator for such an analog-to-digital converter is similar to an open-loop operational amplifier (which changes saturation level when one of the differential input levels crosses the other). Other types of analog-to-digital converters, called flash converters, can do the conversion in a shorter time by use of parallel operations, but they are more expensive.

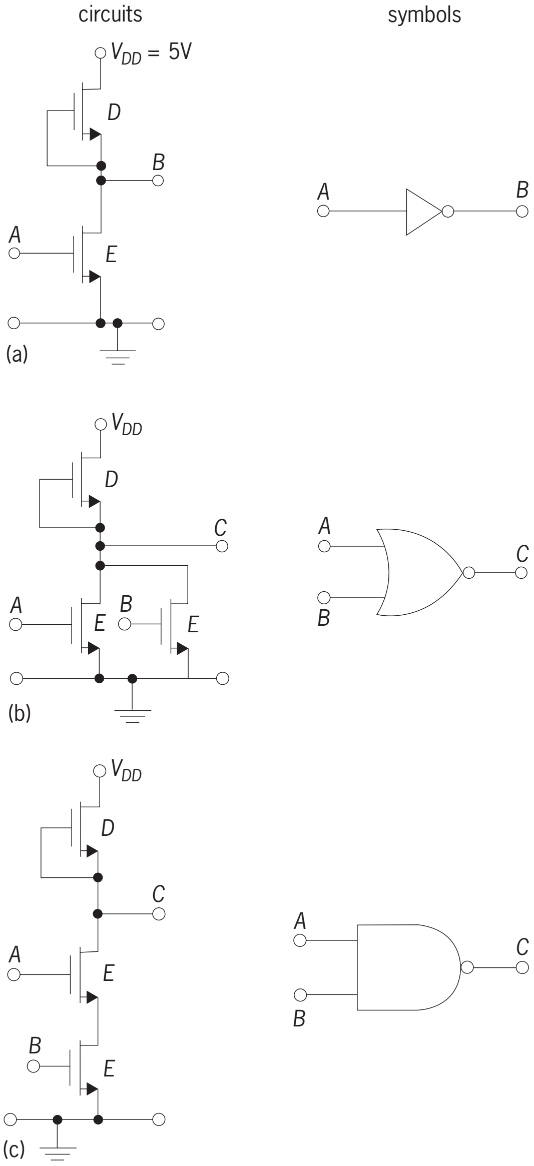

Fig. 9. Digital logic gates and their symbols. *D* = depletion-mode transistor; *E* = enhancement-mode transistor. (*a*) Inverter. (*b*) NOR gate. (*c*) NAND gate.

Other circuits. The field of electronic circuits is very broad and there are a very large number of other circuits besides those discussed above. For example, the differential is a key element in operational amplifier design and in biomedical data acquisition devices which must also be interfaced with specialized electronic sensors. Light-emitting and -detecting diodes allow for signals to be transmitted and received at optical frequencies. Liquid crystals are controlled by electronic circuits and are useful in digital watches, flat-panel color television displays, and electronic shutters. *See* BIOMEDICAL ENGINEERING; ELECTRONIC DISPLAY; LIGHT-EMITTING DIODE; LIQUID CRYSTALS; OPTICAL DETECTORS; TRANSDUCER.

Design

Because some circuits can be very complicated, and since even the simplest circuits may have complicated behavior, the area of computer-aided design

(CAD) of electronic circuits has been extensively developed. A number of circuit simulation programs are available, some of which can be run on personal computers with good results. These programs rely heavily upon good mathematical models of the electronic devices. Fortunately, the area of modeling of electronic devices is well developed, and for many devices there are models that are adequate for most purposes. But new devices are constantly being conceived and fabricated, and in some cases no adequate models for them exist. Thus, many of the commerical programs allow the designer to read in experimentally obtained data for a device from which curve fitting techniques are used to allow an engineer to proceed with the design of circuits incorporating the device. Reproducibility and acceptability of parts with tolerances are required for the commerical use of electronic circuits. Consequently, theories of the reliability of electronic circuits have been developed, and most of the computer-aided design programs allow the designer to specify component tolerances to check out designs over wide ranges of values of the elements. Finally, when electronic circuits are manufactured they can be automatically tested with computer-controlled test equipment. Indeed, an area that will be of increasing importance is design for testability, in which decisions on what to test are made by a computer using knowledge-based routines, including expert systems. Such tests can be carried out automatically with computer-controlled data-acquisition and display systems. *See* CIRCUIT (ELECTRICITY); COMPUTER-AIDED DESIGN AND MANUFACTURING; EXPERT SYSTEMS; RELIABILITY, AVAILABILITY, AND MAINTAINABILITY; ROBOTICS. Circuit breaker

A device to open or close an electric power circuit either during normal power system operation or during abnormal conditions. A circuit breaker serves in the course of normal system operation to energize or deenergize loads. During abnormal conditions, when excessive current develops, a circuit breaker opens to protect equipment and surroundings from possible damage due to excess current. These currents are usually the result of short circuits created by lightning, accidents, deterioration of equipment, or sustained overloads. *See* CIRCUIT (ELECTRICITY); LIGHTNING AND SURGE PROTECTION.

Formerly, all circuit breakers were electromechanical devices. In these breakers a mechanism operates one or more pairs of contacts to make or break the circuit. The mechanism is powered either electromagnetically, pneumatically, or hydraulically. The contacts are located in a part termed the interrupter. When the contacts are parted, opening the metallic conductive circuit, an electric arc is created between the contacts. This arc is a high-temperature ionized gas with an electrical conductivity comparable to graphite. Thus the current continues to flow through the arc. The function of the interrupter is to extinguish the arc, completing circuit-breaking action.

Current interruption. In alternating-current circuits, arcs are usually extinguished at a natural current zero, when the ac voltage applied across the arcing contacts reverses polarity. Within a short period around a natural current zero, the power input to the arc, equal to the product of the instantaneous current and voltage, is quite low. There is an opportunity to remove more energy from the arc than is applied to it, thus allowing the gas to cool and change from a conductor into an insulator. *See* ALTERNATING CURRENT.

In direct-current circuits, absence of natural current zero necessitates the interrupter to convert the initial arc into one that could only be maintained by an arc voltage higher than the system voltage, thus forcing the current to zero. To accomplish this, the interrupter must also be able to remove energy from the arc at a rapid rate. *See* DIRECT CURRENT.

Different interrupting mediums are used for the purpose of extinguishing an arc. In low- and medium-voltage circuits (1110–15,000 V) the arc is driven by the magnetic field produced by the arc current into an arc chute (**Fig. 1**). In the arc chute the arc is either split into several small arcs between metal plates or driven tightly against a solid insulating material. In the former case the splitting of the arc increases the total arc voltage, thus increasing the rate of energy dissipation. In the latter case the insulating material is heated to boiling temperatures, and the evaporated material flows through the arc, carrying a great deal of energy with it.

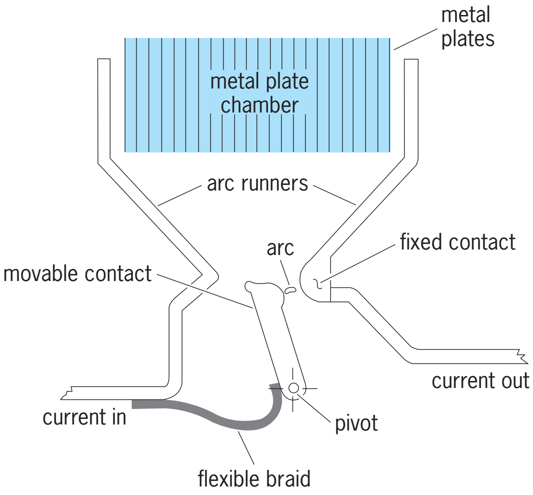

Fig. 1. Cross section of interrupter for a typical medium-voltage circuit breaker.

Oil and gas-blast circuits. For outdoor applications at distribution and subtransmission voltage (10 kV and above), oil breakers are widely used. In the United States, bulk oil breakers are used (**Fig. 2**), and in European and many other countries, "low-oil-content" breakers are quite popular. The principles of operation of both kinds of oil breakers are basically the same. Only the amount of oil used and the detailed engineering design differ. In oil breakers, the arc is drawn in oil. The intense heat of the arc decomposes the oil, generating high pressure that produces a fluid flow through the arc to carry energy away. At transmission voltages below 345 kV, oil breakers used to be popular. They were, however, increasingly replaced by gas-blast circuit breakers such as air-blast breakers (**Fig. 3**) and sulfur hexafluoride (SF_6) circuit breakers (**Fig. 4**).

In air-blast circuit breakers, air is compressed to high pressures (approximately 50 atm $= 5 \times 10^6$ pascals). When the contacts part, a blast valve is opened to discharge the high-pressure air to ambient, thus creating a very high-velocity flow near the arc to dissipate the energy. In SF_6 circuit breakers, the same principle is employed, with SF_6 as the medium instead of air. In the "puffer" SF_6 breaker, the motion of the contacts compresses the gas and forces it to flow through an orifice into the neighborhood of the arc. Both types of SF_6 breakershave been developed

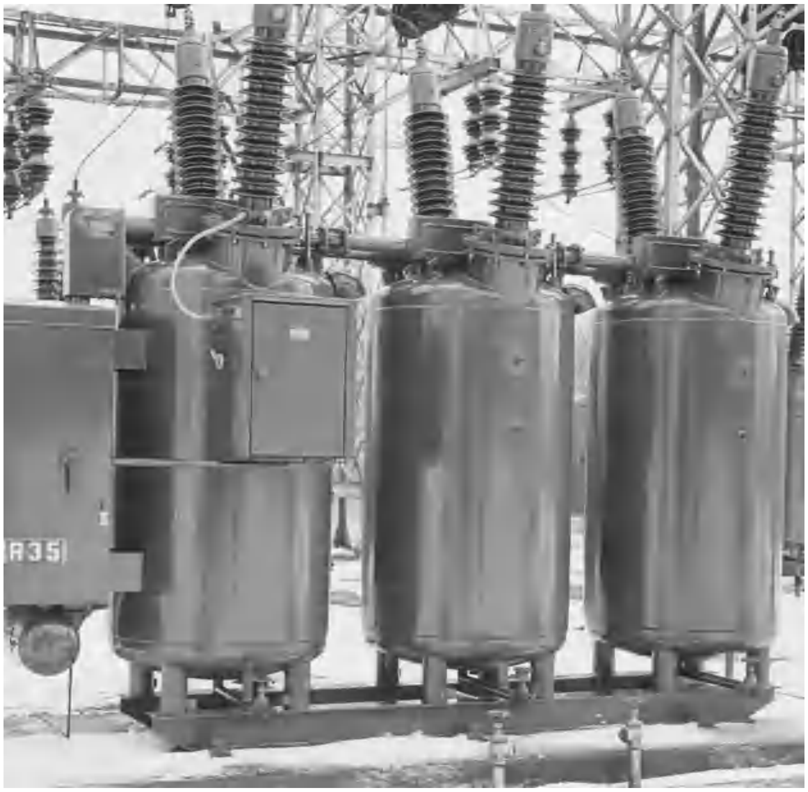

Fig. 2. Bulk oil circuit breaker for 138-kV application.

Fig. 3. Air blast circuit breaker rated for 500 kV.

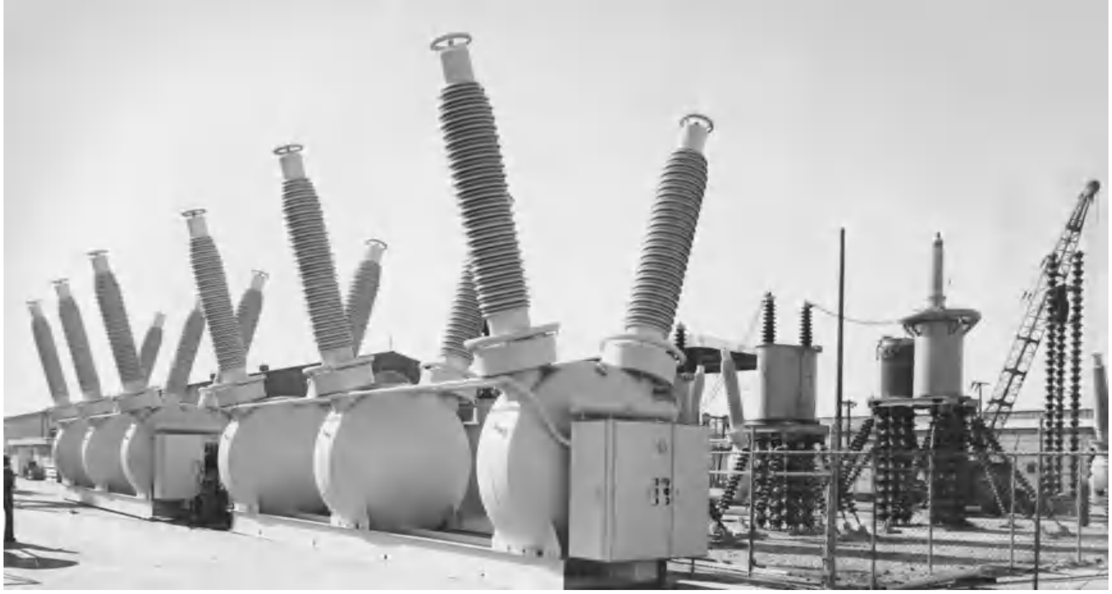

Fig. 4. Sulfur hexafluoride circuit breakers, 500-kV, 3-kA.

for EHV (extra-high-voltage) transmission systems.

For EHV systems, it was discovered that closing of a circuit breaker may cause a switching surge which may be excessive for the insulation of the system. The basic principle is easy to understand. If a breaker is closed at the peak of the voltage wave to energize a single-phase transmission line which is open-circuited at the far end, reflection can cause the transient voltage on the line to reach twice the peak of the system voltage. If there are trapped charges on the line, and if it happens that at the moment of breaker-closing the system voltage is at its peak, equal in magnitude to but opposite to the polarity of the voltage due to the trapped charges left on the line, the switching surge on the line can reach a theoretical maximum of three times the system voltage peak.

One way to reduce the switching surge is to insert a resistor in series with the line (**Fig. 5**) for a short time. When switch A in Fig. 5 is closed, the voltage is divided between the resistance and the surge impedance Z of the line by the simple relationship $V_L = V[Z/(R + Z)]$, where V is voltage impressed, V_L is voltage across the transmission line, R is resistance of the resistor, and Z is surge impedance of the line. Only V_L will travel down the line and be reflected at the other end. The magnitude of the switching surge is thus considerably reduced.

Vacuum breakers. The vacuum breaker, another electromechanical device, uses the rapid dielectric recovery and high dielectric strength of vacuum. A pair of contacts is hermetically sealed in a vacuum envelope (**Fig. 6**). Actuating motion is transmitted through bellows to the movable contact. When the contacts are parted, an arc is produced and supported by metallic vapor boiled from the electrodes. Vapor particles expand into the vacuum and condense on solid surfaces. At a natural current zero the vapor particles disappear, and the arc is extinguished. Vacuum breakers of up to 242 kV have been built (**Fig. 7**).

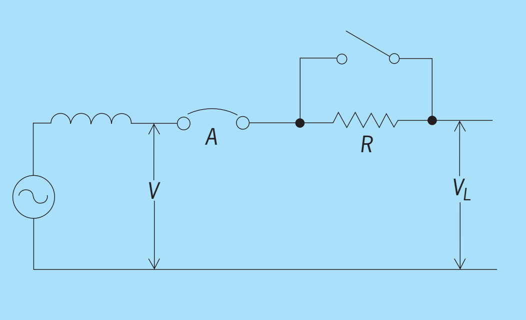

Fig. 5. Resistor insertion to reduce switching surge.

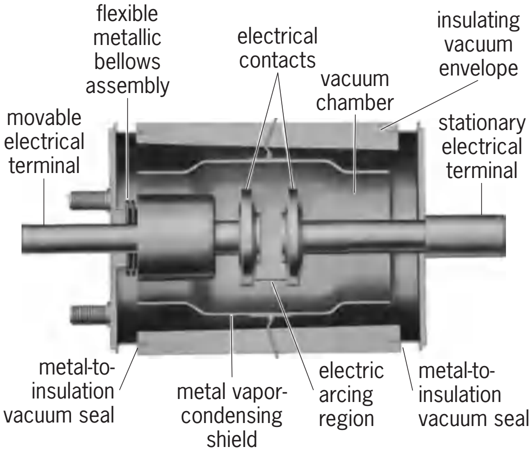

Fig. 6. Cutaway view of vacuum interrupter.

Solid-state breakers. The other type of breaker uses a thyristor, a semiconductor device which in the off state prevents current from flowing but

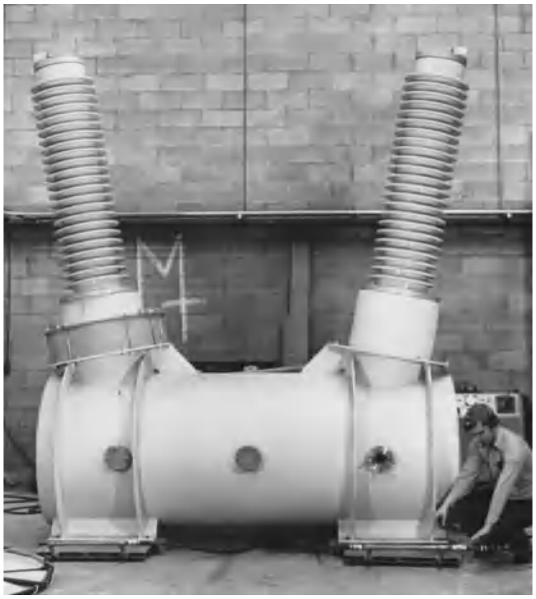

Fig. 7. Vacuum circuit breaker, 242-kV, 40-kA.

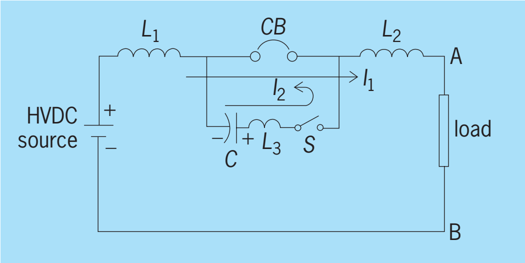

Fig. 8. Commutation principles of circuit interruption.

which can be turned on with a small electric current through a third electrode, the gate. At the natural current zero, conduction ceases, as it does in arc interrupters. This type of breaker does not require a mechanism. Semiconductor breakers have been built to carry continuous currents up to 10,000 A.

Semiconductor circuit breakers can be made to operate in microseconds if the commutation principle is applied. **Figure 8** illustrates the commutation principle for an hvdc (high-voltage direct-current) circuit, but it can easily be extended to ac circuits. During normal operation, the circuit breaker (CB in the diagram) would be closed from the hvdc source. In this diagram, inductances L_1 and L_2 represent the circuit inductance on either side of the breaker. Suppose that a fault occurs which applies a short circuit between points A and B. The current will commence to increase, its rate being determined by L_1 and L_2. When the increased current is detected, the contacts of the circuit breakers are opened, drawing an arc, and the switch (S in the diagram) is closed, causing the precharged capacitors C to discharge through the circuit breaker. The current I_2 so produced is traveling in such a direction as to oppose I_1 and drive it to zero, thereby giving the circuit breaker an opportunity to interrupt.

Thyristors can be used for both circuit breakers and switches. The closing and opening operations are, of course, not mechanical but are controlled by the gates. Such a circuit breaker was built for very special switching applications, such as thermonuclear fusion research. Thomas H. Lee

Circulation

Those processes by which metabolic materials are transported from one region of an organism to another. Ultimately, the essential gases, nutrients, and waste products of metabolism are exchanged across cell membranes by diffusion. Diffusion is the movement of material, by random motion of molecules, from a region of high concentration to one of low concentration. The amount of material moved from one place to another depends on the difference in concentrations and on the distance between the two points. The greater the distance, the less movement of material per unit time for a given difference in concentration. Consequently, in all but the smallest animals, convection (or bulk circulation) of materials to the cell must be employed to supplement diffusion.

Protoplasmic movement aids diffusion at the intracellular level. In multicellular animals, however, either the external medium or extracellular body fluids, or both, are circulated. In sponges and coelenterates (**Fig. 1***a* and *b*), water is pumped through definite body channels by muscular activity or, more often, by cilia or flagella on the cells lining the channels. Even external water currents can be tapped for this purpose. It is generally assumed that flows driven by these mechanisms will be slow. However, this may not be the case.

In sponges, flow driven by flagella in flagellated chambers enters through pores in the body wall and exits through the large central osculum. The cross-sectional area of all the flagellated chambers is approximately 6000 times that of the osculum. Hence, the exceptionally low flow velocity in the flagellated chambers increases markedly as the total volume of water is forced out through the osculum. In fact, water may flow through the osculum at velocities of 5 cm · s^{-1}, approaching those attained in major arterial vessels in vertebrates. This is an example of the principle of continuity, which states that the total volume of fluid moving past any point in a circulation (providing it has no major leaks) must be the same as that flowing past any other point. In regions of large cross-sectional area, the velocity of flow is low, whereas when cross-sectional area is small the flow velocity will be high.

Coelenterates have a body wall derived from two cell layers; an outer ectoderm is separated from an inner endoderm by a noncellular gelatinous

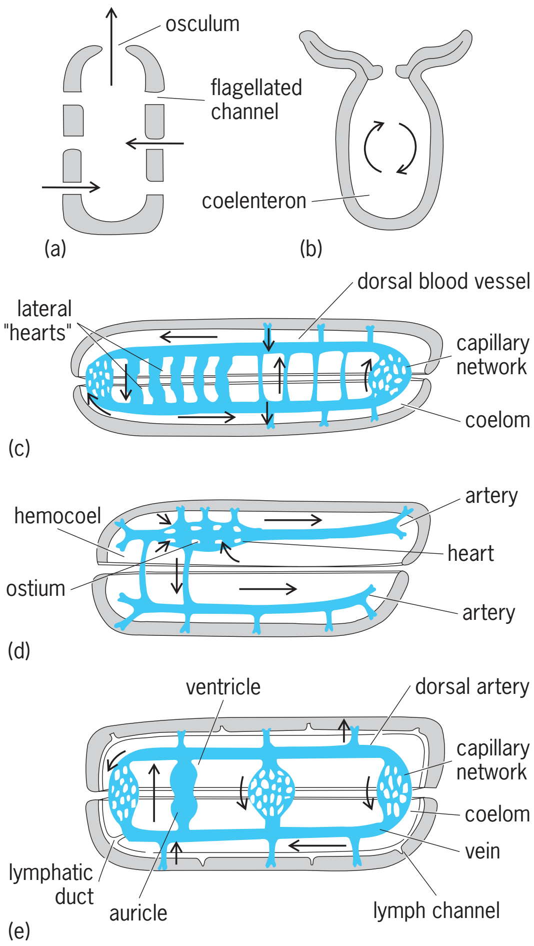

Fig. 1. Systems of internal transport. (*a*) Sponge type, with flagellated channels. (*b*) Coelenterate type. (c) Oligochaete type, with coelom and closed blood system. (*d*) Crustacean-molluscan type, with blood system open to hemocoel which is derived from primary cavity or blastocoel. (*e*) Vertebrate type, with coelom, closed vascular system, and lymphatic channels. (*After C. L. Prosser*, *Comparative Animal Physiology*, 3d ed., *W. B. Saunders*, *1973*)

material (mesoglea). All higher animals have bodies consisting of three cell layers, with the ectoderm being separated from the endoderm by a cellular layer of mesoderm. The mesoderm proliferates and separates to develop a fluid-filled body cavity or coelom. The coelom separates the ectoderm (together with an outer layer of mesoderm) from the endoderm (which has an inner layer of mesoderm). Coelomic fluid is moved around by body movements or ciliary activity, but in larger animals this movement is usually inadequate to supply the metabolic requirements of the organs contained within the coelom. These needs are provided for by pumping a fluid, blood, to them through vessels, the blood vascular system (Fig. 1*c*–*e*).

Open and Closed Circulatory Systems

When the blood is in a separate compartment from the rest of the extracellular fluid, the vascular system is described as closed. In such a system, the blood is circulated by a pump, the heart, through special channels, blood vessels; it comes into close association with the tissues only in the capillaries, fine vessels with walls only one cell thick. In some tissues or regions, larger blood spaces may exist, called sinuses. A closed vascular system is found in most annelids (segmented worms and leeches), cephalopod mollusks (squids and octopods), holothurian echinoderms (sea cucumbers), and vertebrates (Fig. 1*c* and *e*).

In most vertebrates, a functional but anatomically closed connection exists between the extracellular spaces (between the cells) and the blood vascular system in the form of lymph channels. Lymph is derived from the noncellular component of blood (plasma), modified in its passage through the tissues, and is picked up by blind-ending lymphatic vessels, which conduct the lymph to the veins (Fig. 1*e*). The presence of a lymphatic system in fish is controversial. In many fishes, a secondary circulation exists which parallels the primary circulation in extent and connects to it by narrow channels, which are small enough to exclude most red blood cells from the secondary circulation. It is unlikely that the secondary circulation is the evolutionary forerunner of a true lymphatic system, which is first observed in lungfishes, or that the secondary circulation subserves the same function as a true lymphatic system.

In most arthropods (crustaceans, insects), most mollusks (shellfish), and many ascidians (sea squirts), the extracellular spaces are confluent with the blood system. In these animals, blood is pumped through a limited network of vessels into a body cavity called a hemocoel (Fig. 1*d*). After bathing the tissues, blood (called hemolymph in these organisms) collects in sinuses and returns to the heart. This is the open vascular system. In animals with open circulatory systems, the coelom is much reduced.

Dynamics

A pump is required to circulate the blood in animals. The pump (usually called a heart) imparts propulsive energy to the blood, which flows from regions of high fluid energy to regions of low fluid energy (or down an energy gradient). The total energy of flowing blood consists of pressure energy, imparted by the pump, and energy contained in blood due to its motion (kinetic energy). Even in mammals, where blood flows very rapidly, the kinetic energy component is small compared with pressure energy and is usually ignored. Consequently, it is usual to refer to blood flow as taking place down a pressure gradient rather than energy gradient.

As the blood courses around the circulatory system, pressure energy is lost as heat. This loss of energy is described as resistance to flow. In closed circulations, flow resistance is concentrated in short narrow regions of blood vessels, known as resistance vessels. These are fine vessels (diameter of 0.02 mm), and since they have a muscular coat they are able to change their diameter to regulate flow. However, it is not the friction between the wall and blood that causes energy dissipation but rather friction between the various layers of the flowing blood (internal friction or viscosity). Blood flow in tubes is streamlined; the layer of blood at the wall is stationary while that in the middle flows fastest. Hence, slower-moving layers close to the wall tend to slow down and stop faster-moving layers, while they, in turn, will try to speed up slower-flowing layers. It is this internal friction which must be overcome by flowing blood, and the higher the viscosity of the fluid, the more energy will be dissipated in doing this. For instance, it takes much more effort to force treacle (a high-viscosity fluid) than water, at the same flow rate, through the same-diameter pipe. Blood is also much thicker (or more viscous) than water.

In a closed circulation, the total peripheral resistance (*R*) can be expressed by the equation below,

$$R = \frac{P_1 - P_2}{Q}$$

in which P_1 = pressure in the outflow vessels of the heart, P_2 = pressure in the inflow vessels, and Q = the output of a single propulsive chamber (ventricle). This equation is a simplified form of a formula used to describe flow in tubes (Poiseuille's law) and is a direct analog of Ohm's law for the relationship between electrical potential difference (pressure gradient), current (flow), and resistance. The resistance of the vascular system will depend on its geometry, as well as the viscosity of the fluid. Of the geometric factors, the radius of the tubes is far more important than length because only the radius is a variable in the circulation. In fact, flow per unit time changes in proportion to the fourth power of the radius for a given fall in pressure along the vessel. Hence, in the resistance vessels, halving the radius by muscular contraction will reduce flow to one-sixteenth of what it was before for the same pressure gradient.

In open circulations, the concept of total peripheral resistance cannot apply. Certainly, the pump imparts propulsive energy to the blood which is dissipated, due to viscous losses, as the blood courses through the hemocoel. But a pressure difference between the outflow and inflow vessels of the heart can, at best, indicate only the resistance of the major shunts in the circulation. A shunt is a short circuit between the outflow and inflow vessels. In the simplest possible case, when the pump sits in the hemocoel and there are no blood vessels, the heart activity only stirs the blood, and pressure differences across the heart are mostly a reflection of its filling and emptying mechanisms.

Physiology of Open and Closed Systems

In open blood systems, there is no separation between extracellular fluid and blood, so the total volume of hemolymph in these animals is large (up to 40% of the body weight). In closed circulations, blood is separated from fluid around the cells, and blood volume is much smaller, about 5–10% of the body weight. In both open and closed systems, blood is conveyed directly to the organs, but only in closed systems can its distribution be regulated with any precision. The best that can be done to facilitate the normal functioning of open circulations is to regulate hemolymph flow to a particular region by opening or closing valves of the junction of the major arteries and the heart.

On the outflow side of the pump (arterial side), closed vascular systems are effectively overfilled with blood, and the elastic blood vessel walls bear down on their contained volume and maintain a high pressure, even when the pump is in the filling phase (diastole). The arterial system is "topped up" again with each ejection of the pump (systole). Obviously, blood pressure can be maintained only if rapid escape of blood from the arteries is prevented by having a high resistance to flow in the periphery of the circulation. As a consequence, almost continuous blood flow is provided to the tissues by the elastic recoil of the stretched arterial walls during diastole. In open systems, peripheral flow resistance is low, as are the pressures generated in these systems. Furthermore, pressures in the outflow vessels of the pump will be highly pulsatile, reaching a peak in systole (the pump-ejection phase) and perhaps falling to zero in diastole (the pump-filling phase). Likewise, flow will be extremely pulsatile, often stopping between heartbeats.

In both open and closed circulatory systems, the volume of blood pumped by the heart must be the same volume as returns to the heart in any given time period. However, only in closed circulations does this have important consequences with regard to the rate at which blood flows through the vessels in the various regions of the vascular system. The velocity of blood flow at any part of a closed system depends on the cross-sectional area of the vessels in that part. Since the vessels that arise from or join to the heart must necessarily be about the same size, flow velocity in the veins is almost as rapid as in the arteries. Furthermore, since the cross-sectional area of the vessels within all the tissues is many times greater than vessels leaving the heart, the flow in the tissue vessels is very slow (usually less than $1\ \mathrm{mm} \cdot \mathrm{s}^{-1}$), allowing plenty of time for exchange across cell walls.

Components of Circulatory Systems

The two principal components of all circulatory systems are hearts and blood vessels.

Hearts. The circulatory pumps are the hearts, all of which operate by causing a wave of muscular contraction followed by a wave of relaxation (peristaltic wave) to travel over the walls of a tube. When the muscle contracts, the volume is reduced and fluid contents are expelled.

Tubular heart. If the heart persists in adult animals as a tube, such as the dorsal vessel of annelids or the dorsal heart of insects (**Fig. 2*b***), it is called a tubular heart. The peristaltic wave passes along the tube in an anterior direction, pushing the blood before it in the same way the air in a balloon is squeezed down to one end by pulling the balloon through a cupped hand. Therfore, valves are unnecessary to ensure unidirectional flow of blood. In earthworms, the peristaltic waves travel up the dorsal vessel at

rates of 2–4 cm · s^{-1} about 10 times each minute. Vessels in the gills of hagfishes and octopods also contract rhythmically and propel the blood.

Multiple and chambered hearts. In the majority of animals, the zone of propulsive activity is restricted to a localized region. Some animals have many hearts: earthworms have five pairs of lateral hearts connecting the dorsal and ventral vessels (Fig. 2*e*); octopods and squids have hearts which boost blood flow through the gas exchanger (gills) in addition to a main or central heart (Fig. 2*f*); sea cucumbers may have over 150 hearts between dorsal and ventral vessels (Fig. 2*i*). However, many animals have only one heart, and in order to pump a volume equivalent to that pumped by a long contractile vessel, the lumen is greatly enlarged and usually divided into a number of chambers (chambered heart). To ensure undirectional flow of blood, chambered hearts require one-way valves. Valves are flaps of tissue situated around the edges of orifices between heart chambers or in vessels.

Contractile chambers. The more powerful the heart muscle becomes, the faster the blood can be driven into the outflow vessels, but filling the heart then requires a greater force. In vertebrates, there is often enough energy in the fast-flowing venous blood to do this, but other chambers may be necessary to fill the main propulsive chamber (or ventricle) in stages. These chambers are auricles and must have sufficiently thin walls to be expanded by the energy of the inflowing blood, yet must be powerful enough to fill the ventricle when they contract.

Most animals with chambered hearts have a single auricle, but in mollusks there is one for each pair of gills, so there may be from one to four (Fig. 2*f* and *h*). Fishes have a single auricle, but in amphibians the auricle is divided into two atria. In birds and mammals, the ventricle is divided, giving two separate circulations: one to the body and the other to the lungs. Fishes and amphibians have an extra contractile chamber, the sinus venosus, which fills the auricle when it contracts. Elasmobranchs and amphibians also have an extra contractile chamber on the ventricular outflow pathway, the conus arteriosus. Its role has not been established, but it could be in actively closing the outflow valves of the heart.

All vertebrate hearts, and many in invertebrates (such as mollusks and arthropods; Fig. 2*f* and *g*), are enclosed in a small portion of the coelom called the pericardial cavity. This cavity is fluid-filled and serves to prevent the heart from being buffeted by other body organs, but it can also aid in returning blood to the heart. If the pericardial wall is rigid, as in elasmobranchs and most mollusks and crustaceans, one chamber of the heart cannot contract unless another is expanding. If the ventricle starts to contract, the reduction in volume will tend to increase the volume of the pericardial cavity, and since it has rigid walls, the pressure inside it will be reduced. This suction pressure is transmitted through the thin auricular wall and draws blood in from outside the pericardium. This mechanism ensures successful filling of the heart even in open blood systems.

In tubular hearts, blood will tend to be sucked into the lumen when the muscle relaxes behind the wave of contraction. It has even been suggested that the major function of the dorsal contractile vessel in annelids is to prime the lateral hearts with blood. In insects, the tubular heart is suspended by alary or aliform muscles attached to the external skeleton, and when these contract the expansion of the lumen sucks blood through valved openings (ostia) into the heart (Fig. 2*b*).

Electrophysiology. The wave of contraction which passes across the heart is driven by an electrical impulse (action potential) which arises spontaneously, either in modified heart muscle cells, or in special nerve cells located on or near the heart. These cells form the pacemaker, which sets the heart rhythm. When nerve cells initiate the heartbeat, the pacemaker is called neurogenic. A pacemaker of muscle cells is called myogenic. Myogenic pacemakers are found in vertebrates, mollusks, echinoderms, and perhaps in some annelids. Neurogenic pacemakers are found in most arthropods. Many hearts have more than one pacemaker. In tunicates, the tubular heart pumps into the open circulation in two directions. After several hundred beats the rhythm slows and stops, and the direction of the wave of contraction reverses when the heart starts up again. Consequently, the tunicate heart must have at least two pacemakers. In frogs, heart contraction can be driven by electrical impulses arising in the sinus venosus, atria, or ventricle. Usually the sinus pacemaker beats fastest and drives all the others.

In birds and mammals, the heart is large and generates high pressures. To prevent the pressure set up by the contraction of one part of the heart from stretching, and perhaps rupturing, the relaxed part, all of the ventricular muscle must be activated simultaneously. This is achieved by conveying the electrical impulse to all parts of the ventricle through specialized conduction pathways composed of modified muscle cells. *See* CARDIAC ELECTROPHYSIOLOGY.

Chemical and mechanical excitation. Many hearts are innervated by nerves which regulate the beat. When these nerves are active, they liberate chemicals such as noradrenalin or acetylcholine from their terminals, and these neurotransmitters affect the cardiac muscles directly. In general, the pacemaker of myogenic hearts is inhibited by acetylcholine; excitation is produced by noradrenaline (vertebrates) or serotonin (mollusks). In neurogenic hearts, gamma aminobutyric acid (GABA) is inhibitory, whereas glutamic acid is excitatory. Neurotransmitters affect not only the rate but also the strength of cardiac contraction. For example, noradrenaline increases the amount of blood pumped by a single ventricle (stroke volume) while acetylcholine decreases stroke volume. *See* ACETYLCHOLINE; ENDOCRINE MECHANISMS.

Mechanical factors may also affect rate and strength of heart contraction. In earthworms, mollusks, and some fishes, stretching the pacemaker region of the myocardium increases its rhythm. Moreover, in all vertebrates, and probably in all mollusks as well, the length of the muscle fibers in the heart at the end of diastole is directly proportional to the strength of the next muscle contraction (Starling's law of the heart).

Many animals, both vertebrate and invertebrate, take advantage of muscular activity in the body, such as during exercise, as an aid to circulation of the blood. In vertebrates, valved thin-walled veins run through blocks of skeletal muscle and are compressed when the muscle contracts, squeezing blood toward the heart (muscle pump). In other animals, the blood functions directly in locomotion. Spiders have no leg extensor muscles, so leg extension is brought about by forcing hemolymph into the leg at high pressure (50 kilopascals), which is generated by the contraction of lateral cephalothoracic muscles depressing the carapace. Backflow into the abdominal heart (which can generate pressures of only 13 kPa) is prevented by valves on the outflow vessels at the junction of the cephalothorax and abdomen. But there are no valves in the veins, and blood returns rapidly to the abdomen.

Caudal heart. Hagfishes have a unique caudal heart. A longitudinal rod of cartilage separates two chambers, and when body muscles on one side contract, the rod is bent to that side. The bend in the rod causes the volume of the chamber on the actively contracting side to expand so that it fills with blood, while the volume of the chamber on the other side is decreased, expelling blood. Valves at the inflow and outflow ends of the chambers ensure unidirectional flow of blood. *See* HEART (INVERTEBRATE); HEART (VERTEBRATE).

Blood vessels. Blood ejected from the heart is conveyed by vessels which are usually called arteries or aortas. In some animals, structural differences between outflow and inflow vessels are not obvious, and they are usually referred to simply as blood vessels. In closed systems, the arteries (outflow vessels) divide and subdivide so that ultimately tubes only a few micrometers thick (capillaries) run between the cells of each organ.

Capillaries. In vertebrates, each capillary consists of a single layer of endothelial cells surrounded by a basement membrane. In some echinoderms with well-developed circulatory systems (such as holothurians; Fig. 2*i*) capillary structure is similar to that in vertebrates, while in cephalopods (such as the octopus) capillaries are extremely small (1 micrometer in diameter) but are usually more than one cell thick. The total number of capillaries in a vertebrate is large, and in humans it is enormous: over 50 billion in the whole body. Therefore, although each capillary is small the total cross-sectional area of all capillaries is perhaps a thousand times greater than that of the main arterial vessels. Consequently, blood flows very slowly in the capillaries, about one-thousandth of the velocity in the aorta, allowing lots of time for exchange of materials with the cells.

In open circulations, after a greater or lesser number of branchings blood vessels ultimately open to the spaces between the cells. Even so, networks of fine blood pathways may occur, especially in gas-exchange organs, nephridia, and masses of nervous tissue (such as brains or ganglia). In animals with closed circulatory systems, a plexus of fine capillaries brings blood close to the external environment in skin (annelids, frogs), respiratory trees (holothurians), gills (fishes), and lungs. Similar close associations between blood and external media are seen in animals with open circulatory systems (Fig. 2*c* and *d*). For instance, gills of shrimp look similar to those of fish in all but the finest morphological details. Book lungs of spiders are unique structures in which blood is moved across rows of fine air tubes, stacked one on the other, in channels only a few micrometers in width. In insects, air is distributed directly to the body cells by way of the trachea, a system of tubes independent of the circulation. Fine blood channels are lacking in these animals. Nevertheless, the circulation in insects reduces the diffusion distances for metabolites, nutrients, and hormones. Furthermore, in large flying insects it plays an important role in controlling body temperature, particularly in the thoracic region where the large flight muscles are located.

Veins and portal systems. After traversing the capillaries, blood is collected into large vessels which return it to the heart. In cephalopods and vertebrates, these collecting vessels are called veins. In open circulations, channels returning blood to the heart exist, but the pattern of blood flow is less precise than in closed systems. In insects and arachnids, longitudinal membranes impose some direction on blood movement (Fig. 2*b* and *d*).

In many vertebrates, venous blood is transported to another organ (such as the liver or kidney) on its way back to the heart. In these organs the veins divide into a capillary network supplying blood to the tissues at low pressure. This is a portal blood supply, and there are a large number of these in vertebrates. The hepatic portal system occurs in all vertebrates and serves to transport materials from the intestine, where they are absorbed, to the liver, where they are stored (Fig. 2*a*). Another prominent portal system is the renal portal system. It occurs in all vertebrates except mammals, and transports blood from the caudal parts of the body to the kidneys. The function of the renal portal system is not known. *See* KIDNEY; LIVER.

Contraction. Many blood vessels have muscular coats, the muscle cells being rhythmically contractile (myogenic rhythm). Contraction of blood vessels is found in the dorsal and ventral vessels and some capillaries of annelids, in the gill vessels of cephalopods and cyclostomes, and also in the fine vessels leading to the capillary beds in higher vertebrates. In these small vertebrate vessels (called arterioles, with a diameter of 50–200 μm), the muscles are in a continual state of activity, modulating the radius of the vessel and therefore the blood flow. This activity can be altered by nerves, by blood-borne agents such as adrenaline, and also at the local level by changes in the level of tissue metabolites (a fall in oxygen tension in the body tissues causes the muscles to relax).

Aortic elasticity. The aortas (or arteries leaving the heart) are fairly elastic in nearly all animals. In closed circulations, the stroke volume is stored by the elastic distension of the arteries and is fed to the periphery between cardiac ejections. This elastic reservoir (or Windkessel effect) is exemplified by the arterial vessels of vertebrates. In humans, the whole arterial tree participates in producing a Windkessel effect. In contrast, fishes have a very short ventral aorta, and only a very elastic bulb (bulbus cordis) just outside the ventricle provides a pressure reservoir, which smooths blood flow through the gills. Many mollusks with open circulatory systems have a similar elastic expansion of the aortic wall just beyond the ventricle. *See* BLOOD VESSELS.

Evolution of Vertebrate Circulation

The evolution of an organ system which is not preserved in fossils can only be inferred from investigations of extant species. Thus, understanding must always be clouded by uncertainty. For example, a major pattern of increasing complexity, which emerges from comparative studies of circulatory systems, is related in vertebrates to life on land. More promising are investigations of the early stages of development of the heart and circulation. These show that all types of vertebrate circulations can be related to a common ancestral pattern (Fig. 2*a*). The ancestral pattern of circulation in vertebrates is for a ventral heart to pump blood anteriorly in a ventral vessel, connecting to the dorsal vessel through the gas exchanger (gills; Fig. 1*e*). The gills are situated on the high-pressure side of the circulation, and blood flows posteriorly in the dorsal vessel.

Annelid worms exhibit a superficial resemblance to the circulation in the ancestral vertebrate in the pattern of dorsal and ventral vessels (Fig. 1*c*), except that the heart is dorsal, flow in the dorsal vessels is anteriorly directed, and flow in the ventral vessel is posteriorly directed. More important, in most invertebrates the gas exchanger, when it exists as a discrete entity, is on the low-pressure side of the circulation. This arrangement limits metabolic scope, a problem which is solved in large, active invertebrates (such as cephalopods) by the development of high-pressure, prebranchial hearts.

Apparently, the chordate stock arose from ancestors in common with primitive echinoderms, a group with a very poorly developed circulation. Hence, the apparent similarities between the circulations in vertebrates and invertebrates are superficial and presumably arose as an evolutionary response to similar physiological demands. This is an example of convergent evolution due to common selection pressures, the circulatory systems in vertebrate and invertebrate groups being analogous rather than homologous. *See* CARDIOVASCULAR SYSTEM. David R. Jones

Circulation disorders

Circulation disorders include both localized disturbances of circulation and diseases of the circulatory system.

Circulatory system. The function of the circulatory system is to transport and distribute substances either used or produced by cells or both. Excluded are those materials that are discharged directly from sweat glands, digestive glands, and renal tubule cells. Included, however, are nutritive and metabolic substances, hormones, waste products, water, and heat.

The circulating fluids are distributed between the heart, blood vessels, capillaries, intercellular spaces and lymphatics and within the cells. The blood and body fluids are in a constant state of dynamic equilibrium (see **illus.**). Blood flows through the vessels to the capillaries where some fluid passes through the endothelium to the intercellular spaces to bathe the cells. Fluid with contained electrolytes and metabolic substances can then pass into and out of the cells. At the distal end of the capillaries most of this fluid passes back into the vascular compartment. A portion of this fluid is returned to the circulation by way of the lymphatics. *See* CARDIOVASCULAR SYSTEM; LYMPHATIC SYSTEM.

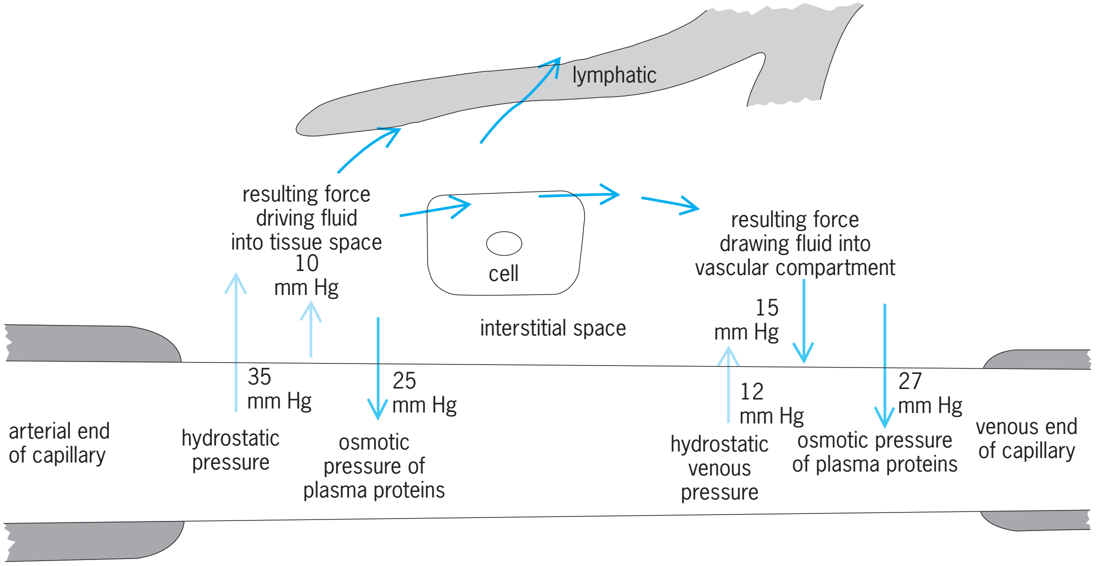
Vascular disturbances. Disturbances in this pattern can either result in or from disease conditions. An example is edema, which is an abnormal accumulation of fluid in the cells, tissue spaces, or cavities of the body. There are three main factors in the formation of generalized edema and a fourth which plays a role in the formation of local edema. They are the permeability of the capillary wall, the colloid osmotic pressure of the plasma proteins, and the hydrostatic pressure in the capillaries. The fourth factor, which is of importance in local edema formation, is lymphatic obstruction.

An example of edema formation secondary to a decrease in the colloid osmotic pressure of the plasma proteins is nephrotic edema. In chronic Bright's disease there is a marked loss of urine albumin and the plasma protein level drops as a result.

Cardiac edema follows the generalized venous congestion of cardiac failure and is an example of edema formation resulting from increased hydrostatic pressure in the capillaries.

Increased permeability of the capillary walls plays an important role in the formation of inflammatory edema, the edema of severe infections, metabolic intoxications, asphyxia, anaphylactic reactions, secondary shock, and acute nephritis. *See* EDEMA; HYPERTENSION.

Deficiencies. A deficiency of circulating blood volume, both cellular elements and fluid, is called oligemia. This may be the result of an acute blood loss or it may be of a chronic nature, such as an anemia combined with dehydration. Anemia, or oligochromemia, is a deficiency of circulating red cell volume or, more specifically, hemoglobin content. This is the oxygen-carrying component of the circulating red blood cell. The normal value for the adult human is 14–16 g/100 ml of blood. The norm for most domestic animals is 10–12 g/100 ml of blood, except for the dog with a norm of 13 g. *See* ANEMIA; HEMOGLOBIN.



arterial end of capillary		venous end of capillary	
hydrostatic pressure (force tending to drive fluid out)	= 35 mm Hg	hydrostatic pressure	= 12 mm Hg
osmotic pressure of proteins (force tending to draw fluid into vascular compartment)	= 25 mm Hg	osmotic pressure of proteins	= 27 mm Hg
resulting force pushing fluid out of vascular compartment into interstitial space	= 10 mm Hg	resulting force drawing fluid back into vascular compartment	= 15 mm Hg

Fluid movements and resulting pressures at the capillary level of circulating blood.

Anemia can result from a variety of causes. It may be secondary to a chronic nutritional deficiency with an inadequate intake of iron. Iron is a necessary substance used by the blood-forming tissue to make hemoglobin. Anemia can also result from a defect in the blood-forming tissue (the bone marrow) so that it is unable to use the materials available to make red blood cells. It can also be the result of a displacement of blood-forming tissue, as from a tumor. It may also follow periods of acute blood loss. These are just a few examples of the causes of anemia. *See* BLOOD; HEMATOPOIESIS.

Pancytopenia, or oligocythemia, is a deficiency of all circulating blood cellular elements. This is usually the result of a deficiency of the blood-forming tissue, the bone marrow.

Ischemia. The decrease of blood flow to an organ or tissue is known as ischemia. This can be sudden as when a vessel is ligated, when a thrombus or blood clot forms, or when an embolus comes to lodge in the vessel. A gradual occlusion can follow arteriosclerotic changes in the vessel wall with resulting diminution of the lumen and blood-carrying capacity of the vessel. The effect of a sudden occlusion depends to a great extent on the collateral circulation to the organ or tissue involved. If an adequate collateral circulation comes to be established, the tissue survives; it not, it dies and an infarct results.

An infarct is a region of necrosis resulting from a vascular obstruction. The usual cause is occlusion of an artery or vein by a thrombus or embolus. If the vessel is the sole source of blood supply, the tissue dies. *See* ARTERIOSCLEROSIS; EMBOLISM; INFARCTION; THROMBOSIS.

Plethora. An excess of blood is referred to as plethora. This increase may be the result of an increase in the size or the number of red blood cells. The increase in red cell volume may be a polycythemia vera, or true polycythemia, which is a primary increase in the number of red blood cells with no regard to the needs of the organism. Polycythemia, or erythrocytosis, is usually a secondary increase in red cells following conditions of chronic hypoxia, such as congenital heart disease, emphysema, or residence at high altitudes. Serous plethora is an increase in the watery part of the blood.

Hyperemia. Hyperemia, or congestion, refers to an excess of blood within an organ or tissue. This condition may be localized or generalized. Active hyperemia is congestion which is caused by an active dilatation of arterioles and capillaries. This occurs under certain physiological conditions, such as in the muscle when there is an increased need for blood during exercise. It also occurs in pathological states such as inflammation. *See* INFLAMMATION.

Passive hyperemia is a condition which results in an accumulation of blood in the venous system. It may be generalized or localized and can result from any obstruction or hindrance to the outflow of blood from the venous circuit. The generalized form can result from valvular diseases of the heart, such as mitral or aortic stenosis or insufficiency, or myocardial failure from any cause. Tricuspid valvular disease is slightly more frequent in animals. *See* HEART DISORDERS.

Diseases of the lungs such as emphysema, fibrosis, or pulmonary hypertension of any origin can result in right ventricular failure and generalized venous congestion. The late stages of these conditions can result in cor pulmonale, which is a hypertrophy and dilatation of the right ventricle secondary to an obstruction to the pulmonary blood flow associated with a generalized venous congestion.

Localized venous congestion results when a main vein from a region is occluded either by a thrombus or some extrinsic pressure such as a tumor or enlarged lymph nodes.

In congestion the organ is usually wet and bloody. Microscopically there is an enlargement of the veins and capillaries associated with edema formation.

Hemorrhage. The escape of blood from within the vascular system is hemorrhage. This process can be the result of trauma to, or disease of, the vessel wall. Diapedesis is the passage of the corpuscular elements of the blood through an intact vessel wall.

The trauma which results in hemorrhage may be direct, such as a cut from a knife, or it may be indirect, such as a blow to the head, resulting in a tearing of cerebral or meningeal vessels.

The causes of hemorrhage other than trauma can be divided into three main groups. In the first group are those conditions in which there is a disease process affecting the vessel wall, such as arteriosclerosis or aneurysm formation. An infarct, or tissue death from any case, can result in hemorrhage.

In the second group are conditions in which there is an acute process affecting the vessel wall, as in septicemia, poisoning by heavy metals, or even anoxia.

The third and last group consists of those conditions in which there is a defect in the blood itself, which results in hemorrhage. Under this heading are included the blood-clotting disorders, thrombocytopenia, leukemia, and pernicious anemia.

Apoplexy, or stroke, is an acute vascular lesion of the brain. This can be the result of hemorrhage of, thrombosis in, or embolism to a cerebral vessel. *See* HEMORRHAGE.

Thrombosis. Thrombosis is the formation of a thrombus, which is a solid body formed during life and composed of the elements of the blood: platelets, fibrin, red cells, and leukocytes.

Thrombosis is essentially platelet deposition and may occur on a vessel wall anywhere that the endothelium is damaged. However, because the platelets release thromboplastinogen, which activates the clotting mechanism, thrombosis and blood coagulation may occur together. Platelets normally exhibit a tendency to stick together. This tendency is increased if the number of platelets is increased, as in thrombocytosis, if the velocity of the stream is decreased below a certain speed, or if the endothelium is roughened. These are the same factors which promote thrombus formation.

Thrombi may form in the veins, arteries, capillaries, or within the heart. The most common sites for the formation of thrombi are in the veins.

The venous thromboses can be divided into two groups: venous thrombosis (phlebothrombosis) and thrombophlebitis. Phlebothrombosis is the more important and is often a sequela of generalized circulatory failure, trauma, or prolonged bed rest from any cause.

Thrombophlebitis is the formation of a thrombus secondary to inflammation in the wall of the vein. Arterial thrombosis is usually the result of local causes, for example, arteriosclerosis of the vessel wall.

Embolism. The sudden blocking of an artery or vein by a clot or other substance which has been brought to its place by the blood current is an embolism. The material carried in the circulation in this process is an embolus. Emboli may be composed of thrombi, fat, air, tumor cells, masses of bacteria or parasites, bone marrow, amniotic fluid, or atheromatous material from the vessel wall.

Emboli originating in the right side of the heart or the great venous system of the body come to lodge in the lungs, those from the portal system in the liver, and those from the pulmonary veins or left side of the heart in some segment of the peripheral arterial tree.

One of the dire consequences of an embolus is infarction or death of the tissue supplied by the occluded vessel. This occurs if the collateral circulation is inadequate to supply the tissue with blood. *See* DEATH; VASCULAR DISORDERS.

Cirrhosis

Severe scarring of the liver due to a marked increase in fibrous connective tissue, resulting in a firm, nodular, distorted liver. Cirrhosis is the eighth most common cause of death in the United States and the fourth leading cause of death among Americans between the ages of 30 and 60.

Etiology. Cirrhosis is the end product of any one of a number of different liver diseases. Regardless of the cause, the potential consequences of cirrhosis are the same. Whereas a healthy liver typically repairs and regenerates itself when injured, once cirrhosis has occurred, the damage may never be undone. Not all liver diseases cause cirrhosis—only those that cause chronic, ongoing damage to the liver. Alcoholic liver disease and chronic hepatitis C are the two most common causes of cirrhosis in the United States. However, there are numerous causes of cirrhosis as listed below.

Viral hepatitis—hepatitis B, C, and D
Autoimmune hepatitis (a disease in which the body's immune system attacks liver cells)

Primary biliary cirrhosis (a liver disease that slowly destroys the bile ducts in the liver)
Nonalcoholic fatty liver disease [a range of liver diseases that commonly affect people who have type 2 diabetes (adult onset diabetes), with hypertriglyceridemia (high level of fats, or triglycerides, in the blood), and who are obese but drink little or no alcohol)]
Excessive alcohol consumption
Hemochromatosis (excessive deposition of iron in the body that may be genetic or acquired)
Excessive intake of vitamins, such as vitamin A
Certain herbal remedies, such as comfrey
Certain medications, such as methotrexate, isoniazid, methyldopa (hypertension)
Primary sclerosing cholangitis (a liver disease characterized by inflammation, narrowing, and scarring of the bile ducts inside and outside the liver)
Vascular anomalies (for example, Budd-Chiari syndrome)
Congestive heart failure
Wilson's disease (a genetic disorder of copper overload)

See ALCOHOLISM; HEPATITIS; LIVER DISORDERS.

Symptoms and complications. The symptoms of cirrhosis are essentially uniform regardless of its cause. Some people with cirrhosis feel perfectly normal or have nonspecific symptoms, such as fatigue, decreased appetite, and loss of libido. These individuals are said to have compensated cirrhosis. People with compensated cirrhosis often live a normal life span with relatively few health-related consequences. However, they remain at risk for developing many life-threatening complications such as portal hypertension, ascites, encephalopathy, jaundice, hepatorenal syndrome, and hepatocellular carcinoma. When one of these complications has occurred, individuals are said to have decompensated cirrhosis.

Portal hypertension. Due to extensive scarring of the liver that occurs in cirrhosis, the vessels associated with blood flow to and from the liver may become obstructed. This, in combination with increased blood flow to the liver, leads to elevated pressure in the portal circulation, a condition known as portal hypertension. The liver attempts to adapt to this situation by creating alternative routes that bypass this obstruction. These alternative passageways for blood flow are known as collateral shunts or simply "collaterals." These shunts enable blood to be rerouted to and circulated within the rest of the body. Unfortunately, the formation of these shunts has its drawbacks, as they can give rise to serious and even life-threatening complications. When any one of the complications associated with portal hypertension (for example, ascites, esophageal varices, and/or encephalopathy) has occurred, the body can no longer "compensate" for the extensive scarring that has occurred in the liver, and the patient has decompensated cirrhosis. People with any form of portal hypertension should be evaluated for liver transplantation.

Portal hypertension can result in congestion of the spleen, leading to a markedly enlarged spleen (splenomegaly).

Esophageal varices portal hypertension may result in the formation of new collateral venous channels that bypass the liver. The most important collateral channels are those in the region of the lower esophagus, called esophageal varices. When varices become dilated, they can erode through the lining of the esophagus, resulting in life-threatening bleeding.

Ascites is the most common complication of portal hypertension. It is characterized by massive accumulation of fluid in the peritoneal cavity (the space between the abdominal organs and the skin). A fever in a person with ascites may indicate that this fluid is infected and constitutes a serious condition known as spontaneous bacterial peritonitis.

Encephalopathy. Encephalopathy is a disorder of brain function, typically leading to a coma that can occur in people with cirrhosis. It is mainly associated with poor coordination, fetor hepaticus (foul-smelling breath), and asterixis (uncontrollable flapping of the hands). The exact cause of encephalopathy is unknown; most researchers believe that it is mainly associated with the ailing liver's inability to clear toxins, primarily ammonia, from the body.

Jaundice. In addition to obstruction of blood flow, the bile ducts within the liver may become distorted and partially obstructed. This results in jaundice, a yellow discoloration of the skin and eyes. *See* JAUNDICE.

Hepatorenal syndrome. Some individuals with cirrhosis develop hepatorenal syndrome, a progressive deterioration of kidney function associated with lack of urination. This may lead to renal failure, and kidney dialysis may become necessary. Hepatorenal syndrome can result in death unless a liver transplantation is performed. *See* KIDNEY DISORDERS.

Hepatocellular carcinoma. Anyone who has cirrhosis, whether compensated or decompensated, is at risk for developing liver cancer—also known as hepatocellular carcinoma or hepatoma. Risk varies with the cause of liver disease. *See* CANCER (MEDICINE).

Morphological changes. In general, cirrhosis results in similar physical damage to the liver, regardless of which type of liver disease caused it. The liver may be slightly enlarged, but as the disease progresses it usually becomes smaller due to progressive loss of liver cells. In the final stage the liver may weigh as little as 14–18 oz (400–500 g; normal is 50–60 oz or 1400–1700 g). Microscopic examination reveals that liver cells of varying size and shape are surrounded by dense fibrous connective tissue that contains inflammatory cells and distorted bile ducts. Fibrosis, or scar tissue, is the liver's effort to keep contained the damage done by alcohol or hepatitis C virus, for example. But scar tissue can block the blood flow through the liver, resulting in an inability to perform its normal duties. *See* LIVER.

Diagnosis. A liver biopsy, the removal of a tiny piece of liver tissue using a special needle, continues to be the “the gold standard” to determine the presence or absence of cirrhosis. However, signs of cirrhosis such as muscle wasting, a hard and bumpy liver, and splenomegaly may be detected on a physical exam. Some laboratory test results (such as a low albumin level, an abnormally low cholesterol level, an elevated or prolonged prothrombin time, a decreased platelet count, and/or an elevated alpha-fetoprotein level) may also suggest cirrhosis. Imaging studies such as a sonogram or computerized tomography (CT) scan of the liver may suggest, but cannot confirm, cirrhosis. Once cirrhosis has occurred, a physician will not be able to definitively identify which liver disorder caused it, even from a liver biopsy specimen.

Treatment. Recent studies have shown that with removal of the cause of the underlying liver disease (for example, alcohol or the hepatitis C virus), and with effective treatment (such as interferon and ribavirin for hepatitis C virus), cirrhosis can be reversed—at least in its very early stages, when scarring is minimal. The point at which cirrhosis becomes irreversible is not clear. However, there is a broad consensus among liver disease experts that once decompensated cirrhosis has occurred, it can never be reversed. Much research is being conducted on drugs (known as antifibrotic agents) and drug combinations that can potentially reverse cirrhosis. Examples of promising antifibrotic agents include interferon, pentoxifylline, prostaglandins, antioxidants, pioglitazone, and angiogenesis inhibitors. Currently, therapy of cirrhosis is aimed primarily at preventing or reducing complications. However, while the complications of decompensated cirrhosis can be controlled, the liver is beyond the point of any possible repair, and a liver transplant must be considered. *See* CARDIOVASCULAR SYSTEM; LIVER DISORDERS.

Cirripedia

An order of the crustacean class Maxillopoda. The cirripedes, particularly the organisms known as barnacles, are the most well-known and easily recognized members of the subclass Thecostraca. The thecostracans are characterized by two features. First, all exhibit a distinctive and unique larva, called the cypris (**Fig. 1***b*). Second, when they have a carapace, it generally envelops the entire body, which typically is composed of a five-segment head, a seven-segment thorax, and a short or rudimentary limbless abdomen. In addition to the cirripedes, the thecostracans include the enigmatic Facetotecta, or “y-larvae,” as well as Ascothoracica, a group of parasites of echinoderms and anthozoan cnidarians. *See* ASCOTHORACICA; CRUSTACEA; MAXILLOPODA.

The Cirripedia sensu stricto are composed of three infraorders: Thoracica (the goose and acorn barnacles), Acrothoracica (the burrowing barnacles), and Rhizocephala (internal parasites of shrimp and crabs) [see **table**].

Thoracica and Acrothoracica

Generally, the two free-living cirripede infraorders bear long, setose, filtering thoracic limbs called cirri. In addition, cirripedes have nauplius larvae that bear peculiar structures called frontolateral horns (Fig. 1*a*), whose function is still not certain. As adults, the free-living cirripedes are permanently attached and commonly referred to as barnacles.

Morphology. The carapace forms a complete cover of the body, and it is usually strengthened by calcareous shell plates (**Fig. 2**). In principle, the head bears the usual five pairs of limbs. However, the antennules and antennae are seen only in the larvae (Fig. 1). The antennules form the points of attachment of the adult barnacle but persist only in adult goose barnacles as the peduncular stalk (Fig. 1*d*). The mouth appendages include the paired mandibles with palps, maxillules, and maxillae. The thorax bears up to six pairs of biramous appendages (cirri) composed of numerous segments, each with a considerable number of setae (Fig. 2*b*). A rostral vessel and/or sinus (Fig. 2*b*) serve as a heart that pumps blood through a virtually closed circulatory system. Naupliar and compound eyes occur only in the larvae (Fig. 1*b*).

Reproduction and development. Thoracican adults are typically hermaphrodites, whereas acrothoracicans have separate sexes. The female genital pore is on the first thoracic segment at the base of cirrus I,

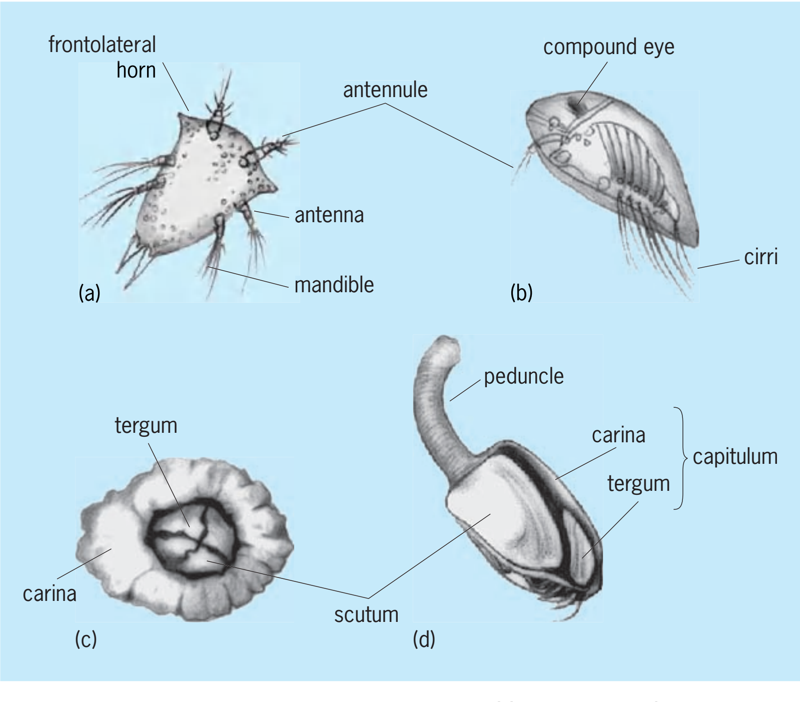

Fig. 1. Larval and adult stages of thoracican barnacles. (*a*) Nauplius larva (note diagnostic frontolateral horns). (*b*) Cypris larva. (*c*) *Balanus*, a typical acorn barnacle (top view). (*d*) *Lepas*, the goose barnacle (lateral view).

Characteristics and some genera of Cirripedia

Infraorder	Characteristics	Some genera
Thoracica	Permanently attached, stalked or sessile, independent or commensal barnacles; with filtering thoracic limbs as long setose cirri; typically with carapace developed as calcareous plates; hermaphroditic	*Lepas, Scalpellum, Conchoderma, Heteralepas, Balanus, Coronula, Verruca*
Acrothoracica	Burrowing barnacles living in shells, coral, or limestone; cirri modified or often reduced in number; carapace without calcareous plates; bisexual with dwarf males	*Trypetesa, Lithoglyptes, Kochlorine*
Rhizocephala	Internal parasites of decapod crustaceans; adult body is a formless ramifying mass among the host tissues; no gut; eggs and larvae produced in an external sac on host's body; bisexual with dwarf males	*Sacculina, Loxothylacus, Thompsonia*

while the male genital pore is on an elongated penis lying medially on the segment posterior to cirrus VI. Cross-fertilization of the hermaphrodites is normal. The extremely long penis is extended out of the shell to grope around for a receptive neighbor. The eggs are incubated in the shell cavity and hatch into free-swimming nauplius larvae (Fig. 1*a*). Thoracicans pass through six successive naupliar stages, whereas acrothoracicans have four. The final nauplius molts into an entirely different form with a bivalved carapace, the cypris larva (Fig. 1*b*), so named because it resembles the ostracode genus *Cypris*. The cypris has prominent antennules and well-developed, though short, cirri. The cypris seeks a suitable substrate or host and attaches by the antennules. Thereafter, an extremely strong cement is secreted from glands in the antennules, and the animal is permanently anchored.

The attached cyprid then undergoes metamorphosis, and a minute replica of the adult (only without calcified shell plates) is produced. By differential growth and elongation of the preoral region, the free body of the animal within the body cavity comes to lie parallel to the substrate with the ventral side uppermost. The thoracic appendages, or cirri, face away from the substrate and are immediately below the opening of the shell, which is uppermost (Fig. 2*b*). Through this aperture, the cirri are extended and unfolded into a fanlike array. The cirri sweep through the water in the manner of a cast net and withdrawn back into the shell with whatever has been netted. Edible particles are then removed from the cirri by the mouthparts and passed to the mouth to be swallowed.

Stalked thoracicans. In the stalked thoracican, or goose barnacles, the antennular region elongates and forms a stalk, or peduncle. At the distal end is the capitulum with the rest of the animal's body inside. In *Lepas* (Fig. 1*d*) the penduncle may be up to 1 ft (30 cm) long and the capitulum only 2–3 in. (5–8 cm). The capitulum in *Lepas* is strengthened by five calcareous plates: thecarina, or keel, extends

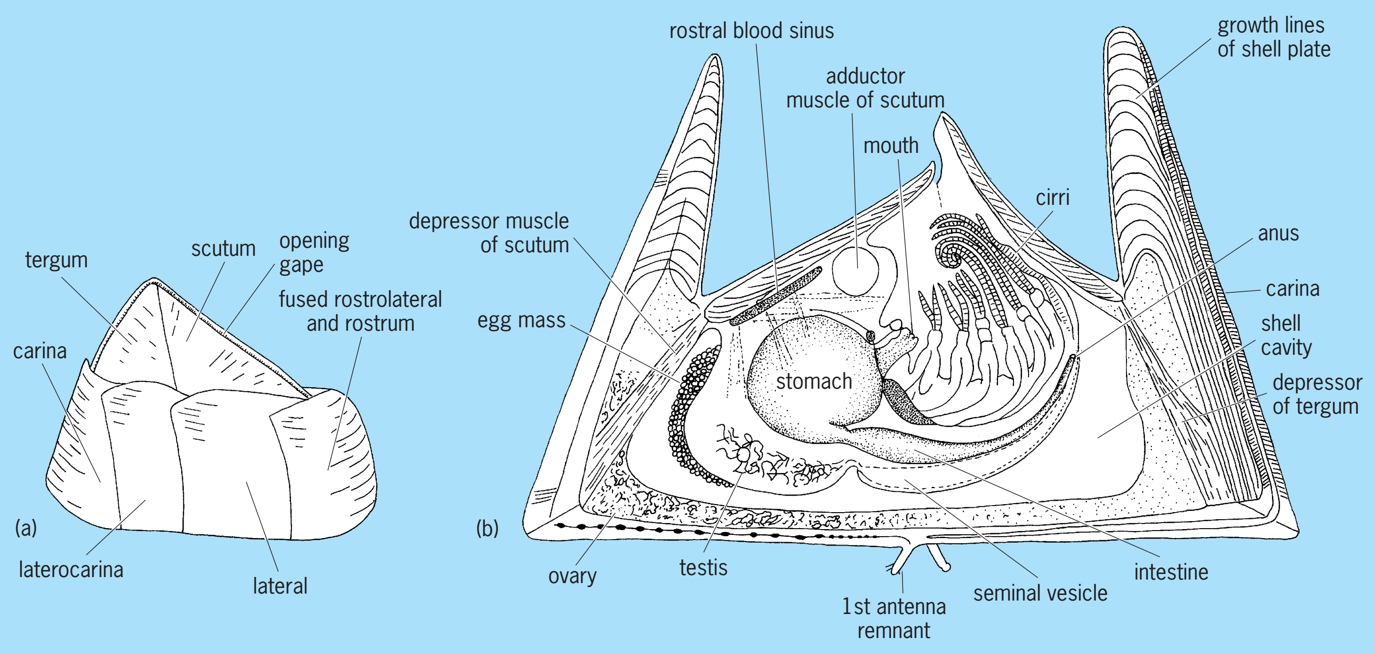

Fig. 2. Diagrams of the anatomy of *Balanus*, a sessile acorn barnacle. (Note the lack of a stalk.) (*a*) Lateral view. (*b*) Vertical cross section. (*After E. R. Ruppert, R. S. Fox, and R. D. Barnes, Invertebrate Zoology: A Functional Evolutionary Approach, 7th ed., Brooks Cole, 2003*)

down the posterior or morphologically dorsal side of the capitulum; and paired scuta and terga lie on either side of the capitulum. Calcification occurs from centers all over the capitulum and peduncle, giving rise to small oval or triangular scales. In many species of *Scalpellum* (sensu lato), in which these peduncular scales are present, there is a ring of larger scales around the base of the capitulum.

The number of capitular plates can be variable both within and between species. However, forms such as the fouling barnacle *Conchoderma* and the commensal of sea urchins *Heteralepas* are protected by the spines of its host and have both lost most of the capitular plates. *Lepas* and *Conchoderma* are found on floating debris in the ocean. *Lepas fascicularis* actually secretes a horny float that supports a cluster of individuals. The more heavily armored species of scalpellids are found on the bottom of the ocean and extend into very deep waters.

The peduculate goose barnacles are not a single monophyletic group. Rather, they form a transition series of distinct lineages leading to the sessile acorn barnacles.

Sessile thoracicans. Most of the sessile thoracicans, or acorn barnacles, live in shallow waters or between the tide marks, where they can be present in immense numbers. They lack any stalk and can be thought of as composed only of a capitulum (Figs. 1*c* and 2). These intertidal forms have economic importance. They settle on any suitable immersed surface, including the hulls of ships and submerged equipment. Their presence interferes with efficient operation and increases running costs. Large sums have been spent devising antifouling paints, principally using tributyl tin, and other techniques to discourage settlement of barnacles. Typically, the shell is formed of six to eight plates and a basal membrane, which may be calcified. The opening of the shell is closed by strong depressor muscles of a pair of movable lids (Fig. 2*a*), each composed of two articulated plates homologous with the scutum and tergum seen in the *Lepas* capitulum. Apart from ship bottoms, rocks, docks, pilings, and shells, acorn barnacles also cling to turtles (*Chelonibia*) and whales (*Cornonula*, *Tubincinella*). *See* THORACICA.

Acrothoracicans. The burrowing acrothoracicans are cryptic forms, millimeters in size. The settled cypris does not develop shell plates on the carapace during metamorphosis. Rather, the carapace bears chitinous teeth that assist in excavating the adult's burrow in the calcarous substrates on which they settle. Although some chemical action in this process has been suspected, apparently most of the burrow excavation is achieved by mechanical abrasion. Once properly housed, virtually little of the adult body ever extends beyond the burrow entrance, with all life processes taking place within the adults snug little home. *See* ACROTHORACICA.

Rhizocephala

The parasitic rhizocephalans can be identified as cirripedes only because of their nauplius larva, which bears frontolateral horns, and the possession of the thecostracan cypris larva. The cypris injects a wormlike stage into a decapod crustacean host, and this grows into an entangling network of female parasitic tissue that effectively takes over the host body. When the time comes to reproduce, an external gonad sac is protruded under the pleon (limbed abdomen) of the host. This attracts a male cypris that settles on the externa and becomes a hyperparasite on the female. Since they do not have an adult body form that can be compared with that of any other crustacean, let alone a thecostracan, the relationship of the rhizocephalans to the barnacles was unclear for a century or more, and until recently most researchers thought they were a group quite separate from the barnacles. However, analysis of DNA sequence data has shown that the rhizocephalans are closely related as a sister group to the thoracicans within Cirripedia. *See* RHIZOCEPHALA.

Fossil Record

Unquestioned fossil remains of Cirripedia are known from the Silurian, but there are also possible plateless forms that occurred earlier in the Cambrian Burgess Shale of Canada. Proper stalked barnacles are known from the Late Paleozoic onward. In Mesozoic and Cenozoic deposits, disarticulated shell plates occur, but only a few intact capitular shells are recognized. *See* FOSSIL; GEOLOGIC TIME SCALE.

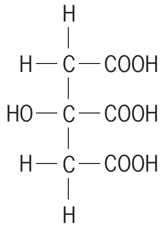
Citric acid

A hydroxytricarboxylic acid, general formula $C_6H_8O_7$, with the structure shown below. It is



$$\begin{array}{ccccc} & & \text{H} & & \\ & & | & & \\ & \text{H}- & \text{C} & -\text{COOH} \\ & & | & & \\ & \text{HO}- & \text{C} & -\text{COOH} \\ & & | & & \\ & \text{H}- & \text{C} & -\text{COOH} \\ & & | & & \\ & & \text{H} & & \end{array}$$

also available primarily as anhydrous material but as the monohydrate. The major commercial salts are sodium and potassium, with calcium, diammonium, and ferric ammonium (complex) also available. *See* ACID AND BASE.

Citric acid and its salts are widely used because they are nontoxic, safe to handle, and easily biodegraded. They are universally accepted, without

restriction on level, as food ingredients, including acceptance by the Joint FAO/WHO Expert Committee on Food Additives and the U.S. Food and Drug Administration. Because of their food use, specifications for purity are included in the *Food Chemicals Codex* (except diammonium citrate). In addition, specifications for citric acid, sodium citrate, and potassium citrate are included in the *U.S Pharmacopeia* and many pharmacopeia throughout the world.

Occurrence. Citric acid occurs in relatively large quantities in citrus fruits. It also occurs in other fruits, in vegetables, and in animal tissues and fluids either as the free acid or as citrate ion (**Table 1**). It is an integral part of the Krebs (citric acid) cycle involving the metabolic conversion of carbohydrates, fats, and proteins in most living organisms. *See* CITRIC ACID CYCLE.

Manufacture. Prior to World War I, all of the world's citric acid was produced by extraction from cull citrus fruit. Today, essentially all of the commercial citric acid is produced by fermentation. Processes employed are surface or submerged fermentation by mold (*Aspergillus niger*) and submerged fermentation by yeast (*Candida guilliermondii, C. lipolytica*), using a variety of substrates including sucrose, molasses, corn syrup, enzyme-treated starch, and normal paraffins. Citric acid is recovered from the fermentation broth by solvent extraction or more commonly by precipitation as calcium citrate, followed by treatment with sulfuric acid to convert the calcium citrate to calcium sulfate and citric acid. The calcium sulfate is removed by filtration, and the citric acid solution is further purified. Crystallization of citric acid from a hot aqueous solution (above the transition temperature of 36.6°C or 97.9°F) yields anhydrous citric acid; crystallization from a cold solution yields the monohydrate. Although total chemical syntheses for citric acid have been published, they have never achieved commercial success. *See* FERMENTATION; INDUSTRIAL MICROBIOLOGY.

Properties. Key properties of anhydrous citric acid are summarized in **Table 2**. Citric acid is a relatively strong organic acid (see dissociation constants), and is very soluble in water.

Uses. Citric acid is widely used in the food and pharmaceutical industries. In foods it is used primarily to produce a tart taste and to complement fruit flavors in carbonated beverages, beverage powders, fruit-flavored drinks, jams and jellies, candy, sherbets, water ices, and wine. It is also used to reduce pH in certain canned foods to make heat treatment more effective, and in conjunction with antioxidants to chelate trace metals and retard enzymatic activity. *See* FOOD MANUFACTURING.

In pharmaceuticals, citric acid provides the acid source in effervescent tablets in addition to being used to adjust pH, impart a tart taste, and chelate trace metals. It is also used as a blood anticoagulant. *See* PHARMACEUTICAL CHEMISTRY.

Citric acid, because of its low toxicity, relative noncorrosiveness, and biodegradability, is also being used for applications normally reserved for the strong mineral acids. These include preoperational and operational cleaning of iron and copper oxides from boilers, nuclear reactors, and heat exchangers; passivation of stainless steel tanks and equipment; and etching of concrete floors prior to coating. It is also used as a dispersant to retard settling of titanium dioxide slurries and as a sequestering and pH control agent in the textile industry. *See* TEXTILE CHEMISTRY.

Salts. Since citric acid is a tribasic acid, it can form acid and neutral salts, and will buffer over a broad pH range. The salts which are readily available commercially are trisodium citrate (dihydrate and anhydrous), tripotassium citrate (monohydrate), calcium citrate (tetrahydrate), diammonium citrate (anhydrous), and ferric ammonium citrate. *See* BUFFERS (CHEMISTRY); PH.

Trisodium citrate dihydrate, the salt which is most widely used, is a stable white crystal or granule. It is used as an emulsifier in processed cheese products where it prevents fat separation, imparts good meltdown properties, and produces slices with proper flexibility. In other dairy products, such as ice cream, whipping cream, and evaporated milk, it acts as a stabilizer and viscosity control agent. The sharpness of high-acid beverages is mellowed with sodium citrate, and it is used as a buffer to control pH in jams and jellies, gelatin desserts, and many pharmaceutical preparations. It is also used as a blood anticoagulant. Its largest single industrial use is as a detergent builder since it is rapidly biodegradable, environmentally acceptable, and can chelate

TABLE 2. Properties of anhydrous citric acid

calcium, magnesium, and other metal ions. Sodium citrate is also used as a water conditioner, set-retardant for cement, buffer, and scrubbing agent to remove sulfur dioxide from stack gases or process tail gases. In most applications the dihydrate is used since it is less expensive. Occasionally, certain dry formulations require the use of the anhydrous salt. *See* CHEESE; DETERGENT.

Potassium citrate is a white crystalline granule or powder which readily absorbs moisture from the air. It is often used as a substitute for sodium citrate in special food products where sodium ion is undesirable. Calcium citrate is a stable, white, free-flowing powder used as a source of calcium either for nutritional purposes or for functional purposes (that is, as a firming agent). Ferric ammonium citrate is a complex salt, of undetermined structure, composed of iron, ammonia, and citric acid. Product containing 14.5–16% iron is green in color, and product containing 14.5–18.5% iron is brown. Both absorb moisture readily and are affected by light. They are used as a nutrient source of iron in food and in pharmaceutical syrups and elixirs. Diammonium citrate is a white granule or powder which is stable in air and used in dry formulations for metal cleaning. Fred Sauer

Citric acid cycle

In aerobic cells from animal and certain other species, the major pathway for the complete oxidation of acetyl coenzyme A (the thioester of acetic acid with coenzyme A); also known as the Krebs cycle or tricarboxylic acid cycle. Reduced electron carriers generated in the cycle are reoxidized by oxygen via the electron transport system; water is formed, and the energy liberated is conserved by the phosphorylation of adenosine diphosphate (ADP) to adenosine triphosphate (ATP). Reactions of the cycle also function in metabolic processes other than energy generation. The role of the cycle in mammalian tissues will be emphasized in this article. *See* ADENOSINE DIPHOSPHATE (ADP); ADENOSINE TRIPHOSPHATE (ATP); COENZYME; ENZYME.

Reactions. The first step in the cycle involves the condensation of the acetyl portion of acetyl coenzyme A (CoA) with the four-carbon compound oxaloacetate to form citrate, a tricarboxylate containing six carbons (see **illus.**). A shift of the hydroxyl group of citrate to an adjacent carbon results in the formation of D-threo-isocitrate, which in turn is oxidized to the five-carbon compound α-ketoglutarate and carbon dioxide (CO_2). In a second oxidative decarboxylation reaction, α-ketoglutarate, in the presence of CoA, is converted to succinyl CoA and another molecule of CO_2. In the subsequent formation of the four-carbon compound succinate and CoA, the energy in the thioester bond of succinyl CoA is conserved by the formation of guanosine triphosphate (GTP) from guanosine diphosphate (GDP) and inorganic phosphate. Fumarate is formed from succinate by the removal of two atoms of hydrogen, and the unsaturated compound is then hydrated to L-malate. The dehydrogenation of malate forms oxaloacetate, the starting four-carbon compound of the metabolic cycle. Thus, beginning with the two-carbon acetyl group, one completion of the cycle results in the formation of two molecules of carbon dioxide. The obligatory role of the intact cycle for the complete oxidation of acetyl CoA has been demonstrated by inhibiting enzymes required for specific reactions (for example, inhibition of succinate dehydrogenase by the substrate analog malonate) or by altering the regeneration or depletion of an intermediate of the cycle.

Electron transport and oxidative phosphorylation. The oxidation of acetyl CoA to CO_2 in the cycle occurs without direct reaction with molecular oxygen. The oxidations occur at dehydrogenation reactions in which hydrogen atoms and electrons are transferred from intermediates of the cycle to the electron carriers nicotinamide adenine dinucleotide (NAD^+) and flavin adenine dinucleotide (FAD). The NAD-specific dehydrogenase reactions are isocitrate dehydrogenase [reaction (1)], α-ketoglutarate dehydrogenase (2), and malate dehydrogenase (3). FAD is the coenzyme for succinate dehydrogenase, (4). The electrons from NADH and $FADH_2$ are transferred to molecular oxygen via a series of electron transport carriers, with regeneration of NAD^+ and FAD. The energy liberated in the electron transport chain is partially conserved by the formation of ATP from ADP and inorganic phosphate, by a process called oxidative phosphorylation. The energy generated as oxygen accepts electrons from the reduced coenzymes generated in one turn of the cycle results in the maximal formation of 11 molecules of ATP. Because GTP obtained by phosphorylation of GDP at the succinyl CoA to succinate step of the cycle is readily converted to ATP by nucleotide diphosphokinase, as in reaction (5), the yield is 12 molecules of ATP per molecule of acetyl CoA metabolized. *See* NICOTINAMIDE ADENINE DINUCLEOTIDE (NAD).

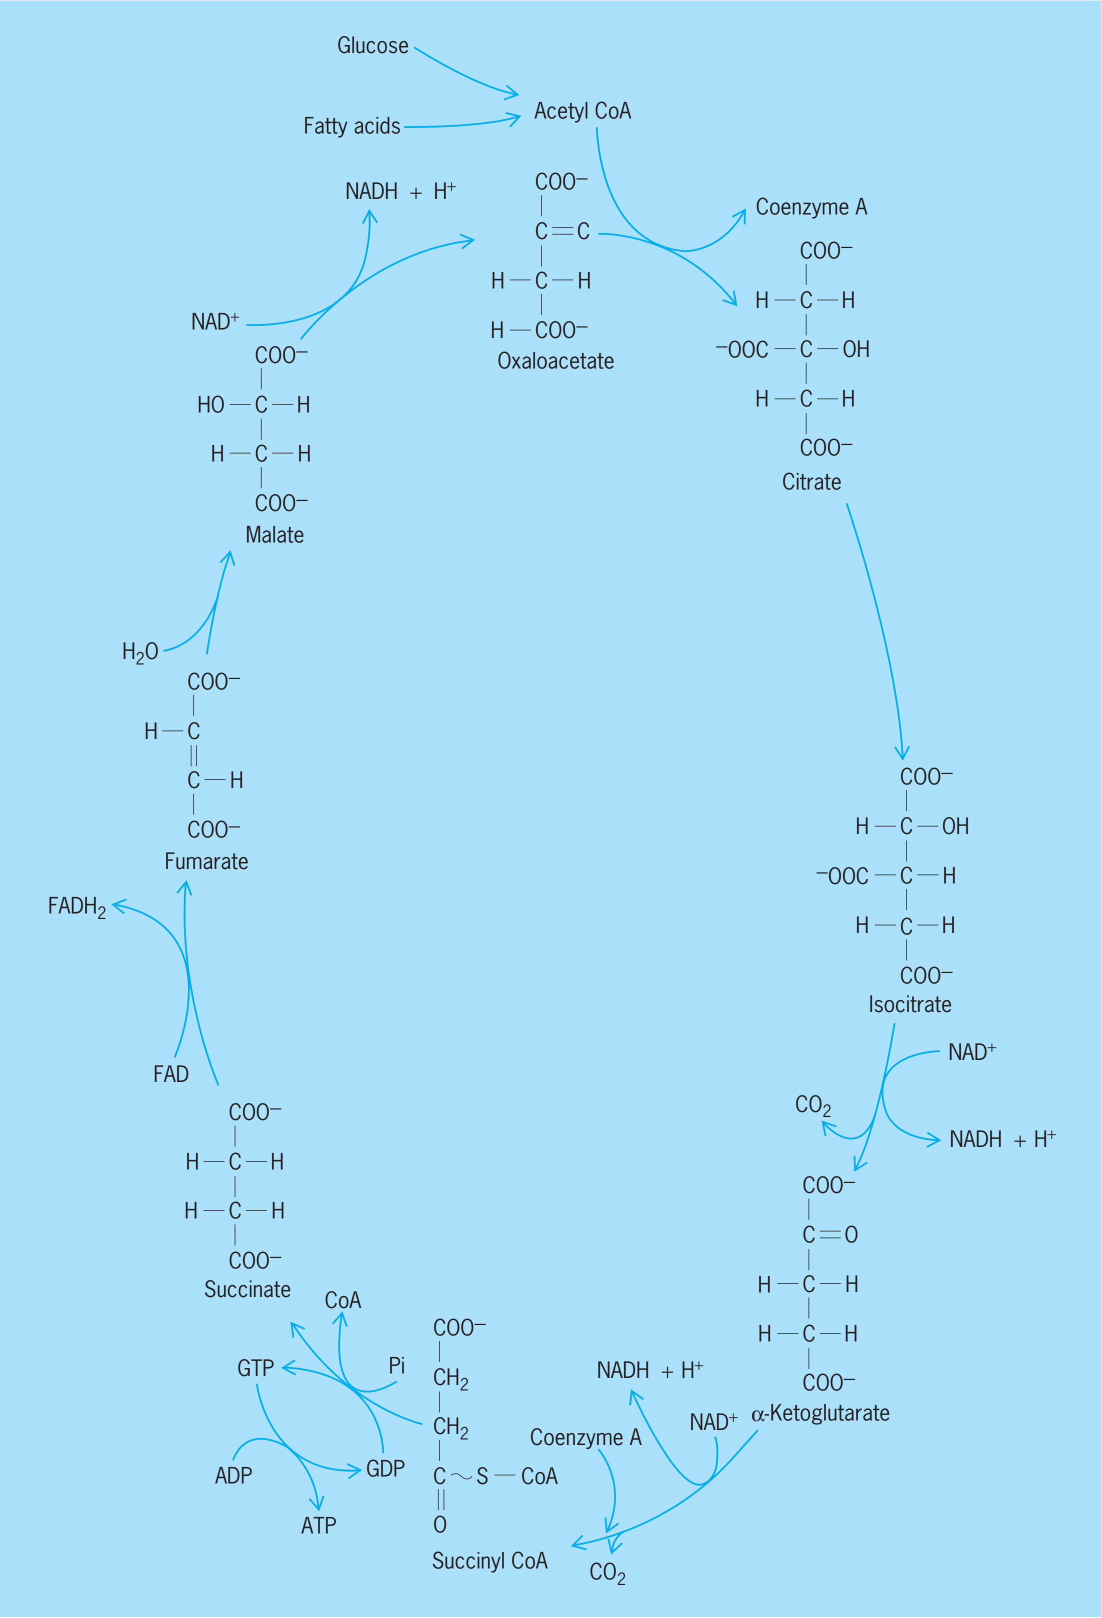
$$\begin{aligned}&\text{Isocitrate} + \text{NAD}^+ \longrightarrow\\&\qquad \alpha\text{-ketoglutarate} + \text{CO}_2 + \text{NADH} + \text{H}^+ \qquad (1)\end{aligned}$$

$$\begin{aligned}&\alpha\text{-Ketoglutarate} + \text{CoA} + \text{NAD}^+ \longrightarrow\\&\qquad \text{succinyl CoA} + \text{CO}_2 + \text{NADH} + \text{H}^+ \qquad (2)\end{aligned}$$

$$\text{Malate} + \text{NAD}^+ \longleftrightarrow \text{oxaloacetate} + \text{NADH} + \text{H}^+ \qquad (3)$$

$$\text{Succinate} + \text{FAD} \longleftrightarrow \text{fumarate} + \text{FADH}_2 \qquad (4)$$

$$\text{GTP} + \text{ADP} \longleftrightarrow \text{GDP} + \text{ATP} \qquad (5)$$



Citric acid cycle.

The electron transport and oxidative phosphorylation systems and the enzymes required for the citric acid cycle are located in the mitochondria of cells. These mitochondrial systems are the major source of ATP for energy-consuming reactions in most tissues. The citric acid cycle does not occur in all cells. For example, mature human red blood cells do not contain mitochondria and the cycle is absent. In these cells, ATP is formed by the anaerobic conversion of glucose to lactate (anaerobic glycolysis). *See* MITOCHONDRIA; PHOSPHATE METABOLISM.

Regulation. A major rate-limiting step of the citric acid cycle in aerobic mammalian tissues (for example, heart) is at NAD-specific isocitrate dehydrogenase [reaction (1)]. The activity of the enzyme is dependent on the concentration of the substrate (magnesium isocitrate): it is activated by ADP, calcium (Ca^{2+}), and citrate, and it is inhibited by NADH and reduced nicotinamide adenine dinucleotide phosphate (NADPH). Differences in energy demand affect the rate of citric acid flux and concentrations of modulators of NAD-dependent isocitrate dehydrogenase. At rest, the flux through the cycle is slowed, the cellular concentration of the isocitrate dehydrogenase inhibitor NADH is raised; and the activator ADP is lowered; the opposite occurs during high energy demand. The rate of cycle oxidation in liver mitochondria increases with decreased NADPH concentration; increased mitochondrial free Ca^{2+} enhances cycle flux. *See* NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE (NADP).

Formation of acetyl CoA and intermediates. Acetyl CoA is formed from carbohydrates, fats, and the carbon skeleton of amino acids. The origin of a precursor and the extent of its utilization depend on the metabolic capability of a specific tissue and on the physiological state of the organism. For example, most mammalian tissues have the capacity to convert glucose to pyruvate in a reaction called glycolysis. Pyruvate is then taken up from cellular cytosol by mitochondria and oxidatively decarboxylated to acetyl CoA and carbon dioxide by pyruvate dehydrogenase, as in reaction (6). Acetyl CoA is also the end product of fatty acid oxidation in mitochondria. However, the fatty acid oxidation pathway occurs in fewer tissues than does glycolysis or the citric acid cycle. For example, nervous tissue utilizes the complete oxidation of glucose but not of fatty acids to maintain energy needs. In prolonged starvation, the level of blood glucose declines to a concentration inadequate to support the optimal energy needs of brain, whereas the level of blood ketone bodies (formed from fatty acids in liver) rises. In this case, the oxidation of ketone bodies (acetoacetate and 3-hydroxybutyrate) via acetyl CoA supplements the diminished oxidation of glucose to fulfill the energy requirements of the brain.

$$\text{Pyruvate} + \text{NAD}^+ + \text{CoA} \longrightarrow \text{acetyl CoA} + \text{CO}_2 + \text{NADH} + \text{H}^+ \quad (6)$$

The amino acids follow varied pathways for forming compounds that can enter the citric acid cycle. For example, the paths of degradation of leucine and lysine lead directly to formation of acetyl CoA; only part of the carbons of aromatic amino acids and of isoleucine are converted to acetyl CoA. Pyruvate, formed bytransamination of alanine with the citric acid cycle intermediate α-ketoglutarate [reaction (7)], can be oxidatively decarboxylated to acetyl CoA by pyruvate dehydrogenase [reaction (6)] or carboxylated to the cycle intermediate oxaloacetate by pyruvate carboxylase [reaction (8)]. Oxaloacetate can also be formed by aspartate aminotransferase [reaction (9)]. Portions of the carbon skeletons of valine, isoleucine, methionine, and threonine are converted to methylmalonyl CoA, which rearranges to the citric acid cycle intermediate succinyl CoA. *See* AMINO ACIDS.

$$\text{Alanine} + \alpha\text{-ketoglutarate} \longleftrightarrow \text{pyruvate} + \text{glutamate} \quad (7)$$

$$\text{Pyruvate} + \text{CO}_2 + \text{ATP} \longrightarrow \text{oxaloacetate} + \text{ADP} + \text{P}_1 \quad (8)$$

$$\text{Aspartate} + \alpha\text{-ketoglutarate} \longleftrightarrow \text{oxaloacetate} + \text{glutamate} \quad (9)$$

Role in lipogenesis and gluconeogenesis. In addition to the cycle's role in yielding catabolic energy, portions of it can supply intermediates for synthetic processes, such as the synthesis of the fatty acid moiety of triglycerides from glucose (lipogenesis), and formation of glucose from the carbon skeletons of certain amino acids, lactate, or glycerol (gluconeogenesis).

Lipogenesis. When dietary intake exceeds the energy needs of the body, the excess calories are deposited as body fat. Under these conditions in humans, the synthesis of fatty acids from glucose occurs mainly in the liver. It is favored by metabolic changes resulting principally from a rise in blood insulin: (1) The rate of pyruvate formation increases because of the rise in tissue glucose and enhancement of glycolysis. (2) Increases in enzyme activities catalyzing the conversion of pyruvate to acetyl CoA at pyruvate dehydrogenase [reaction (6)] and to oxaloacetate at pyruvate carboxylase [reaction (8)] raise the concentrations of both of these substrates for citrate synthesis. When this occurs at a rate exceeding that of the citric acid cycle, the citrate concentration rises and citrate exits from the mitochondria to the cytosol. (3) In the cytosol, citrate is cleaved to oxaloacetate and acetyl CoA in a reaction requiring CoA and ATP. The acetyl CoA is converted to palmitate and other long-chain fatty acids in a series of condensation steps requiring CO_2, ATP as energy source, and NADPH as reductant. *See* LIPID METABOLISM.

Gluconeogenesis. Dietary deprivation of an adult human for more than 2–3 days results in the depletion of liver glycogen stores supporting blood glucose, and the oxidation of fatty acids derived from body triglyceride depots becomes the principal body energy source. However, certain tissues, such as brain and red and white blood cells, remain partially or wholly dependent on glucose as the energy source. In the starved state, where blood insulin decreases and glucagon increases, increased mobilization of amino acids from skeletal muscle proteins occurs, and carbons from some of these amino acids become available for glucose synthesis. The interactions of degradation pathways of individual amino acids in various tissues result in markedly increased blood alanine, an important substrate for gluconeogenesis.

Some of the steps in the conversion of alanine to glucose are as follows: (1) Alanine is taken up from the bloodstream by the liver and converted to pyruvate by transamination [reaction (7)]. (2) The further metabolism of pyruvate in liver mitochondria is affected by the increase in the rate of fatty acid oxidation in the starved state, which raises the levels of acetyl CoA and NADH. Since NADH inhibits pyruvate dehydrogenase [reaction (6)], and acetyl CoA activates pyruvate carboxylase [reaction (8)], the conversion of pyruvate to oxaloacetate rather than acetyl CoA is favored. The increased NADH displaces the malate dehydrogenase reaction [reaction (3)] from oxaloacetate toward malate. Malate is transported from the mitochondria to the cytosol, where it is reoxidized by NAD^+ to oxaloacetate by cytosolic malate dehydrogenase. (3) Oxaloacetate is converted to phosphoenolpyruvate (PEP) by the PEP-carboxykinase reaction [reaction (10)].

$$\text{Oxaloacetate} + \text{GTP} \longrightarrow \text{PEP} + \text{CO}_2 + \text{GDP} \qquad (10)$$

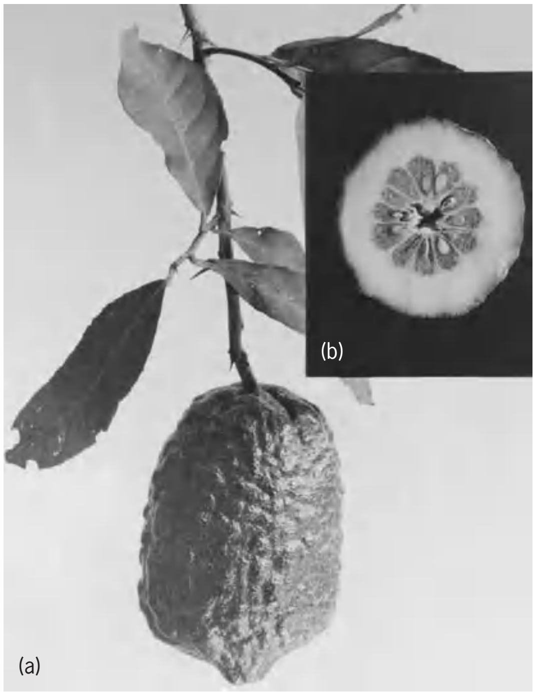
Phosphoenolpyruvate is an intermediate of both gluconeogenesis and glycolysis. In the starved state, the levels of modulators, metabolites, and so forth activate certain rate-limiting steps favoring the formation of glucose from PEP, and also inhibit key enzyme activities facilitating glycolysis. The net effect of these opposing trends is to funnel the flux of carbons from amino acids toward glucose synthesis. *See* BIOLOGICAL OXIDATION; CARBOHYDRATE METABOLISM; CELL (BIOLOGY); GLUCOSE; GLYCOGEN; METABOLISM. Gerhard W. E. Plaut

Citron

Citrus medica, a species of true citrus. The plant has a long and interesting history, being the first contact between citrus, which came from the Far East, and western Judaeo-Christian civilization. A citron, the Etrog, was the "hadar" or "goodly fruit" offering at the ancient Jewish Feast of the Tabernacles. At the time of the first Jewish revolt against Rome in A.D. 66–70, the rebels minted their own coins with the Etrog substituting for Nero's imperial visage.

Commercially, citrons are still grown almost exclusively in the Mediterranean area, principally in Italy, Sicily, Corsica, Greece, and Israel. The tree is evergreen, as are all citrus, and frost-tender. It is thorny, straggly, shrubby, and tends to be short-lived.

The fruit is scarcely edible fresh, having a very thick skin with little flesh and that lacking in juice (see **illus.**). However, it is very fragrant and was valued in ancient times for its aroma and its fragrant peel oil, used in perfumes and as a moth repellent. Later, when the citron was the only known citrus fruit, it was very highly valued. Today, it is grown commercially only as a source of candied peel for use in cakes and confections. The actual candying is usually done in the importing country, the citron peel being exported in brine. Traditionally the fruit was halved and held in large unsealed casks in seawater, a mild fermentation taking place for a week or more, after which additional coarse salt was added and the casks sealed. Today brining is more typically done in a 15% salt solution to which about 2000 parts per million of SO_2 has been added as a preservative and 1% $CaCl_2$ to firm the tissues. The candying process involves first leaching out the brine with boiling water and then transfers through successive syrups of increasing strength up to about 75%.



Commercial citron (*Citrus medica*), approximately one-half natural size. (*a*) Foliage and fruit. (*b*) Cross section of fruit. (*From J. Horace McFarland Co.*)

Confusion sometimes arises due to the name "citron" also being used for a small, wild, inedible melon in the United States and for lemons (*C. limon*) in France. *See* FRUIT; FRUIT, TREE. William Grierson

Citronella

A tropical grass, *Cymbopogon nardus,* from the leaves of which oil of citronella is distilled. This essential oil is pale yellow, inexpensive, and much used in cheap perfumes and soaps. It is perhaps best known as an insect repellent. A large acreage is devoted to the cultivation of this grass in Java and Ceylon. *See* CYPERALES; ESSENTIAL OILS.

Perry D. Strausbaugh; Earl L. Core

Civet

The common name for any of various carnivorous catlike mammals of the family Viverridae of Africa and Asia. These small and medium-sized carnivores are often called “weasel cats” because of their long, slender weasel-like body with short limbs and their long, bushy tail and catlike disposition. They inhabit the warmer parts of the Old World, including southern Asia, the East Indies, portions of Africa, and Madagascar.

Classification. The family Viverridae includes 35 species divided among the following genera: genets (*Genetta*, *Osbornictis*), linsangs (*Poiana*, *Prionodon*), binturongs (*Arctictis*), Oriental civets (*Viverra*), the African civet (*Civettictis*), lesser Oriental civet (*Viverricula*), African palm civet (*Nandinia*), small-toothed palm civet (*Arctogalidia*), masked palm civet (*Paradoxurus*, *Paguma*), Sulawesian palm civet (*Macrogalidia*), banded palm civet (*Hemigalus*), Hose’s palm civet (*Diplogale*), Owston’s palm civet (*Chrotogale*; see **illustration**), otter civets (*Cynogale*), Malagasy civet (*Fossa*), and falanoucs (*Eupleres*).

Morphology. The civet’s head is elongate and the muzzle is pointed. Civets have five toes on each foot, with each toe ending in a sharp claw. Claws may be retractile, semiretractile, or nonretractile. Like cats, civets walk softly and spring swiftly upon their prey. Like skunks, civet cats are strikingly marked so that they are easily recognized, remembered and avoided by potential enemies. They may be striped, spotted, or have a uniform color pattern. In some species the tail is banded or ringed. Females usually have two or three pairs of abdominal mammae. There are between 32 and 40 teeth, with the carnassial teeth being well developed. The senses of slight, hearing, and smell are well developed. Head-body length is 350–950 mm (13.5–37 in.), tail length is 130–900 mm (5–35 in.), and adult weight is 0.6–20 kg (1.3–44 lb).

Habitat. Viverrids are primarily forest dwellers, although they also inhabit dense brush and thick grass. Most species are terrestrial, although many are skillful climbers and spend most of their lives in trees. Shelters include burrows, caves, crevices, tree cavities, or thick brush. Some civets are solitary, whereas others live in pairs or groups. They may be diurnal or nocturnal.

Otter civets (*Cynogale*) are semiaquatic. They have the flat head, broad toes and feet, and thick, dense fur of an aquatic animal. They swim and fish like otters and are as much at home in the water as on dry land.

Diet. Civets are omnivorous. Food consists of small vertebrates and invertebrates and occasionally some vegetable matter such as fruits, bulbs, and nuts. Carrion is taken by some species. Since civets do not digest the seeds of fruits and berries, they distribute the seeds over a considerable distance where they germinate and eventually grow into trees and shrubs.

Owston’s palm civet (*Chrotogale owston*). (*Photo © by Mark Kostich*)

Breeding and longevity. Breeding may occur seasonally or throughout the year. Some species produce two litters of one to six young annually. Newborn civets are blind but covered with hair. Potential longevity ranges from 5 to 15 years.

Economic importance. Members of the family Viverridae are valued for their musk, fur, and meat.

Civet musk. Most members of this family possess scent, or musk, glands in the anal region that secrete a fluid with a musky odor, known as civet, as a defensive measure. This thick yellowish substance is composed of ammonia, resin, fat, and volatile oil. When rubbed on tree trunks, the ground, and similar objects, the secretion is probably used as a means of communication between individuals of the same species. Civet is obtained from several genera (*Civettictis*, *Viverra*, and *Viverricula*) for use in perfumes and medicine, primarily in the Orient. Some civets are tamed and kept in captivity specifically for their musk, which is extracted every 14 to 20 days. Many perfume manufacturers now use civetone, a synthetic alternative.

One excellent producer of civet is the Oriental civet (*Viverra*), as its musk glands are greatly enlarged. It typically has a head-body length of 60 cm (2 ft), a 45-cm (18-in.) tail, and a weight of 11 kg (25 lb). The Oriental civet has a full, black-and-white ringed tail, many ill-defined markings on its grizzled body, and a broad black band set off by areas of white across the throat. A prominent crest of long erectile hairs extends down the middle of the back. The feet are black, and the fur is soft and thick, making it of considerable importance to the fur trade. *See* SCENT GLAND.

Fur and meat. Besides their importance to the perfume industry, civets are prized for their fur and meat. The civet cat is considered a delicacy in southern China. It has been suggested that the practice of eating civets may have resulted in the severe acute respiratory disease (SARS) virus outbreak of 2003. SARS, a type of atypical pneumonia, first broke out in Guangdong province in southern China in November 2002. In January 2004, Guangdong province banned sales of civet cats and ordered the slaughter of all captive civets. In January 2004, the United States announced an embargo on the importation of civets.

Status. Several species are listed as either vulnerable or endangered by the International Union for the Conservation of Nature and Natural Resources (IUCN) and/or the U.S. Department of the Interior. The Malabar civet (*Viverra civettina*) is one of the world's rarest mammals and is listed as critically endangered. It is known only from an isolated belt of rainforests in the Western Ghats of southwestern India. Extensive deforestation has reduced the forests it inhabits to a series of isolated patches. Habitat loss continues. Cashew plantations, which probably hold most of the surviving populations of this species, are now threatened by large-scale clearing for planting rubber. *See* CARNIVORA; ENDANGERED SPECIES; MAMMALIA. Civil engineering

A branch of engineering that encompasses the conception, design, construction, and management of residential and commercial buildings and structures, water supply facilities, transportation systems for goods and people, as well as control of the environment for the maintenance and improvement of the quality of life. Civil engineering is a people-serving profession; it includes planning and design professionals in both the public and private sectors, contractors, builders, educators, and researchers who strive to meet the needs and desires of the community.

The civil engineer holds the safety, health, and welfare of the public paramount. Civil engineering projects and systems should conform to governmental regulations and statutes; should be built economically to function properly for a reasonable period of time with a minimum of maintenance and repair while withstanding anticipated usage and weather; and should conserve energy and allow hazard-free construction while providing healthful, safe, and environmentally sound utilization by society.

Because the desired objectives are so broad and encompass an orderly progression of interrelated components and information to arrive at the visually pleasing, environmentally satisfactory, and energy-frugal end point, civil engineering projects are actually systems requiring the skills and inputs of many diverse technical specialties, all of which are subsets of the overall civil engineering profession.

The infrastructure is the foundation of the modern industrialized urban society. The infrastructure includes roads; mass transit; railroads; bridges; airports; storage buildings; terminals; communication and control towers; water supply and treatment systems; storm water control systems; wastewater collection, treatment and disposal systems; as well as living and working areas, recreational buildings, and ancillary structures for civil and civic needs. Without a well-maintained and functioning infrastructure, the urban area, and society, cannot stay healthy, grow, and prosper. Civil engineers, with their various technical specialties, play a major role in developing workable solutions to construct, renovate, repair, maintain, and upgrade this infrastructure. The civil engineer works with other professionals in developing functional projects, arriving at realistic cost estimates, and advocating reasonable investment strategies.

Civil engineers who move into management combine their technical training and skills with the ability to organize and properly employ the four basics of any project—personnel, time, materials, and money. Civil engineers in management may work for private engineering firms, for industries, for the military, for governmental agencies, or for regional authorities. The civil engineer may also choose a career in education. The teaching civil engineer educates students in technical specialties, inculcates engineering ethics and standards of safety, and engages in research and scholarly endeavors. Civil engineering faculty members are frequently involved as consultants or specialists on boards or commissions for standards, planning, or educational certification.

Photogrammetry, surveying, and mapping. The civil engineer in this specialty precisely measures the Earth's surface to obtain reliable information for locating, planning, and designing engineering projects. This specialty involves everything from traditional land surveying to high-technology methods using aerial surveying, satellites, and computer-processing of photographic imagery. The information obtained by optical sighting, radio signal, laser scan, or sonic beam is converted to maps to provide accurate locations for designing planned developments, boring tunnels, building highways or pipelines, plotting flood control, irrigation or hydroelectric projects with dams and other structures, delimiting subsurface geologic formations that may affect construction projects, and aiding many other building uses. *See* AERIAL PHOTOGRAPH; PHOTOMETRY; REMOTE SENSING; SURVEYING; TOPOGRAPHIC SURVEYING AND MAPPING.

Community and urban planning. Those engaged in this segment of civil engineering evaluate environmental, social, and economic factors in affecting the use and development of land and natural resources as they plan to establish planned developments, recreational park areas, or industrial complexes for regions, cities, or portions of a community. They work with other professionals to coordinate required infrastructure to ensure social, economic, and environmental well-being. *See* LAND-USE PLANNING.

Geotechnical engineering. Civil engineers in this specialty analyze and evaluate the behavior of earth materials and the ability of these materials to support structures on or below the ground. They design and establish procedures to prevent the pressure or weight of structures from compressing the supporting earth and causing settlement. They are also concerned with methods to stabilize slopes and fills, to protect structures and infrastructure from earthquakes, and to mitigate the unwanted effects of ground water. *See* ENGINEERING GEOLOGY; FOUNDATIONS; PERMAFROST; PILE FOUNDATION; ROCK MECHANICS; SOIL MECHANICS.

Construction engineering. Civil engineers in this area manage and direct the physical construction of a project from start to finish; this field is also known as construction management. Construction engineers apply the knowledge of construction methods and equipment along with principles of financing, scheduling, planning, organization, and coordination to convert the paper designs into completed usable facilities. They maintain a continuous record of the personnel, time, materials, and costs expended and prepare periodic reports depicting the project's progress to completion. *See* CONSTRUCTION ENGINEERING; CONSTRUCTION METHODS; ENGINEERING AND ARCHITECTURAL CONTRACTS.

Structural engineering. In this specialty, civil engineers plan, design, and evaluate a wide variety of structures, including buildings, bridges, offshore platforms, space platforms, amusement park rides, towers, and any other construction that must support its own weight and the loads it must carry. These structures must be designed for, and capable of withstanding, the loads due to rain, snow, or ice; the forces due to wind, hurricanes, and earthquakes; the effects of temperature changes and the like. The structural engineer must determine which construction materials or combinations of them such as steel, concrete, stone, brick, aluminum, plastics, and glass are most economical, safe, and appropriate for the project under the site-specific conditions. *See* BRIDGE; BUILDINGS; STRUCTURAL ANALYSIS; STRUCTURAL DESIGN; STRUCTURAL MATERIALS; STRUCTURE (ENGINEERING).

Environmental engineering. In this branch of the profession, civil engineers plan, design, construct, operate, and supervise systems to protect human health and the ecological balances necessary for environmental quality in both natural and humanmade environments. These systems include development and treatment of drinking water; collection and treatment of sanitary and industrial wastes to prevent contamination of the land and water; containment of hazardous and toxic materials; safe disposal of garbage, refuse, and other solid wastes; minimization or elimination of air pollution caused by industrial manufacturing or combustion processes; and design for containment of radioactive discharges. The environmental engineer is involved, either personally or through a team effort, to reduce, mitigate, or eliminate the hazards and risks associated with air, food, and water contaminants, radiation, toxic chemicals, solid wastes, disease vectors, safety hazards, and habitat alterations to preserve or conserve ecological biomes. *See* AIR POLLUTION; HAZARDOUS WASTE; INDUSTRIAL WASTEWATER TREATMENT; LAND RECLAMATION; SEWAGE TREATMENT; WATER POLLUTION; WETLANDS.

Water resources engineering. Civil engineers who specialize in this area deal with all aspects of the physical control of water. They plan, evaluate, design, construct, supervise, and operate systems to control floods; to supply water for cities; to develop irrigation; to manage and control river navigation, locks, and banks; to prevent beach erosion; and to maintain waterfront facilities. They are also involved in the planning and design of harbors, docks, wharfs, port facilities, canals, and offshore platforms and systems. They are involved with other civil engineers in planning and designing flood control dikes, dams, and hydroelectric power impoundments. *See* CANAL; COASTAL ENGINEERING; DAM; HARBORS AND PORTS; RESERVOIR; REVETMENT; RIVER ENGINEERING; WATER SUPPLY ENGINEERING.

Waste management and risk assessment. Civil engineers involved in this area must function as a part of a team. The improper disposal of hazardous or toxic wastes, as well as the indiscriminate dumping of wastes in landfills, has created a situation that impacts on the land and subsurface water supplies. A subset of environmental engineering has evolved that is specifically concerned with the management of these sites. At the same time it is imperative that the available time, money, and personnel be utilized to treat these existing sites in a systematic and cost-effective manner. One method of establishing the hierarchy for treating the existing sites is to perform a risk assessment and establish which areas pose the greatest threat to people and natural resources. The civil engineers in this area of work must develop treatability procedures and estimate costs needed to reduce the risk. The data must then be presented to the public to explain the trade-offs of potential risk and the costs necessary to reduce them, since the locally affected community must be willing to expend time, effort, and money to clean up and manage the site. *See* RISK ASSESSMENT AND MANAGEMENT.

Transportation engineering. Civil engineers working in this specialty plan, design, construct, and maintain facilities to safely and efficiently move people and goods. Accomplishing this task involves modal system planning for pedestrians, bikeways, streets, roads, highways, mass transit, railroads, airports, ports, and harbors. The ancillary structures to the vehicles and the travel way, which includes parking areas and terminals as the transfer facilities between the various modes of traffic, must be considered. Transportation engineers must apply technological acumen and consider the economic, social, and political factors that impact on each system. It is essential that transportation planning be done in conjunction with community and urban planners. The goal is an acceptable means of enhancing the movement of goods and people from residence to place of employment or entertainment, to shopping areas, and to health care facilities while always permitting quick response of emergency vehicles. The prosperity and quality of life of a community are intimately tied up with the transportation system. *See* AIRPORT ENGINEERING; HIGHWAY ENGINEERING; RAILROAD ENGINEERING; TRANSPORTATION ENGINEERING.

Pipeline engineering. Civil engineers in this highly specialized task of transporting liquids, gases, or slurries plan, design, maintain, and operate the pipelines in which these various types of noncombustible to highly combustible materials are moved from one location to another. The engineers determine pipeline design, location, and the environmental and economic impacts on the region that the line traverses. They select the material for constructing the line based on the qualities of durability and safety. Further, they specify installation techniques, methods of testing, and controls for maintaining proper pressure and rate of flow of the material within the line. When a hazardous or toxic material is to be carried, safety is a major concern. *See* ENGINEERING; PIPELINE.

Cladding

An old jewelry art, now employed on an industrial scale to add the desirable surface properties of an expensive metal to a low-cost or strong base metal. In the process a clad metal sheet is made by bonding or welding a thick facing to a slab of base metal; the composite plate is then rolled to the desired thickness. The relative thickness of the layers does not change during rolling. Cladding thickness is usually specified as a percentage of the total thickness, commonly 10%.

Uses. Gold-filled jewelry has long been made by this process; the surface is gold, the base metal bronze or brass with the cladding thickness usually 5%. The process is used to add corrosion resistance to steel and to add electrical or thermal conductivity, or good bearing properties, to strong metals. One of the first industrial applications, about 1930, was the use of a nickel-clad steel plate for a railroad tank car to transport caustic soda; by 1947 stainless-clad steels were being used for food and pharmaceutical equipment. Corrosion-resistant pure aluminum is clad to a strong duralumin base, and many other combinations of metals are widely used in cladding; a development includes a technique for cladding titanium to steel for jet-engine parts.

Fig. 1. Rolls of copper clad with copper-nickel facing for minting composite coins.

Today's coinage uses clad metals as a replacement for rare silver. Since 1965 dimes and quarters have been minted from composite sheet consisting of a copper core with copper-nickel facing. The proportion of core and facing used duplicates the weight and electrical conductivity of silver so the composite coins are acceptable in vending machines (**Fig. 1**).

A three-metal composite sole plate for domestic steam irons provides a thin layer of stainless steel on the outside to resist wear and corrosion. A thick core of aluminum contributes thermal conductivity and reduces weight, and a thin zinc layer on the inside aids in bonding the sole plate to the body of the iron during casting.

Cladding supplies a combination of desired properties not found in any one metal. A base metal can be selected for cost or structural properties, and another metal added for surface protection or some special property such as electrical conductivity. Thickness of the cladding can be made much heavier and more durable than obtainable by electroplating.

Combinations. The following clad materials are in common use.

Stainless steel on steel. Provides corrosion resistance and attractive surface at low cost for food display cases, chemical processing equipment, sterilizers, and decorative trim.

Stainless steel on copper. Combines surface protection and high thermal conductivity for pots and pans, and for heat exchangers for chemical processes.

Copper on aluminum. Reduces cost of electrical conductors and saves copper on appliance wiring.

Copper on steel. Adds electrical conductivity and corrosion resistance needed in immersion heaters and electrical switch parts; facilitates soldering.

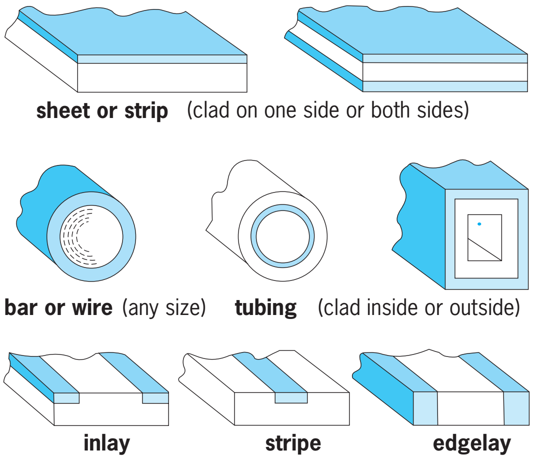

Fig. 2. Types of cladding.

Nickel or monel on steel. Provides resistance to corrosion and erosion for furnace parts, blowers, chemical equipment, toys, brush ferrules, and many mechanical parts in industrial and business machines; more durable than electroplating.

Titanium on steel. Supplies high-temperature corrosion resistance. Bonding requires a thin sheet of vanadium between titanium and steel.

Bronze on copper. Usually clad on both sides, for current-carrying springs and switch blades; combines good electrical conductivity and good spring properties.

Silver on copper. Provides oxidation resistance to surface of conductors, for high-frequency electrical coils, conductors, and braiding.

Silver on bronze or nickel. Adds current-carrying capacity to low-conductivity spring material; cladding sometimes is in form of stripes or inlays with silver areas serving as built-in electrical contacts.

Gold on copper. Supplies chemical resistance to a low-cost base metal for chemical processing equipment.

Gold on nickel or brass. Adds chemical resistance to a stronger base metal than copper; also used for jewelry, wristbands, and watchcases.

Types. Cladding can be added to both sides of a sheet or strip of base metal. Tubing can be supplied with a clad surface on inside or outside; round and rectangular wire can be clad similarly (**Fig. 2**).

For some forms of electrical contact, the composite materials are bonded side by side, or silver is inset as a stripe on one side or along the edges. This construction can place solid silver just where it is needed to form an electrical contact with no waste of costly metal.

Another related form of cladding is found in thermostatic bimetals in which equal thicknesses of low- and high-expansion metals are bonded together. With a change in temperature, differing expansion rates of the two metals cause the composite material to bend and thus operate valves in automobile cooling systems, or electrical contacts in room thermostats.

Clad wires with properly chosen proportions of materials of different thermal-expansion rates can match the thermal expansion of types of glass used for vacuum-tight seals for conductors in lamp bulbs and hermetically sealed enclosures.

In making parts from clad metal, the composite material can be bent, drawn, spun, or otherwise formed just the same as the base metal without breaking the bond. The maximum service temperature is limited by the melting point of the material at the juncture of the two metals; annealing temperatures during manufacturing are similarly limited.

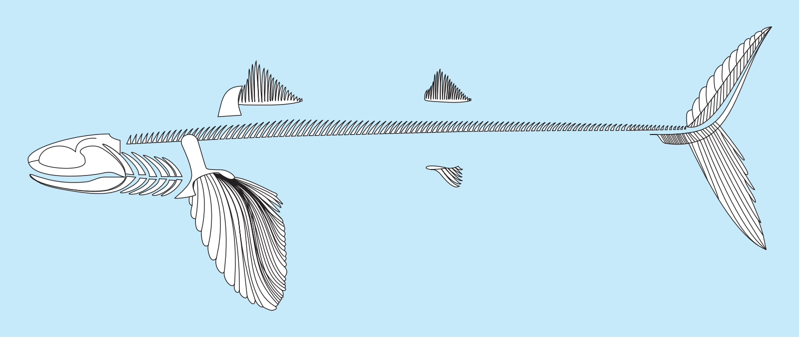
Cut edges of clad sheets expose the base metal and thus may require special protection. Welding of thick clad sheets sometimes offers special problems in maintaining the integrity of the protective surface, but joining methods are generally the same as for the base metal. *See* ELECTROPLATING OF METALS; METAL COATINGS.

Robert W. Carson

Cladoselache

A genus of Paleozoic chondrichthyan "sharks," characterized by broad-based paired fins, a short stout bony spine preceding the first of the two dorsal fins, and a large lunate tail-fin. Often cited as among the best known, earliest, and/or most primitive of the early chondrichthyans (cartilaginous fishes including modern chimaeroids, sharks and rays), *Cladoselache* now appears ill defined and poorly diagnosed. Most of the best fossil specimens of *Cladoselache* are from the Upper Devonian Cleveland Shales, and include complete individuals of around 1 m (3.3 ft) in length. Several of these have mineralized traces of soft tissues, including much of the superficial jaw and gill musculature, and even apparent traces of internal organs such as the kidneys. The dentition consists of small tricuspid teeth in which the central cusp is largest; the body is mostly naked except for compound scales on the head and fins. No specimens of *Cladoselache* are known to have claspers—the sex organs of male chondrichthyans used for internal fertilization (otherwise preserved as skeletal rods extending from the rear of the hind set of paired fins). *See* CHONDRICHTHYES.

In the context of more recent discoveries of early sharklike fishes, *Cladoselache* is emerging as unusual and specialized in several respects. The high-aspect-ratio (tall and narrow) tail is like that of only a subset



***Cladoselache fyleri*, from the Upper Devonian of Cleveland. (*After S. E. Bendix-Algreen, 1975*)**

of Paleozoic sharks, all of which have a transformed stretch of the vertebral column supporting the upper lobe, but this is far from primitive and completely absent from most contemporaneous chondrichthyan and nonchondrichthyan fishes. The pectoral fins are remarkably large for the total body size, and are supported by a series of broad straplike cartilages—most of which extend directly from the shoulder girdle. This pattern was once considered primitive because it resembled a hypothesized archetypical fin condition (the continuous lateral fin-fold model) for which there is now little fossil and embryological support. Comparisons with paired fins among other early fishes now highlight the cladoselachian pattern as unusual. The braincase (neurocranium) is known in outline only; it is peculiarly wide, although this might result from postmortem compression.

Few other aspects of the paleobiology of *Cladoselache* are known. The Cleveland Shale was deposited in a shallow inland sea covering what is now northeastern Ohio. *Cladoselache* was probably a medium-sized pelagic member of the fauna, dwarfed by large arthrodire placoderms (such as *Dunkleosteus*) known from the same fossil localities. Stomach contents of *Cladoselache* include the intact remains of small ray-finned (actinopterygian) fishes (*Kentuckia*), preserved with heads directed toward the front of the enclosing gut-trace. This rare detail from a fossil fish suggests that they (the ray-finned prey) were engulfed from the rear, tail-first, implying that in this instance *Cladoselache* behaved as an active, pursuit predator. *See* ACTINOPTERYGII; PLACODERMI.

Clarification

The removal of small amounts of fine, particulate solids from liquids. The purpose is almost invariably to improve the quality of the liquid, and the removed solids often are discarded. The particles removed by a clarifier may be as large as 100 micrometers or as small as 2 micrometers. Clarification is used in the manufacture of pharmaceuticals, beverages, rayon, nylon, and other fiber and film polymers; in the reconditioning of electroplating solutions; in the recovery of dry-cleaning solvent; and for the purification of drinking water and wastewater. The filters in the feed line and lubricating oil system of an internal combustion engine are clarifiers.

The methods of clarification include gravity sedimentation, centrifugal sedimentation, filtration, and magnetic separation. Clarification differs from other applications of these mechanical separation techniques by the low solid content of the suspension to be clarified (usually less than 0.2%) and the substantial completion of the particle removal.

Gravity sedimentation is employed, usually in continuous settling tanks of simple construction, to concentrate the solid fraction and to clarify the liquid fraction of suspensions amenable to separation by this method. Gravity clarifiers differ from thickeners only in the concentration of solids in the feed and in the demand that the overflow be practically particle free. *See* SEDIMENTATION (INDUSTRY); THICKENING.

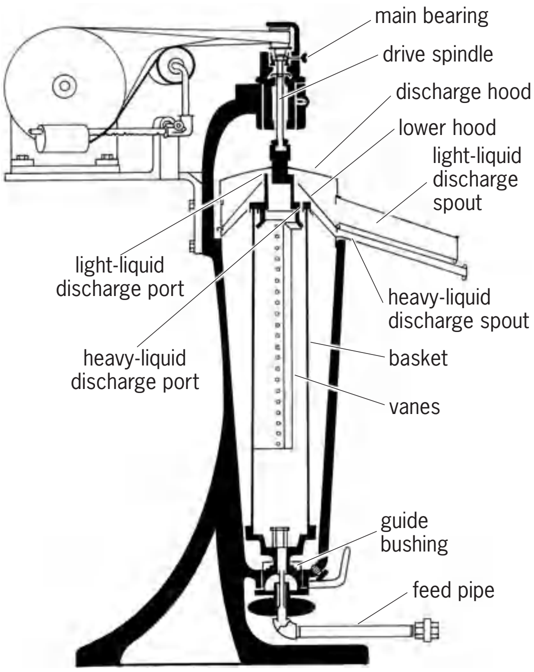

Fig. 1. Continuous high-speed clarifying centrifuge. (*After W. L. Bader and J. T. Banchero, Introduction to Chemical Engineering, McGraw-Hill, 1955*)

When the settling rate is too slow for gravity sedimentation to be feasible, centrifugal force up to approximately 100,000 times the force of gravity may be employed to clarify a suspension. In a separator called a centrifuge the suspension is passed through a rapidly rotating tube or basket (**Fig. 1**). The relatively dense solids are forced to the walls of the rotor, and the clarified liquid overflows a dam in the end of the centrifuge. *See* CENTRIFUGATION; ULTRACENTRIFUGE.

Clarifying filters comprise a versatile class of mechanical separators that are effective over the entire range of particle sizes encountered in clarification (from 0.1 mm down to molecules with a molecular weight on the order of 1000), regardless of relative densities and in spite of high viscosities. Sand or coal filters are used extensively for potable and industrial water clarification. Precoat filters are used for water and suspensions carrying slimy, amorphous impurities. Disk and plate filters (**Fig. 2**) service a wide variety of clarifying demands, removing particles over a range of 0.1 to 5 μm. Cartridge filters are in-line units with cleanable or replaceable elements that can remove particles in the range of 0.5 to 50 μm. Ultrafilters (also called microfilters and hyperfilters) contain fibrous sheets or porous membranes with carefully sized pores. These can remove particles as small as 0.002 μm. *See* FILTRATION; STERILIZATION; ULTRAFILTRATION.

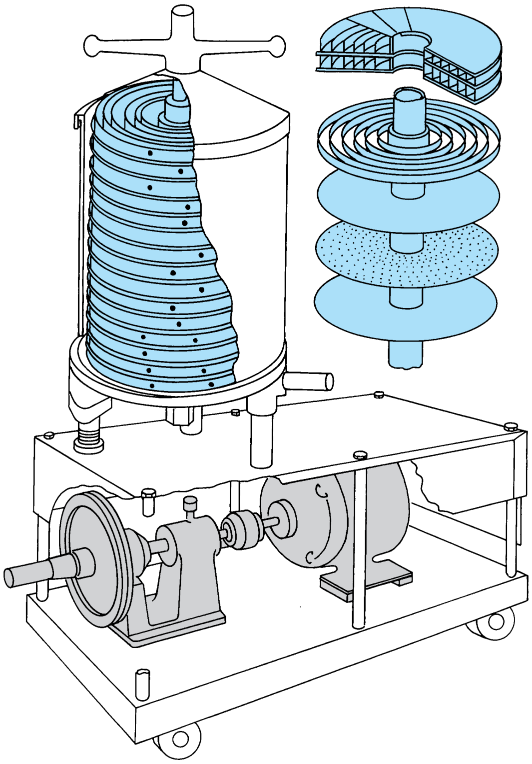

Fig. 2. Disk-and-plate clarifying filter. (*After R. H. Perry and D. Green, eds., Perry's Chemical Engineers' Handbook, 6th ed., McGraw-Hill, 1984*)

Magnetic separators are effective for the removal of ferrous particles. *See* MAGNETIC SEPARATION METHODS.

Clarification processes often depend on flocculating agents for their success. These are additives that cause the suspended solids to agglomerate into flocs that settle more rapidly or are more readily filtered than their smaller components. **Shelby A. Miller**

Classical field theory

The mathematical discipline that studies the behavior of distributions of matter and energy when their discrete nature can be ignored; also known as continuum physics or continuum mechanics. The discrete nature of matter refers to its molecular nature, and that of energy to the quantum nature of force fields and of the mechanical vibrations that exist in any sample of matter. The theory is normally valid when the sample is of laboratory size or larger, and when the number of quanta present is also very large. *See* PHONON; PHOTON; QUANTUM MECHANICS.

Classical field theories can be formulated by the molecular approach, which seeks to derive the macroscopic (bulk) properties by taking local averages of microscopic quantities, or by the phenomenological approach, which ignores the microscopic nature of the sample and uses properties directly measurable with laboratory equipment. This article follows the phenomenological course, although the microscopic treatment sometimes yields profounder insights. The problems considered below illustrate a selection of classical field theories without long mathematical discussions. Partial differential equations are used because the neglect of microscopic structure allows quantities like density and pressure to be expressed by continuously varying numbers.

Bending of a beam. A first example, leading to an ordinary differential equation, is the bending of a solid beam. To calculate the bending, isolate a segment of length dx (see **illus.**), and take account of the conditions that produce a mechanical equilibrium. The forces exerted up and down on the beam must balance, as well as the moments or torques tending to turn it. These conditions, combined with some geometry, lead to an equation from which the curvature of the beam can be calculated.

The quantity $M(x)$ is defined to be the moment or torque exerted by the part of the beam to the right of point x on the part to the left, and similarly $S(x)$ is the shear force exerted from right to left. If $\rho(x)$ is the beam's linear density, it follows from definitions that S and M change as in Eqs. (1) and (2), where g is

$$dS = -\rho g dx \qquad \frac{dS}{dx} = -\rho g \tag{1}$$

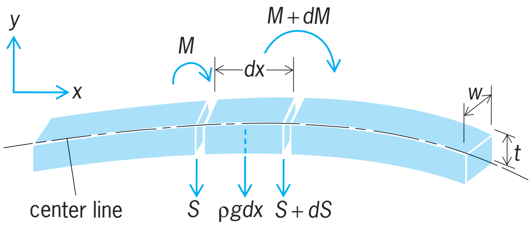
$$dM = S dx \qquad \frac{dM}{dx} = S \tag{2}$$

the acceleration of gravity. To find the bending, the beam is assumed to consist of parallel fibers; those above the center line are in tension and those below in compression. It is easy to see that at any point x, M is as given in Eq. (3), where R is the beam's

$$M = \frac{E}{R} I \qquad I = \int y^2 dA \tag{3}$$

radius of curvature, E is Young's modulus of elasticity for the material, dA is an element of area, and I is the moment of inertia of the cross section. If the beam is nearly horizontal, Eq. (4) relates R to the second derivative of y. For the rectangular cross section

$$\frac{d^2y}{dx^2} = \frac{1}{R} \tag{4}$$



Portion of a rectangular solid beam, showing quantities used in calculating the bending of the beam.

shown, I is evaluated around the center line and is given by Eq. (5).

$$I = {}^{1}/_{12}\omega t^{3} \tag{5}$$

See MOMENT OF INERTIA; SHEAR; STATICS.

Combining Eqs. (1)–(4) gives Eq. (6) for the shape

$$\frac{d^{4}y}{dx^{4}} = -\frac{pg}{EI} \tag{6}$$

of the beam. It can be integrated, requiring four boundary conditions, to find the curve under different conditions of loading; for example, if the beam is of length l and is supported horizontally at one end, the sag Y at the other end, given in Eq. (7), varies as

$$Y = -\frac{pg}{EI}\frac{l^{4}}{8t^{3}} \tag{7}$$

l^4/t^3. Historically, the analysis in terms of the moment of inertia I was begun by G. W. Leibniz in 1694, and results equivalent to the foregoing were obtained by C. Coulomb in 1773. The representation of the beam as a sheaf of fibers of infinitesimal thickness leads to the field equation (6), which is extremely simple in form and involves only the bulk properties of the material. *See* LOADS, TRANSVERSE.

Diffusion. In a vessel of fluid (liquid or gas) a small quantity of a different fluid is released and spreads slowly (in the absence of convection) through the vessel. To calculate the rate at which it spreads, let $n(x)$ be the number of molecules of the new fluid per unit volume, and $\mathbf{j}(x)$ be the flow (molecules per unit area per unit time) produced by any nonuniform distribution of n. This current has the direction in which n changes most rapidly, and the simplest assumption is that it is given approximately by Eq. (8),

$$\mathbf{j}(x) = -D\nabla n(x) \tag{8}$$

proposed by A. Fick in 1855, where D is the diffusivity, a coefficient which for simplicity is here assumed independent of x. If the molecules of the new fluid are neither created nor destroyed, $\mathbf{j}$ satisfies the conservation equation (9), and Fick's law becomes the

$$\nabla \cdot \mathbf{j} + \frac{\partial n}{\partial t} = 0 \tag{9}$$

field equation (10) giving the variation of n with po-

$$\frac{\partial n}{\partial t} = D\nabla^{2}n \tag{10}$$

sition and time. *See* CALCULUS OF VECTORS.

If the initial distribution of n is $n_0(x)$ and the region is so large that its boundaries are far away, this equation is easy to solve. Let $\tilde{n}(k)$ be the Fourier transform of $n_0(x)$, so that Eq. (9) is solved by Eq. (11) where

$$n(x, t) = \int \tilde{n}(k)\exp(i\mathbf{k}\cdot\mathbf{x} - k^{2}Dt)d^{3}k \tag{11}$$

the integration is over all values of k; this expression satisfies Eq. (9) whatever the function $\tilde{n}$ may be. If $t = 0$, the value of the integral is n_0, and if $t > 0$, Eq. (11) shows what happens as time goes on. For any $\tilde{n}$, as t becomes large, the distribution spreads and becomes uniform. (If $t < 0$, the integral shows correctly only in exceptional cases what happened earlier.)

The diffusion equation contains a single parameter, the diffusivity D. It can be determined from experiment and also in other ways, for diffusion can be analyzed as a random molecular process. The drag β that a diffusing particle experiences as it moves through the fluid is defined by Eq. (12), where v is

$$F = -\beta v \tag{12}$$

the particle velocity. Then the diffusivity can be calculated as in Eq. (13), where k is Boltzmann's con-

$$D = \frac{kT}{\beta} \tag{13}$$

stant and T is the absolute temperature. Evidently the warmer the environment and the less the resistance, the faster the diffusion. Equation (13) was first given by A. Einstein in 1905. *See* DIFFUSION.

Temperature, T, is another field quantity in classical physics, and the argument used for diffusion makes it plausible that heat diffusing through a solid follows the same law. Equation (14) duplicates the

$$\frac{\partial T}{\partial t} = \alpha^{2}\nabla^{2}T \tag{14}$$

diffusion equation and has the same solutions. The coefficient α is calculated in the theory of solids by methods that differ according to the physical properties of the solid. *See* CONDUCTION (HEAT).

Hydrodynamics. The calculation of the flow of a fluid presents great mathematical difficulties; in fact, the essentially chaotic nature of turbulence often makes it impossible to represent flow in terms of a continuously varying field. The following discussion is therefore restricted to nonturbulent motion. *See* TURBULENT FLOW.

The basic equation of fluid flow was given by L. Euler in 1755. In modern notation, it can be derived as follows: A small volume of the fluid moves with velocity $\mathbf{v}$. The force exerted on it by the pressure p of the surrounding fluid is

$$-\oint p d\mathbf{A}$$

where dA is an outward-directed element of area, and this is transformed by a vector identity into

$$-\int \nabla p dV$$

that is to say, the force on the element of fluid is $-\nabla p$ per unit volume. If p is the density of the fluid, Newton's law gives the equation of motion, Eq. (15), where the gravitational force on the element is included. It is more convenient mathematically to study changes in velocity at a given point in space than to follow an element of fluid as it moves.

$$\frac{\rho d\mathbf{v}}{dt} = -\nabla p + p\mathbf{g} \tag{15}$$

It is easy to show that Eq. (16) is valid, which gives Euler's equation (17).

$$\frac{d\mathbf{v}}{dt} = \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v}\cdot\nabla)\mathbf{v} \qquad (16)$$

$$\frac{\partial \mathbf{v}}{\partial t} = -(\mathbf{v}\cdot\nabla)\mathbf{v} - \frac{1}{\rho\nabla}p + \mathbf{g} \qquad (17)$$

Solutions of Euler's equation are as varied as the conditions under which fluids flow; to see what it does and does not contain let us look at a very simple case, the propagation of sound through a fluid. Let $p = p_0 + p'$ and $\rho = \rho_0 + \rho'$, where p_0 and ρ_0 are the ambient values, and assume that the amplitude is so small that second-order terms in p, ρ, and $\mathbf{v}$ can be neglected, as well as $\mathbf{g}$. In addition, $\mathbf{v}$ can be represented as $\nabla\phi$, where ϕ is called the velocity potential. Then Euler's equation gives Eqs. (18). Equations (19) compare the time derivative of Eqs. (18) with the conservation equation (9) expressed in terms of ϕ. An equation for ϕ is possible if p' can be expressed in terms of ρ'. To do this requires a hypothesis that is not included in either Euler's equation or the conservation law, namely, an equation of state for the fluid. If $(\partial p/\partial\rho)_0$ is denoted by c^2, comparison of Eqs. (18) and (19) gives Eq. (20),

$$\begin{aligned} \nabla\left(\frac{\partial\phi}{\partial t} + \frac{p'}{\rho_0}\right) &= 0 \\ \rho_0\frac{\partial\phi}{\partial t} + p' &= 0 \end{aligned} \qquad (18)$$

$$\begin{aligned} \rho_0\frac{\partial^2\phi}{\partial t^2} + \frac{\partial p'}{\partial t} &= 0 \\ \rho_0\nabla^2\phi + \frac{\partial\rho'}{\partial t} &= 0 \end{aligned} \qquad (19)$$

$$\nabla^2\phi - \frac{1}{c^2}\frac{\partial^2\phi}{\partial t^2} = 0 \qquad (20)$$

which is d'Alembert's equation for a wave traveling with velocity c.

The foregoing example shows how the equation of motion for the acoustical field arises from three hypotheses: Newton's second law, the conservation of the fluid, and its equation of state. Whereas the previous examples of field equations could have been derived by reasoning from the microscopic properties of matter, Eq. (20) would have been very difficult to derive in this way. *See* FLUID-FLOW PRINCIPLES; HYDRODYNAMICS; SOUND; WAVE EQUATION; WAVE MOTION.

Electromagnetic field. The theory of the electromagnetic field, which J. C. Maxwell developed during the 1860s, was intended as a phenomenological theory of the ether analogous to the theories outlined above. There is of course no ether, and therefore no phenomenological properties, but this was not known at the time, and to discover the properties of ether was generally considered the most important task of physics. Maxwell based his work on a microscopic model of the ether involving tiny whirling vortices, but when it was finished the model's phenomenological constants had almost entirely disappeared from the equations; only one remained. The electric current could be calculated from the theory in two ways, and the constant, now called c, is determined by the ratio of the two resulting numbers. During the succeeding 40 years Maxwell's equations were regarded as a clever device that gave correct answers while avoiding the important questions.

In terms ofthe electrodynamic potentials, using the modern International System of Units (SI), Maxwell's equations can be written in the form of Eqs. (21); here $\mathbf{A}(x)$ and $\varphi(x)$ are vector and scalar potentials, respectively, and $\mathbf{j}(x)$ and $\rho(x)$ are the current and charge densities, respectively, that produce them. They occur on the right sides multiplied by μ and $1/\epsilon$, respectively, and since $\mathbf{j}$ is simply the result of moving ρ, the units are effectively different in the two equations. Their ratio is $c^2 = 1/(\epsilon\mu)$; in Maxwell's day its value was approximately known. In empty space, $\mathbf{j} = \rho = 0$, and the equations are d'Alembert's for waves traveling at a speed c. The correspondence between this c and the measured speed of light was convincing evidence that light is an electromagnetic phenomenon.

$$\begin{aligned} \nabla^2\mathbf{A} - \epsilon\mu\frac{\partial^2\mathbf{A}}{\partial t^2} &= -\mu\mathbf{j} \\ \nabla^2\varphi - \epsilon\mu\frac{\partial^2\varphi}{\partial t^2} &= -\frac{1}{\epsilon}\rho \end{aligned} \qquad (21)$$

Maxwell's equations are still phenomenological in content, but they are now considered to describe the electromagnetic fields and potentials and not properties of the ether. They are fully relativistic and survive in form, though not exactly in content, in the modern theory of quantum electrodynamics. *See* ELECTROMAGNETIC RADIATION; MAXWELL'S EQUATIONS; QUANTUM ELECTRODYNAMICS; RELATIVISTIC ELECTRODYNAMICS.

Gravitational field. During the nineteenth century, tentative efforts were made to create a theory of gravity along the same lines as Maxwell's theory of electromagnetism. The results, however, were trivial, and the development of special relativity showed that they could not possibly be correct. Only with a reformulation of the entire problem in terms of curved space-time was Einstein able in 1915 to create a classical theory of the gravitational field. Like the classical theories mentioned above, it gives its results in terms of phenomenological constants: the speed of light and the force of attraction between two unit masses one unit distance apart. It is very successful in explaining not only the phenomena of gravitation known in 1915 but also various new facts that have been learned since. Unlike Maxwell's equations, however, Einstein's do not give reasonable results in the context of a quantum theory of gravity. They must represent some sort of approximation, but so far no successful quantum version has been developed with which they can be compared. *See* GRAVITATION; QUANTUM GRAVITATION; RELATIVITY.

Mathematical development. The foregoing examples illustrate some of the most important classical field theories. Solving the equations has produced a vast body of mathematics. Computers have aided in special calculations, but many mathematicians are working on the analytical theory of partial differential equations, and new results continue to be produced. *See* DIFFERENTIAL EQUATION. David Park

Bibliography. G. Carrier, *Partial Differential Equations*, 2d ed., 1988; G. Joos and I. M. Freeman, *Theoretical Physics*, 3d ed., 1986; L. Landau, *Course of Theoretical Physics*: *The Classical Theory of Fields*, 4th ed., 1980.

Classical mechanics

The science dealing with the description of the positions of objects in space under the action of forces as a function of time. Some of the laws of mechanics were recognized at least as early as the time of Archimedes (287?–212 B.C.). In 1638, Galileo stated some of the fundamental concepts of mechanics, and in 1687, Isaac Newton published his *Principia*, which presents the basic laws of motion, the law of gravitation, the theory of tides, and the theory of the solar system. This monumental work and the writings of J. d'Alembert, J. L. Lagrange, P. S. Laplace, and others in the eighteenth century are recognized as classic works in the field of mechanics. Jointly they serve as the base of the broad field of study known as classical mechanics, or Newtonian mechanics. This field does not encompass the more recent developments in mechanics, such as statistical, relativistic, or quantum mechanics.

The general principles of classical mechanics are stated in mathematical form. With mathematical logic, one can deduce countless possible motions of bodies and then compare the predictions with experimental observations. Classical mechanics illustrates the essential nature of a physical theory, and it is usually an important ingredient in or a starting point for the various branches of modern physics. Its study offers one the opportunity to become acquainted with mathematical techniques and procedures which are useful in other fields.

In the broad sense, classical mechanics includes the study of motions of gases, liquids, and solids, but more commonly it is taken to refer only to solids. In the restricted reference to solids, classical mechanics is subdivided into statics, kinematics, and dynamics. Statics considers the action of forces that produce equilibrium or rest; kinematics deals with the description of motion without concern for the causes of motion; and dynamics involves the study of the motions of bodies under the actions of forces upon them. An important example of a force whose effect on bodies is often studied is the Earth's gravitational force. For some of the more important areas of classical mechanics *see* BALLISTICS; CANONICAL COORDINATES AND TRANSFORMATIONS; CELESTIAL MECHANICS; COLLISION (PHYSICS); DYNAMICS; ENERGY; FORCE; GRAVITATION; KINEMATICS; LAGRANGE'S EQUATIONS; MASS; MOTION; PRECESSION; RIGID-BODY DYNAMICS; STATICS; WORK.

The mathematical structure of classical mechanics is essential to understand both the historical development and the current status of relativity theory and of quantum mechanics. *See* QUANTUM MECHANICS; RELATIVITY. Newell S. Gingrich; John L. Safko

Saletan, *Classical Dynamics: A Contemporary Approach*, 1998; Theme issue on classical mechanics and non-linear dynamics, *Amer. J. Phys.*, 72(4):423–559, April 2004.

Classical swine fever

A highly contagious epizootic disease of pigs, also known as hog cholera. The causative agent is a virus in the family Flaviviridae, genus *Pestivirus*. Due to its significant economic impact, this disease is the subject of statutory controls in a majority of countries. It has been eradicated from many areas, including the United States, Canada, Australasia, and most parts of Europe. Clinically and pathologically, it closely resembles African swine fever, which is caused by an unrelated virus.

Transmission. Classical swine fever affects domestic and feral pigs as well as European wild boar. Humans are not susceptible. The primary mode of transmission is by contact or proximity. Infected animals shed virus in all bodily secretions. The virus may also be spread by contact with contaminated equipment and vehicles. It can survive for many months in frozen or refrigerated meat from infected pigs, and is not inactivated by mild forms of curing. Most primary outbreaks of classical swine fever are attributable to the feeding of pigs with waste human foodstuffs containing uncooked pig meat. Pregnant sows that recover from classical swine fever infection may give birth to congenitally infected carrier piglets with or without clinical signs that are a source of infection for other pigs.

Clinical signs. Pigs of any age may be affected; however, clinical signs are more severe in young pigs. High fever, loss of appetite, and dullness are the most typical symptoms of the acute form of the disease. Other symptoms may include blotchy discoloration of the skin (particularly the extremities), incoordination and weakness of the hindquarters, constipation followed by diarrhea, conjunctivitis, and coughing. Death may occur within 4 to 7 days after onset of symptoms. Mortality is usually high among young animals. Older pigs often develop immunity and recover completely. Recovered sows may abort or may give birth to poor litters that experience congenital tremors and convulsions.

Some pigs develop chronic disease that is characterized by undulating fever, dullness, poor performance (such as decreased daily weight gain), capricious appetite, and variable degrees of coughing, diarrhea, and emaciation. There may be joint swellings and ulceration of the skin. These animals will die after 2 or 3 months.

Piglets that have been infected during pregnancy will develop the late-onset form of the disease, and death will occur within a few months after birth.

Strains vary in virulence, and classical swine fever may still be suspected when milder signs occur in epizootic form. Low-virulence strains may produce few signs apart from reproductive failure in sows or congenital tremors in their offspring.

Pathology. A few days after the infection, white blood cells and thrombocytes (platelets) are greatly reduced. Petechial (small, round) to confluent hemorrhages occur in the body, but particularly in the lymph nodes, kidneys, laryngeal mucosa, and urinary bladder. Infarcts are sometimes seen in the spleen. In chronic cases, a characteristic lesion is button ulceration of the large intestine. In cases of congenital infection, a proportion of piglets may show incomplete development of the cerebellum or other developmental abnormalities.

Microscopic and ultrastructural lesions include signs of microthrombosis (blood clot formation in the capillaries and other small blood vessels) and apoptosis (programmed cell death) as well as activation of macrophages and platelets. Damaged capillary endothelial cells lead to either obstruction or dilation of the vascular lumen and affect permeability. In addition, there is depletion of lymphocytes in the lymphoid tissues.

Diagnosis. The majority of outbreaks of classical swine fever are diagnosed on clinical grounds, especially in the severe acute form of disease; however, it is essential to carry out laboratory tests to confirm a presumptive diagnosis. Differential diagnoses include African swine fever, pseudorabies, porcine epidemic abortion and respiratory syndrome, porcine dermatitis and nephropathy syndrome, parvovirosis, bacterial septicemias (for example, salmonellosis, leptospirosis, swine erysipelas), thrombocytopenic purpura (a bleeding disorder), and poisoning with the rodenticide warfarin. Infections of pigs with the related pestivirus from cattle (bovine viral diarrhea virus) can occasionally cause similar symptoms and cross-reactions in diagnostic laboratory tests. *See* LEPTOSPIROSIS; SALMONELLOSES.

Control and vaccination. There is no specific treatment for classical swine fever. In classical swine fever–free countries, disease outbreaks are controlled by a stamping-out policy; that is, once the disease has been confirmed all pigs on affected and suspected farms are slaughtered to prevent further spread. Vaccination is usually prohibited, as it interferes with international trade. In areas with dense pig populations this policy might be very costly. Vaccination programs are widely practiced in regions with enzootic infection. Vaccination can control the severe clinical effects of the disease but cannot completely prevent infection and spread of the virus. Recently marker vaccines have been licensed. These vaccines are promising tools in the control of the infection, since they allow the distinction between vaccinated and infected animals. (Serological tests can be performed that detect the presence of antibodies to viral proteins that are produced only by the infected animals.) Thus, they can prevent the unnecessary slaughter of healthy animals. Epidemics of classical swine fever in wild boar populations may be long lasting and difficult to control. They are a threat to any local domestic pig holding. Specific hunting measures and oral vaccination campaigns are suitable tools to shorten the duration of these epidemics. *See* ANIMAL VIRUS; SWINE PRODUCTION; VACCINATION.

Classification, biological

Arrangements of the names of species and groups of species meant to convey how these organisms are related to one another. The purposes of biological classifications are to organize the known biodiversity, provide a framework that will incorporate newly discovered biodiversity, and provide a predictive framework for studying biodiversity. Systematics focuses on studies of biodiversity and relationships among organisms. Taxonomy is a subdiscipline of systematics that focuses on formal classifications of organisms. *See* ANIMAL SYSTEMATICS; BIODIVERSITY; TAXONOMY.

Hierarchy of Ranks

Most, but not all, biological classifications are hierarchical, group-within-group arrangements in which a larger group will include one to many smaller groups within it. A group, or taxon, is given a formal name. The name refers to the organisms that are classified in the group. For example, *Homo sapiens* is the taxon name for all of the organisms classified as living humans, whereas Eukaryota is the taxon name for all plants, animals (including humans), and fungi. The place within a hierarchy is traditionally indicated using ranks. *See* TAXON; TAXONOMIC CATEGORIES.

Domain Eukaryota (organisms with organelles)
    Kingdom Metazoa (multicellular animals)
        Phylum Chordata (vertebrate animals and kin)
            Class Mammalia (mammals)
                Order Primates (primate mammals)
                    Family Hominidae (fossil and living humans)
                        Genus *Homo* (living humans and close relatives)
                            Species *Homo sapiens* (living humans)

Purposes and Applications of Modern Biological Classifications

Most systematists now agree that modern biological classifications must serve two purposes. First, they must serve the primary biological function of expressing the common ancestry relationships (phylogenies) of organisms when possible, that is, when we have reliable information from which we can infer these relationships. One of the major activities of systematists is discovering these phylogenies using the characters of organisms (from DNA to behavior) and building from their studies the Tree of Life. Second, biological classifications must serve as systems from which information about the relationships of organisms can be reliably obtained. This requires that the classifications be consistent with the Tree of Life for groups of organisms with reliable phylogenies. It also requires that names be used consistently so that all biologists understand their meaning.

Classifications have very important applications. For example, the manner in which bacteria are classified forms the basis for predicting the pathogenesis of newly discovered or unknown bacteria. The entire genomes of organisms, such as the mouse and roundworm, are used as model systems to understand the development and causes of disease. Where these organisms fit into a classification has great value in predicting how generalizable the results of this research might be and to which other organisms the findings might apply.

Medical researchers frequently use rats and mice as the first subjects of studies, but it is understood that research using monkeys and great apes is critical if the findings are to be applied to humans. This is because our biological classifications show a close evolutionary relationship between humans and chimps, and we know that the more a medical breakthrough applies to species closely related to humans, the better the chances that they are applicable to humans.

Development of Modern Biological Classifications

The history of the development of the purposes and uses of modern biological classifications has two major themes: (1) how biologists have agreed to name taxa in a way that the use of names is consistent across international borders and over generations and (2) how the function of classifications to serve the needs of modern evolutionary biology emerged with increasing understanding of the nature of taxa.

Use of consistent names. Our modern biological classifications date to classifications published by the eighteenth-century Swedish botanist Carol Linnaeus (1707–1778). Linnaeus gathered both his work and the works of others into volumes outlining his system for organizing plant (*Species Plantarum*, 1753) and animal diversity (*Systema Naturae*, 1758). Linnaeus was by no means the first person to classify plants and animals, but his system of binomial nomenclature (that is, giving each species a two-part name, such as *Homo sapiens*) was widely adopted.

Three International Codes of Nomenclature. By the midnineteenth century, the chaos caused by individual taxonomists proposing different names for the same groups resulted in international efforts to propose rules that govern both the way that names were formed and what names should be used for any particular group. These rules have evolved into the three International Codes of Nomenclature, one each for plants, animals, and prokaryotes (bacteria). Each code specified when the official nomenclature of a particular group begins. For example, animal names proposed before 1758 (that is, before publication of the 10th edition of *Systema Naturae*) cannot be used; only names proposed in the *Systema Naturae* or after the publication of this work are permissible. Other works were selected for other groups as the starting point for names. Further, when possible, the oldest name that was proposed for a group is the official name of the group (Principle of Priority). Finally, each code includes a principle of typification.

Typification signals the intention of the person who names a group, usually by pointing to an actual specimen (for species names) or species (for group names) that the original author meant to include in the taxon. For example, the commercially important Indo-Pacific tuna commonly known as the kawakawa tuna was first described in 1849 by T. E. Cantor. The current name of this species is *Euthynnus affinis* (Cantor, 1849) and a dry skin of the fish used by cantor in his description can be found in the Natural History Museum, London. We understand that Cantor's intention was to apply this name to this specimen because he made reference to the specimen and it still exists and can be studied. We infer that this is the same fish that Cantor named by comparing the skin to specimens that we continue to collect and harvest for commercial purposes, taking into consideration modern concepts of how species in nature can vary and how the specimens we collect might differ from the type specimen as a result of this variation.

Naming is also regulated by the various Codes. For example, all Codes require that species have two names, the name of a genus and a specific epitaph. *Homo sapiens* is the name for living humans, not "*sapiens*." *Pinus ponderosa* is the name of the ponderosa pine tree, not "*ponderosa*." The genus name is always capitalized and the specific epitaph is never capitalized. And, the name is always set apart from the rest of the text, usually by using italics. The names of higher taxa (those that have ranks higher than species) may have specific endings and are frequently formed using the names of lower taxa. For example, in zoological nomenclature, priority and typification extends to the level of the rank family. Family names take on the root of a genus name and end in "idea." Subfamilies take on the name of a type genus and carry the ending "inae." The names of Tribes take on a genus name and end with "ini." Using this knowledge, we can actually "decode" the classification of the kawakawa tuna:

Kingdom Animalia (animals)
- Phylum Chordata (animals with notochords)
  - Subphylum Vertebrata (animals with backbones)
    - Superclass Gnathostomata (vertebrates with jaws)
      - Class Osteichthyes (ray-fin fishes and tetrapods)
        - Subclass Actinopterygii (ray-fin fishes)
          - Order Perciformes (fishes related to perches)
            - Suborder Scombroidei (mackerels, billfishes, and tunas)
              - Family Scombridae (mackerels and tunas, but not billfishes)
                - Subfamily Scombrinae (tunas, mackerels)
                  - Tribe Thunni (tunas but not mackerels)
                    - Genus *Euthynnus* (lesser tunas, but not the larger tunas)
                      - Species *Euthynnus affinis* (Cantor, 1849)

These efforts to regulate the names of organisms were designed to result in an international language of classification; biologists in China would use the same name for the same organisms as biologists in Sweden. Since Latin was the unofficial language of western scientists when Linnaeus formed his systems of classification, Latin continued to be used. Although cumbersome for the layperson, this has effect of producing a "neutral" language for international communication, setting aside national or regional preferences.

Zoological Code. From Kingdom to Suborder, the rules of priority and typification do not apply in the Zoological Code, so zoologists are free to use the names they wish, subject to general community consensus. However, some names are traditionally derived from lower group names. For example, Perciformes is a name formed around the genus name *Perca*, to which the common yellow perches of Europe and North American belong. At the rank level Family, the rules begin to apply. Scombridae and Scombrinae refer to all fishes of the family that includes the genus *Scomber* (mackerels), Thunni refers to a tribe that includes the large tunas of the genus *Thunnus* and relatives, including *Euthynnus; E. affinis* is one of three species of that genus. The form of the name is subject to the grammatical rules of Latin, thus "Scombridae" rather than "Scomberidae." *See* ZOOLOGICAL NOMENCLATURE.

Botanical and Bacteriological Codes. The rules for plants and prokaryotes (bacteria) work a bit differently and are independent of zoological rules. The names of prokaryotes names must be registered in the approved Lists of Prokaryotic Names, but no such requirement exists for zoological or botanical names. Name endings of plant and prokaryote groups are mostly similar, but they differ from the endings for animal groups. In botany, typification is applied to all ranks, whereas in prokaryotes, it is applied only to ranks below class, and thus naming is more rigid. For example, the classification of the ponderosa pine tree is as follows:

Kingdom Plantae
- Division Pinophyta (the conifers)
  - Class Pinopsida (the conifers again)
    - Order Pinales (living conifers)
      - Family Pinaceae (pines but not yews or cypresses, etc.)
        - Genus *Pinus* (pines but not spruces, etc.)
          - Species *Pinus ponderosa*

This classification is very simple to decode because each name after Plantae refers to conifers, and *Pinus* is the type name of the entire Division, so all names leading to *Pinus* are formed around this name. Note that some names refer to the same group. For example, Pinophyta contains only one class, so Pinophyta and Pinopsida refer to exactly the same group of organisms. This redundancy is one of the quaint features of nomenclature when the rules state that each category rank be associated with a name. The first name, Pinophyta, serves a purpose, which is to classify conifers relative to other plants. The second name is redundant (and thus biologically unnecessary) but was retained to present a complete hierarchy of ranks. *See* BACTERIAL TAXONOMY; PLANT TAXONOMY.

Changing ideas of taxa. The International Codes have largely achieved their goal of promoting the consistent and regular use of taxon names. However, from the eighteenth century to the middle of the twentieth century, there was no general agreement on what constituted a "natural" classification. There were many ideas. Some of them, such as grouping in fives, seem quite quaint to modern readers. As late as the 1960s, there were three general "schools" competing for the attention of systematists (the others having faded into history). The evolutionary taxonomists, who emerged during the 1930s with the rise of the Neo-Darwinian Revolution, asserted that classifications should be based on phylogeny and similarity. The pheneticists, who emerged with the Computer Revolution of the 1950s, asserted that ideas of phylogeny were speculative and that taxonomic classification should be based on similarity alone. The phylogeneticists (cladists), led by the German entomologist Willi Hennig, emerged in the 1960s and asserted that there was a rigorous method for building phylogenies and that classifications should be based on phylogeny (common ancestry) alone, letting similarity fall where it may.

The pheneticists lost, in spite of sophisticated computer algorithms for calculating similarity, because there were too many ways to calculate similarity. Similarity, it seems is in the eyes of the beholder, and each beholder has a different idea. In addition, classification based purely on similarity mixes up the different types of similarities. That is, some similarities may be due to descent from a common ancestor (the evolutionary concept of homology), whereas other similarities may be gained independently, perhaps due to similar environmental selection pressures (the evolutionary concept of convergence). Classifications that mix the two kinds of similarity might miss some important phenomena. The evolutionary taxonomists also lost because their idea of basing classifications on a combination of phylogeny and similarity would make it difficult to determine whether a particular classification was based on phylogeny or on similarity (the use of which had already been rejected).

The phylogeneticists won for two reasons. First, they demonstrated rigorous methods for the reliable reconstruction of common ancestry relationships. Second, they demonstrated that their classifications had predictive power. However, there are costs; for example, many traditional taxonomic groups (such as Reptilia) are no longer recognized, and some groups traditionally ranked at very high levels (such as Aves) have been demoted. The group Reptilia has been abandoned because birds are more closely related to crocodiles than crocodiles are to lizards. Reptilia was what Hennig called a "paraphyletic group," a group that did not include all the descendants of a common ancestor. Only "monophyletic groups," groups that include all the descendants of a common ancestral species, are permitted. Otherwise, the classification becomes inconsistent with the phylogeny, and efficient retrieval systems cannot be based on inconsistency. Thus, groups such as Reptilia no longer appear in the most modern classifications even if they persist in introductory and general-interest publications. Further, there is no longer a "Class" Aves. Birds and crocodiles are classified along with dinosaurs in the taxon Archosauria. If ranks were applied (they are not in the National Center for Biotechnology Information, NCBI, taxonomy system), Aves would probably be a suborder (as would Mammalia), not a class. Further, certain questions simply disappear. For example, the question of whether *Archaeopteryx lithographica*, the famous "missing link" between birds and reptiles, is a bird or a reptile disappears if "Reptilia" is not a natural group and is thus unrecognized in taxonomy. Rather, two new questions appear: What is the relationship of *A. lithographica* to Aves and other archosaurs? Is this species more closely related to birds than to, for example, dromaeosaur dinosaurs (the raptors made famous in the movie "Jurassic Park")?

Biological meaning of classifications. The Codes of Nomenclature are designed to stabilize the names applied to organisms and regulate how names are formed. However, the modern rules are not meant to impose a particular view of what the names mean biologically. The debate over the biological meaning of classifications is significant because classifications form the framework for comparing organisms.

From the time of Linnaeus to the middle of the twentieth century, taxonomists generally thought that the rank of a taxon had some biological meaning. Exactly what was meant varied from taxonomist to taxonomist and from system to system, but generally the fact that a taxon was classified at the rank "Family" as opposed to the rank "Subfamily" was thought to confer some significance on the taxon that made it comparable to other taxa of the same rank. In one system this might take on the significance of some perceived perfection, echoing "the great chain of being," with classifications arranged from "lower" forms of life to "higher" forms of life, with humans at the pinnacle, an idea quite popular with medieval philosophers. In other cases, it might have signified the uniqueness of form or adaptation; this approach treated the arrangement of organisms as a form of strict classification in which the ranks formed classes and the classes had biological significance quite apart from the taxa. Thus, a group of fishes classified at the level in the hierarchy of Family (for example, mackerels and tunas in Scomberidae) was considered comparable to a group of frogs placed at the same Family level (for example, toads in Bufonidae).

Classification to systematization. Today, systematists are moving away from this old idea of classification. Linnaean ranks are meant only to place taxon names in the hierarchy. A family of frogs and a family of fishes are no longer considered equivalent in terms of some biological attributes; they are ranked as families only because that is where they happen to fit in the classification hierarchy relative to other fishes or other frogs. The exception is the species category. Species are hypothesized units of process (species give rise to other species through various evolutionary processes) and thus all recognized species are thought to be comparable. Monophyletic groups of species are not units of process, but they are units of history.

Using ranks to show relationships rather than to express a biological level of organization is referred to as systematization rather than classification. As biological classifications change to reflect strictly evolutionary/common ancestry relationships rather than grades or levels of organization, they no longer reflect ancient and outmoded ideas reflected in older notions of "classification." This is because we have come to understand that taxa, groups of organisms in nature, are not the static classes of Aristotle but the dynamic evolutionary units of Darwin. We can express the evolutionary relationships of these groups through the use of Linnaean ranks (such as family, order, genus) because the Linnaean system is a hierarchical system easily adapted to express the relationships that result from evolutionary descent. But, the ranks no longer have the same meanings; they are simply placeholders for which we could substitute any number of alternative systems, such as numerical codes or even simply the phylogeny. For example, the Tree of Life Project uses taxon names and tree graphs to express the relationships among taxa, dispensing with Linnaean ranks (but not Linnaean names) entirely. The NCBI, a repository for all the genetic information known for most organisms, is very consistent in following the various Codes in naming taxa but dispenses with ranking in favor of a linked indented list that can be used to navigate within and between taxa.

In the modern era, classifications are meant to convey specific information as to the evolutionary relationships of organisms to form predictive systems for comparison. Given this, is there any use for the seemingly outmoded, eighteenth-century systems of nomenclature represented by the various Linnaean Codes of Nomenclature? Interestingly, the answer is "yes." The major functions of the codes are to promote stability and correct use of the names of taxa. That these names now refer to groups of evolutionary significance rather than to static classes of preevolutionary taxonomists does not mean that the need for stable and universally understood names has disappeared. In fact, it means just the opposite: Natural taxa are the result of evolutionary descent and thus have biological significance and biological predictability. The need to have international codes that govern the use of these names is as important now as in the past. E. O. Wiley

Clathrate compounds

Well-defined addition compounds formed by inclusion of molecules in cavities existing in crystal lattices or present in large molecules. The constituents are bound in definite ratios, but these are not necessarily integral. The components are not held together by primary valence forces, but are the consequence of a tight fit preventing the smaller partner, the guest, from escaping from the cavity of the host. Thus, the geometry of the molecules is the decisive factor.

Clathrate compounds are of theoretical interest because they represent a special type of bonding. In practice they can be used for separation of hydrocarbons, for stablization of drugs or pesticides, and as enzyme models.

Inclusion compounds can be subdivided into (1) lattice inclusion compounds (inclusion within a lattice which, as such, is built up from smaller single molecules); (2) molecular inclusion compounds (inclusion into larger ring molecules with holes); and (3) inclusion compounds of macromolecules (see **table**).

The best-known lattice inclusion compounds are the urea and thiourea channel inclusion compounds, which are formed by mixing hydrocarbons, carboxylic acids, or long-chain fatty alcohols with solutions of urea. Urea, in this case the host lattice, crystallizes in the presence of the other molecules in a particular crystal structure which contains long channels or tubes 0.4–0.5 nanometer in diameter. The hydrocarbons are accommodated in these channels, but only unbranched molecules find enough space to fit into the urea channel. The molar ratio of urea to hydrocarbon is simply determined by the lengths of the hydrocarbon molecule, not by any functional group. The longer the paraffin chain, the

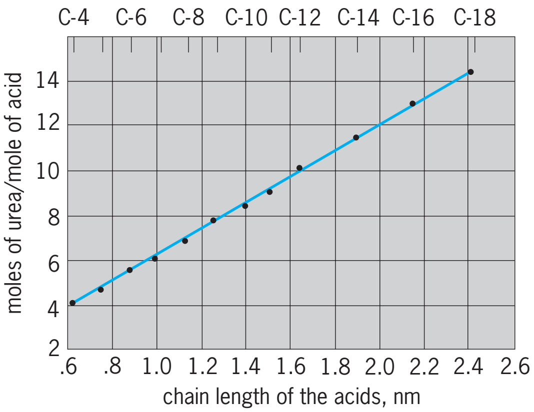

Fig. 1. Dependence of the urea/fatty acid composition of the inclusion compound on the chain length of the fatty acid. (*After W. Schlenk, Jr., Organic occlusion compounds, Fortschr. Chem. Forschg., 2:92–145, 1951*)

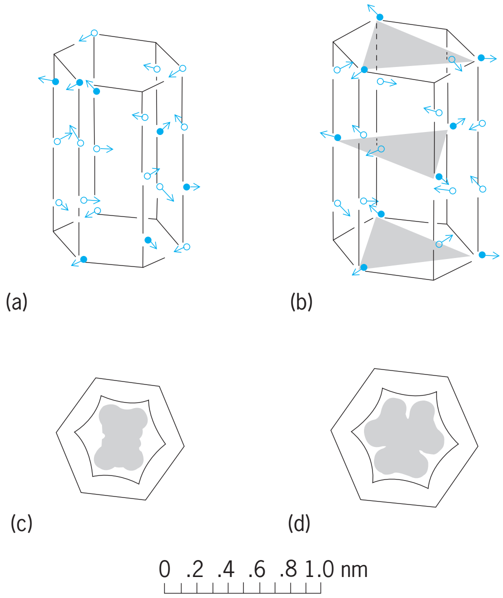

Fig. 2. Schematic drawing of the lattices of (*a*, *c*) urea and (*b*, *d*) thiourea; *c* and *d* show accommodation of unbranched and branched paraffin chains, respectively.

Inclusion compounds

Host substance	Shape of cavity	Guest substance examples
Lattice inclusion compounds		
Urea	Channel	Derivatives of straight-chain hydrocarbons
Thiourea	Channel	Branched-chain hydrocarbons
Deoxycholic acid	Channel	Paraffins, fatty acids, aromatic hydrocarbons
Dinitrodiphenyl	Channel	Diphenyl derivatives
Hydroquinone, phenol	Cage	Hydrogen chloride, sulfur dioxide, acetylene
Gas hydrates	Cage	Halogens, inert gases, hydrocarbons
Trithymotide	Cage	Benzene, chloroform
Nickel dicyanobenzene	Cage	Benzene, chloroform
Cyclodextrins	Channel or cage	Hydrocarbons, iodine, aromats
Molecular inclusion compounds		
Cyclodextrins	Cage	Hydrocarbons, iodine, aromats
Bis(*N,N′*-alkyl benzidines)	Cage	Benzene, dioxane
Crown ether compounds	Cage	Inorganic cations
Ionophore antibiotics	Cage	Inorganic cations
Inclusion compounds of macromolecular substances		
Clay minerals	Channel or sheet	Hydrophilic substances
Graphite	Sheet	Oxygen, bisulfate ion, alkali metals
Cellulose, starch	Channel	Hydrocarbons, dyes, iodine

more urea is necessary in order to envelop the paraffin (**Fig. 1**). Thiourea has a similar lattice structure, but a larger diameter of the channel. Therefore, only branched paraffins are included; the unbranched ones are too small, and cannot be held tightly (principle of closest packing), as shown in **Fig. 2**.

Other representatives of lattice inclusion compounds are the choleic acids, which are adducts of deoxycholic acid with fatty acids, and other lipoic substances. Most likely, these compounds play a role in the digestion process by emulsifying or dissolving fat and fat-soluble substances. Hydroquinone and phenol, cyclic anhydrides of phenol carboxylic acids, such as *o*-trithymotide and tetrasalicylide, as well as some other aromatic compounds, form an open crystal lattice which can accommodate smaller gas and solvent molecules (clathrates in the stricter sense of the word). The gas hydrates, which have been known since about 1810 (for example, $Cl_2 \cdot 6H_2O$), are inclusion compounds of gases in a somewhat expanded ice lattice. The gas or solvent molecules are inserted into definite places within the ice lattice and are surrounded by water molecules on all sides.

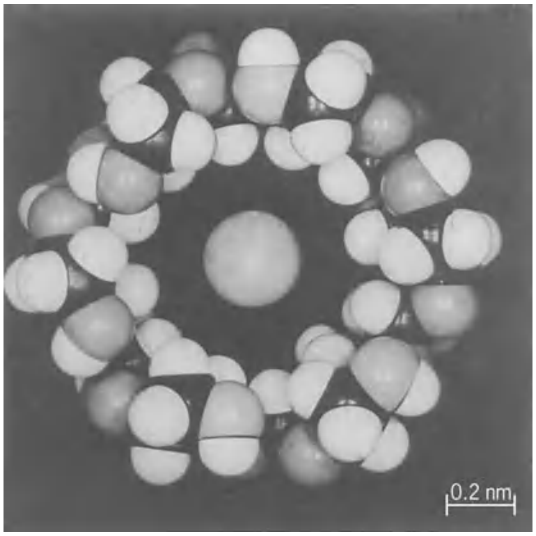

Fig. 3. Molecular model of α-dextrin–iodine compound seen in the direction of the *c* axis, that is, in the direction of the iodine chains, which lie in channels.

The cyclodextrins (cycloamyloses) are cyclic degradation products of starch which contain six, seven, or eight glucose residues (α-, β-, γ-cyclodextrin) and have the shape of large-ring molecules, the cavity diameters being 0.6–1.0 nm. Here, a great number of inclusion compounds in solution or in the crystalline state can be prepared with various kinds of molecules, the only requirement being the fit of the guest within the cyclodextrin cavity. α-Cyclodextrin forms blue iodine inclusion compounds in which the host molecules are stacked to form a cylinder reminiscent of the starch helix (**Fig. 3**). Polyiodide, located within the thus formed channellike cavity, consists of I_2, I_3^-, or I_5^- units in α-cyclodextrin, as well as in starch. A similar structure is likely for the blue iodine poly(vinyl alcohol) inclusion compound which exhibits a strong dichroism when stretched. This is used technically to prepare (light) polarizing sheets and spectacles.

Crown ether compounds are cyclic or polycyclic polyether compounds (for example, with the repeating unit . . . $O—CH_2—CH_2$. . .) capable of including another atom in the center of the ring. In this way, sodium or potassium compounds can be solubilized in organic solvents. Similarly, a series of ionophore antibiotics can complex inorganic cations. *See* MACROCYCLIC COMPOUND.

Some clay minerals are made up of distinct silicate layers. Between these layers some free space may exist in the shape of channels. Smaller hydrocarbon molecules can be accommodated reversibly within these channels. This phenomenon is used in some technical separation processes for separating hydrocarbons (molecular sieves). Furthermore, ion-exchange processes used for water deionization are based on similar minerals. *See* CLAY MINERALS; MOLECULAR SIEVE; ZEOLITE.

Enzymes are believed to accommodate their substrates in active sites, pockets, or clefts prior to the chemical reaction which then changes the chemical structures of the substrates. These binding processes are identical to those of low-molecular-weight inclusion compounds. On the other hand, some low-molecular-weight inclusion compounds can mimic enzyme action, such as ester hydrolysis, but only with modest efficiency.

Clay

A term used to refer to the finest-grain particles in a sediment, soil, or rock. According to the Wentworth scale (see **table**), clay is finer than silt, characterized by a grain size of less than approximately 4 micrometers. However, the term clay can also refer to a rock or a deposit containing a large component of clay-size material. Thus clay can be composed of any inorganic materials, such as clay minerals, allophane, quartz, feldspar, zeolites, and iron hydroxides, that possess a sufficiently fine grain size. Most clays, however, are composed primarily of clay minerals. *See* CLAY MINERALS; FELDSPAR; QUARTZ; ZEOLITE.

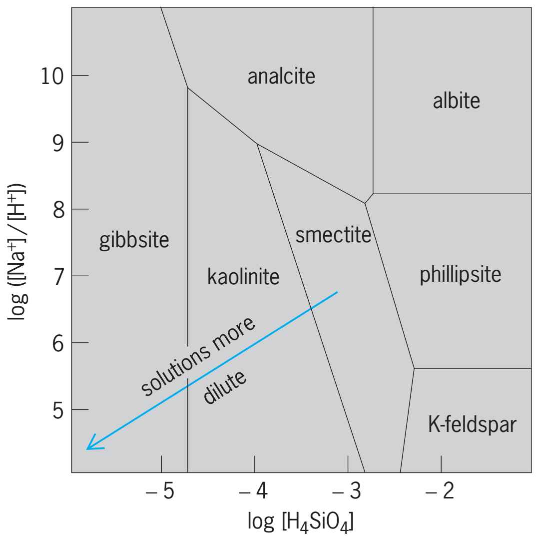
Although the composition of clays can vary, clays can share several properties that result from their fine particle size. These properties include plasticity when wet, the ability to form colloidal suspensions when dispersed in water, and the tendency to flocculate (clump together) and settle out in saline water. *See* COLLOID.

Origin and occurrence. Clays occur most abundantly in nature in soils, sediments, sedimentary rocks, and hydrothermal deposits.

Clays, together with organic matter, water, and air, are one of the four main components of soil. Clays can form directly in a soil by precipitation from solution (neoformed clays); they can form from the partial alteration of clays already present in the soil (transformed clays); or they can be inherited from the underlying bedrock or from sediments transported into the soil by wind, water, or ice (inherited clays). *See* SOIL.

Wentworth scale for size classification of sediment particles

Particle	Grain size, mm
Boulder	>256
Cobble	64–256
Pebble	4–64
Granule	2–4
Sand	1/16–2
Silt	1/256–1/16
Clay	<1/256



Example of a stability diagram for the system Na_2O-K_2O-Al_2O_3-SiO_2-H_2O drawn for log ($[K^+]/[H^+]$) = 4. The soluble species in brackets are in activity units. (*After J. I. Drever, The Geochemistry of Natural Waters, Prentice-Hall, 1982*)

The type of clays neoformed in a soil depends on the composition of the soil solution, which in turn is a function of climate, drainage, original rock type, vegetation, and time. Generally, neoformed clays that have undergone intense leaching, such as soils formed under wet, tropical climates, are composed of the least soluble elements, such as ferric iron, aluminum, and silicon. These soils contain clays such as gibbsite, kaolinite, goethite, and amorphous oxides and hydroxides of aluminum and iron. Clays formed in soils that are found in dry climates or in soils that are poorly drained can contain more soluble elements, such as sodium, potassium, calcium, and magnesium, in addition to the least soluble elements. These soils contain clays such as smectite, chlorite, and illite, and generally are more fertile than those formed under intense leaching conditions. The importance of the composition of soil solution to the type of clay neoformed at equilibrium can be shown quantitatively in mineral stability diagrams, such as that given in the **illustration**. *See* CHLORITE; GOETHITE; ILLITE; KAOLINITE.

Examples of clays formed by the transformation of other clays in a soil include soil chlorite and soil vermiculite, the first formed by the precipitation of aluminum hydroxide in smectite interlayers, and the second formed by the leaching of interlayer potassium from illite. Examples of inherited clays in a soil are illite and chlorite-containing soils formed on shales composed of these minerals. *See* SHALE.

Clays also occur abundantly in sediments and sedimentary rocks. For example, clays are a major component of many marine sediments. These clays generally are inherited from adjacent continents, and are carried to the ocean by rivers and wind, although some clays (such as smectite and glauconite) are neoformed abundantly in the ocean. Clays also are a chief constituent of shale, are found in pore spaces in sandstones, and are found dispersed in limestones, dolomites, and coals. The ashes that remain after coal is burned, for example, are the residue of clays and silts washed into coal swamps and later incorporated into the coal. Hydrothermal clays can form abundantly where rock has been in contact with hot water or steam. Illite and chlorite, for example, form during the deep burial of sediments, and smectite and chlorite form by the reaction of hot, circulating waters at ocean ridges. Kaolinite can form hydrothermally where hot springs invade volcanic ash, given proper solution chemistries. *See* COAL; DOLOMITE; GLAUCONITE; LIMESTONE; MARINE SEDIMENTS; SANDSTONE; SEDIMENTARY ROCKS.

Properties and uses. Various clays possess special properties which make them important industrially. Bentonite, a smectite formed primarily from the alteration of volcanic ash, swells; is readily dispersible in water; and possesses strong absorptive powers, including a high cation exchange capacity. These properties lead to uses in drilling muds, as catalysts and ion exchangers, as fillers and absorbents in food and cosmetics, and as binders for taxonite and fertilizers. Swelling clays also must be taken into account in building design. In agriculture, swelling clays in a soil may lead to undesirable tilth and water runoff characteristics, and to unexpected reactions with soil additives, such as the catalytic conversion of pesticides into other compounds, or the fixation of ammonia fertilizer. *See* BENTONITE; CATALYSIS; ION EXCHANGE; SOIL CHEMISTRY.

Kaolinite-rich clays are used as paper-coating materials because they are white and show desirable rheological properties; as additives to rubber because they can bind with organic compounds; and as refractory materials due to their high melting point. Other important uses for clays include the manufacture of brick, ceramics, molding sands, decolorizers, detergents and soaps, medicines, adhesives, liners for ponds and landfills, lightweight aggregate, desiccants, molecular sieves, pigments, greases, paints, plasticizing agents, emulsifying, suspending, and stabilizing agents, and many other products. Ore deposits sometimes are composed of clays (for example, lateritic nickel and bauxites), and clay in shale may play an important role in the generation of petroleum. *See* CLAY, COMMERCIAL; REFRACTORY.

Clay, commercial

Commercial clays, or clays utilized as raw material in manufacturing, are among the most important nonmetallic mineral resources. The value of clays is related to their mineralogical and chemical composition, particularly the clay mineral constituents kaolinite, montmorillonite, illite, chlorite, and attapulgite. The presence of minor amounts of mineral or soluble salt impurities in clays can restrict their use. The more common mineral impurities are quartz, mica, carbonates, iron oxides and sulfides, and feldspar. In addition, many clays contain some organic material. *See* CLAY MINERALS.

Clay is an abundant raw material; however, certain high-grade types of clay deposits are limited in geographic occurrence and extent. Examples are the white kaolin clays found in abundance only in Georgia and South Carolina; the high-quality bentonites found in Wyoming, South Dakota, California, Texas, and Mississippi; and the attapulgite clays found in Georgia and Florida.

Kaolinitic clays. Clays containing a preponderance of the clay mineral kaolinite are known as kaolinitic clays. Several commercial clays are composed predominantly of kaolinite. These are china clays, kaolins, ball clays, fireclays, and flint clays. The terms china clay and kaolin are used interchangeably in industry. *See* KAOLINITE.

China clay. China clays are high-grade white kaolins found in the southeastern United States, England, Brazil, and many other countries. In Georgia and South Carolina, the largest producing states, the deposits are composed almost wholly of the mineral kaolinite and occur as lenticular-shaped bodies generally 6–25 ft (1.8–7.5 m) in thickness. Many grades of kaolin are used in the manufacture of ceramics (whitewares, refractories, and porcelain), paper, rubber, paint, plastics, insecticides, adhesives, catalysts, and ink. They are also used for many other industrial purposes.

Kaolin has the desirable properties of being white in color, very fine in particle size, nonabrasive (hardness 2–2.5 on Mohs scale), and chemically inert in most uses. The individual kaolin particle is a thin, flat, pseudohexagonal platelet, so tiny that approximately 10,000,000 spread on a postage stamp would form a layer thinner than the thickness of a human hair. This thin, flat particle shape is a distinct advantage in many uses. The grades of kaolin that are commercially available generally are based on particle size, color, and brightness.

By far the largest consumer of white kaolins is the paper industry, which uses them to make paper products smoother, whiter, and more printable. The kaolin is used both as a filler in the sheet to enhance opacity and receptivity to ink and as a thin coating (about 0.005 in. or 0.013 cm) on the surface of the sheet to make it smoother and whiter for printing. The clay coating makes possible sharp photographic illustrations and brilliant color printing. Other important properties of kaolin for paper manufacture are softness of texture, ease of dispersion in the coating formulation, and ability to produce a high-gloss finish.

Because of the trend toward whiter coatings and lighter-weight paper (to minimize postal charges), the kaolin producers have developed new products. The colorant in kaolin is generally iron and titanium minerals; through flotation procedures, selective flocculation, and high intensity magnetic separation, a portion of the iron and titanium can be removed, making a significantly whiter product. To aid in the development of lighter-weight coatings, a delaminated kaolin is produced. The thicker kaolin particles are separated by force to produce thin, white particles which give excellent coated-sheet properties with lighter coat weights.

In ceramics the kaolin clays are used in whitewares, sanitary ware, special refractories, and porcelain insulators. In whitewares and sanitary ware the kaolin provides a white body, gives easy molding properties, and adds strength, dimensional stability, and smooth surfaces to the finished product. Refractoriness, dimensional stability, and chemical inertness make the kaolins uniquely suitable for special refractories. In addition, the excellent dielectric properties of kaolin are very suitable for porcelain electric insulators. *See* CERAMICS; PORCELAIN.

In the manufacture of both natural and synthetic rubber, kaolin clays are used as a functional filler. The kaolin adds strength, abrasion resistance, rigidity, and whiteness. It costs less than most other fillers used in rubber.

In paint and ink kaolins are used as extenders because of their chemical inertness, smooth flow properties, ease of dispersion, nonabrasiveness, relatively low cost, and the high pigment volume concentrations that can be attained.

In plastics kaolin is used to provide smooth surfaces, dimensional stability, and better resistance to chemical attack, and to improve physical and electrical properties, to minimize water absorption, to reduce brittleness, and to lower costs.

In insecticides the inertness, low abrasiveness, and good adsorption and flow properties of kaolin make it an effective carrying agent in dust and spray forms.

A relatively new field is the chemical modification of kaolinite to make it an effective catalyst for use in petroleum refining. The kaolin is treated and calcined to produce zeolites, which are used as molecular sieves. Molecular sieves are widely used in petroleum refining.

Because the United States has very small reserves of bauxite, kaolin, which contains 38% Al_2O_3, has been studied as a source of alumina. Many patents utilizing either bases or acids to extract the alumina have been issued. Some companies which are basic producers of aluminum metal have acquired large reserves of kaolin, but to date no processing plants have been constructed.

Calcined clay is another commercial product of the kaolins. It is used in paint, ceramics, plastics, paper, and other materials. The calcined kaolins have the advantage of increased opacity and brightness. The kaolinite is changed during the calcination to the minerals mullite and cristobalite. The hardness after calcination is about 6.5 to 7 on Mohs scale, and therefore the calcined kaolin makes an exceptional, very fine polishing agent. This product is used in toothpaste, automobile polishes, and silver and brass polishes. High-temperature calcined kaolins (1803–2703°F or 984–1484°C) are used as grog by the refractory industry.

Ball clay. Ball clays are composed mainly of the mineral kaolinite but usually are much darker in color than kaolin. The term ball clay is used for a fine-grained, very plastic, refractory bond clay. Most ball clays contain minor amounts of organic material and the clay mineral montmorillonite. Usually ball clays are finer grained than china clays. This fineness, together with the montmorillonite and organic material, gives ball clays excellent plasticity and strength. For these reasons and because they fire to a light-cream color, ball clays are commonly used in whitewares and sanitary ware. Commercial deposits of ball clay are located in western Kentucky, western Tennessee, northern Mississippi, and northeastern Texas.

Fireclay. This term is used for clays that will withstand temperatures of 2730°F (1500°C) or higher. Such clays are composed primarily of the mineral kaolinite. The most common fireclays are the underclays, which occur directly under coal seams. Not all under-clays are fireclays because many contain materials that lower the fusion point to below 2730°F (1500°C). Fireclays are generally light to dark gray in color, contain minor amounts of mineral impurities such as illite and quartz, and fire to a cream or buff color. Most fireclays are plastic, but some are nonplastic and very hard; the latter are known as flint clays.

Fireclays are used primarily by the refractories industry. The refractoriness of fireclays is proportional to the amount of alumina present in the clay and is reduced by impurities such as calcium carbonate and iron compounds. The foundry industry uses fireclay to bind sands into shapes in which metals can be cast. From 10 to 15% fireclay is necessary to bind the sand grains together. Fireclay-bonded sands give the metal a smoother surface than when other clays, such as bentonite, are used, but equivalent or higher mold strengths can be attained with approximately one-third as much bentonite. In many cases even though the strength properties of bentonite-bonded sands are higher, fireclays are used if the cost of clay and transportation is lower. Large quantities of fireclay are mined in Pennsylvania, West Virginia, Kentucky, Ohio, and Missouri.

Flint clay. This term is used for a special type of fireclay. Flint clays are composed essentially of kaolinite and are also refractory but are nonplastic and very hard.

Diaspore clay. This clay is composed of the minerals diaspore and kaolinite. Diaspore is a hydrated aluminum oxide with an Al_2O_3 content of 85% and a water content of 15%. This mineral is quite hard (6.5–7 on Mohs scale) and very refractory. Diaspore clay is used almost exclusively by the refractories industry in making refractory brick. However, after calcination, it is sometimes used as an abrasive material. Diaspore clay is produced commercially in Missouri and Pennsylvania. It is found in nature mixed with flint and plastic fireclays. High-grade diaspore clay contains 65–70% Al_2O_3. When its Al_2O_3 content is 50–65%, this material is called burley clay.

Mullite. Mullite is a high-temperature conversion product of many aluminum silicate minerals, including kaolinite, pinite, topaz, dumortierite, pyrophyllite, sericite, andalusite, kyanite, and sillimanite. Mullite is used in refractories to produce materials of high strength and great refractoriness. Mullite does not spall, withstands the shock of heating and cooling exceptionally well, and is resistant to slag erosion. It is used in making spark plugs, laboratory crucibles, kiln furniture, saggars, and other special refractories. Mullite crystals occur as long needlelike or lathlike forms. The intermeshing of these crystals produces high-strength bodies. The only natural occurrence of mullite is on the island of Mull in the Western Isles of Scotland, and here it is found in such small quantities that it has no commercial significance.

Bentonites. Those clays that are composed mainly of the clay mineral montmorillonite and are formed by the alteration of volcanic ash are known as bentonites. They are used in many industries; the most important uses are as drilling muds, as bonding clays in foundries, as bonding agents for taconite pellets, and as adsorbents in many industries. *See* MONTMORILLONITE.

The largest producing areas of bentonite are Wyoming, western South Dakota, central and eastern Texas, and northeastern Mississippi. The Wyoming and South Dakota bentonites are known as sodium bentonites, because the montmorillonite has a relatively high sodium content. The Texas and Mississippi bentonites are known as calcium bentonites, because the montmorillonite has a relatively high calcium content. Sodium montmorillonite and calcium montmorillonite have significantly different physical properties which regulate their use and acceptance by many industries.

The term bentonite is a rock term, but in industrial usage it has become almost synonymous with swelling clay. Bentonite contains minor amounts of other clay minerals, particularly illite, chlorite, and kaolinite, and up to approximately 30% opal C-T, a partially amorphous form of silicon dioxide. The properties of the bentonites are largely dependent on the type and amount of montmorillonite present.

Drilling mud. Drilling mud consists of bentonite, water, a weighting material such as barite, and various electrolytes. This mud is circulated in the hole at all times while the drilling is progressing. The functions of the drilling mud are to remove the drill cuttings from the drill hole, to form a filter cake on the wall of the drill hole to keep the drilling fluid in the hole and prevent water in the rock formations from entering, to cool and lubricate the bit, and to prevent blowouts. Bentonite, especially the sodium variety, imparts high viscosity and shear strength to the mud and also imparts a property called thixotropy. A thixotropic body acts as a fluid when agitated and as a thick gel when standing. Because the properties imparted by the bentonites to the drilling fluid are so important to the success of the oil industry, these clays are an extremely important mineral commodity.

Bonding clay. Bentonites are used in the foundry industry to bind sands into desired shapes in which metals can be cast. Only 3–5% bentonite is needed to bond the sand grains together. Because of their fine particle size and their nature of their water adsorption, bentonites give the mold a higher green, dry, and hot strength than does any other type of clay.

Another use of bentonite as a bonding agent is in the taconite industry. Taconite, low-grade iron ore, is crushed into a fine powder and the iron particles are separated from silica and other rock particles magnetically or by flotation. The fine iron particles are pelletized with the aid of bentonite, of which 12–18 lb (5.4–7.2 kg) is used to pelletize a ton of ore.

Other uses. Bentonites are also used as bleaching clays to remove coloring matter from oils, and as clarifying agents for products such as wines and beers. Bentonite is used as an adsorbent for oils, insecticides, alkaloids, vitamins, proteins, and many other materials. Calcium montmorillonites generally have better decolorizing and adsorbent properties than the sodium variety. Bentonite suspensions in water are widely used in industry, in addition to that suspension used as a drilling mud by the petroleum industry. Some applications are as fire retardants, as media for suspending materials for medicinal purposes, and as media for suspending lumps of coal to separate them from heavier impurities. Sodium bentonites are the better suspending agents because of their higher viscosities. Large quantities of sodium bentonite are used to line irrigation ditches and to seal leaks in dams, because it forms an impermeable cake or film by swelling and filling the pores. Sodium montmorillonite swells in water to many times its original size. Other uses are as catalysts, emulsion stabilizers, deinking agents, suspending agents in enamels, plasticizers in ceramics and pastes, and ingredients in cosmetics. *See* BENTONITE.

Attapulgite clays. Attapulgite is a hydrated magnesium aluminum silicate with a needlelike shape. It is commercially produced from a small area in southwestern Georgia and northwestern Florida. The needlelike shape gives attapulgite its unusual properties; each individual needle is exceedingly small, about 1 micrometer in length and approximately 0.01 micrometer across. Attapulgite is used as a suspending agent, and gives high viscosity because of the interaction of the needles. Some commercial uses are as an oil well drilling fluid, in adhesives as a viscosity control, in oil base foundry sand binders, as thickeners in latex paints, in liquid suspension fertilizers, and as a suspending agent and thickener in pharmaceuticals. Other uses are as adsorbent beds for pets, floor adsorbents, carriers for agricultural chemicals, catalyst, flatting agent in paint, and anticaking agent. An unusual use is as a coating on paper used in NCR (no carbon required) multicopy business forms. The attapulgite acts as a catalyst to convert the dye intermediates to the colored dyes when the encapsulated intermediates are released by pressure. The names attapulgite and palygurskite are synonymous.

Miscellaneous clays. Most of these clays and shales contain mixtures of differing proportions of illite, chlorite, kaolinite, and montmorillonite, plus a variety of nonclay minerals. By far the largest user of these miscellaneous clays is the structural clay products industry. This industry manufactures brick, drain tile, sewer pipe, conduit tile, glazed tile, terra cotta, and other items.

The clays that can be used for the different structural clay products necessarily have wide variations in properties. For example, a clay that can be used for conduit tile must be very plastic and have high green and dry strength and uniform shrinkage; for drain tile or common brick, these properties do not have to be controlled so closely. In general, however, the properties of clays that are important in the manufacture of structural clay products are plasticity, green strength, dry strength, drying and firing shrinkage, vitrification range, and fired color. These properties are largely dependent on the composition of the clay and the particle size of the constituents.

Mining and processing. Almost all the commercial clays are mined by open-pit methods, with overburden-to-clay ratios ranging as high as 10 to 1. The overburden is removed by motorized scrapers, bulldozers, shovels, or draglines. The clay is won with draglines, shovels, or bucket loaders, and transported to the processing plants by truck, rail, aerial tramways, or belt conveyors, or as slurry in pipelines.

The clay is processed dry or in some cases, wet. The dry process usually consists of crushing, drying, and pulverizing. The clay is crushed to egg or fist size or smaller and dried usually in rotary driers. After drying, it is pulverized to a specified mesh size, such as 90% retained on a 200-mesh screen with the largest particle passing a 30-mesh screen. In other cases, the material may have to be pulverized to 99.9% finer than 325 mesh. The material is shipped in bulk or in bags. All clays are produced by this method.

Where more exacting products must be produced, as in the case of kaolins for the paper industry and bentonites for certain pharmaceutical uses, wet processing is used. In the case of kaolins, the material is slurried in water at the mine face at about 35–40% solids with the aid of a dispersant. The slurry is pumped to a degritting station, where the very coarse impurities are removed, and then through pipelines to the processing plant. The general processing steps are particle size fractionation, that is, separation into coarse and fine particles; magnetic separation and/or flotation to remove titanium and iron minerals, leaching out colloidal iron impurities; dewatering by filtration; and drying and pulverization. Fractionation is done by centrifuging or by gravity settling; dewatering by centrifuges, filter presses, or rotary vacuum drum filters; and drying by rotary, apron, drum, or spray driers. Most of the kaolin is shipped dry bulk by rail, but about 20% is bagged and shipped by rail or truck. Some kaolin is shipped in slurry form in tank cars at 70% solids.

Properties. Most clays become plastic when mixed with varying proportions of water. Plasticity of a materal can be defined as the ability of the material to undergo permanent deformation in any direction without rupture under a stress beyond that of elastic yielding. Clays range from those which are very plastic, called fat clay, to those which are barely plastic, called lean clay. The type of clay mineral, particle size and shape, organic matter, soluble salts, adsorbed ions, and the amount and type of nonclay minerals all affect the plastic properties of a clay.

Strength. Green strength and dry strength properties are very important because most structural clay products are handled at least once and must be strong enough to maintain shape. Green strength is the strength of the clay material in the wet, plastic state. Dry strength is the strength of the clay after it has been dried. Plasticity and green strength are closely related and are affected largely by the same variables. Dry strength is dependent on the proportion of fine particles present, the degree of hydration of the colloidal fraction, the method of forming the ware, and the extent of drying. The presence of a small amount of montmorillonite, which is of very fine particle size and highly hydrated, generally increases the dry strength.

Shrinkage. Both drying and firing shrinkages are important properties of clay used for structural clay products. Shrinkage is the loss in volume of a clay when it dries or when it is fired. Drying shrinkage is dependent on the water content, the character of the clay minerals, and the particle size of the constituents. Drying shrinkage is high in most very plastic clays and tends to produce cracking and warping. It is low in sandy clays or clays of low plasticity and tends to produce a weak, porous body. Montmorillonite in relatively large amounts (10–25%) causes excessive shrinkage, cracking, and slow drying. Firing shrinkage depends on the volatile materials present, the types of crystalline phase changes that take place during firing, and the dehydration characteristics of the clay minerals.

Vitrification range. The temperature range of vitrification, or glass formation, is a very important property in structural products. Vitrification is due to a process of gradual fusion in which some of the more easily melted constituents begin to produce an increasing amount of liquid which makes up the glassy bonding material in the final fired product. Some clays have a short vitrification range so that the temperature of the kiln must be very closely regulated. Illites, montmorillonites, and chlorites all have lower vitrification temperatures than kaolinite. Some nonclay minerals such as calcite and feldspar lower the vitrification temperature of the body by acting as fluxes. The degree of vitrification developed depends on the duration of firing as well as on the temperature attained. Usually the degree of vitrification is regulated by the amount of shrinkage and porosity that is needed in the final product. There is, however, a practical limit as to the amount of shrinkage and reduction in porosity than can be attained at a given temperature.

Color. Color is important in most structural clay products, particularly the maintenance of uniform color. The color of a product is influenced by the state of oxidation of iron, the state of division of the iron minerals, the firing temperature and degree of vitrification, the proportion of alumina, lime, and magnesia in the clay material, and the composition of the fire gases during the burning operation. The best white-burning clays contain less than 1% Fe_2O_3. Buff-burning clays contain 1–5% Fe_2O_3 and red-burning clays contain 5% or more Fe_2O_3. Other constituents also affect the color, but finely divided iron-bearing minerals are considered to be the principal colorants.

Uses. All types of clay and shale are used in the structural products industry but, in general, the clays that are used are considered to be relatively low grade. Clays that are used for conduit tile, glazed tile, and sewer pipe are underclays and shales that contain large proportions of kaolinite and illite. The semirefractory plastic clays found directly beneath the coal seams make the best raw material for the above mentioned uses. Brick and drain tile can be made from a wide variety of clays depending on their location and the quality of product desired. Clays used for brick and drain tile must be plastic enough to be shaped. In addition, color and vitrification range are very important. For common brick, drain tile, and terra-cotta, shales and surface clays are usually suitable, but for high-quality face bricks, shales and underclays are used. Geographic location is a prime factor in the type of clay used for structural clay products because, in general, these products cannot be shipped great distances without excessive transportation costs. Many raw materials of questionable quality are utilized in certain areas because no better raw material is available nearby. *See* BRICK; TILE.

Lightweight aggregate is produced from many types of clays and shales. The raw material is heated very rapidly in rotary kilns or sintering machines to the temperature range between incipient and complete fusion. After fusion has developed a molten jacket around the particle, certain constituents, if present, release gas to produce bloating and vesiculation. The molten jacket must be viscous enough to retain the expanding gas. Shales containing illites, montmorillonites, or chlorites, plus nonclay materials such as carbonates, sulfates, and organic matter, are the best raw material for lightweight aggregate. Adequate testing of a clay or shale is the only way to determine whether or not it will make a suitable lightweight aggregate. Mineral and chemical composition, particle size distribution, fusion temperature, and final strength of the aggregate particles are all important factors which control the production of lightweight aggregate from a clay or shale. The presence of a high percentage of kaolinite causes the material to be too refractory and the presence of excess fluxing agents causes the material to melt much too rapidly to control the vesiculation necessary to make the material lightweight.

The cement industry uses large quantities of impure clays and shales. Clays are used to provide alumina and silica to the charge for the cement kiln. Generally, a suitable clay can be found in the area in which the cement is being manufactured. *See* CEMENT; POTTERY; REFRACTORY.

Velde, *Introduction to Clay Minerals*: *Chemistry, Origins, Uses, and Environmental Significance*, 1992; W. E. Worrall, *Clays and Ceramic Raw Materials*, 1986.

Clay minerals

Fine-grained, hydrous, layer silicates that belong to the larger class of sheet silicates known as phyllosilicates. Their structure is composed of two basic units. (1) The tetrahedral sheet is composed of silicon-oxygen tetrahedra linked to neighboring tetrahedra by sharing three corners to form a hexagonal network (**Fig. 1**). The fourth corner of each tetrahedron (the apical oxygen) points into and forms a part of the adjacent octahedral sheet. (2) The octahedral sheet is usually composed of aluminum or magnesium in sixfold coordination with oxygen from the tetrahedral sheet and with hydroxyl. Individual octahedra are linked laterally by sharing edges (**Fig. 2**). Tetrahedral and octahedral sheets taken together form a layer, and individual layers may be joined to each other in a clay crystallite by interlayer cations, by van der Waals and electrostatic forces, or by hydrogen bonding.

Because clay minerals are nearly ubiquitous in the Earth's upper crust, they offer a unique record of earth processes and earth history. Thus, the study of clay minerals forms an important branch of the science of geology. It has been suggested also that clay minerals may have been a necessary precursor for the origin of life by providing protection for primitive organic molecules, and by catalyzing their transformation into more complex substances. *See* PREBIOTIC ORGANIC SYNTHESIS.

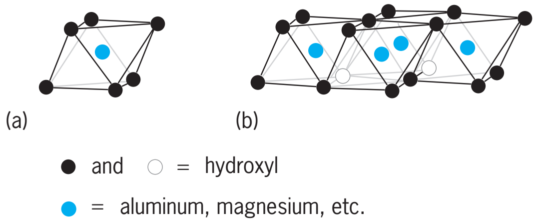

Fig. 2. Diagrammatic sketch showing (*a*) single octahedral unit and (*b*) sheet structure of octahedral units. (*After R. E. Grim*, *Clay Mineralogy*, *McGraw-Hill*, *1953*)

Classification. Clay minerals are classified by their arrangement of tetrahedral and octahedral sheets. Thus, 1:1 clay minerals contain one tetrahedral and one octahedral sheet per clay layer; 2:1 clay minerals contain two tetrahedral sheets with an octahedral sheet between them; and 2:1:1 clay minerals contain an octahedral sheet that is adjacent to a 2:1 layer (see **table**).

Ionic substitutions may occur in any of these sheets, thereby giving rise to a complex chemistry for many clay minerals. For example, cations small enough to enter into tetrahedral coordination with oxygen, cations such as Fe^{3+} and Al^{3+}, can substitute for Si^{4+} in the tetrahedral sheet. Cations such as Mg^{2+}, Fe^{2+}, Fe^{3+}, Li^{+}, Ni^{2+}, Cu^{2+}, and other medium-sized cations can substitute for Al^{3+} in the octahedral sheet. Still larger cations such as K^{+}, Na^{+}, and Cs^{+} can be located between layers and are called interlayer cations. F^{-} may substitute for $(OH)^{-}$ in some clay minerals. *See* COORDINATION CHEMISTRY.

Clay minerals and related phyllosilicates are classified further according to whether the octahedral sheet is dioctahedral or trioctahedral. In dioctahedral clays, two out of three cation positions in the octahedral sheet are filled, every third position being vacant. This type of octahedral sheet is sometimes known as the gibbsite sheet, with the ideal composition $Al_2(OH)_6$. In trioctahedral clay minerals, all three octahedral positions are occupied, and this sheet is called a brucite sheet, composed ideally of $Mg_3(OH)_6$. Some dioctahedral and trioctahedral clay minerals and related phyllosilicates are listed in the table.

Clay minerals can be classified further according to their polytype, that is, by the way in which adjacent 1:1, 2:1, or 2:1:1 layers are stacked on top of each other in a clay crystallite. For example, kaolinite shows at least four polytypes: *b*-axis ordered kaolinite, *b*-axis disordered kaolinite, nacrite, and dickite. Serpentine shows many polytypes, the best-known of which is chrysotile, a mineral that is used to manufacture asbestos products. *See* KAOLINITE; SERPENTINE.

Finally, clays are named on the basis of chemical composition. For example, two types of swelling clay minerals are the 2:1, dioctahedral smectites termed beidellite and montmorillonite. The important difference between them is in the location of ionic substitutions. In beidellite, charge-building substitutions are located in the tetrahedral sheet; in montmorillonite, the majority of these substitutions are located in the octahedral sheet. Other examples of chemistry used in classification are nontronite, an iron-rich beidellite, and sauconite, a zinc-containing beidellite.

Another family of clay minerals is the chain clays, which have a structural resemblance to the chainlike arrangement of silica tetrahedra in pyroxene. In sepiolite and palygorskite, 2:1 layers are joined at their corners to form long channels that can contain water, a few exchangeable cations, and other substances.

Because clay minerals are composed of only two types of structural units (octahedral and tetrahedral sheets), different types of clay minerals can articulate with each other, thereby giving rise to mixed-layer clays. The most common type of mixed-layer clay is mixed-layer illite/smectite, which is composed of an interstratification of various proportions of illite and smectite layers. The interstratification may be random or ordered. The ordered mixed-layer clays may be given separate names. For example, a dioctahedral mixed-layer clay containing equal proportions of illite and smectite layers that are regularly interstratified is termed potassium rectorite. A regularly interstratified trioctahedral mixed-layer clay mineral containing approximately equal proportions of chlorite and smectite layers is termed corrensite.

Properties. Many of the properties of clay minerals are related to their crystal structure. Some of these properties are discussed below.

Kaolinite-serpentine group. These 1:1 layer silicates possess a *c* dimension of approximately 0.7 nanometer. The dioctahedral clays include the polytypes of kaolinite mentioned previously. The trioctahedral minerals include varieties of serpentine such as chrysotile, antigorite, lizardite, and amesite. These clays are nonswelling in water, with the exception of halloysite, a variety of kaolinite which can swell to about 1.0 nm. Kaolinites, however, can be made to swell by using intercalation compounds. Kaolinites can be distinguished from serpentines in x-ray diffraction analysis by their smaller *b* dimension, and by heat treatment: the kaolinite structure will decompose at 550°C (1020°F), whereas the serpentine structure will not. Also, serpentines are more susceptible to acid attack and will not intercalate. The 1:1 clay minerals possess a cation exchange capacity of 3–15 milliequivalents per 100 g, this arising mainly from broken bonds on crystal edges. Kaolinites are used in the manufacture of ceramics, paper, rubber, and medicine. A variety of serpentine (chrysotile) is used to manufacture asbestos products such as fireproof cloth and brake linings. *See* HALLOYSITE.

Pyrophyllite-talc group. These 2:1 layer silicates possess a *c* dimension of slightly more than 0.9 nm and exist in several polytypes and chemical varieties. Talc generally shows a triclinic structure (lTc), but a disordered variety is called kerolite. Minnesotaite is an iron-rich variety of talc, and willemseite is a nickel-rich variety. Polytypes of pyrophyllite are monoclinic, triclinic, and disordered pyrophyllite. Generally, these 2:1 minerals possess a high thermal stability, have a low cation-exchange capacity, and do not swell in water or in intercalation agents. *See* PYROPHYLLITE; TALC.

Smectite group. These 2:1 clays possess a variable *c* dimension because of their ability to swell. It ranges generally from 1.2 to 1.5 nm in air, depending on the type of interlayer cation, on the layer charge, and on the relative humidity. When saturated with ethylene glycol, however, smectites will swell to approximately 1.7 nm regardless of these factors, and therefore this treatment is a commonly used test for smectite. The ability to swell and other unusual properties associated with this group arise from isomorphous

Some dioctahedral and trioctahedral clay minerals and related phyllosilicates

Type	Layer structure*	Mineral	Idealized formula
		DIOCTAHEDRAL	
1:1		Kaolinite	$Al_2Si_2O_5(OH)_4$
2:1		Pyrophyllite	$Al_2Si_4O_{10}(OH)_2$
		Dioctahedral smectite	
		Beidellite	$Al_2(Si_{3.7}Al_{.3})O_{10}(OH)_2Na_{.3} \cdot nH_2O$
		Montmorillonite	$(Al_{1.7}Mg_{.3})Si_4O_{10}(OH)_2Na_{.3} \cdot nH_2O$
		Dioctahedral vermiculite	$Al_2(S_{3.2}Al_{.8})O_{10}(OH)_2Mg_{.4} \cdot nH_2O$
		Illite	
		Muscovite	$Al_2(Si_{3.2}Al_{.8})O_{10}(OH)_2K_{.8}$
		Celadonite	$Al_2(Si_3Al)O_{10}(OH)_2K$
		Leucophyllite	$(Fe,Al,Mg)_2Si_4O_{10}(OH)_2K$
		Mixed-layer illite/smectite	
2:1:1		Dioctahedral chlorite	$Al_4Si_4O_{10}(OH)_8$
		TRIOCTAHEDRAL	
1:1		Serpentine	$Mg_3Si_2O_5(OH)_4$
2:1		Talc	$Mg_3Si_4O_{10}(OH)_2$
		Trioctahedral smectite	
		Saponite	$Mg_3(Si_{3.7}Al_{.3})O_{10}(OH)_2Na_{.3} . nH_2O$
		Hectorite	$(Mg_{2.7}Li_{.3})Si_4O_{10}(OH)_2Na_{.3} . nH_2O$
		Trioctahedral vermiculite	$Mg_3(Si_3Al)O_{10}(OH)_2Mg_{.5} . nH_2O$
		Phlogopite	$Mg_3(Si_3Al)O_{10}(OH)_2K$
2:1:1		Trioctahedral chlorite	$Mg_6Si_4O_{10}(OH)_8$
		Sepiolite	$Mg_8Si_{12}O_{30}(OH)_4(OHH)_4 \cdot 8H_2O$
Chain		Palygorskite (attapulgite)	$Mg_5Si_8O_{20}(OH)_2(OHH)_4 \cdot 4H_2O$

*Tetrahedral sheets are drawn as trapezoids, octahedral sheets as rectangles, and interlayer cations as circles. The *c* axis is approximately parallel to the table's columns.

substitutions in the tetrahedral and octahedral sheets which give rise to a negative charge on the 2:1 layers. This charge is balanced by interlayer cations which usually are hydrated.

The association of water with interlayer cations gives rise to crystalline (or first-stage) swelling for smectites. Smectities may undergo further osmotic (second-stage) swelling in wet environments if the interlayer cation is Na^+ or Li^+. In third-stage swelling, 2:1 layers are dispersed completely in water. An osmotically swelling smectite may be transformed into a smectite that undergoes only the more limited form of crystalline swelling by exchanging interlayer Na^+ for a divalent cation such as Ca^{2+}. Other properties related to the expanded interlayer region are a large cation-exchange capacity, a large surface area, and a Brönsted acidity related to a greater degree of dissociation for interlayer water. Many of these properties may be lost, either reversibly or irreversibly, by heating smectite in air to drive off interlayer water, thereby causing the 2:1 layers to collapse around interlayer cations. Water also can be driven out of the interlayer by increasing negative charge on 2:1 layers. This process happens spontaneously in nature during burial metamorphism, wherein layer charge is increased, leading to water expulsion and layer collapse around interlayer K^+, thereby transforming smectite into illite. The many industrial uses for smectite include drilling muds, binders, cation exchangers, and catalysts.

Vermiculite group. Clays in this group are similar to smectite, except that a larger layer charge leads to a decreased ability to swell, although some can swell osmotically under certain conditions. Their *c* dimension is about 1.4 nm, and generally, unlike smectite, they will not swell further in ethylene glycol. Many vermiculites will collapse to 1.0 nm on potassium exchange and on heating in air. Like smectite, these clays also possess special properties related to the expanding interlayer region, including a large cation-exchange capacity and surface area. Macroscopic vermiculite is exploded by heating in air for use in potting soil and insulation. Some micas and illites can be transformed into vermiculite by replacing interlayer K^+ with cations of greater hydration energy. *See* VERMICULITE.

Illite group. These clays possess a *c* dimension of about 1.0 nm. They are nonswelling and possess a small cation-exchange capacity, unless they are interlayered with smectite to form mixed-layer illite/smectite. Illite/smectites show properties intermediate between pure illite and smectite. Illite's layer charge and potassium content are less than those of a true mica. *See* ILLITE.

Chlorite group. Chlorites, like vermiculites, show a *c* dimension of about 1.4 nm, but unlike vermiculite, they will not collapse on heating or potassium saturation. Chlorites share many polytypes and chemical varieties. *See* CHLORITE.

Sepiolite and palygorskite. The structure of these minerals are similar, except that sepiolite shows a *b* dimension of about 1.21 nm, whereas that for palygorskite is about 1.04 nm. This difference arises from the fact that palygorskite incorporates only two linked pyroxenelike chains in each 2:1 layer rather than three. Both clays possess a fibrous morphology and channels which can accommodate water and a few cations. The ability of these channels to absorb organic substances gives rise to their use in clarification. Sepiolite also is used to manufacture meerschaum tobacco pipes. *See* SEPIOLITE; ZEOLITE.

Origin. A primary requirement for the formation of clay minerals is the presence of water, because clay minerals are hydrous silicates. Hence clay minerals are not expected to form on the Moon because there is no water on the Moon. Evidence for the presence of water on Mars, and the unusual catalytic properties of Martian soil, suggest that clay minerals may be present on this planet. Likewise, the presence of clay minerals in some meteorites suggests that these materials have been exposed to water during some part of their long and complex history.

Clay minerals form on Earth in many different environments, including the weathering environment, the sedimentary environment, and the diagenetic-hydrothermal environment. Clay minerals composed of the more soluble elements (for example, smectite and sepiolite) are formed in environments in which these ions can accumulate (for example, in a dry climate, in a poorly drained soil, in the ocean, or in saline lakes), whereas clay minerals composed of less soluble elements (for example, kaolinite and halloysite) form in more dilute water such as that found in environments that undergo severe leaching (for example, a hilltop in the wet tropics), where only sparingly soluble elements such as aluminum and silicon can remain. Illite and chlorite are known to form abundantly in the diagenetic-hydrothermal environment by reaction from smectite. *See* CLAY; CLAY, COMMERCIAL; LITHOSPHERE; SILICATE MINERALS.

Clear-air turbulence

Turbulence above the boundary layer but not associated with cumulus convection. The atmosphere is a fluid in turbulent motion. That turbulence of a scale sensed by humans in aircraft is primarily associated with the boundary layer within a kilometer or so of the Earth, where it is induced by the surface roughness, or in regions of deep convection such as cumulus cloud development or thunderstorms. However, aircraft occasionally encounter turbulence when flying at altitudes well above the surface and far from convective clouds. This phenomenon has been given the rather unsatisfactory name of clear-air turbulence (CAT).

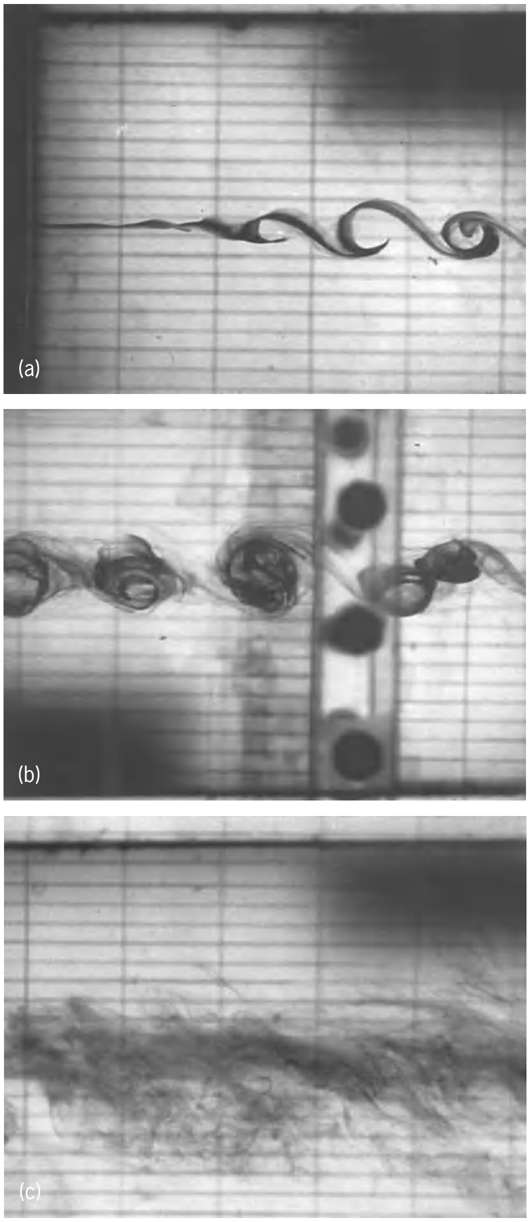
What is a primarily sensed in clear-air turbulence by the human is vertical acceleration. This acceleration will depend on the person's location in the plane, the speed of flight relative to the air, and the response characteristics of the airframe. A plane with a wing that generates aerodynamic lift more efficiently or an airframe with less weight per unit wing area will respond more strongly to a given gust magnitude. When allowances are made for different tolerance thresholds in different humans, a rough scale for subsonic aircraft has become accepted, with one-tenth the acceleration of gravity (*g*) as the threshold for light clear-air turbulence, 0.5 *g* for moderate, and 1 *g* for severe. *See* AEROELASTICITY.

Occurrence. Clear-air turbulence is encountered in the atmosphere with probability depending on flight altitude, geographical location, season of the year, and meteorological conditions. Given this variability and the small scale of the phenomenon, it is difficult to establish reliable statistics on the frequency of its occurrence. A number of extensive investigations have been carried out with this aim. One of these was a series of 90 flights by the National Aeronautics and Space Administration (NASA) supersonic aircraft YF-12A. At commercial-jet cruising levels (around 7.5 mi or 12 km), clear-air turbulence was encountered during approximately 12% of flight time in winter and 4% in summer. Above 11 mi (18 km) altitude (in the stratosphere) the frequency falls off rapidly. Other NASA studies have estimated clear-air turbulence frequency below 7.5 mi (12 km) to be somewhat increased, especially over mountainous terrain. The turbulent patches varied from 0.5 or 1.5 mi (1 or 2 km) in length to as large as 30 mi (50 km), although such large patches were very infrequent. The depth of the turbulent air was found to be almost always less than 0.6 mi (1 km).

Although clear-air turbulence may be encountered in unexpected meteorological contexts, there are highly favored locations for its occurrence. One is in the vicinity of the jet stream, particularly in ridges and troughs where the wind direction is turning sharply. A second and even more common location of occurrence is in the lee of a mountain range when a strong air flow is distorted by being forced over the range. In this situation a gravity lee wave is generated, which propagates to stratospheric heights. At various altitudes and distances from the mountain, this wave may break, and as many as a dozen or more patches of clear-air turbulence, light to severe, may be formed. *See* JET STREAM.

Forecasting and detection. Despite knowledge of these favored meteorological areas, it is not possible to forecast with confidence the precise location of a patch of clear-air turbulence. Warning forecasts for substantial portions of routes are typically given to pilots when conditions of clear-air turbulence prevail.

In view of this situation, effort has been expended to develop remote-sensing systems to give warning of a patch of clear-air turbulence with sufficient lead time to be avoided by minor diversions of flight path or at least to assure that all passengers are seated with safety belts fastened. Some ground-based techniques have the capability to produce a unique clear-air turbulence signature; of these, ultrasensitive radar probably has had the most demonstrable success. However, it is clearly impracticable to attempt to monitor any significant portion of commercial flight paths with costly ground-based instrumentation. Airborne infrared and microwave sensors, some using multiple frequencies, detect sharp temperature gradients or water-vapor concentration irregularities. The usefulness of these as clear-air turbulence warning systems is a subject of vigorous debate and investigation. *See* AERONAUTICAL METEOROLOGY; METEOROLOGY.



Laboratory realization of (*a*) Kelvin-Helmholtz instability, (*b*) the subsequent generation of turbulent eddies, and (*c*) mixing and dissipation. Fluid flow is left to right. (*Courtesy of Drs. G. G. Koop and F. K. Browand*)

Flight safety. Despite sophisticated design techniques applied to airframe response and despite pilot avoidance procedures, clear-air turbulence is still a factor in 10% of air transport accidents and safety incidents in the United States. Of all weather-related accidents, at least 20% may be associated with turbulence in flight.

Origin and explanation. The early observational documentations of clear-air turbulence excited much theoretical interest and speculation as to the fluid-dynamic explanation of this phenomenon. The consensus of researchers is that clear-air turbulence is the result of Kelvin-Helmholtz instability, a breakdown of smooth flow that occurs when the destabilizing velocity gradient of the fluid becomes large relative to the stabilizing density gradient.

It was initially obvious that this hypothesis was consistent with the occurrence of clear-air turbulence in the jet stream and in distorted flow downwind of mountain ranges where velocity gradients are large. Further quantitative experiments in the field identified a number of clear-air turbulence events precisely under the theoretically predicted conditions. In the laboratory it has been possible to reproduce the instability mechanism and follow its breakdown into turbulence (see **illus.**). This is the dynamic mechanism widely thought to be the fundamental one in clear-air turbulence.

One way of viewing clear-air turbulence is as an increase in energy of the smaller scales (30 ft to 0.6 mi, or 10 m to 1 km) of atmospheric motion. This is best presented in a spectral diagram, that is, a graph of energy versus wavelength.

Aside from the practical implications of clear-air turbulence for air transport, this phenomenon plays a role of undetermined magnitude in the dissipation of the kinetic energy of the atmosphere. *See* UPPER-ATMOSPHERE DYNAMICS.

Cleavage (developmental biology)

The subdivision of fertilized eggs (zygotes) into progressively smaller cells called blastomeres. **Figure 1** shows the development of the frog *Xenopus laevis* from the fertilized egg to the stage of the hatched larva (tadpole). At an intermediate stage called blastula, the *Xenopus* embryo is a hollow sphere of blastomeres surrounding a fluid-filled cavity called the blastocoel. Cleavage covers the period from egg to midblastula, when the *Xenopus* embryos consists of about 1200 cells. *See* BLASTULATION.

Cleavage shares the basic characteristics of most cell divisions. First, the cell nucleus is duplicated in a process known as mitosis. Then the cytoplasmic body of the cell divides so that each daughter cell inherits part of the cytoplasm along with one nucleus. The division of cytoplasm, called cytokinesis, may be executed by a contractile ring of proteins that pinches the daughter cells apart. This mode of cytokinesis is typical of eggs that are cleaved in their entirety, as in *Xenopus* and many other species. Alternatively, cytokinesis may occur by folds growing out from the outer cell membrane. This mode is characteristic of large eggs that contain major amounts of yolk, as do the eggs of birds, reptiles, and fishes. Here, only a small disc of yolk-free cytoplasm is cleaved while the yolky part of the egg remains undivided. *See* CELL DIVISION; CYTOKINESIS; MITOSIS.

Nucleocytoplasmic ratio and midblastula transition. Cleavage differs from later cell divisions by its fast pace, which leaves little or no time for cell growth. Thus, blastomeres become smaller and smaller while the overall size of the embryo remains nearly constant. One advantage of this fast pace is the rapid increase of the nucleocytoplasmic ratio, that is, the number of gene copies (typically two) relative to the volume of cytoplasm. Most cells need nuclear DNA to maintain a healthy turnover of their RNA and protein molecules. Embryos can synthesize new proteins using an endowment of maternal RNA (stored while the egg was growing in the ovary) but only for a limited time. Another advantage of rapid cleavage is the shortening of embryonic development, a period during which organisms are especially vulnerable to parasites and predators.

Typically, cleavage divisions slow down during the blastula stage. The longer cell cycles leave time for blastomeres to transcribe their nuclear DNA into RNA, which then replaces the maternal RNA. Along with making their own RNA, blastomeres may synthesize more protein and begin to grow between cell divisions. As blastomeres use their own genetic information, they may drive their cell cycles at different speeds, causing them to fall out of synchrony. Around the same time, blastomeres may also start moving relative to one another in different ways. In *Xenopus*, all these changes occur simultaneously at the blastoderm stage and are known as the midblastula transition, or MBT. In other species, MBT events may occur at successive stages. It is thought that key MBT events are triggered when the nucleocytoplasmic ratio reaches a threshold level, possibly as some cytoplasmic component is titrated out by nuclear DNA. *See* CELL CYCLE; DEOXYRIBONUCLEIC ACID (DNA); RIBONUCLEIC ACID (RNA).

Role of cleavage in cell determination. Cleavage is the beginning of a developmental process that will lead to the formation of specialized cells, such as epidermal or blood cells. What becomes of a blastomere in the course of normal development is called its fate. However, in most species early blastomeres are not restricted to their fate but are pluripotent, meaning they are capable of forming multiple embryonic parts. For instance, when the blastomeres of a frog embryo are teased apart at the two-cell stage, each may give rise to a complete larva. Conversely, two complete mouse embryos, when stuck together experimentally and reinserted into the uterus of a foster mother, will give rise to one mouse consisting of a mosaic of cells derived from the two constituent embryos.

The stepwise process that restricts pluripotent blastomeres to their fate is known as cell

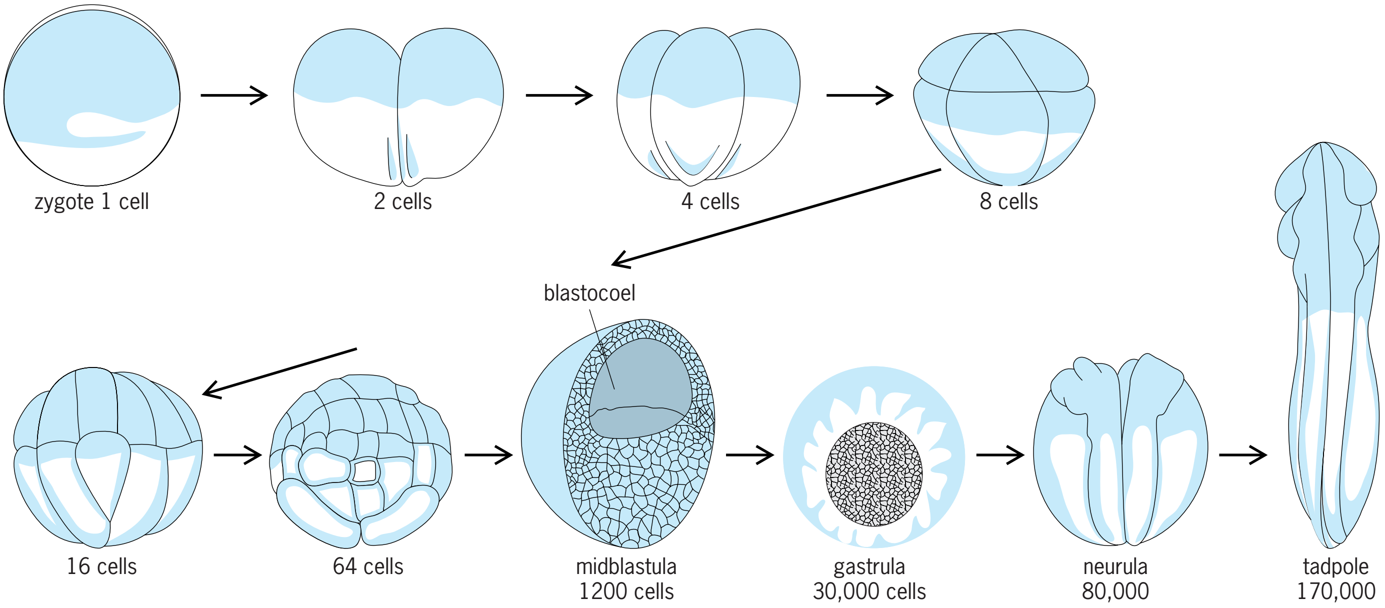

Fig. 1. Development of the African clawed frog, *Xenopus laevis*, from the fertilized egg to the tadpole stage. The midblastula stage is shown in section to reveal the blastocoel. (*Modified from K. Kalthoff, Analysis of Biological Development, 2d ed., McGraw-Hill, 2001*)

determination. In many embryos, such as amphibians, cell determination relies in part on asymmetrically distributed molecules in the egg cytoplasm, which are segregated into different blastomeres as the egg is cleaved. These cytoplasmic determinants elicit different patterns of gene activity in the enclosed cell nuclei. Blastomeres that have inherited different cytoplasmic determinants may later exchange signals that lead to increasingly complex patterns of cells with different determined states. In some species, the process of cell determination occurs early; their embryos cleave in stereotypical patterns that are virtually identical from one embryo to the next. In other species, cleavage patterns are more variable, and blastomere determination relies more on later adjustments by intercellular signals.

Cleavage of mammalian embryos. Cleavage of mammalian embryos is peculiar in several respects. The mammalian egg is unusually small (about 0.1 mm in diameter) and cleaves at a very leisurely pace. Embryonic RNA synthesis starts at the two-cell stage, and cell growth begins early on. All these traits are possible because the embryo develops in the uterus, which provides nutrients and protects the embryo from parasites and predators. The mammalian cleavage pattern produces a ball of cells, which secrete fluid to generate a blastocoel in an off-center position. This leads to the hallmark stage of mammalian development known as the blastocyst (**Fig. 2**). The blastocyst consists, in part, of an outer cell layer known as the trophoblast, which contributes to the formation of the placenta. Positioned excentrically within the trophoblast is the inner cell mass, or ICM, which gives rise to the embryo proper.

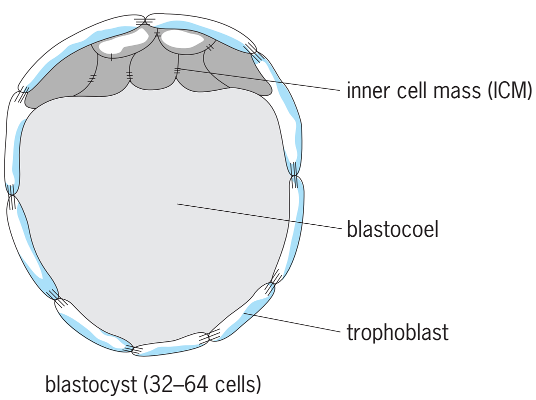

Fig. 2. Mammalian embryo at the blastocyst stage (about 50 cells). (*Reprinted with permission from K. Kalthoff, Analysis of Biological Development, 2d ed., McGraw-Hill, 2001*)

ICM cells are of medical interest because, if cultured under favorable conditions, they may give rise to embryonic stem cells, or ES cells. ES cells divide and grow indefinitely in an undifferentiated state, and they can divide asymmetrically, with one daughter being again an ES cell while its sister cell becomes a committed progenitor cell. The latter, depending on signal molecules in the culture medium, may give rise to all kinds of specialized cells, such as neurons or heart muscle cells. ES cells may, therefore, be used for cell replacement therapy for patients with diseases that leave certain cell lineages dysfunctional, such as Parkinson's disease or heart muscle failure. Cell replacement would be especially useful in conjunction with another technique known as nuclear transfer. Here, the nucleus of a cell from the patient is transferred into an enucleated human egg, which is grown in culture to the blastocyst stage. ICM cells are then harvested to raise ES cells that carry the patient's genetic information, so that their descendants will not be rejected by the patient's immune system. *See* EMBRYONIC DIFFERENTIATION; STEM CELLS.

Cleft lip and cleft palate

Two of the most common congenital anomalies in humans, resulting from incomplete closure of the lip and palate during early embryonic life. During the first trimester of pregnancy, the face and mouth are formed by the fusion of several different parts. The lip is fully fused 6 or 7 weeks after fertilization. The palate, which forms the roof of the mouth and separates the oral cavity from the nasal cavity, is fully fused 10 weeks after fertilization. If fusion fails to occur or breaks down, an opening, or cleft, occurs in the lip, the palate, or both. Although cleft lip and cleft palate are associated with separate embryologic events, that is, are separated by a long time on the embryonic time scale, both often occur in an affected individual. Clefts vary in frequency among racial subgroups, with incidence ranging from 1 per 250 live births to 1 per 750 live births. *See* MOUTH.

Clefts of the lip may occur on one side (unilateral, **Fig. 1**) or both sides (bilateral). When they occur in the exact midline of the lip, they are often associated with severe anomalies of the brain. The cleft usually extends through the lip and nostril floor. The underlying dental arch is also typically involved.

The palate consists of an anterior bony portion (hard palate) and a posterior muscular portion (soft palate). The soft palate alone may be cleft, or both the soft and hard palate may be cleft (**Fig. 2**), but rarely is the hard palate cleft with the soft palate intact. A variant of cleft palate is the submucous cleft palate, in which the muscles of the palate are cleft but the overlying mucous membrane is intact.

Fig. 1. Unilateral, incomplete cleft lip in which the notch does not extend to the nose.

Fig. 2. Cleft palate, resulting in a fissure in the palate connecting the nasal and oral cavities.

Causes. Clefts are the only major abnormality in approximately half of newborns who have them. In the other half, they occur as a part of a pattern of multiple anomalies (a syndrome). It has been determined that most clefts are associated with genetic factors; the genetic patterns range from autosomal dominant inheritance (50% risk of inheritance) in many syndromes to a genetic predisposition for clefting (about 4% risk of inheritance). Clefting is often associated with chromosome abnormalities, intrauterine disturbances (such as tears in the amnion), and teratogenic (malformation-causing) substances, such as alcohol, anticonvulsant drugs, and excessive levels of retinoic acid (vitamin A). *See* HUMAN GENETICS.

Secondary complications. Cleft lip is both an esthetic and a functional problem because of the disruption of the lip musculature. The defect in the floor of the nose causes asymmetry of the nose. The cleft of the dental arch causes orthodontic and occlusal (bite) problems, including congenitally missing teeth. The palatal cleft may result in some minor difficulties with feeding in early life, but a more significant problem is abnormal speech, including excessive nasal resonance (hypernasality) and articulation disorders. Clefting is also associated with chronic middle-ear disease (ear infections) and mild hearing loss. Additional structural or functional disorders can be associated with other features of a syndrome that includes cleft lip or cleft palate. *See* HEARING (HUMAN); SPEECH.

Management. Because of the combination of esthetic, structural, and functional requirements for total repair of clefts, that is, surgical, dental, ear, hearing, and speech, the care of children with clefts has usually been managed by comprehensive teams of specialists, including plastic surgeons, speech pathologists, audiologists, geneticists, otolaryngologists, oral surgeons, orthodontists, and pediatricians.

Cleft lip is typically repaired within the first few months of life, and the palate is most often surgically closed before speech development.

Extensive dental work is normally deferred until some of the permanent teeth have erupted. Middle-ear disease is usually treated aggressively through surgery in order to prevent long-term hearing loss. In general, the outlook for children with these problems is very favorable, and in many cases the problems associated with clefts are completely remediable. Genetic counseling is extremely important. *See* CONGENITAL ANOMALIES. Robert Shprintzen

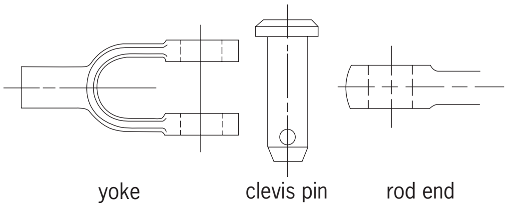
Clevis pin

A fastener with a head at one end and a hole at the other used to join a clevis to a rod. A clevis is a yoke with a hole formed or attached at one end of a rod (see **illus**.). When an eye or hole of a second rod is aligned with the hole in the yoke, a clevis pin can be inserted to join the two. A cotter pin can then be inserted in the hole of the clevis pin to hold it in, yet the fastening is readily detachable. This joint is used for rods in tension where some flexibility is required. Paul H. Black



Clevis pin which joins yoke to rod end.

Click chemistry

A simplified chemical reaction method recognized in 2001 by a group led by Nobel Laureate Prof. K. Barry Sharpless at the Scripps Research Institute. "Click" is meant to signify that joining molecular pieces is as easy as clicking together the two pieces of a buckle. The buckle works no matter what is attached to it, as long as its two pieces can reach each other and the components of the buckle can make a connection only with each other. Click reactions are easy to perform, give rise to their intended products in very high yields with little or no by-products, work well under many conditions (usually especially well in water), and are unaffected by the nature of the groups being connected to each other.

The central question posed by Sharpless and colleagues is whether desired functions can be obtained from molecules made using only click chemical reactions. In this deliberate eschewing of more sophisticated synthetic techniques is an implicit challenge to organic chemists that make complex structures by complex methods (can complex structures be made by simple methods?), and an explicit tip of the hat to the synthesis of functional polymers, which cannot occur without the use of reactions that meet the click chemistry standard. *See* ORGANIC SYNTHESIS.

Reactions. Click reactions share the following attributes. (1) Many click components are derived from alkenes and alkynes, and thus ultimately from the cracking of petroleum. Carbon-carbon multiple bonds provide both energy and mechanistic pathways to be made into reactive structures for click connections. (2) Most click reactions involve the formation of carbon-heteroatom (mostly N, O, and S) bonds. This stands in contrast to much of synthetic organic chemistry of recent years, which has emphasized the formation of carbon-carbon bonds. (3) Click reactions are strongly exothermic by virtue of highly energetic reactants or strongly stabilized products. (4) Click reactions are usually fusion processes (leaving no by-products) or condensation processes (producing water as a by-product). (5) Many click reactions are highly tolerant of and often accelerated by the presence of water. *See* ALKENE; ALKYNE.

These features are illustrated by the case of epoxide ring opening by a wide range of nucleophiles (**Fig. 1**). Since the epoxide is a strained three-membered ring, its ring opening is a strongly favored process. Yet that ring opening is required to occur in a particular way; that is, the nucleophile can attack the epoxide carbon atom only along the C-O bond axis, so by-products are avoided and yields are high. In addition, epoxides are relatively unreactive with water, while the hydrogen bonding ability and polar nature of water both serve to support the epoxide ring-opening reaction by other nucleophiles. *See* ELECTROPHILIC AND NUCLEOPHILIC REAGENTS; EPOXIDE; HYDROGEN BOND.

Most click reactions were discovered many years ago and have been widely appreciated, but have not been tapped for their full potential. They include the following classes of reactions, some of which are shown in **Fig. 2**.

Nucleophilic opening of spring-loaded electrophiles. The opening of the three-membered epoxide, aziridine, aziridinium, and episulfonium rings are all simple and versatile reactions. Included in this category are Michael addition reactions to α,β-unsaturated carbonyl compounds, which are also strongly favored processes.

Mild condensation reactions of carbonyl compounds. The formation of 1,3-dioxolane rings from aldehydes or ketones and of 1,3-diols, hydrazones, and oximes from aldehydes and hydrazines or hydroxylamine ethers, and of heterocycles from α- and β-carbonyl aldehydes, ketones, and esters are highly reliable and widely used reactions. *See* ALDEHYDE; CARBONYL; HETEROCYCLIC COMPOUNDS; KETONE; OXIME.

Cycloaddition reactions. Distinguished by the relatively nonpolar nature of their reactive groups, these fusion reactions comprise a wide range of processes, including the Diels-Alder reaction. Most useful are 1,3-dipolar cycloaddition reactions, with the cream of the crop being the reaction of organic azides with alkynes. *See* AZIDE; DIELS-ALDER REACTION.

Azide-alkyne cycloaddition. The goals and philosophy of click chemistry have been most extensively explored with the uncatalyzed (**Fig. 3***a*) and copper-catalyzed (Fig. 3*b*) versions of the cycloaddition reaction between azides and alkynes to form triazines. The former was first reported by A. Michael in 1893 and was later studied and popularized by the German chemist Rolf Huisgen in 1960s through the 1980s. The latter reaction was discovered independently in 2002 by the research groups of M. Meldal in Holland and K. B. Sharpless in the United States, and requires the use of a terminal alkyne. The abbreviation AAC (azide-alkyne cycloaddition) is used for the uncatalyzed process and CuAAC for the copper-mediated version.

These processes are uniquely useful because of the properties of the reactive substituents. Both azides and alkynes are high in chemical potential energy, and their fusion to make triazoles is exothermic by more than 45 kcal/mol. However, the rate of this reaction is quite slow, normally requiring prolonged heating for unactivated (not strongly electron-deficient or strained) alkynes. The azide and alkyne groups are stable in the presence of the nucleophiles, electrophiles, and solvents common to standard reaction conditions, with the azide being the only 1,3-dipolar reagent to have this quality. Most importantly, azides and alkynes are almost completely unreactive toward biological molecules. They are small and incapable of significant hydrogen bonding, and thus are unlikely to significantly change the properties of structures to which they are attached. Both can be easily introduced into organic compounds.

Click chemistry in situ. Because of their special reactivity—inert toward everything else and only sluggishly reactive with each other—azides and alkynes have been used to assemble molecules that bind very tightly to enzymes by using the enzyme itself as the reaction vessel (**Fig. 4**). The technique, known as click chemistry in situ, involves the tagging of molecules that bind to adjacent locations on an enzyme with azide and alkyne groups. If the derivatized molecules can interact simultaneously with the target in the proper orientation to hold the azide and alkyne units in proximity, a triazole may form to link the enzyme-binding components to each other. Since attachments to any target by two arms is better than either arm alone, the result is invariably a molecule of much higher binding affinity. Prior knowledge of the structure of the target is not required, nor is an assay for enzyme activity necessary. Since no reaction occurs between azides and alkynes at the concentrations used in these experiments without templating by the target enzyme, the formation of a new product is easy to detect by mass spectrometry

and is proof of the creation of an excellent enzyme inhibitor. *See* ENZYME.

Click chemistry in situ has been used to create novel high-affinity binders to the important neurotransmitter enzyme acetylcholinesterase, the metabolic enzyme carbonic anhydrase, and HIV protease. It has become apparent in these and other studies that the triazole linkage has advantageous properties for drug discovery. Having a strong dipole moment, the capacity for significant hydrogen bonding, and the ability to engage in π-stacking interactions, triazoles can engage in productive interactions with proteins. The creation of this unit from two "invisible" pieces in a pocket of an enzyme is an event that influences the selectivity of bond formation during in-situ drug discovery efforts. The click chemistry in-situ technique is used in many laboratories and pharmaceutical companies around the world as a complement to traditional methods of synthesis and screening. *See* DIPOLE MOMENT.

While not yet used directly in living cells because of the cytotoxicity and attendant bioregulation of copper, the copper-catalyzed reaction has achieved extraordinarily wide use in organic chemistry and materials science. Applications include the synthesis of biologically active compounds, the preparation of conjugates to proteins and polynucleotides, the synthesis of dyes, the elaboration of known polymers and the synthesis of new ones, the creation of responsive materials, and the covalent attachment of desired structures to surfaces.

Conclusion. Click chemistry expands the scope of structures that can be made by expert chemists and nonchemists alike. The rationale is simply that the more tolerant is the connection reaction between chemical pieces, the more diverse the pieces that can be brought to bear on any problem. Chemists possess neither the ability to control reactions as well as living cells do, nor the ability to manufacture large structures such as proteins for every purpose. Therefore, while nature can inspire us, making such complex molecules comes at a fearful cost of time and expense. If indeed it is chemical function that is the goal, keeping it simple is a useful rule.

Client-server system

A computing system that is composed of two logical parts: a server, which provides services, and a client, which requests them. The two parts can run on separate machines on a network, allowing users to access powerful server resources from their personal computers (**Fig. 1**). *See* LOCAL-AREA NETWORKS; WIDE-AREA NETWORKS.

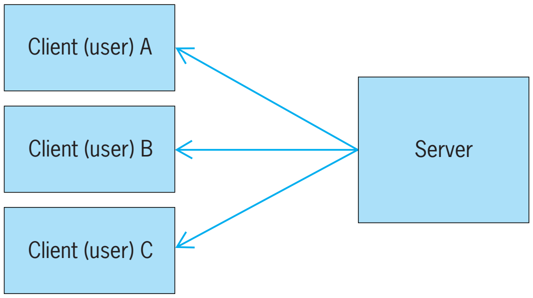

Fig. 1. Client-server system. Clients request services of the server independently but use the same interface.

Client-server systems are not limited to traditional computers. An example is an automated teller machine (ATM) network. Customers typically use ATMs as clients to interface to a server that manages all of the accounts for a bank. This server may in turn work with servers of other banks (such as when withdrawing money at a bank at which the user does not have an account). The ATMs provide a user interface and the servers provide services, such as checking on account balances and transferring money between accounts.

To provide access to servers not running on the same machine as the client, middleware is usually used. Middleware serves as the networking between the components of a client-server system; it must be run on both the client and the server. It provides everything required to get a request from a client to a server and to get the server's response back to the client. Middleware often facilitates communication between different types of computer systems. This communication provides cross-platform client-server computing and allows many types of clients to access the same data.

The server portion almost always holds the data, and the client is nearly always responsible for the user interface. The application logic, which determines how the data should be acted on, can be distributed between the client and the server (**Fig. 2**). The part of a system with a disproportionately large amount of application logic is termed "fat"; a "thin" portion of a system is a part with less responsibility delegated to it. Fat server systems, such as groupware systems and web servers, delegate more responsibility for the application logic to the server, whereas fat client systems, such as most database systems, place more responsibility on the client. *See* HUMAN-COMPUTER INTERACTION.

Multitiered systems. The canonical client-server model assumes two participants in the system. This is called a two-tiered system; the application logic must be in the client or the server, or shared between the two. It is also possible to have the application logic reside in a third layer separate from the user interface and the data, turning the system into a three-tier system. Complete separation is rare in actual systems; usually the bulk of the application logic is in the middle tier, but select portions of it are the responsibility of the client or the server.

The three-tier model is more flexible than the two-tier model because the separation of the application logic from the client and the server gives application logic processes a new level of autonomy. The processes become more robust since they can operate independently of the clients and servers. Furthermore, decoupling the application logic from the data allows data from multiple sources to be used in a single transaction without a breakdown in the client-server model. This advancement in client-server architecture is largely responsible for the notion of distributed data. *See* DISTRIBUTED SYSTEMS (COMPUTERS).

Standard web applications are the most common examples of three-tier systems. The first tier is the user interface, provided via interpretation of Hyper Text Markup Language (HTML) by a web browser. The embedded components being displayed by the browser reside in the middle tier, and provide the application logic pertinent to the system. The final tier is the data from a web server. Quite often this is a database-style system, but it could be a data-warehousing or groupware system. *See* WORLD WIDE WEB.

Software components. The desire to distribute servers across a network and have clients find them on demand has led to the development of component technologies. Components are the smallest self-managing, independent, and useful parts of a system that can work with other components to provide useful services. Each component provides an interface, which is a contract to do certain things asked of it. Therefore, systems can be quickly assembled by reusing existing components. For example, a program that needs to sort a list may ask a sorting component to do this so the programmer writing the new application need not write the sorting code. Components that provide the same interfaces can be interchanged for one another; for example, a user could purchase and install a faster sorting component, and programs using the old sorting component would automatically use the improved version.

Middleware packages. The use of components requires additions to the traditional middleware package that can coordinate components and help components locate one another. The two primary middleware packages providing these services are the Common Object Request Broker Architecture (CORBA) and the Distributed Component Object Model (DCOM).

CORBA. An industry-wide consortium created and advocates the standard known as CORBA. CORBA

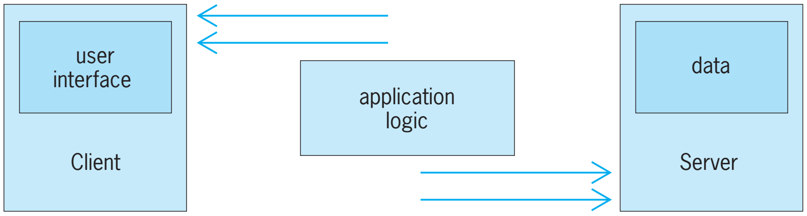

Fig. 2. Distribution of elements of a client-server system. Since the distribution of the user interface and data is fixed, the distribution of the application logic distinguishes fat client systems from fat server systems.

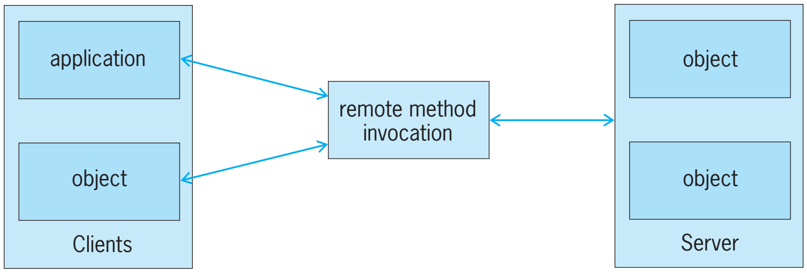

Fig. 3. Client-server computing using distributed objects. Communication between components (denoted by arrows) is facilitated by object request brokers (ORBs), which have been omitted for clarity. The remote method invocation system allows an object on one host to cause a method of an object that resides on another host to be executed on that remote host.

objects can exist anywhere on a network; their location is completely transparent (**Fig. 3**). Details such as an object's language or its operating system are also hidden from clients. Thus, the implementation of an object is of no concern to an invoking object; the interface is the only entity that a client needs to consider when selecting a serving object (Fig. 2).

The most important part of a CORBA system is the object request broker (ORB). CORBA uses the object request broker to establish a client-server relationship between components. The object request broker intercepts service requests from the client objects and routes them to an appropriate server. CORBA uses an interface file written in an interface definition language (IDL) to specify the services that an object can provide, but programmers write code in their language of choice.

When clients request services, the requests are routed to the remote server using a local "stub" object and the object request broker. The stub relieves the application programmer from the burden of routing the message.

CORBA specifies two means by which an object can locate another object in a system. The first is the Naming Service. This service is analogous to the white pages in a phone book: An object looks up another object by the name under which the object registered itself with the object request broker when it was initialized. The second service is the Trading Service, which is like the yellow pages: Objects can ask the Trading Service which objects have registered with certain service characteristics. The trading repository then returns references to salient objects and gives the client information regarding the properties of the services. *See* OBJECT-ORIENTED PROGRAMMING.

DCOM. Like CORBA, DCOM separates interface from functionalty by using an interface definition language. The client-server contract is fulfilled by using object interfaces that make the implementation language and the location of objects transparent. When a DCOM client needs a server, it issues a request for an object supporting the required interface instantiated so that the interface becomes available.

Using interface pointers to mask stublike objects, DCOM supports transparent communication between clients and remote server objects. DCOM uses a model quite similar to the mechanism employed by CORBA to provide location-independent access to objects. Since DCOM provides access to interfaces only (and not objects), there is no means by which to locate specific objects.

Java. Java is a programming language that allows programs to run on a variety of computing platforms without being modified; such a system is referred to as a mobile code system. Mobile code is distinguished from traditional application code in that it is dynamically executed by an application that provides the run-time environment. For code to be considered mobile, it must be portable, meaning the code can be run on a variety of platforms. Java uses bytecodes to provide portability and security. The bytecode system calls for programs to be "compiled" to the point where they can be run on a Java virtual machine, which translates the bytecodes into actual machine instructions in real time. Java virtual machines must adhere to a standard; this ensures that a Java program executes in the same manner on any machine. To provide security, the Java Verifier checks all code scheduled to be executed for malicious code.

Java's promise of "write once, run anywhere" makes it an appealing language in which to author pieces of a client-server system. Java also provides core classes that are a part of standard Java implementations. These core classes provide basic services that many programs require, and can decrease application development times by reducing the amount of code a programmer needs to write and debug.

When coupled with distributed object technology, Java forms a strong basis for the development of a robust system that supports client-server computing. A platform for universal network computing can be created by using Java as a programming language and mobile code system and CORBA or DCOM as an integration technology. Using DCOM or CORBA allows Java components to be split into client- and server-side components in many cases, providing the system with enhanced flexibility in distributing web-based applications. *See* DIGITAL COMPUTER; PROGRAMMING LANGUAGES. Climate history

The long-term records of precipitation, temperature, wind, and all other aspects of the Earth's climate. The climate, like the Earth itself, has a history extending over several billion years. Climatic changes have occurred at time scales ranging from hundreds of millions of years to centuries and decades. Processes in the atmosphere, oceans, cryosphere (snow cover, sea ice, continental ice sheets), biosphere, and lithosphere (such as plate tectonics and volcanic activity) and certain extraterrestrial factors (such as the Sun) have caused these changes of climate.

The present climate can be described as an ice age climate, since large land surfaces are covered with ice sheets (for example, Antarctica and Greenland). The origins of the present ice age may be traced, at least in part, to the movement of the continental plates. With the gradual movement of Antarctica toward its present isolated polar position, ice sheets began to develop there about 30 million years ago. For the past several million years, the Antarctic ice sheet reached approximately its present size, and ice sheets appeared on the lands bordering the northern Atlantic Ocean. During the past million years of the current ice age, about 10 glacial-interglacial cycles have been documented. Changes in the Earth's orbital parameters, eccentricity, obliquity, and longitude of perihelion are thought to have initiated, or paced, these cycles through the associated small changes in the seasonal and latitudinal distribution of solar radiation. The most recent glacial period ended between about 15,000 and 6000 years ago with the rapid melting of the North American and European ice sheets and an associated rise in sea level, and the atmospheric concentration of carbon dioxide.

The present interglacial climate reached its maximum warmth about 6000 years ago when, compared to the present, the high northern latitudes were slightly warmer, the northern continental interiors were drier, and the monsoon lands of Africa and southern Asia were wetter. These differences appear also to have been caused, at least in part, by differences in Earth's orbital parameters, compared to the present.

Changes of climate spanning centuries to decades occur within the more gradual changes just described. For example, the climate of northern Europe was slightly warmer about 1000 years ago than at present, but colder than at present 100 to 300 hundred years ago, when mountain glaciers advanced beyond present-day limits in Scandinavia and the Alps. The causes of these shorter-term changes of climate are not well understood, although volcanic activity, solar variability, and the internal dynamics of the atmosphere and ocean may all be involved. There is concern that human activities, such as massive deforestation and the burning of fossil fuels, may become causes of climatic change.

The climates of the distant geologic past were strongly influenced by the size and location of continents and by large changes in the composition of the atmosphere. For example, around 250 million years ago the continents were assembled into one supercontinent, Pangaea, producing significantly different climatic patterns than are seen today with widely distributed continents. In addition, based upon models of stellar evolution, it is hypothesized that the Sun's radiation has gradually increased by 10–20% over the past several billion years and, if so, this has contributed to a significant warming of the Earth. *See* CONTINENTS, EVOLUTION OF; GLACIAL EPOCH; PALEOCLIMATOLOGY.

Evidence. Instrumental records of climatic variables such as temperature and precipitation exist for the past 100 years in many locations and for as long as 200 years in a few locations. These records provide evidence of year-to-year and decade-to-decade variability, but they are completely inadequate for the study of century-to-century and longer-term variability. Even for the study of short-term climatic fluctuations, instrumental records are incomplete, because most observations are made from the continents (covering only 29% of the Earth's surface area). Aerological observations, which permit the study of atmospheric mass, momentum and energy budgets, and the statistical structure of the large-scale circulation, are available only since about the mid-1960s. Again there is a bias toward observations over the continents. It is only with the advent of satellites that global monitoring of the components of the Earth's radiation budget (clouds; planetary albedo, from which the net incoming solar radiation can be estimated; and the outgoing terrestrial radiation) became possible. *See* METEOROLOGICAL SATELLITES.

There remain important gaps in the ability of climatologists to describe the present state of the climate. For example, precipitation estimates, especially over the oceans, are poor. Oceanic circulation, heat transport, and heat storage are only crudely estimated. Thus, although climatic changes are discernible from instrumental records, the task of defining the scope of these changes and diagnosing potential causes is difficult.

In spite of the inadequacy of the instrumental records for assessing global climate, considerable evidence of regional climatic variations exists. For example, there is evidence of climatic warming in the polar regions of the Northern Hemisphere during the twentieth century. *See* GREENHOUSE EFFECT.

Evidence of climatic changes prior to instrumental records comes from a wide variety of sources. Tree rings, banded corals, and pollen and trace minerals retrieved from laminated lake sediments and ice sheets yield environmental records for past centuries and millennia. Advanced drilling techniques have made it possible to obtain long cores from ocean sediments that provide geologic records of climatic conditions going back hundreds of millions of years. *See* DENDROCHRONOLOGY; PALYNOLOGY.

Causes. Many extraterrestrial and terrestrial processes have been hypothesized to be possible causes of climatic fluctuations. These include solar irradiance, variations in orbital parameters, motions of the lithosphere, volcanic activity, internal variations of the climate system, and human activities. It is likely that all of the natural processes have played a role in past climatic changes. Also, the climatic response to some particular causal process may depend on the initial climatic state, which in turn depends upon previous climatic states because of the long time constants of lithosphere, oceans, and cryosphere. True equilibrium climates may not exist, and the climate system may be in a continual state of adjustment.

Solar irradiance. Variations in solar irradiance would almost certainly have an influence on climate. In addition to the possible long-term evolution of the Sun, the changing appearance of the Sun, the so-called sunspots, hint at shorter-term variability on the scale of years to centuries. Satellite observations have detected decadal-scale fluctuations in solar radiation on the order of 0.1%. Radiance variability in limited portions of the solar spectrum has also been observed but has not been linked clearly to climate variability. *See* SOLAR RADIATION.

Orbital parameters. Variations of the Earth's orbital parameters (eccentricity of orbit about the Sun, longitude of perihelion, and inclination or tilt of the rotational axis) lead to small but significant variations in incoming solar radiation with regard to seasonal partitioning and latitudinal distribution. These variations occur at times scales of 20,000 to 100,000 years and have been linked to glacial-interglacial cycles and sedimentation cycles in geologic records. *See* EARTH ROTATION AND ORBITAL MOTION.

Lithosphere motions. Sea-floor spreading and continental drift, continental uplift, and mountain building operate over long time scales and are almost certainly important factors in long-term climate. *See* CONTINENTAL DRIFT; MARINE GEOLOGY; OROGENY; PLATE TECTONICS.

Volcanic activity. Volcanic activity produces gaseous and particulate emissions that lead to the formation of persistent stratospheric aerosol layers. It may be a factor in climatic variations at all time scales. *See* VOLCANO.

Internal variability of climate system. Components of the climate system (atmosphere, ocean, cryosphere, biosphere, land surface) are interrelated through a variety of feedback processes operating over a wide range of time scales. These processes could, in principle, produce fluctuations of sufficient magnitude and variability to explain any observed climatic change. For example, atmosphere-ocean interactions may operate over time scales up to centuries, the basic period of overturning of the ocean thermohaline circulation; and atmosphere-ocean-cryosphere interactions may operate over time scales up to tens of millennia, the time required to build a major ice sheet. Several hypotheses have been proposed to explain glacial-interglacial fluctuations as complex internal feedbacks among atmosphere, ocean, and cryosphere. (Periodic buildup and surges of the Antarctic ice sheet and periodic fluctuation in sea ice extent and deep-ocean circulation provide examples.) Atmosphere-ocean interaction is being studied intensively as a possible cause of short-term climatic variations. It has been observed that anomalous ocean temperature patterns (both equatorial and midlatitude) are often associated with anomalous atmospheric circulation patterns. Although atmospheric circulation plays a dominant role in establishing a particular ocean temperature pattern (by means of changes in wind-driven currents, upwelling, radiation exchange, evaporation, and so on), the anomalous ocean temperature distribution may then persist for months, seasons, or longer intervals of time because of the large heat capacity of the oceans. These anomalous oceanic heat sources and sinks may, in turn, produce anomalous atmospheric motions. The Earth's biosphere may also be actively involved in climatic changes. For example, the atmospheric concentration of carbon dioxide is linked to the carbon reservoirs of the continents and oceans via photosynthesis-respiration cycles, and gas exchange at the air-ocean interface. *See* ATMOSPHERIC GENERAL CIRCULATION; BIOSPHERE; OCEAN CIRCULATION.

Human activities. Forest clearing and other large-scale changes in land use, changes in aerosol loading, and the changing concentration of carbon dioxide in the atmosphere are examples of possible mechanisms through which human activities may influence the large-scale climate. Because of the large observational uncertainties in defining the state of the climate, it has not been possible to establish the relative importance of human activities (as compared to natural processes) in recent climatic fluctuations. There is, however, considerable concern that future human activities may lead to large climatic variations (for example, continued increases in atmospheric carbon dioxide concentration due to burning of fossil fuels) by the early twenty-first century. *See* AIR POLLUTION; CLIMATE MODIFICATION.

Modeling. Because of the complexity of the real climate system, simplified numerical models of climate are being used to study particular processes and interactions. Some models treat only the global-average conditions, whereas others, particularly the dynamical atmosphere and ocean models, simulate detailed patterns of climate. These models will undoubtedly be of great importance in attempts to understand climatic processes and to assess the possible effects of human activities on climate. *See* CLIMATE MODELING; CLIMATIC PREDICTION; CLIMATOLOGY.

Climate modeling

Construction of a mathematical model of the climate system of the Earth capable of simulating its behavior under present and altered conditions. The Earth's climate is continually changing over time scales ranging from hundreds of years to a few years. Since the climate is determined by the laws of classical physics, it should be possible in principle to construct such a model. The advent of a worldwide weather-observing system capable of gathering data for validation and the development and widespread routine use of digital computers have made this undertaking possible, starting in the mid-1970s.

The first attempts at modeling the planetary climate showed that the Earth's average temperature is determined mainly by the balance of radiant energy absorbed from sunlight and that emitted by the Earth system. About 30% of the incoming radiation is reflected directly to space, and 72% of the remainder is absorbed at the surface (**Fig. 1**). The incoming solar radiation is divided among reflection, absorption by the atmospheric constituents, and absorption by the surface of the planet. The outgoing infrared radiation comes from the surface, atmospheric gases, and clouds. In addition, the atmosphere radiates down to the surface, and the surface gives energy to the atmosphere in the forms of latent and sensible heat. The radiation is absorbed unevenly over the Earth, which sets up thermal contrasts that in turn induce convective circulations in the atmosphere and oceans. Climate models attempt to calculate from mathematical algorithms the effects of these contrasts and the resulting motions in order to understand better and perhaps predict future climates in some probabilistic sense. *See* SOLAR RADIATION; TERRESTRIAL RADIATION.

Climate models differ in complexity, depending upon the application. The simplest models are intended for describing only the surface thermal field at a fairly coarse resolution. These mainly thermodynamical formulations are successful at describing the seasonal cycle of the present climate, and have been used in some simulations of past climates, for example, for different continental arrangements that occurred millions of years ago. At the other end of the spectrum are the most complex climate models, which are extensions of the models used in weather forecasts. These models aim at simulating seasonal and even monthly averages just shortly into the future, based upon conditions such as the temperatures of the tropical-sea surfaces. Intermediate to these extremes are models that attempt to model climate on a decadal basis, and these are used mainly in studies of the impact of hypothesized anthropogenically induced climate change. *See* CLIMATE MODIFICATION.

Climate models are used in a large variety of applications that aid in the understanding of Earth history. Many simple climate model simulations have been used to sort out the mechanisms responsible for climate change in the past. For example, although not yet fully understood, the astronomical theory of the ice ages states that the waxing and waning of the great continental ice sheets has been forced by the periodic changes in the Earth's ellipitical orbit parameters in the past. Similarly, the onset of glaciation in Antarctica and Greenland has been studied by such means. *See* CLIMATE HISTORY.

A problem that has received considerable attention is the greenhouse effect. Models are studied to achieve better understanding of how the increase of atmospheric carbon dioxide and other trace gases from anthropogenic sources is likely to change the climate in the coming decades. The models are compared to past climates ranging from the ice ages to the records of the last hundred years, for which an instrumental record exists. *See* GREENHOUSE EFFECT.

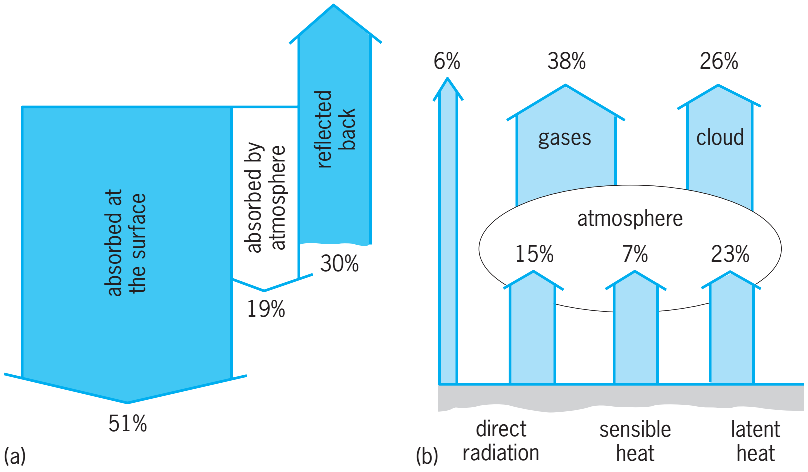

Fig. 1. Schematic diagram of the budget of incoming and outgoing radiation affecting the Earth's climate. (*a*) Solar radiation. (*b*) Terrestrial radiation.

Anatomy of models. Since the main interest of climate modelers is in computing the thermal field over the Earth, a primary objective is to represent the conservation of energy at each location in the system. One requirement is accurate formulations of the absorption and reflection of solar radiation as it passes through the atmosphere and strikes surfaces. Another is the radiation emitted from each mass element in the Earth–atmosphere system. Conversions of heat from latent to sensible must be taken into account as water changes its phase in the system. Clouds must be included since they participate in the radiation transfer and in the changes of water phase. Similarly, snow and ice cover enter both energy disposal accounts. The thermodynamic expression of the conservation of energy is not complete until allowance is made for the flow of matter of a different temperature into a given region. To include this effect, a model of the circulation must be considered, and this in turn is governed by the same thermal contrasts given by the thermodynamic equation.

The circulation of atmospheric and oceanic material is governed by Newton's second law: local acceleration of a fluid element is proportional to total forces on it. In fluid mechanics this is known as the Navier-Stokes equation. It is a nonlinear partial differential equation that is exceedingly complex. Climate models that include a detailed attempt to solve the fluid dynamics equations must be approached by computer simulation. Even here the solutions are known to differ in detail from nature after only a few weeks at most. However, it is thought that statistics, for example, long-term means for the climate of the numerical model and those of nature, should agree; and this has been borne out in numerous tests. *See* NAVIER-STOKES EQUATIONS.

In order to simulate the climate system, the problem must be cast onto a three-dimensional grid in the global ocean–atmosphere volume. The intermediate-sized models typically being used for decadal simulations have a horizontal resolution of about 300 to 600 mi (500 to 1000 km) and vertical resolutions of about 0.6 to 1.8 mi (1 to 3 km). This implies about 25,000 grid points, at each of which the model is keeping track of about six meteorological variables. The system is solved by numerically advancing in time at each grid point, updating at each time step (typically about intervals of 1 h of so-called model time). Simulation of 15 years of model time, which is typical of models that include only simple formulations of the oceanic interaction, may take tens of hours on the fastest computers. About a half dozen models of this type are being investigated around the world. The models as a group simulate the present seasonal cycle of different geographical regions with remarkable fidelity, considering the short time that has passed since the inception of this field. The models are best at simulating the thermal surface field and weakest in modeling such secondary features as precipitation. *See* SIMULATION.

Simulation models which include ocean circulation are important in understanding the adjustment processes in going from one climate state to another. Inclusion of the ocean dynamics adds significantly to the computational burden, since a finer grid is required owing to the importance of small-scale motions. The irregularity of the bottom topography also complicates the problem. Gerald R. North

Feedback mechanisms and sensitivity. Attempts at modeling climate have demonstrated the extreme complexity and subtlety of the problem. This is due largely to the many feedbacks in the system. One of the simplest and yet most important feedbacks is that due to water vapor. If the Earth is perturbed by an increase in the solar radiation, for example, the first-order response of the system is to increase its temperature. But an increase in air temperature leads to more water vapor evaporating into the air; this in turn leads to increased absorption of space-bound long-wave radiation from the ground (greenhouse effect), which leads to an increased equilibrium temperature. This effect, known as a positive-feedback mechanism, is illustrated in **Fig. 2**. Water vapor feedback is not the only amplifier in the system. Another important one is snowcover: a cooler planet leads to more snow and hence more solar radiation reflected to space, since snow is more reflecting of sunlight than soil or vegetation. Other, more subtle mechanisms that are not yet well understood include those involving clouds, oceans, and the biosphere.

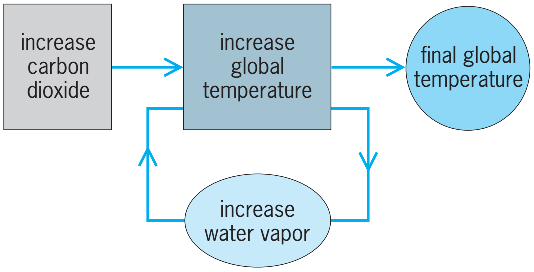

Fig. 2. Water vapor feedback in amplifying the sensitivity of the Earth's climate to increases in atmospheric carbon dioxide concentration. Increases in the Earth's temperature cause an increase in water vapor, causing a warming of the surface because of the greenhouse effect. The net effect is to amplify the response to increases of carbon dioxide.

While water vapor and snowcover feedback are fairly straightforward to model, the less understood feedbacks differ in their implementations from one climate model to another. These differences as well as the details of their different numerical formulations have led to slight differences in the sensitivity of the various models to such standard experimental perturbations as doubling carbon dioxide in the atmosphere. All models agree that the planetary average temperature should increase if carbon dioxide concentrations are doubled. However, the predicted response in planetary temperatures ranges 4.5–9°F (2.5–5.0°C). Regional predictions of temperature or precipitation are not reliable enough for detailed response policy formulation. Many of the discrepancies are expected to decrease as model resolution increases (more grid points), since it is easier to include such complicated phenomena as clouds in finer-scale formulations and coupling with dynamic models of the ocean. Similarly, it is anticipated that some observational data (such as rainfall over the oceans) that are needed for validation of the models will soon be available from satellite sensors. *See* METEOROLOGICAL SATELLITES.

Atmosphere–ocean–land models. Simulating the naturally varying present-day climate and its future evolution can be accomplished only with coupled atmosphere–ocean–land models.

Atmosphere models. Numerical models of the atmosphere are used to reveal its underlying dynamics and to predict the weather. The climatic application of models requires a knowledge of the change in lower-boundary conditions as the model evolves in time: over the oceans, sea surface temperature; and over land, more complex descriptors of the land surface.

Both the ocean and land interact with the atmosphere on multiple time scales. Ocean interactions depend on the thermal capacities of water columns that undergo rapid vertical exchanges, usually about 165–3300 ft (50–1000 m) of water. An unchanging field of sea surface temperature may be used as a model boundary to predict weather a few days in advance (at most) because the huge thermal capacities of the oceans cause hardly any change in the bottom boundary. Dry land, however, interacts with the atmosphere with effective heat capacities of a fraction of a meter of water, so that large thermal variations in interaction with the atmospheric boundary occur over time scales as short as the diurnal cycle. Longer time scales occur for moist soils: for example, soil moisture stores may require several weeks to be depleted. Also, the atmosphere above the boundary layer may require several weeks to be influenced by the underlying boundaries. For simulations or predictions beyond a week, the correct time evolution of the bottom boundary conditions for sea surface temperature and land soil moisture must be calculated.

Coupled models. To consistently simulate both atmospheric and boundary quantities, it is necessary to couple the media and allow them to mutually and consistently evolve. Even to predict evolution of the atmosphere alone, climate models must be coupled atmosphere–ocean–land models.

Numerical models of the ocean are used to understand its underlying dynamics and to predict the sea surface temperature. For these purposes, the fluxes of heat and momentum from the atmosphere must be specified. On sufficiently long time scales, the atmosphere requires sea surface temperatures from the ocean, and the ocean requires momentum and heat fluxes from the atmosphere. Numerical models of the land are used to study basic hydrological processes and to predict temperature, stored moisture, and runoff. Fluxes of heat and water from the atmosphere must be specified because the atmosphere requires land properties and the land requires atmospheric fluxes. Many atmospheric processes must be adequately simulated in order to correctly supply the fluxes of heat, momentum, and moisture to the ocean and to the land surfaces, for example, those processes involving rainfall, cloud optical properties, surface winds, radiation, and atmospheric temperature. These variables, in turn, are affected by the properties of the underlying surface.

Sensitivity studies. Significant properties of the ocean and land components of coupled climate models can be tested and demonstrated by the use of sensitivity studies. These studies assume simple changes in model parameters and assess the significance of the responses. They have demonstrated that changes in surface boundary conditions can have a profound influence on regional rainfall patterns and intensities and can also determine the specifics of how the surface conditions influence atmospheric precipitation.

Surface–precipitation interactions are affected by the heat and moisture supplied by the lower boundary to the planetary boundary layer. Moist convection occurs when an atmospheric column is unstable with respect to a parcel of boundary layer air. Wetter and warmer surfaces promote this instability, as does colder air in the overlying atmosphere. Convection occurring in one location acts to warm and stabilize the atmosphere elsewhere. Therefore, convective rainfall in one location can suppress convection elsewhere. Over land, the diurnal cycle of solar heating promotes the greatest convective instability in the afternoon. Over oceans, warmest sea surface temperatures usually, but not always, produce the greatest convective instabilities. Climate model simulations can test their treatment of surface coupling through comparisons of the simulated and observed diurnal variations of rainfall. These diurnal variations are especially pronounced over land, but they are also notable over the tropical oceans. For example, a model with initially dry soil predicts substantially lower summer convective rainfall in subsequent days, or even weeks, than does a model with initially wet soil. *See* CONVECTIVE INSTABILITY.

Uses of coupled models. Coupled atmosphere–ocean–land models are used to simulate climate over time scales of longer than a few weeks. These models are used to predict future natural variations (that is, variations that occur without human-induced changes of the gas and aerosol composition of the atmosphere) or to project responses to human-induced changes such as the addition of greenhouse gases.

One natural variation is El Niño, the complex of phenomena connected with warm sea surface temperature in the eastern and central tropical Pacific that seems to occur on an irregular 4-year time scale. The simulation of such warm and cold sea surface temperature variations is difficult for the present generation of global coupled climate models. The resolution required for such simulation is approximately 20 km (12 mi), in the tropical Pacific, in order to resolve the thin strip of equatorial upwelling of cold water from below, a crucial process in changing sea surface temperature. Questions such as the dependence of the El Niño cycle on global warming cannot be answered until global coupled models successfully incorporate the full range of processes known to be important for this cycle. By limiting the active extent of the coupled models to the tropical Pacific, such high resolution can easily be attained and predictions of El Niño using such models become possible. Data in the tropical Pacific are used to initialize the forecast, that is, to specify the initial internal state of the upper ocean. The coupled model is then allowed to run freely, and the future evolution of the entire system is predicted. Used in this way, coupled models have provided correct predictions up to a year in advance that have been useful in making economic decisions in nations bordering the tropical Pacific. Extending this approach to the United States is a far more difficult problem for coupled models, but remains a future possibility. *See* EL NIÑO; TROPICAL METEOROLOGY.

In terms of human-induced changes, coupled atmosphere–ocean–land models are used to project a climatic response to the increase of greenhouse gases. Difficulty arises because models are limited in their resolution (that is, in the fineness with which it is possible to subdivide the atmosphere and ocean) and in the parametrization of those processes that cannot be resolved by the present resolution (for example, clouds and turbulence in the atmosphere, small eddies in the ocean).

To project what the climatic response would be to an increase of greenhouse gases, the present climate must first be simulated. Next, an assumption must be made that the composition of the atmosphere will change in a specified way; for example, it may be assumed that carbon dioxide will increase by 1% per year. Current atmosphere–ocean–land models of long-term response to the anthropogenic addition of atmospheric gases have indicated that carbonaceous and sulfate aerosols have a major cooling affect (by direct blocking of the Sun's rays) on regions of the Earth's surface local to the emissions of such constituents. They may also have an indirect cooling effect by acting as cloud condensation nuclei to increase the amount of cloud cover. Future projections of the climatic response to additions of greenhouse

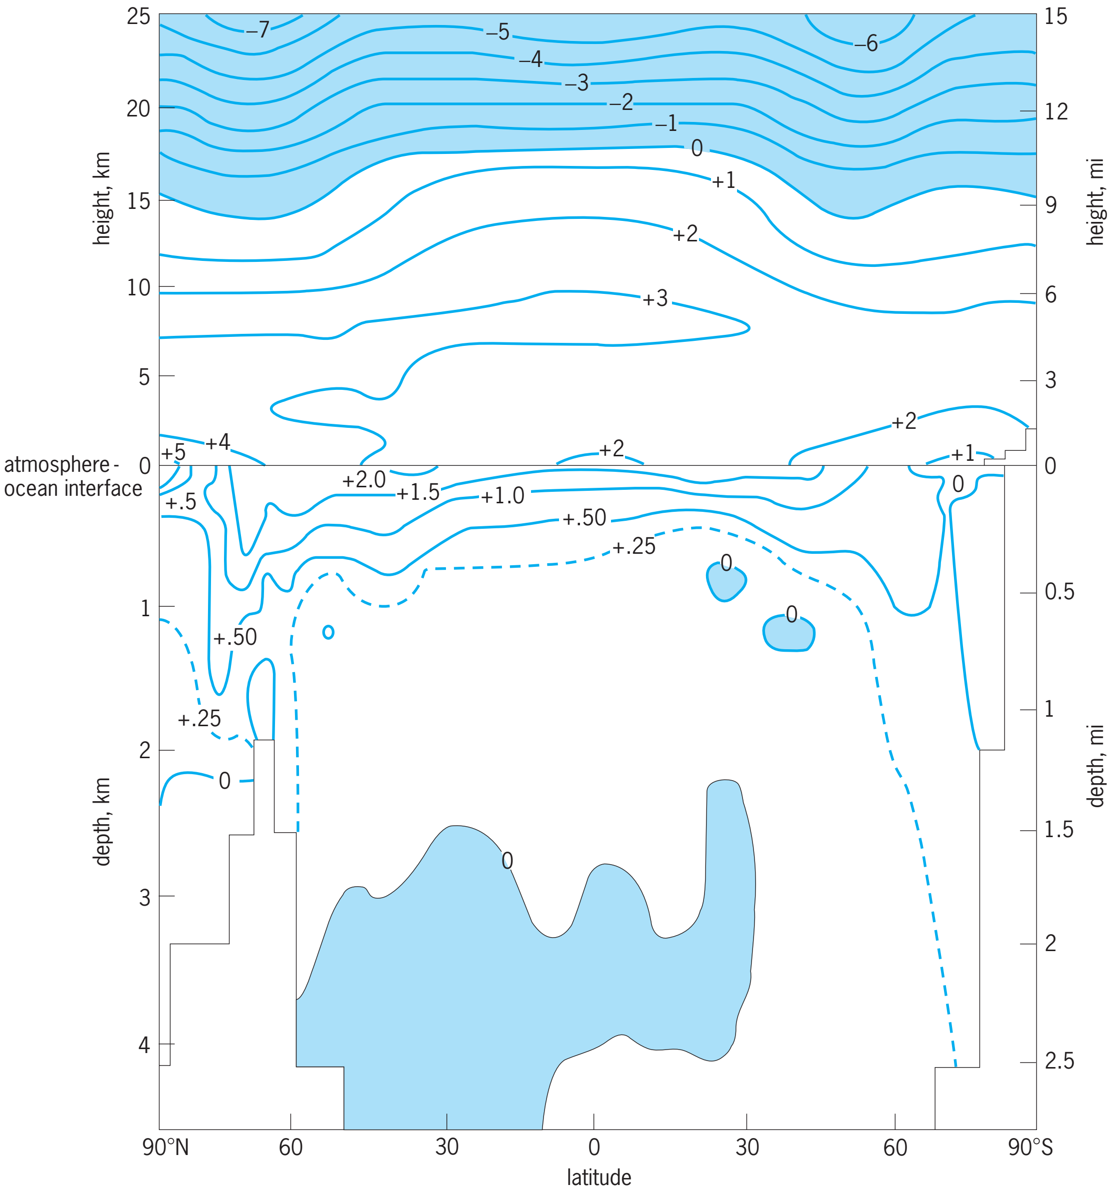

Fig. 3. Model showing the change of temperature (°C) in the atmosphere and ocean averaged over the 60th to 80th year of integration in response to an increase of 1% per year in the concentration of carbon dioxide. The temperature changes are averaged around circles of longitudes. The shaded areas are regions where cooling occurred. 1°C = 1.8°F. (*After S. Manabe, M. J. Spelman, and K. Bryan, Transient response of a coupled atmosphere–ocean model to gradual changes of atmospheric CO$_2$, pt. I: Annual mean response, J. Climate, 4:785–818, 1991*)

gases must include both the direct and poorly understood indirect effects of aerosols. With this information, a 70-year projection of a climate response, using a state-of-the-art coupled model (**Fig. 3**), shows that the higher latitudes warm more than the tropics, the ocean surface temperatures increase less than the surface atmosphere temperatures, the ocean warms very little below 0.6 mi (1 km) in depth, and the stratosphere cools. The model also shows a substantial summer drying of soils in midlatitudes of the summer hemisphere. This drying could have serious consequences if it were to occur. *See* CLIMATIC PREDICTION; CLIMATOLOGY; WEATHER FORECASTING AND PREDICTION. Robert E. Dickinson; E. S. Sarachik

Uncertainties in climate models. Because the Earth's climate is far too complex to reproduce in a laboratory, scientists have developed numerical climate models, based on the conservation of energy, momentum, and mass, which can be used to simulate past, present, and future climate conditions. These models incorporate the key physical parameters and processes that govern the climate behavior. Climate models that simulate the entire global atmosphere are called general circulation models (GCMs). Those models applied to a limited domain are called regional climate models (RCMs). The horizontal resolution of most general circulation models is 100 km (60 mi) or larger. Regional climate models have a horizontal resolution of a few tens of kilometers, but the initial and lateral boundary conditions of the RCMs depend upon the GCM output or reanalysis, which is a combination of the GCMs' output and observations. Consequently, RCMs may have more detailed physics and finer resolution, but the uncertainties of the GCM may pass to the RCMs through initial and/or boundary conditions when the RCM is used to predict the future climate.

Climate models (referring to atmospheric models coupled with ocean and land-soil models, hereafter) can be used to simulate changes in temperature, rainfall, snow cover, winds, soil moisture, sea ice, and ocean circulations for periods from seasons to decades. However, the mathematical models used are obviously simplified versions of the real Earth and cannot capture its full complexity. The nonlinear partial differential equations of the climate systems (that is, Navier-Stokes equations) cannot be solved analytically. In climate models, these equations are converted into the discrete difference equations in both time and space and solved numerically. Many numerical schemes and grid structures have been developed and applied in climate models to obtain the approximate numerical solutions. Theoretically, the numerical solutions should converge to the analytical (or true) solutions, but the accuracy can quickly deteriorate as the number of integrations increases in a model using coarse resolution, inappropriate numerical schemes, or improper grid structure. The discrete mode of the solutions also imposes a constraint that the smallest element that can be resolved by the model is twice the resolution (2Δ). The nonlinear terms of the Navier-Stokes equations can generate waves shorter than 2Δ. Those short waves can be misrepresented as the resolvable waves (that is, aliasing), causing nonlinear instability. Artificial filters or smoothing (which can also be generated by truncation errors of the numerical schemes) have been applied to control these instabilities.

Because of the resolution, climate models cannot resolve individual clouds, small-scale turbulence, detailed features of complex terrain, soil properties, or land distributions. They are called the subgrid-scale properties. The effect of the subgrid-scale properties should be formulated by parametrizations. For example, the effect of the subgrid-scale clouds is assumed as a function of the moisture convergence and other fields, which can be resolved by the models. Meteorologists have proposed various cumulus parametrizations to represent the effect of the subgrid-scale clouds; however, it is very difficult to formulate the cumulus parametrizations or other subgrid-scale features based on rigorous mathematics and physics. Models with a fine resolution can resolve the majority of the flow explicitly and reduce the spurious contributions from the subgrid-scale features. But the subgrid-scale parametrizations are still important, even in J. W. Deardorff's large-eddy simulation of a convective boundary layer with a model resolution of 50 m (160 ft). Subgrid-scale features and short-wave disturbances may affect the large-scale weather/climate pattern through the nonlinear terms of the equations.

Uncertainties also exist in formulating cloud physics, radiation, ocean current, and the effects of aerosol, as well as snow–land-surface, air–sea, sea-ice interactions. For example, using the same observed data as the initial conditions, a comparison of the snow–land-surface models shows considerable variation among the results, and most were unable to reproduce the observations due to deficiencies in numerical schemes, physics, or model resolution. For this reason, land models need to be refined before they can appropriately represent the effect of the soil and snow in a climate system. Better parametrizations in cloud physics, turbulence, radiation, aerosols, sea-ice and air-sea interactions, as well as finer model resolution are required in most models. *See* CLOUD PHYSICS.

The accuracy of the initial conditions is very important for numerical weather forecasting. The initial conditions for a GCM come from the reanalysis, which combines observations and model results, both of which may contain errors. The errors of observations may come from instruments or interpretation errors in both time and space. The sources of errors from modeling may be due to numerical schemes, physics, resolution, as well as initial and boundary conditions used in the model. These errors may be amplified or suppressed during the climate model integration. The result of the numerical simulations can become quite different from the observation after just 1 or 2 weeks.

Since uncertainty always exists in a numerical weather prediction model, scientists have applied ensemble-forecasting techniques. The ensemble method may include running the same model with different initial and boundary conditions (for example, to disturb the initial conditions or to start to integrate the model at different times), running several different models with the same initial/boundary conditions, or running different models with different initial/boundary conditions to estimate the probability of the model forecasting. If the results diverge, the confidence of the results is low; otherwise, the confidence is high. There is no guarantee that the real climates are completely covered by the model results. For example, if all of the models are deficient in describing specific physical process, the ensemble average of these models will also be deficient. The model also may not be able to predict extreme cases, which are needed most.

If a model can reasonably simulate the current weather and produce good short-term forecast (7–14 days), it has a better chance to predict future climate change or simulate the past climate because the climate is an accumulation of daily weather processes. A model with more detailed physics, finer resolutions, and more accurate numerical schemes and initial/boundary conditions usually performs better. Although an RCM can simulate the observations reasonably well even after a few years integration when reanalysis is used as the initial/lateral boundary conditions, it cannot be used alone to predict the climate in the future without coupling with a GCM. On the other hand, it is unlikely that GCM-simulated weather systems will compare favorably with observations after a few weeks of integration. Climate studies usually emphasize statistics instead of describing any single weather event. The climate simulations also depend more on the boundary conditions, which include solar radiation and properties of the soil and ocean, than the initial conditions. Currently, many climate models are being used to simulate the climate in the future or the past. For example, the climate models show that the mean atmosphere becomes warmer under the doubled atmospheric carbon dioxide (CO_2) scenario, with quite different regional responses. When climate models are applied to forecast the future climate, they also encounter uncertainties in volcanic activity, forest fires, the change of trace gases/aerosols and emission, and the change of vegetation and land surface due to human activities. Climate modification

Alteration of the Earth's climate by human activities; humans have the capacity to modify the Earth's climate in several important ways.

Local and regional scale. Conventional agriculture alters the microclimate in the lowest few meters of air, causing changes in the evapotranspiration and local heating characteristics of the air-surface interface. These changes lead to different degrees of air turbulence over the plants and to different moisture and temperature distributions in the local air.

Another example of human influence on climate at a larger scale is that the innermost parts of cities are several degrees warmer than the surrounding countryside, and they have slightly more rainfall as well. These changes are brought about by the differing surface features of urban land versus natural countryside and the unique ways that cities dispose of water (for example, storm sewers). The altered urban environment prevents evaporation cooling of surfaces in the city. The modified surface texture of cities (that is, horizontal and vertical planes of buildings and streets versus gently rolling surfaces over natural forest or grassland) leads to a more efficient trapping of solar heating of the near-surface air. The characteristic scales of buildings and other structures also lead to a different pattern of atmospheric boundary-layer turbulence modifying the stirring efficiency of the atmosphere. *See* MICROMETEOROLOGY; URBAN CLIMATOLOGY.

At the next larger scale, human alteration of regional climates is caused by changes in the Earth's average reflectivity to sunlight. For example, the activities of building roads and highways and deforestation change the reflectivity characteristics of the Earth's surface and alter the amount of sunshine that is reflected to space, as opposed to its being absorbed by the surface and thereby heating the air through contact. Such contact heating leads to temperature increases and evaporation of liquid water at the surface. Vapor wakes from jet airplanes are known to block direct solar radiation near busy airports by up to 20%.

Human activities also inject dust, smoke, and other aerosols into the air, causing sunlight to be scattered back to space. Dust particles screen out sunlight before it can enter the lower atmosphere and warm the near-surface air. An extreme case is popularly referred to as the nuclear winter scenario, where a massive injection of smoke particles into the upper atmosphere occurs during a hypothetical exchange of nuclear blasts. The resulting smoke veil theoretically remains in the atmosphere for up to 6 months and leads to a shading of the world and a resulting cooling of continental interiors by as much as 90°F (50°C) for several months. Ocean and coastal regions would experience less than about 18°F (10°C) of cooling. *See* AIR POLLUTION; NUCLEAR EXPLOSION; SMOG.

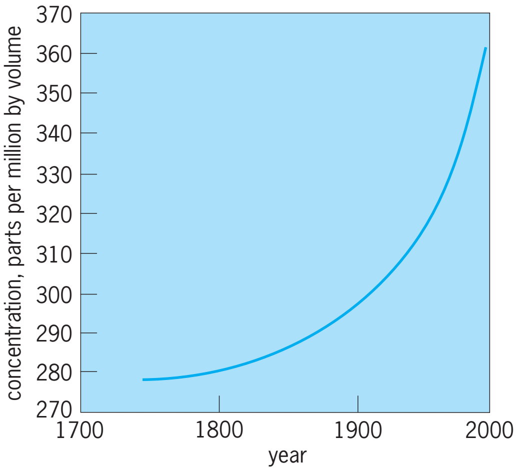
Global scale. Humans are inadvertently altering the atmospheric chemical composition on a global scale, and this is likely to lead to an unprecedented warming of the global atmosphere during the next generation. It comes about by anthropogenic injection into the atmosphere of relatively inert trace gases that perturb the radiation balance of the globe as a whole. Most of this gaseous waste comes from burning fuels that contain carbon and nitrogen. Other sources include inert gases used in aerosol spray cans and cooling devices. *See* ATMOSPHERIC CHEMISTRY.

Since alteration of the atmospheric composition by human activities has taken place for more than 150 years, it is important to ask whether the climate system has started to respond to the forcing. While no definitive answer exists, globally averaged temperature data suggest that on the whole the Earth has been warming over the last 100 years. *See* ATMOSPHERE; CLIMATIC PREDICTION; WEATHER MODIFICATION. Gerald R. North

Global warming. One of the most important and best understood features of the atmosphere is the process that keeps the Earth's surface much warmer than it would be with no atmosphere. This process involves several gases in the air that trap infrared radiation, or heat, emitted by the surface and reradiate it in all directions, including back to the surface. This recycling of heat maintains the surface and lower atmosphere of the Earth at a temperature higher than it would otherwise be.

Heat-trapping gases. The heat-trapping gases include water vapor, CO_2, CH_4, and N_2O. These gases constitute only a small fraction of the atmosphere, but their heat-trapping properties raise the surface temperature of the Earth by a large amount, estimated to be more than 55°F (30°C).

Human activities, however, are increasing the concentrations of CO_2, CH_4, and N_2O in the atmosphere, and in addition industrially synthesized chemicals—chlorofluorocarbons (CFCs) and related compounds—are being released to the air, where they add to the trapping of infrared radiation. Carbon dioxide is released to the air mainly from fossil fuel use, which also contributes to the emissions of CH_4 and N_2O. Agricultural and industrial processes add to the emissions of these gases. These concentration increases add to the already powerful heat-trapping capability of the atmosphere, raising the possibility that the surface will warm above its past temperatures, which have remained roughly constant, within about 3°F (1.7°C) for the past 10,000 years. The atmospheric concentration of CO_2 has increased to about 363 parts per million by volume (ppmv) from its preindustrial value of about 280 ppmv (see **illus.**); CH_4 has increased at a greater rate, from 0.75 ppmv to more than 1.7 ppmv. Nitrous oxide is growing slowly, at about 0.2% per year, and has a present concentration of 0.32 ppbv. The CFCs and related halocarbons have had the fastest rates of growth, up to 15% per year, but their concentrations are very small—300 parts per trillion by volume (pptv) for CFC-11, 535 pptv for CFC-12, and 3 pptv for halon-1301—the fastest growing species. Treaties are in existence that control internationally the production and use of many of the CFCs and related compounds, so their rate of growth has slowed, and for some a small decrease in atmospheric concentration has been observed. Large emissions of sulfur dioxide in industrial regions are thought to result in airborne sulfate particles that reflect sunlight and decrease the amount of heating in the Northern Hemisphere. *See* GREENHOUSE EFFECT.



History of atmospheric CO_2 concentration as inferred from an analysis of bubbles taken from ice cores in the Antarctic. (*After E. M. Neftel, H. Oeschger, and B. Stauffer, Evidence from polar ice cores for the increase in atmospheric CO_2 in the past two centuries, Nature, 315:45–47, 1985; and for measurements since 1970, data from Carbon Dioxide Information Analysis Center home page*)

Climate warming impacts. Estimates indicate that if human-induced emissions of heat-trapping gases continue according to the current pattern the globally averaged surface temperature could increase at a rate of about 0.4°F (0.22°C) per decade in the twenty-first century. This rate of global temperature change is much faster than any sustained global average temperature change documented in the last 10,000 years. Lifeforms have evolved with and are adapted to current climate conditions, including temperature. For this reason it is anticipated that should the warming occur as estimated, there will be serious damage to ecological systems.

Even slow, small climate changes can have large regional effects. There is evidence that about 6000 years ago parts of the Sahara Desert had sufficient rainfall to support vegetation and large mammals, while prairies advanced eastward and replaced forests, in what is now the United States, because of lack of rain. These changes were part of a global change characterized by an average temperature increase of only 2–4°F (1–2°C).

Rapid regional changes in climate occurring more than 10,000 years ago have been deduced from evidence in ice cores and from pollen found in layers in bogs and ponds; these changes were accompanied by major ecological changes in the region of the climate change. For example, about 11,000 years ago in what is now Europe trees were suddenly replaced by shrubs at the time of a large cooling in areas around the North Atlantic. Such events add to the evidence that a rapid climate change can damage ecosystems. Besides ecological damage, higher temperatures will melt glaciers and expand seawater, thereby raising sea level. Some regions will have climate changes considerably larger or smaller than the global average.

Even though the process is called global warming, the focus on temperature is partly for convenience; all climate features are expected to change by varying amounts as part of an overall climate change. For example, the temperature of the stratosphere is expected to decrease, and total precipitation is expected to increase while its annual distribution shifts in time and place. The role of CFCs in climate warming will be to increase the amount of heat trapped in the lower part of the atmosphere but, by destroying ozone in the stratosphere, to increase the ability of heat to leave the atmosphere. The net heating by CFCs will therefore be small; they will produce instead a change in the vertical temperature distribution of the atmosphere.

Climate change theory. There are many difficulties in producing a completely convincing calculation of the rate of average climate warming to be expected, and a specification of the detailed change in each climate parameter that will be experienced in each major region. These difficulties stem from the fact that the climate system consists of many components—atmosphere, oceans and ocean biota, ice caps and sea ice, land surface and ecosystems, and the human societies that are forcing rapid changes in the composition of the air—making the calculation very complex. In addition, small changes in the amount of sunlight reaching the Earth and large volcanic eruptions that place sulfur dioxide in the stratosphere complicate studies of human-induced climate change.

Attempts to simulate the interactions of all of these climate components, though using the largest computers available, require great simplification in the description both of the components and of the interactions among them. These simplifications lead to sizable uncertainties, especially when they involve processes that tend to amplify or diminish the degree of warming. Increased evaporation of water from the oceans as the surface warms and an increased water-holding capacity of the warmer air will lead to a higher water vapor concentration in the atmosphere. Water vapor is a heat-trapping gas; an increase in its average concentration in the air will add its heat-trapping effect to that of the human-emitted gases and amplify the warming. The size of the warming will be decreased by the fact that a warmer Earth will emit more infrared radiation to space, increasing the Earth's heat loss.

Some of the most complicated processes that are important in the calculation describe the role of clouds and the changes that clouds would undergo on a warmer Earth. Clouds both reflect sunlight away from the Earth and trap infrared radiation in the lower atmosphere, so changes not only in the amount of cloud but also in their optical characteristics must be correctly estimated. However, recent progress in climate calculations has contributed to improved agreement between observed climate heating since 1870 and model results, suggesting that the simple treatment of clouds in models is not seriously deficient. The comparison has also been aided by the rapid surface heating since 1975 that provides a larger heating signal compared to random temperature fluctuations. *See* CLOUD PHYSICS.

In addition to the known model deficiencies, there is reason to believe that models in general do not adequately represent sudden changes in complex systems. Thus a gradual change in surface temperature might lead to a sudden reversal of a major ocean current, or a gradual change in rainfall might lead to a collapse of a tropical ecosystem, without either event being foreseen in the model calculations.

All of these difficulties combine to produce a wide range of estimates for the rate of future climate warming. The Intergovernmental Panel on Climate Change (IPCC) of the United Nations estimates that if the current pattern of emissions of heat-trapping gases continues the average surface temperature should increase 0.31–0.43°F (0.17–0.24°C) per decade. But the IPCC asserts that there are enough uncertainties that a faster or slower change cannot be completely ruled out, and the threat of surprises must also be kept in mind. *See* CLIMATE HISTORY; CLIMATE MODELING; HEAT BALANCE, TERRESTRIAL ATMOSPHERIC.

Response to climate warming. The presence of numerical uncertainties and the possibility of surprises increase the difficulty for those who must develop national and international responses to the threat implicit in the human-induced climate change. Their task of selecting a response is made simpler, however, by the fact that the principal driving force for such a climate change—the use of fossil fuels—is also the driving force for a number of other atmospheric problems. Urban air pollution, regional pollution by low-altitude ozone, visibility problems over scenic vistas, and acid precipitation all involve fossil fuel emissions, so that an uncertainty in specific aspects of any one problem does not shift the focus away from reduced fossil fuel use as the core strategy for slowing harmful human impacts on the atmosphere. *See* ACID RAIN. John Firor

Climate Change Impacts

Substantial uncertainties exist as to the severity, timing, and rate of human-induced global climate change. Nevertheless, there are particular attributes of Earth's physical processes, natural ecosystems, and human socioeconomic activities that would be affected by a changing climate.

Climatic change is often broadly discussed in global terms, but the impacts of a warmer Earth would be experienced at the local and regional levels. Many potential impacts may be considered undesirable from an environmental or socioeconomic perspective, whereas others may be seen as beneficial. Although it is difficult to predict with certainty what the impacts of a possible global climate change may be in particular regions, a range of possible consequences can be described.

Physical processes. Global warming is projected to be greater in the higher latitudes and polar regions than in the tropics, causing a decrease in the difference in temperatures between the poles and the tropics as well as altering global atmospheric circulation patterns. This in turn would change the timing, distribution and amount of regional precipitation, affect the occurrence and location of extreme weather events such as hurricanes and tornadoes, alter the timing of mountain snowmelt and river basin runoff, reduce high-latitude snow and ice cover, and eventually lead to rising sea levels around the world. *See* ATMOSPHERIC GENERAL CIRCULATION; HURRICANE; PRECIPITATION (METEOROLOGY); TORNADO.

Natural ecosystems. The projected climate change may occur at a faster rate than any natural climatic warming has occurred in the past 10,000 years—a period covering the entire history of human civilizations. A rapid warming, or abrupt shifts in regional climate, could harm biological communities that have developed under relatively stable climatic conditions over the past several centuries and exist within relatively narrow ranges of average climatic conditions.

Terrestrial natural ecosystems would be the first to be affected by global warming, followed by marine ecosystems. The terrestrial environment is sensitive not only to average climatic conditions but also to extreme conditions such as extended periods of high or low temperatures, droughts, floods, and other weather hazards. Some species of vegetation can survive and reproduce under a broad range of climate conditions. Other species require not only a stable climate but a narrow range of meteorological extremes such as high and low temperatures, precipitation, and soil moisture. The Intergovernmental Panel on Climate Change, created by the United Nations in 1988, has concluded that over the next 50 years projected changes in regional temperatures and precipitation could cause climatic zones to shift hundreds of kilometers toward the polar regions. Some biotic communities may be capable of adapting to a climatic shift of such magnitude, while others would experience substantial loss that could include some species extinction. *See* EXTINCTION (BIOLOGY).

In the Northern Hemisphere's midlatitude temperate zone spanning North America and the Eurasian landmass, such a large climatic shift would have a tremendous impact on forest ecosystems. Individual tree species might not be able to migrate into climatic zones similar to those that they presently occupy. If climate change were to proceed more rapidly than temperate forests could successfully migrate poleward, large-scale demise of trees could be anticipated. Climate change could cause weather-related stress for individual tree species, exposing them to pest damage. Changes in forestry would also affect associated flora and fauna that are adapted to existing forest ecosystems and climatic conditions. *See* FOREST ECOSYSTEM.

According to the IPCC, the permafrost that presently underlies the 20–25% of the Northern Hemisphere that is perenially frigid may begin to thaw during the next 40–50 years. Degradation of the permafrost cover would damage high-latitude surface ecosystems, destabilize terrain, and cause soil erosion. *See* PERMAFROST.

Rising sea levels would inundate low-lying river estuaries and coastal wetlands (including tropical mangrove forests), which support established biotic communities. Again, the degree of environmental impact would be a function of both the rate and extent of sea-level rise, as rapid change would not permit adaptation by biotic communities. In addition, some low-elevation islands could be partially inundated, with substantial impacts to coastal ecology and freshwater supplies as well as to terrestrial biota.

The biological productivity and diversity of marine ecosystems would be affected by changes in water temperature and, in the long term, changes in ocean currents and ocean circulation. Inundation of estuaries and coastal wetlands would adversely affect the reproductive cycles of valuable fish and shellfish species. *See* BIOMETEOROLOGY; CLIMATOLOGY; ECOSYSTEM; MARINE ECOLOGY.

Climatic prediction

The description of the future state of the climate, that is, the average or expected atmospheric and Earth-surface conditions, for example, temperature, precipitation, humidity, winds, and their range of variability. *See* CLIMATOLOGY.

Seasonal and interannual climate predictions, made many months in advance, provide useful information for planners and policy makers. Various countries are working on operational (systematic and regular) climate prediction products, and by the beginning of the twenty-first century climate prediction will be added to weather prediction as an operational mission requirement of the world's major meteorological services. *See* METEOROLOGY.

Jay S. Fein

Seasonal to Interannual Prediction

It is well known that the Earth revolves around the Sun in a periodic orbit giving rise to a well-defined annual cycle in the Earth's climate, and that the annual cycle in the incident solar radiation is nearly identical from one year to the next. The question as to why the winter climate of one year is so different from the winter climate of another year has long interested climate scientists, because an understanding of the causes of interannual variations of the Earth's climate might provide some clues about the predictability of these variations. *See* SOLAR CONSTANT; SOLAR RADIATION.

The fundamental reason for departures from perfectly periodic variations in the atmosphere and oceans—in spite of the fact that the solar forcing is nearly perfectly periodic—is that the physical laws that determine the motions of air and water in the Earth-atmosphere-ocean system are inherently nonlinear and chaotic. The internal instabilities of this nonlinear dynamical system are capable of producing a nonperiodic behavior even if the external forcing (the Sun) is perfectly periodic. Because of the nonlinear nature of the mathematical equations describing motions in the Earth-atmosphere-ocean system, it is impossible to predict these motions for a long time in the future. One major endeavor of researchers in the field of meteorology and oceanography is to determine the range at which different properties of the nonperiodic components of atmospheric and oceanic motions can be predicted.

Weather prediction. The day-to-day changes of weather cannot be predicted for a long time because even minute errors in observations amplify with time and become quite large within a few days or a few weeks, destroying the value of the forecast. The track of a storm seen on a weather map for a given day, for example, can be predicted for several days; but beyond a week or two the storm intensity, structure, and position are unpredictable. Improvements in weather-observing systems and the use of more complete equations in the weather prediction models will improve the quality of weather forecasts and the time for which they are valid, but the limitations arising from the amplification of imperceptible errors in the initial conditions of the forecast calculation will always restrict detailed weather forecasts to periods of a week or two in the future.

Despite this fundamental limitation in the ability of meteorologists to predict day-to-day changes in weather, it seems possible to predict seasonal averages of weather with sufficient accuracy to be of benefit to society. For example, even if it is not possible to predict the life cycle of individual weather disturbances that provide the monsoon rainfall over Asia, it may be possible to predict the seasonal mean rainfall over the monsoon region. *See* MONSOON METEOROLOGY; WEATHER FORECASTING AND PREDICTION.

Boundary conditions at Earth's surface. The conditions at the Earth's surface lower boundary of the atmosphere (for example, surface temperature, soil moisture and vegetation, or snow and sea ice cover) can have large variations from one year to another. It has been proven by statistical analysis of observations and by experiments using mathematical climate models that interannual changes in these boundary conditions are directly responsible for interannual changes in the seasonal mean climatic conditions in many parts of the globe. Therefore, if changes in these boundary conditions could be predicted, it would be possible to predict changes in seasonal mean climatic conditions in certain regions of the globe. Since changes in the boundary conditions are caused by interactions with the atmosphere, there is no guarantee that they are predictable. However, boundary conditions change rather slowly, and therefore they can be assumed to persist for periods up to a season. Thus it is possible to predict seasonal mean climatic conditions for the coming season (to the extent that they are influenced by the anomalous boundary conditions) by using the current boundary conditions. For longer periods, the boundary conditions cannot be assumed to persist, so that prediction of climatic conditions must necessarily involve coupled models of the land-atmosphere-ocean system, which enable prediction of future boundary conditions. *See* CLIMATE MODELING.

Seasonal predictions. For seasonal climate predictions to be useful, the seasonal climate variability caused by interactions with the atmosphere's lower boundary (for example, sea surface temperature) must be significantly larger than the changes in the atmosphere that can occur in the absence of any boundary forcing (normally referred to as the natural variability). The natural variability of seasonal mean climate is different in different seasons and in different regions. Therefore, the extent to which seasonal mean climate variations can be usefully predicted is also different for different regions. For example, the weather fluctuations over North America are far more vigorous during the winter season than during the summer season. The weather fluctuations over large parts of the tropics are far less energetic (day-to-day changes are generally small) compared to those in the higher latitudes. Therefore, the seasonal mean climate in the tropics is far more predictable than that in the higher latitudes. Likewise, seasonal mean climate in high latitudes is more predictable in summer than in winter.

Tropical droughts. Most of the tropical regions, and especially the regions that experience monsoons, have well-defined rainy seasons. For example, most of the annual rainfall over India and sub-Saharan Africa occurs during the summer monsoon season (June–September), and over northeast Brazil during March–May. Although the individual rainfall episodes occur in association with individual clouds and weather-scale disturbances, it is the large-scale convergence of moisture, generally associated with the intertropical convergence zone, that is responsible for the seasonal mean rainfall. Most of the tropical droughts and floods can be understood as space-time shifts in the annual cycle. For example, severe droughts in northeast Brazil occur whenever the intertropical convergence zone remains farther north of its mean position during the rainy season. Likewise, droughts over India and Australia are often associated with the eastward shift of the mean climatological rainfall maximum, giving rise to large increases in rainfall in the central Pacific. An important discovery was the recognition that these space-time shifts of rainfall maxima in the tropics are due to changes in the boundary conditions of sea surface temperature and land surface conditions. The tropical atmosphere has a unique property, distinct from that of mid and high latitudes, that seasonal and interannual variations are largely determined by changes in the slowly varying boundary conditions at the Earth's surface. Therefore, the prospects for long-range forecasting in the tropics are good. *See* DROUGHT; PRECIPITATION (METEOROLOGY); TROPICAL METEOROLOGY.

Extratropical variations. Seasonal climate variations in the extratropics are not as strongly controlled by the boundary conditions, but are strongly influenced by the internal dynamical processes in the atmosphere. For example, a major blocking event over North America can significantly change the monthly or even seasonal mean climate for that year. Prediction of seasonal and interannual variations during the winter season is particularly difficult because the day-to-day fluctuations are highly energetic and so give rise to large uncertainty in the prediction of the seasonal mean climate. Some evidence, however, indicates that large changes in the boundary conditions in the tropics, causing large changes in tropical rainfall and therefore atmospheric heating, can produce predictable effects even in the extratropics. This result is possible because the tropical influences can propagate away from the Equator and influence the extratropical climate variations. This mechanism of tropical-extratropical interaction has given some hope for seasonal and interannual prediction in the extratropics.

The day-to-day variations in the extratropics in the late spring and summer season bear some similarity to the tropical weather variations because they are not as energetic or intense as during the winter season. This reduction in the uncertainty due to the internal dynamical processes should make it possible to predict the influences of slowly varying boundary conditions in the spring and summer season. Relationships between spring rainfall and summer droughts over North America are good examples of predictability due to the effects of the land surface boundary conditions. *See* ATMOSPHERIC GENERAL CIRCULATION; STORM.

El Niño Southern Oscillation (ENSO). The outstanding example of interannual climate variability is the occurrence of multiyear episodes of warm and cold sea surface temperature in the central and eastern tropical Pacific; these episodes are generally referred to as El Niño. These variations are a consequence of the interactions between the upper layers of the ocean and the overlying atmosphere. Changes in the prevailing southeasterly winds over the equatorial Pacific can produce changes in the wave activity in the upper layers of the ocean and the upwelling of cold water, giving rise to changes in sea surface temperature, which in turn can produce changes in the surface winds. This mutual enforcement of oceanic and atmospheric changes (a form of instability of the coupled ocean-atmosphere system) is responsible for multiyear variations in sea surface temperature in the equatorial Pacific and the associated changes in sea-level pressure. In particular, the simultaneous occurrence of higher-than-average pressure in the Pacific Ocean and lower-than-average pressure in the Indian Ocean, and vice versa, is noteworthy. This recurrent seesaw pattern of pressure changes is referred to as the Southern Oscillation.

Associated with these changes in sea surface temperature, surface pressure, and surface wind are large changes in rainfall along the equatorial belt. During the episodes of colder-than-average sea surface temperature in the central and eastern Pacific and stronger-than-average southeasterly trades, the maximum seasonal rainfall is found at the extreme western position near the warmest surface waters of western Pacific. During these years, monsoon rainfall over India and Australia is generally above average. During the episodes of warmer-than-average sea surface temperature in the central and eastern Pacific and weaker-than-average surface winds, the rainfall maximum shifts eastward, producing severe droughts over India and Australia and heavy floods over the central Pacific and the west coast of South America. Actually, there are global effects of these changes in sea surface temperature, rainfall, and circulation in and over the tropical Pacific Ocean.

The discovery of these interrelationships among sea surface temperature, rainfall, and circulation, and the ability to predict these variations by using coupled models of the ocean-atmosphere system, has established a scientific basis for prediction of seasonal and interannual climate variations by using dynamical models of the climate system.

Forecasts. Several countries, including the United States, routinely issue forecasts for the coming season. These forecasts, generally issued in terms of probabilities of occurrence of above- or below-average temperature and rainfall, are based on empirical methods in which certain properties of atmospheric circulation, rainfall, and surface boundary conditions (generally sea surface temperature and snow cover) in the preceding months are used to forecast the climate for the coming season. It is generally accepted that there is some skill in these forecasts. Efforts have been made to develop and implement dynamical models of varying complexity of the coupled land-atmosphere-ocean system to predict seasonal and interannual variations. J. Shukla

Decadal-to-Century Climate Prediction

While the potential benefits of being able to predict climate on the decadal-to-century time scale are very large, so too are the problems associated with trying to make such predictions. To understand the nature of these problems, it is useful to consider first the decadal-to-century prediction of the change in the surface temperature averaged over the Earth, and then to consider the even more difficult problem of predicting the geographical distributions of surface temperature and the other climatic quantities of importance to humanity, especially precipitation.

Global average temperature. To facilitate thinking about predicting future global average surface temperature, it is necessary to consider the past behavior of this quantity. The observed record of decadal average temperature, T, relative to its value in 1860–1869 (**Fig. 1**) shows that during the first six decades of the

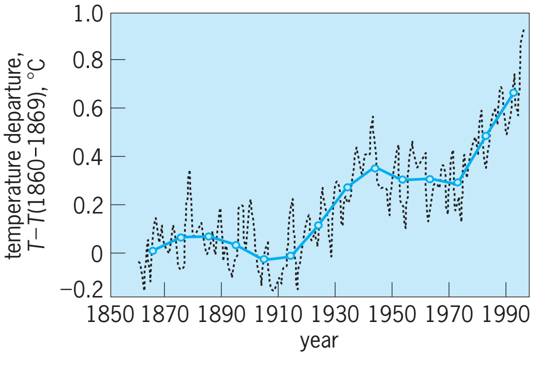

Fig. 1. Observed decadal-average global-average surface temperature (solid line) and observed annual-average global-average surface temperature (broken line). Temperature change in °F equals 1.8 times the temperature change in °C.

record, 1860–1869 to 1910–1919, T varied very little, with no discernible trend. From 1910–1919 to 1940–1949, T increased each decade. This warming trend then ceased. Then T increased from 1970–1979 to 1990–1998 such that it was 0.66°C (1.19°F) warmer in 1990–1998 than in 1860–1869. In order to understand why the decadal average temperature varied in this manner, to determine if predictions of such variations can be made and by what means, it is necessary to consider the transfer of energy across the top of the Earth's atmosphere.

When the amount of infrared thermal radiation emitted by the Earth to space equals the amount of solar radiation absorbed by the Earth from the Sun (240 W m^{-2}), the net input of energy into the atmosphere-Earth system is zero. If somehow the net input energy becomes positive, energy will enter the system, the decadal average temperature will increase, and the infrared radiation emitted to space (which depends on the decadal average temperature) will increase. Conversely, if the net energy input becomes negative, energy will leave the system, the decadal average temperature will decrease, and the infrared radiation emitted to space will decrease. In either case the net input of energy into the atmosphere-Earth system will be restored to zero. Consequently, any factor that causes the net energy input to become nonzero can cause the decadal average temperature to vary. To predict the change in this temperature value, the change in the net energy input from zero (the radiative forcing) must be predicted.

One factor that has changed the net energy input since the mideighteenth century, and will likely change it in the future, is the rising concentrations of atmospheric greenhouse gases: carbon dioxide, methane, nitrous oxide, and chloroflurocarbons (whose emission is now restricted by international convention). Acting alone, the increaseing greenhouse gases would have made the net energy input positive by about 2.6 W m^{-2} in 1998 (**Fig. 2**). Another factor influencing the net energy input is the input of sulfur dioxide gas into the atmosphere near the Earth's surface by the anthropogenic burning of sulfur-containing coal and oil. This gas is chemically converted into sulfate aerosol particles, which enhance the reflection of solar radiation to space in cloudless air. It is thought that these particles also act as nuclei for the formation of cloud droplets, smaller than would be the case in their absence, which therefore enhance the reflection of solar radiation in cloudy air. The enhanced reflection in clear and cloudy air reduces the absorption of solar radiation by the Earth, which, acting alone, would make the net energy input negative. The size of this anthropogenic sulfate aerosol radiative forcing is quite uncertain, particularly that for cloudy air. One estimate gives a value of about -1.1 W m^{-2} in 1998 (Fig. 2). *See* GREENHOUSE EFFECT; TERRESTRIAL RADIATION.

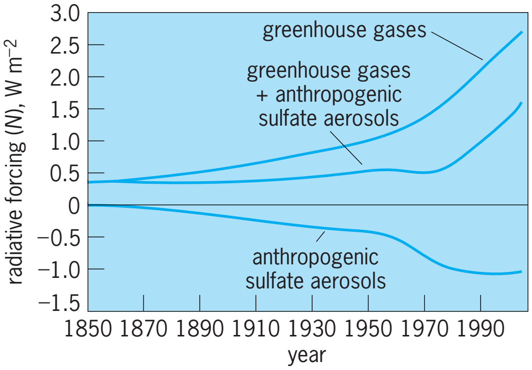

Fig. 2. Radiative forcing of climate by greenhouse gases and anthropogenic sulfate aerosols, together with their sum. The greenhouse gas forcing is taken to be zero in 1765, and the anthropogenic sulfate aerosol forcing is taken to be zero in 1850.

If the future radiative forcing of climate change could be predicted as a function of time, to make a prediction of the resulting climate change a climate model would be needed. A climate model is the mathematical expression of the fundamental laws of nature, for the present example, conservation of energy. The resulting equations express the time rate of change of the decadal average temperature at any time in terms of the value of the decadal average temperature at that time. Starting from the known value of this temperature at some initial time, the time rate of change of the decadal average temperature is calculated from the equations and multiplied by a small time interval; and the result is added to the initial temperature value to give a value at a future time. This procedure is then repeated to predict temperatures at further time increments. The climate model must include the ocean as well as the atmosphere, for the rate of heat removal from the upper ocean by transport into the deeper ocean, together with the net energy input into the atmosphere-Earth system at a given time, determines the rate at which the decadal average temperature changes in time.

In one simple climate model, the ocean is divided vertically into many layers, with the uppermost being the mixed layer wherein temperature is uniform with depth. Also, the ocean in each hemisphere is divided horizontally into a polar region where bottomwater is formed, and a nonpolar region where there is vertical upwelling. In the nonpolar region of each hemisphere, heat is transported upward toward the surface by the water upwelling there, and downward by physical processes whose effects are treated as an equivalent diffusion. Heat is also removed from the mixed layer in the nonpolar region of each hemisphere by transport to the polar region and downwelling toward the bottom. This heat is ultimately transported upward from the ocean floor in the nonpolar region.

Several quantities must be prescribed in this simple climate model. One of the most important is the sensitivity of the climate system, a parameter that represents the change in the global average surface temperature resulting from a radiative forcing equal to that caused by doubling the concentration of carbon dioxide (the net energy input equals 4.4 W m^{-2}) after sufficient time has passed for the net energy input to be restored to zero. The value of the sensitivity is quite uncertain. The most comprehensive climate models that predict this value—the general circulation models—give values that range from about 1.5 to about 4.5°C (2.7 to 8.1°F). The simple climate model can be used to estimate the sensitivity of the climate system, together with the radiative forcing of the anthropometric sulfate aerosol for a specific year, by minimizing the discrepancy between the simulated and observed decadal average temperature, together with the discrepancy between the simulated and observed interhemispheric temperature difference. The resulting decadal average temperature simulated by the model does reproduce the overall increase in the observed decadal average temperature, but not the detailed variations.

One possible reason for the discrepancy between the observed and simulated temperatures is that one or more factors influencing the net energy input may not have been taken into account. For example, some scientists believe that the energy emitted by the Sun has varied over time, thereby causing a variation in the solar radiation entering the top of the Earth's atmosphere—the solar irradiance. Although there are no useful observations of solar irradiance prior to 1978, when satellite observations began, and although these satellite observations show irradiance variations that are too small to influence the decadal average temperature by more than a few hundredths of a degree Celsius, observations of sunspots since the seventeenth century and of solar magnetic activity during the twentieth century, plus astronomical observations of Sun-like stars since 1970, suggest that variations of solar irradiance sufficiently large to influence the decadal average temperature cannot be ruled out. Other scientists believe that variations in the occurrence of large volcanic eruptions may influence the decadal average temperature by varying the amount of solar radiation reflected to space. Although the sulfate aerosols created in the stratosphere by the injection of sulfur dioxide gas there by large volcanic eruptions do tend to reflect more solar radiation to space and decrease the decadal average temperature, the episodic nature of volcanic eruptions limits the temporal influence of a single volcanic eruption to less than a decade. It is argued, nevertheless, that the variation in the number of large volcanic eruptions per decade can significantly influence the decadal average temperature. Yet another factor which can influence the net energy input is the aerosol particles released into the lower atmosphere by biomass burning, such as by tropical deforestation and slash-and-burn agriculture. Furthermore, changes in the fraction of solar radiation reflected by the Earth's surface—the surface albedo—due to anthropogenic modifications of the surface can also change the net energy input. *See* ALBEDO.

A different possible reason for the discrepancy is that, even if there were no changes in the net energy input due to factors such as those described above, the decadal average temperature might vary because of interactions between the atmosphere and ocean, or by variations within the ocean itself. A well-known example of an atmosphere-ocean interaction is the El Niño Southern Oscillation, which occurs irregularly over the tropical Pacific Ocean with a time scale of 3–7 years. One analysis of the discrepancy suggests that it is likely the result of a temperature oscillation within the North Atlantic Ocean, with a time scale of about 65 years.

Distributions of temperature and precipitation. Although the future course of global average surface temperature can, in principle, be predicted with a simple climate model, the prediction of the geographical distributions of temperature and other climatic quantities requires a much more complex climate model, one at the other terminus of the climate model hierarchy.

Only the general circulation model determines the geographical and vertical distributions of an ensemble of climatic quantities, including temperature, wind, water vapor, clouds and precipitation in the atmosphere; soil moisture, soil temperature, and evaporation on the land; and temperature, currents, salinity, and sea ice in the ocean. The mathematical equations in general circulation models that express the fundamental laws of nature are so complex, however, that they can be solved only at discrete geographical and vertical locations, and only over discrete time intervals. A typical general circulation model divides the atmosphere into thousands of three-dimensional volumes, each having dimensions of about 250 km (155 mi) in both the north-south and east-west directions, and 1 km (0.6 mi) in the vertical direction. Reducing these dimensions is severely constrained by the speed of available supercomputers. For example, increasing the horizontal resolution of a general circulation model from 250 km (155 mi) to 25 km (16 mi) would increase the required computer time a thousandfold, from about 2 weeks to compute a greenhouse-gas induced change in equilibrium climate—the climate change when the net energy input is restored to zero—to more than 30 years.

The constraint on horizontal resolution imposed by available supercomputers also has profound significance for the physical processes that can be included in a general circulation model. In particular, the Earth's climate system encompasses physical processes ranging in horizontal size from 40,055 km (24,889 mi) for disturbances that span the entire circumference of the Earth, to about one-millionth of a meter (0.00004 in.) for the condensation of water vapor onto aerosol particles and dust to form clouds. General circulation models using supercomputers explicitly include physical processes having horizontal sizes of about 250 km (155 mi) and larger. Worse yet, the physical processes smaller than 250 km (155 mi) cannot be ignored, because their effects significantly determine climate and climate change. Thus, climate modelers face the dilemma that their models cannot resolve the small-scale physical processes, and they cannot ignore the effects. This is the major difficulty in modeling the Earth's climate.

The approach taken to overcome it is to determine the effects of the unresolved physical processes on the scales resolved by a general circulation model by using information available only on the resolved scales. This approach is called parametrization. The principal differences among general circulation models lie in their different parametrizations, particularly of cloud and precipitation processes. These parametrization differences have a significant influence on the climate simulated by the general circulation models.

The geographical distributions of the change in surface air temperature simulated by general circulation models for a doubling of the carbon dioxide concentration show that although there are similarities in the regional temperature changes simulated by the global circulation models, there are also marked differences. This fact is even more apparent in the changes in precipitation simulated by the general circulation models. This fact is not surprising because many of the physical processes that determine precipitation have horizontal scales smaller than the resolutions of the general circulation models, and it is these unresolved processes that have had to be parametrized in the models. To improve this situation will require that at least mesoscale meteorological processes, with horizontal sizes down to 50 km (31 mi), be explicitly resolved by the models. A fivefold increase in the horizontal resolution of the general circulation models and an attendant 125-fold increase in computer speed will be required. Such high-speed supercomputers, capable of performing several trillion mathematical operations per second, are projected to be available about the year 2000.

However, to be able to predict the regional climate on a decadal-to-century time scale requires the knowledge of the three-dimensional distributions of temperature, salinity, and velocity in the ocean at the beginning of the prediction period. The panoceanic measurement system required to obtain this knowledge does not yet exist. Michael E. Schlesinger

Climatology

The scientific study of climate. Climate is the expected mean and variability of the weather conditions for a particular location, season, and time of day. The climate is often described in terms of the mean values of meteorological variables such as temperature, precipitation, wind, humidity, and cloud cover. A complete description also includes the variability of these quantities, and their extreme values. The climate of a region often has regular seasonal and diurnal variations, with the climate for January being very different from that for July at most locations. Climate also exhibits significant year-to-year variability and longer-term changes on both a regional and global basis.

Climate has a central influence on many human needs and activities, such as agriculture, housing, human health, water resources, and energy use. The influence of climate on vegetation and soil type is so strong that the earliest climate classification schemes were often based more on these factors than on the meteorological variables. While technology can be used to mitigate the effects of unfavorable climatic conditions, climate fluctuations that result in significant departures from normal cause serious problems even for modern industrialized societies and more so for the less developed ones. The goals of climatology are to provide a comprehensive description of the Earth's climate over the range of geographic scales, to understand its features in terms of fundamental physical principles, and to develop models of the Earth's climate for sensitivity studies and for the prediction of future changes that may result from natural and human causes. *See* CLIMATE MODELING; CLIMATIC PREDICTION.

Physical basis of climate. The global mean climate and its regional variations can be explained in terms of physical processes. For example, the temperature is warmer near the Equator than near the poles (see **table** and **Figs. 1** and **2**). This is because the source of heat for the Earth is the radiant energy coming from the Sun (insolation), and the Sun's rays fall more directly on the Equator than on the poles. The circulations in the atmosphere and in the oceans transport heat poleward and thereby reduce the Equator-to-pole temperature difference that is continually forced by insolation. The energy released by the rising of warm air in the tropics and the sinking of cold air in high latitudes drives the great wind systems of the atmosphere, such as the trade winds in the tropics and the westerlies of middle latitudes. *See* ATMOSPHERIC GENERAL CIRCULATION; OCEAN CIRCULATION; TROPICAL METEOROLOGY; WIND.

The flux of solar energy at the mean distance of the Earth from the Sun is about 1367 $W \cdot m^{-2}$. The supply of energy per unit of the Earth's surface area is controlled by geometric and astronomical factors. Because the axis of rotation of the Earth is inclined at an oblique angle to the plane of the Earth's orbit, the declination angle of the Sun undergoes a seasonal variation as the Earth makes its annual circuit around it. The declination angle is equivalent to the latitude at which the Sun is directly overhead at noon. The declination angle varies between 23.5° N at northern summer solstice (June 21) and 23.5° S at northern winter solstice (December 22), for the current

alignment of the Earth's orbit. The approximate sphericity of the Earth and the annual variation of the declination angle of the Sun cause the incoming solar radiation to be a function of latitude and season (**Fig. 3**). The annual mean insolation is largest at the Equator and decreases toward the poles. The seasonal variation is largest at high latitudes. At the poles 6 months of daylight alternate with 6 months of darkness. The Earth is closer to the Sun during summer in the Southern Hemisphere, so this region receives about 7% more insolation at this time than the Northern Hemisphere. *See* INSOLATION.

About half of the energy from the Sun that is incident at the top of the atmosphere is transmitted through the atmosphere and absorbed at the Earth's surface (**Fig. 4**). About 30% is reflected back directly to space, and another 20% is absorbed in the atmosphere. The fraction of the incoming solar radiation that is reflected to space is called the albedo. The albedo increases where clouds or surface ice and snow are present. It increases toward the poles because the amount of cloud cover and surface ice increases and because the Sun is closer to the horizon. The albedo of desert areas is generally higher than that of heavily vegetated areas or oceans. The solar energy that reaches the surface may be used to raise the surface temperature, or the energy can be used to evaporate water. The energy that is used to evaporate water (latent heat) is later released into the atmosphere when the water vapor condenses to form clouds and returns to the surface in the form of precipitation (**Fig. 5**). *See* ALBEDO; PRECIPITATION (METEOROLOGY).

Greenhouse effect. In order to achieve an energy balance, the solar energy that is absorbed by the Earth must be balanced by an equal amount of energy that is returned to space. The Earth emits radiative energy at frequencies that are substantially different from those of the Sun because of the Earth's lower temperature. The Earth emits primarily thermal infrared radiation [wavelengths from 4 to 200 micrometers], whereas most of the energy from the Sun arrives in the form of visible and near-infrared radiation (0.4–4 μm). The atmosphere is much less transparent to Earth's thermal radiation than to solar radiation, because water vapor, clouds, carbon dioxide, and other gases in the atmosphere absorb thermal radiation. Because the atmosphere prevents thermal radiation emitted from the surface from escaping to space, the surface temperature is warmer than it would be in the absence of the atmosphere. The combination of the relative transparency of the atmosphere to solar radiation and the blanketing effect of the gases in the atmosphere that absorb thermal radiation is often referred to as the greenhouse effect. The greenhouse effect on Earth is quite important. For example, the net emission of 21 units of

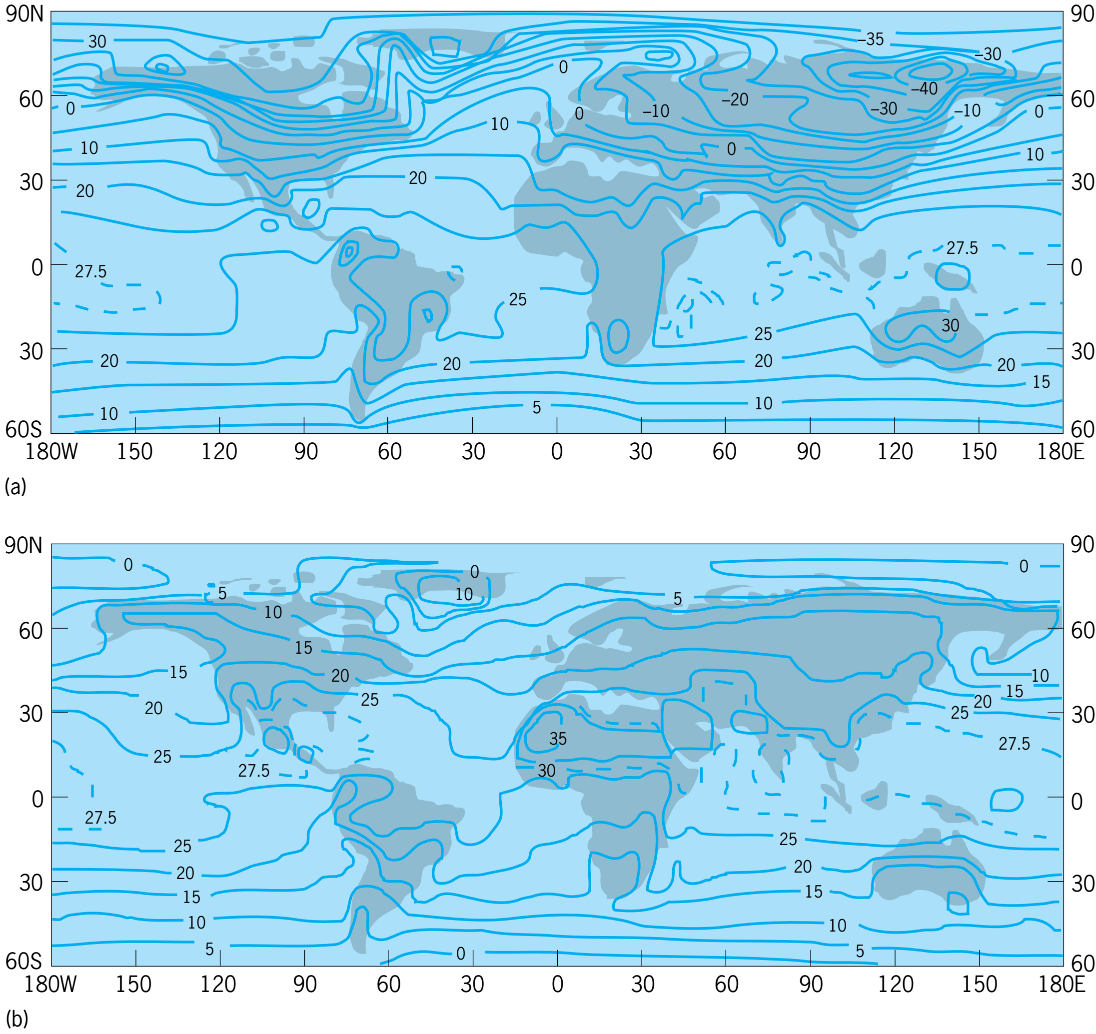

Fig. 1. **Mean surface temperature (°C) for (*a*) January and (*b*) July. Note the cold temperatures in the centers of the large northern landmasses in January. The broken contour line (27.5) is included to give more information concerning the tropics. °F = (°C × 1.8) + 32. (*After D. L. Hartmann, Global Physical Climatology, Academic Press, 1994*)**

infrared thermal radiation from the surface (Fig. 4) is the difference between a downward flux from the atmosphere of 89 units and a surface emission of 110 units. The downward flux of infrared radiation from the atmosphere is nearly double the solar radiation directly absorbed by the surface. *See* ATMOSPHERE; GREENHOUSE EFFECT.

Clouds affect the energy emission of the Earth.

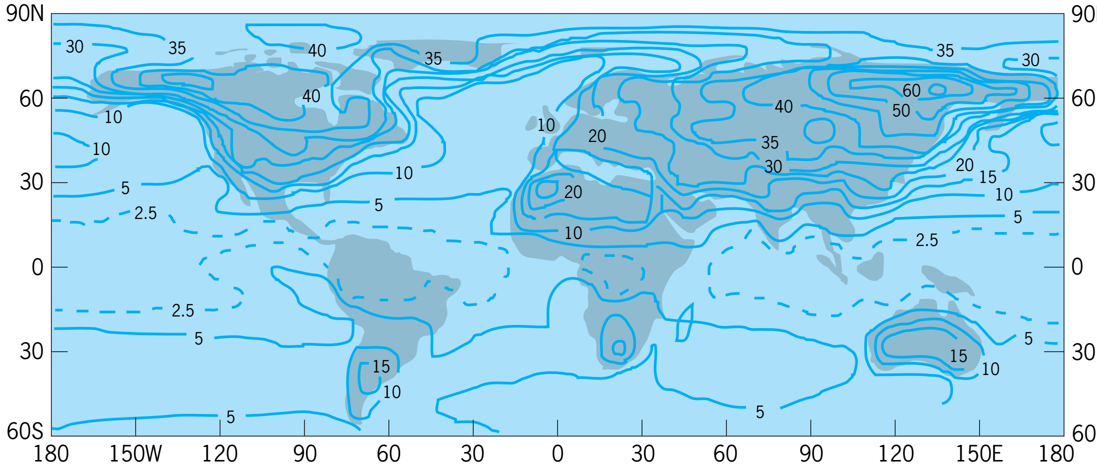

Fig. 2. **Annual range of temperature (°C), the difference between the warmest and the coldest months. The broken contour line (27.5) is included to give more information concerning the tropics. °F = (°C × 1.8) + 32. (*After D. L. Hartmann, Global Physical Climatology, Academic Press, 1994*)**

The thermal emission is low over tropical regions where high, cold clouds are present, such as the major precipitation regions of equatorial Africa, South America, southern Asia, Indonesia, and the band of clouds along the Equator. Because the albedo is higher, less solar energy is absorbed when clouds are present. Since clouds decrease both the solar energy absorbed and the terrestrial energy emitted to space, the net effect of tropical convective clouds on the energy balance of the Earth is less than their individual effects on solar and terrestrial energy. As a result, the distribution of the net radiative energy exchange at the top of the atmosphere does not clearly reflect the influence of the tall cloud so clearly. In general, the net radiation shows a strong influx of energy at those latitudes where the insolation is strongest. *See* TERRESTRIAL RADIATION.

A striking feature of the distribution of net radiation during July is the low values over the Sahara and Arabian deserts compared with the surrounding ocean and moist land areas. This is because desert sand has a relatively high albedo, so that less solar radiation is absorbed there. In addition, few clouds and little water vapor are present in the atmosphere over the deserts to absorb the thermal radiation emitted by the very hot surface. Since the emitted thermal radiation is high and the absorbed solar radiation is low, desert areas often show a net loss of radiative energy. This fact plays a central role in the maintenance of desert dryness. The loss of radiative energy is often balanced by convective transport of heat energy into the desert regions by the atmosphere. This results in downward motion of dry air, which flows outward near the ground and prevents the moist surface air of surrounding regions from reaching the desert interior. *See* DESERT.

Continentality. Annual temperature ranges are much greater near the center of continents in middle and high latitudes than they are over oceans. Land and ocean areas have very different seasonal variations because of their different capacities to store heat. Because the ocean is a fluid, its upper 150–300 ft (50–100 m) is generally in direct thermal communication with the surface. Therefore solar energy incident on the surface can be absorbed in this large heat reservoir without raising the surface temperature very much. In addition, over the oceans it is possible for solar energy to evaporate water and thus never be realized as heat at the surface. In contrast,

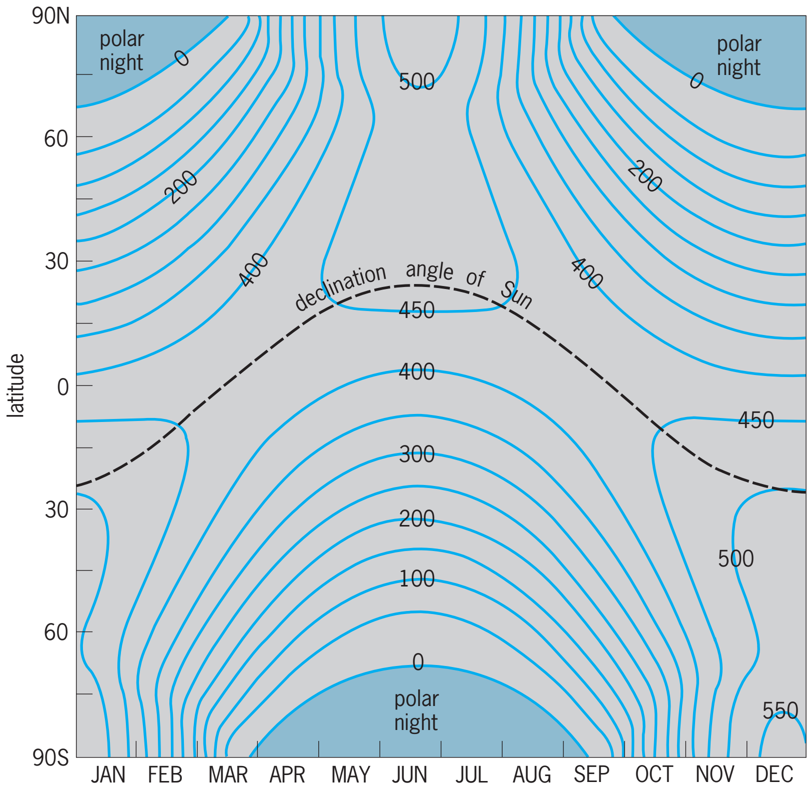

Fig. 3. Daily-average solar energy incident at the top of the atmosphere as a function of latitude and season in watts per square meter of surface area.

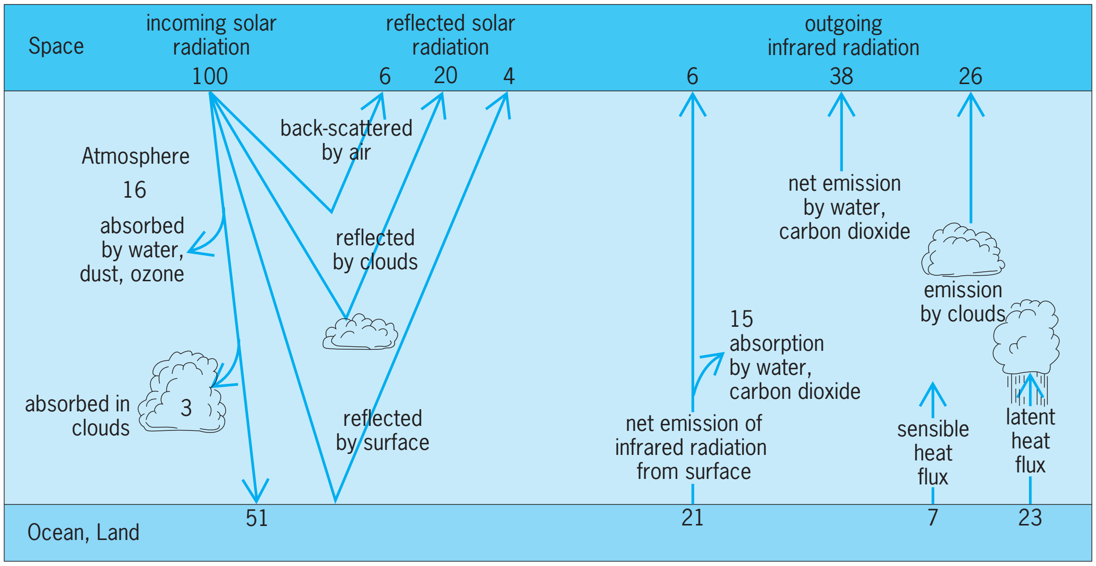

Fig. 4. Annual-mean global energy balance for the Earth–atmosphere system. Numbers given are percentages of the globally averaged solar energy incident upon the top of the atmosphere. (*After J. M. Wallace and P. V. Hobbs, Atmospheric Science: An Introductory Survey, Academic Press, 1977*)

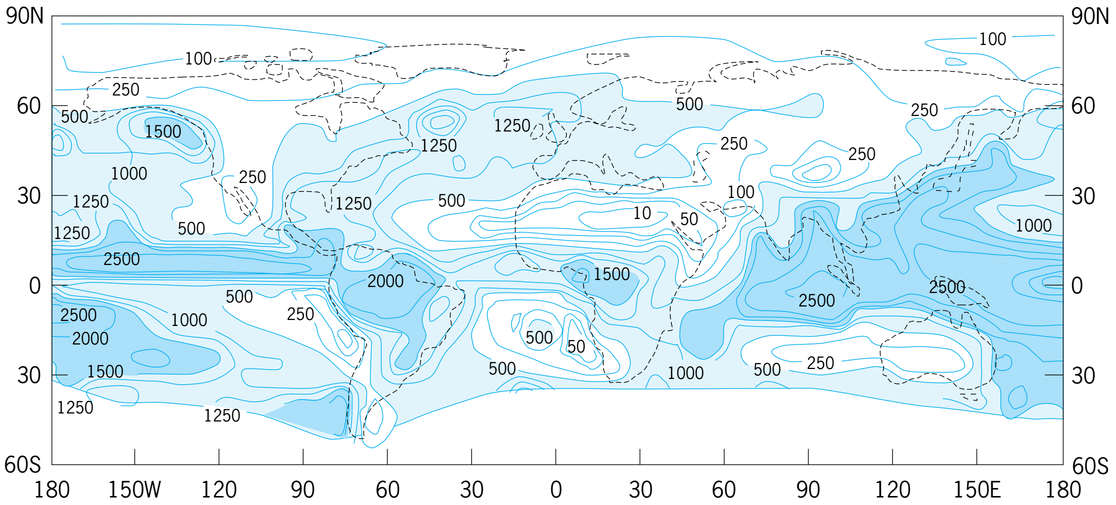

Fig. 5. **Geographic distribution of annual mean precipitation in millimeters. (*After D. L. Hartmann, Global Physical Climatology, Academic Press, 1994*)**

over land only about the first meter of soil is in thermal contact with the surface, and much less water is available for evaporation. During the winter, the ocean can return heat stored during the summer to the surface, keeping the surface relatively warm. The land cools off very quickly in winter, warms up rapidly in summer, and experiences large day-night differences. Continental climates in middle latitudes are characterized by hot summers and cold winters, whereas climates that are over or near the oceans are more equable with milder seasons (Figs. 1 and 2).

The distinction between maritime and continental climates can be seen by comparing the annual variations of temperature and precipitation for Tatoosh Island, Washington, with those for Minneapolis, Minnesota (**Fig. 6**). The temperature at Tatoosh Island

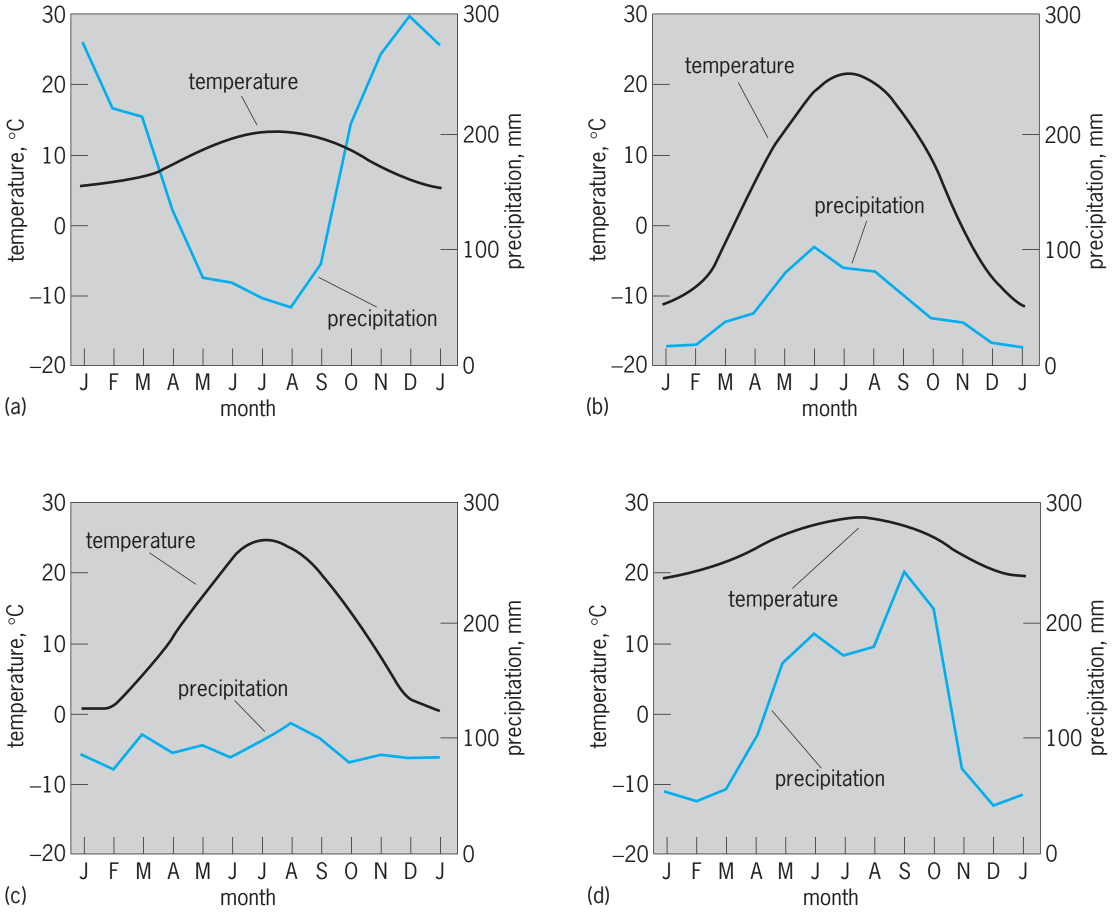

Fig. 6. **Annual variation of monthly mean temperature and precipitation at (*a*) Tatoosh Island, Washington; (*b*) Minneapolis, Minnesota; (c) New York, New York; and (*d*) Miami, Florida. °F = (°C × 1.8) + 32; 1 mm = 0.04 in.**

varies between a mean of 42°F (5.6°C) for January and a mean of 56°F (13.3°C) for August. This narrow temperature range results from the strong influence of the ocean, which is adjacent to and upwind of the Pacific coast, and has a small seasonal variation in temperature because of its large capacity to store and release heat. Although it is at nearly the same latitude, Minneapolis has a much larger annual variation of monthly mean temperatures, with readings of 12°F (−10.9°C) for January and 72°F (22.4°C) for July. Figures 1 and 2 show the large annual variation of temperature near the centers of the continents. *See* MARITIME METEOROLOGY.

The annual variation of precipitation is also very different in the two climate regimes (Fig. 6). At Tatoosh Island the precipitation peaks in the winter season in association with rainfall produced by the cyclones and fronts of wintertime weather. In Minneapolis the precipitation peaks in the summer season. Most of this precipitation is associated with thunderstorms. Adequate precipitation during the warm summer season is an essential ingredient of the agricultural productivity of the American Midwest.

New York City shows an annual variation of temperature and precipitation that is a combination of maritime and continental. It is near the Atlantic Ocean, but because the prevailing winds are out of the west, it also comes under the influence of air that has been over the continent. It has a fairly large annual variation of temperature, but monthly mean precipitation is almost constant through the year (Fig. 6*c*). It receives precipitation both from winter storms and summer thunderstorms. Miami, Florida is in the subtropics at 26°N. The annual variation of insolation is small, so that the seasonal variation of temperature is also modest. The precipitation shows a strong seasonal variation, with maximum precipitation during the summer half-year associated primarily with thunderstorm activity. *See* THUNDERSTORM.

General circulation of atmosphere and climate. Many aspects of the Earth's climate are influenced by the nature of the circulation that results from the radiative heating of the tropics and cooling of the polar regions. In the belt between the Equator and 30° latitude the bulk of the poleward atmospheric energy transport is carried by a large circulation cell, in which air rises in a narrow band near the Equator and sinks at tropical and subtropical latitudes. The upward motion near the Equator is associated with intense rainfall and wet climates, while the downward motion away from the Equator results in the suppression of rainfall and very dry climates (Fig. 5). Most of the world's great deserts, including the Sahara, Australian, Arabian, Kalahari, and Atacama, are in the belts between 10 and 30° latitude.

In middle latitudes the poleward flow of energy is produced by extratropical cyclones rather than by a mean circulation cell. These storms are thousands of miles wide and are characterized by poleward motion of warm, moist air and equatorward motion of cold, dry air. Most of the wintertime precipitation in middle latitudes is associated with weather disturbances of this type.

Surface features are also of importance in determining local climate. Mountain ranges can block the flow of moist air from the oceans, resulting in very low rainfall beyond the mountain ranges. The dryness of the Great Basin of North America and the Gobi Desert of Asia is maintained in this way. On the upwind side of mountain ranges, forced ascent of moist air can result in very moist climates; this occurs, for example, on the west slope of the coastal mountains of western America and the south slope of the Himalayas during the summer monsoon. The downwind sides of such mountains are often very dry, since the moisture precipitates out on the upwind side. Two locations that show the effect of topography on local climates are Puerto Aisén, Chile, and Comodoro Rivadavia, Argentina, which are both located near a latitude of 45°S (see table). Puerto Aisén is on the westward and upwind side of the Andes mountains in a deep valley that is exposed to the midlatitude westerly winds coming off the Pacific Ocean. It receives more than 10 ft (3 m) of precipitated water annually. Only a few hundred miles downwind of the Andes on the Atlantic seaboard, Comodoro Rivadavia receives only about 8 in. (0.2 m) of precipitation each year.

Complete climate system. The climate of the Earth results from complex interactions among externally applied parameters, like the distribution of insolation, and internal interactions among the atmosphere, the oceans, the ice, and the land (**Fig. 7**). The composition of the atmosphere, which plays a key role in determining the surface temperature through the greenhouse effect, has been radically changed by the life-forms that have developed, and continues to be modified and maintained by them. The atmosphere and the oceans exchange heat, momentum, water, and important constituent gases such as oxygen and carbon dioxide. The exchange of constituent gases is strongly influenced by life in the ocean. The hydrologic cycle of evaporation, cloud formation, and precipitation as rain or snow is intimately connected to the climate through the effects of water vapor, clouds, and surface ice on the radiation balance of the planet. Vegetation interacts strongly with the hydrologic cycle over land to determine the soil moisture, surface albedo, evaporation, precipitation, and surface water runoff. *See* HYDROLOGY.

Evolution of Earth's climate. The climate of the Earth is unique among the planets in the solar system. All of them evolved out of material in the rotating cloud from which the solar system was formed. The subsequent evolution of the planets' atmospheres depended critically on the mass of each planet and its distance from the Sun.

The mass of the Earth and its distance from the Sun are such that water can exist in liquid form rather than being frozen or escaping to space. The liquid water formed the oceans and led to the development of photosynthetic life, which reduced the carbon dioxide content and increased the molecular oxygen content of the atmosphere. Planets closer to the Sun receive more solar energy per unit area and are thus much hotter than the Earth. The surface of Venus is sufficiently hot that water vapor cannot

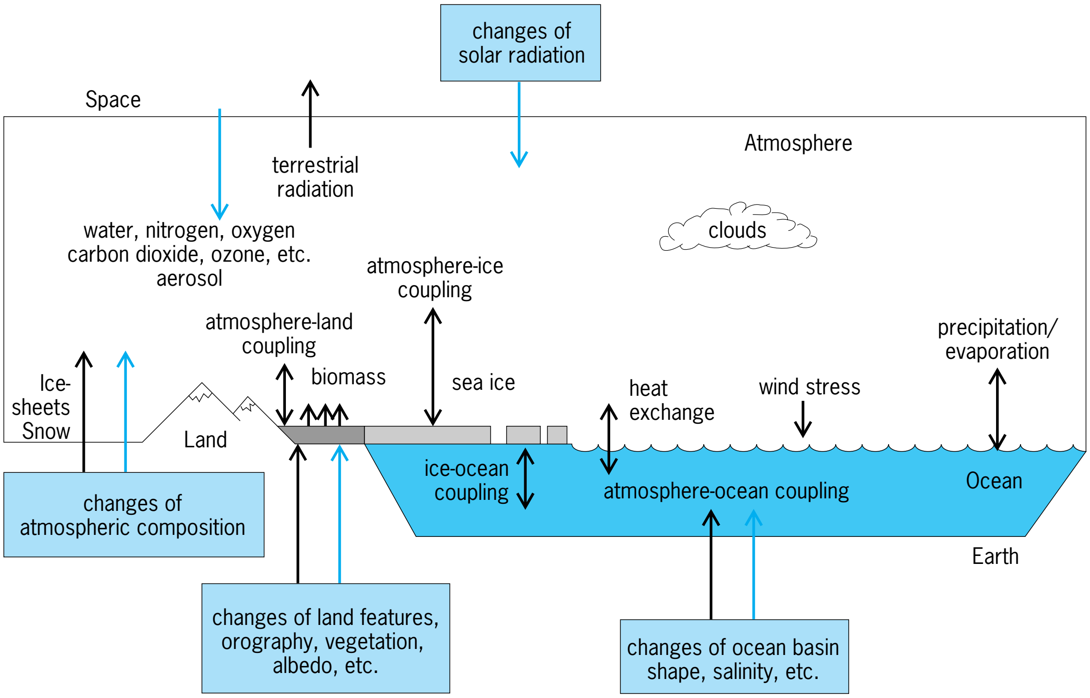

Fig. 7. Schematic illustration of the processes and interactions in the climate system. The colored arrows indicate externally applied conditions, and black arrows show internal processes that act to influence climate change. (*After J. G. Lockwood, Causes of Climate, Halstead Press, 1979*)

condense. Venus has a very thick atmosphere composed mostly of carbon dioxide. On Mars, which is farther from the Sun than the Earth and therefore colder, water freezes, leaving a very thin atmosphere of carbon dioxide. Thus the basic climatic conditions of a relatively circular orbit at a favorable distance for the Sun led to a drastically different evolutionary history for the Earth than for the neighboring planets. *See* ATMOSPHERE, EVOLUTION OF; SOLAR SYSTEM.

History of Earth's climate. Direct measurements allow the estimation of global mean surface temperature of the Earth for only about the last 100 years (**Fig. 8**). Global surface air temperature rose by about 0.9°F (0.5°C) between 1880 and 1940 and then declined slightly in the following three decades. The decade of the 1980s contained some of the warmest years on record.

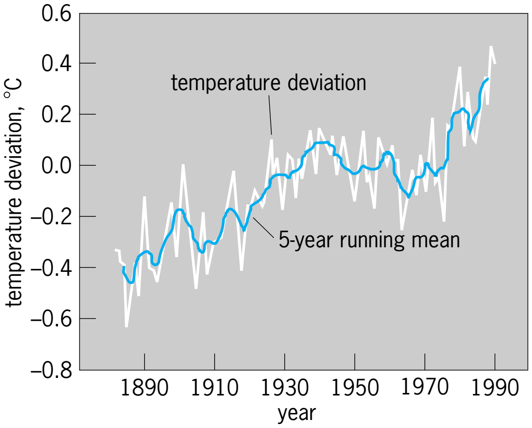

Fig. 8. Global surface air temperature change (°C) over the last century inferred from measurements. Temperature deviation is from 1951–1980 mean. °F = (°C × 1.8) + 32. (*After D. L. Hartmann, Global Physical Climatology, Academic Press, 1994*)

Evidence of climate variations in prehistoric times must be obtained from proxy indicators in dated sediments, such as pollen spores, the shells of small animals, or isotopic abundances, or from geologic features such as terminal moraines of glaciers or dry lake beds. A wealth of geological evidence exists to indicate that the Earth underwent a great glaciation as recently as 20,000 years ago. During this period, ice sheets nearly 2 mi (3 km) thick covered parts of North America and western Europe. Variations in the relative abundance of oxygen isotopes in deep-sea cores indicate that there has been a succession of periods of major glaciations separated by relatively warm, ice-free periods called interglacials during the last million years of Earth history (**Fig. 9**). *See* GLACIAL EPOCH; PALEOCLIMATOLOGY.

Analyses of time series show a relationship between global ice volume and known variations in the Earth's orbit. The parameters of the Earth's orbit include the eccentricity, which measures the departure from a circular orbit to a more elliptical one; the obliquity, which measures the tilt of the axis and therefore the magnitude of the annual variation in the declination angle of the Sun; and the longitude of perihelion, which measures the season at which the Earth makes its closest approach to the Sun. These parameters control the seasonal and latitudinal distribution of insolation. Because ice sheets form primarily on land and much of the land area is in northern latitudes, ice sheets form more readily when the summertime insolation is relatively low, which allows some of the winter snow accumulation to survive the summer season. The global climate responds to the presence of the ice sheets through a process called ice-albedo feedback. Ice sheets are more reflective to solar radiation than other surfaces, so that their presence tends to reduce the amount of solar heat absorbed by the Earth. This in turn leads to a cooling of the planet and a greater tendency for the ice sheets to grow. *See* EARTH ROTATION AND ORBITAL MOTION.

Evidence from air bubbles trapped in glacial ice indicates that there were lower atmospheric concentrations of greenhouse gases such as carbon dioxide and methane during past glacial ages than there is at present. The concentration of carbon dioxide 20,000 years ago during the last glacial age was only about 190 parts per million by volume (ppmv), compared with the preindustrial level of 280 ppmv and the current concentration of 355 ppmv. During past glacial periods, the rather low values of carbon dioxide are thought to have been produced by changes in ocean chemistry and biology. Such low greenhouse gas concentrations contribute significantly to the cooling associated with glacial advances.

Future climate changes. Past relationships between the Earth's orbital parameters and global ice volume indicate that the Earth will undergo another major glacial age within about 25,000 years from now. Currently, however, the composition of the Earth's atmosphere is changing rapidly as a result of human influences. Of climatic interest are industrial gases that are transparent to solar radiation entering the Earth's atmosphere, but are opaque to the thermal radiation emitted by the Earth. Gases with these characteristics are called greenhouse gases. In order to achieve an energy balance in the presence of increased concentration of greenhouse gases, the Earth's surface must warm, so that its thermal emission will increase to offset increasing downward emission of thermal energy from an atmosphere that is becoming more effective at intercepting outgoing thermal radiation, if other factors remain the same. The principal greenhouse gases are carbon dioxide, which is increasing principally because of the burning of coal and oil; methane or natural gas, whose increase is related to agriculture and coal and gas mining; nitrous oxide, which is a product of the decay of fixed nitrogen in plants or artificial fertilizer; and chlorofluorocarbons, which are gases used in industry for refrigeration, foam-blowing, and cleaning, and as aerosol propellants. Carbon dioxide is expected to contribute most of the increase in atmospheric thermal opacity due by the year 2030.

Within the next 100 years, if current trends continue, climate models indicate that human activities will result in a climate that is 4–8°F (2.2–4.4°C) warmer than it is today. The magnitude of this increase is similar to that between the present climate and the last glacial age, and would represent an extremely rapid warming by the standards of natural climate variability and change. Studies also suggest increased probability of drought during the summer growing season in midlatitude agricultural areas and rising sea levels that may be 27 in. (70 cm) higher than present levels by the year 2080. *See* CLIMATE HISTORY; CLIMATE MODIFICATION; DROUGHT; MESOMETEOROLOGY; METEOROLOGY; MICROMETEOROLOGY.

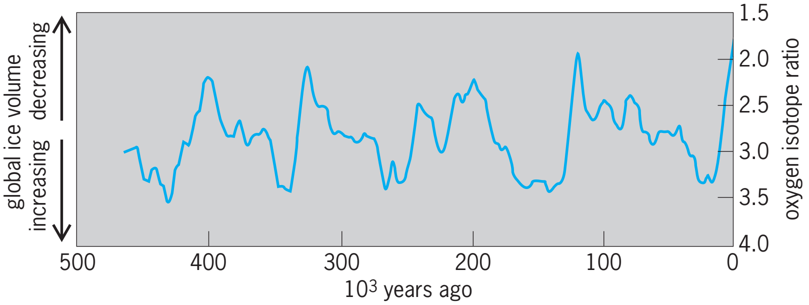

Fig. 9. Climate of the past half-million years. Oxygen isotope ratios are from ocean sediments, which reflect variations in the global volume of ice in glaciers and ice sheets (*After J. Imbrie, Ice Ages: Solving the Mystery, Enslow Publishers, 1979*)

Clinical immunology

A branch of clinical pathology concerned with the role of the immune defense system in disease. The subject encompasses diseases where a malfunction of the immune system itself is the basic cause, together with diseases where some external agent is the initiating factor but an excessive response by the immune system produces the actual tissue damage. It also extends to the monitoring of the normal immune response in infectious diseases and to the use of immunological techniques in disease diagnosis. *See* CLINICAL PATHOLOGY.

Clinical immunology is a specialization born of the rapid expansion of knowledge in basic immunology together with the recognition that many diseases have an immunological component. Some areas of medicine which might logically be classified as clinical immunology were developed before immunology emerged as a separate discipline, and these have become the province of other medical departments. For example, vaccination against infectious disease is part of the practice of pediatrics, and asthma is treated by respiratory physicians.

Immune defense system. Many features of the immune system make it prone to shift from protecting the body to damaging it. This complex system not only must distinguish between the body's own cells and a foreign invader but must also recognize and eliminate the body's own cells if they are damaged or infected with a virus. The recognition receptors used to make this fine distinction between "self" and "not self" are not encoded in the genes. Rather, they are assembled following random rearrangement of information carried in small gene segments. During their development, immune system cells are subjected to a selective process, those bearing potentially useful receptors being preserved while those bearing dangerous, self-reactive receptors are eliminated. This process is closely balanced, and some potentially self-reactive cells often persist.

The cells that carry these highly discriminating surface receptors are the lymphocytes. They are migratory cells, concentrated in lymph nodes and also found among the white cells of blood. Lymphocytes are of two types: B cells (which are formed in bone marrow) and T cells (which are formed in the thymus). CD8 T cells on activation directly kill the body cells presenting the foreign antigens. CD4 T cells on activation produce short-range factors (cytokines) that recruit and activate macrophages and natural killer cells, which in turn release their own cytokines. These less specific cells are also the first line of defense early in infection. If this complex immune response system is not well controlled, it can cause substantial damage to normal cells besides eliminating abnormal cells and foreign invaders. *See* CELLULAR IMMUNOLOGY; CYTOKINE.

Immunodeficiency diseases. Immune deficiencies may be acquired as a consequence of an external factor such as an infection or may be inherited as a genetic defect. Immunodeficient individuals are subject to recurrent infections by organisms that are not normally a hazard. Some immunodeficiencies affect only one part of the immune system. In Di George's syndrome, T lymphocytes are deficient because of a developmental failure of the thymus. Hypogammaglobulinemia results from a developmental failure of B lymphocytes. Chronic granulomatosis disease results from an enzyme deficiency in phagocytic cells. *See* IMMUNOLOGICAL DEFICIENCY.

AIDS. Acquired immunodeficiency syndrome (AIDS) is a worldwide epidemic. It is caused by infection with the human immunodeficiency virus (HIV), transmitted sexually or through contaminated blood transfusion or by use of contaminated needles for injections. In the late stages of the disease, there is a massive loss of CD4 T cells, resulting in susceptibility to multiple infections. *See* ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS).

Autoimmune diseases. Many diseases have an autoimmune component, that is, the central cause of the disease, or much of the pathology, is due to the action of the immune system on the body's own tissues. The factor triggering self-reactivity is usually unknown; it may be a viral infection. In some diseases there is a genetic predisposition according to the human cell surface antigen (HLA) type of the individual.

In some autoimmune diseases one particular organ is targeted, as in thyroiditis, where antibodies react with thyroid hormones; or in juvenile onset diabetes, where the insulin-producing cells of the pancreas are attacked. In others, a widespread but particular cell type is the target. One example is autoimmune hemolytic anemia, where antibodies initiate complement lysis of red cells. Finally, some complex diseases with multiple targets are the result of autoimmune phenomena. For example, systemic lupus erythematosus can affect most organs of the body, especially kidney, skin, and joints, and is associated with antibodies against many intracellular components, including deoxyribonucleic acid (DNA). Rheumatoid arthritis is another multisystem disease, but synovial joints bear the brunt of the inflammatory response, and an antibody against the body's own immunoglobulin (rheumatoid factor) is often present. *See* ANTIBODY; AUTOIMMUNITY; IMMUNOGLOBULIN.

Hypersensitivity or allergic states. These represent an extreme response of particular individuals to environmental antigens that are not intrinsically harmful. Examples are allergies to drugs, food components, pollen, or house-dust mites. The nature of the response varies, but the most common response involves immunoglobulin E antibodies. When complexed with the antigen, these bind to the surface of mast cells, triggering the release of histamine and other pharmacological agents. This is the basis of atopic diseases, including dermatitis, allergic rhinitis (hay fever), bronchial asthma, and even extreme anaphalactic shock. *See* ALLERGY.

Cancer. The body mounts an immune response against at least some forms of cancer. It is not yet clear whether it is possible to generate an effective immune response against all types of cancer cells. Some forms of cancer represent the uncontrolled proliferation of component cells of the immune system itself. These include myelogenous leukemia (phagocytic cells), lymphatic leukemia (B lymphocytes), and multiple myeloma (antibody-producing cells). *See* CANCER (MEDICINE).

Transplantation. The response of the immune system to cells of another individual was first apparent in blood transfusion, where a match for the A, B, O, and other blood groups was needed to avoid a reaction. The transplantation of skin or internal organs presents the more difficult task of matching the complex HLA antigens. These major histocompatibility complex proteins, whose normal function is to present antigenic fragments to T cells, can trigger an especially vigorous T-cell response. The best available matching for HLA type, as well as careful immunosuppression, is needed for graft survival. *See* IMMUNOLOGY; TRANSPLANTATION BIOLOGY.

Therapy. There are several approaches to suppressing excessive immune reactivity. Drugs with a general toxicity for dividing cells have been used, although now more selective and better-tolerated drugs such as cyclosporin may be employed. The most widely used immunosuppressive agents are corticosteroids, which affect many body systems but have a particularly strong action on lymphoid cells. Desensitization, or modifying the nature of the response by injecting small amounts of the foreign antigen, is sometimes used to treat allergic states. *See* IMMUNOSUPPRESSION.

There are few therapies for enhancing immune responses. Bone marrow transplantation is used to restore the immune system in some immunodeficiency diseases. Passive transfer of preformed antibody protects against some infections, and transfusion of immunoglobulin is used to treat immunoglobulin deficiencies. However, vaccination or immunization, the introduction of modified forms of an infectious agent in order to develop specific protection against infectious diseases, is one of the most effective of all medical procedures. *See* IMMUNOLOGICAL DEFICIENCY; VACCINATION.

The clinic. Many large hospitals have separate clinical immunology departments. However, clinical immunology also is part of the practice of other specialists, such as endocrinologists who treat individuals with thyroiditis or diabetes, or hematologists who treat individuals with pernicious anemia. In addition, common immunological diseases such as allergies or rheumatoid arthritis are often handled in specialized clinics. Individuals in a pediatric clinical immunology department are typically children with immunodeficiency diseases or leukemias. Hematologists and oncologists may be involved in their treatment. The adult patients of a clinical immunology department are usually a diverse group, ranging from hospitalized patients requiring continuous care (for severe allergic responses, late-stage AIDS, infection following immunosuppression) to outpatients whose progress needs regular but not continuous monitoring (for immunoglobulin deficiencies being treated by immunoglobulin transfusion, autoimmune diseases being treated with immunosuppressive drugs).

Clinical immunologists take blood samples as a convenient indicator of the status of the immune system. These samples are analyzed in the laboratory. Other immunological tests use the skin as an indicator of the immune response, most often to test for hypersensitive or allergic states. Test materials are placed in contact with the skin or are injected subcutaneously. A local red inflammatory reaction indicates a positive response. A rapid response, that is, within hours, is referred to as immediate hypersensitivity; this indicates the presence of preformed antibody reactive with the test material. A slow response, within days (delayed hypersensitivity), indicates the development of an immune response involving recruitment of lymphocytes. *See* HYPERSENSITIVITY.

Laboratory tests. The specialized clinical immunology laboratory within a hospital is often directed by the same clinician who sees the patients in the clinic, with trained technicians performing most of the actual tests. Most tests utilize blood samples, although other body fluids and tissue samples are occasionally analyzed. Tests on blood may be divided into those that analyze the serum and those that analyze blood cells. The concentration, type, and specificity of antibodies in serum may be measured by using tests that range from simple agglutination assays, through immunoelectrophoresis, to more sophisticated enzyme-linked immunosorbent assays (ELISA). The number of lymphocytes in the blood may simply be counted, or they may be analyzed or separated to test their function in culture. A preliminary separation of lymphocytes from other blood cells may be made by centrifugation procedures. Further separation into subclasses of lymphocytes is usually effected by a combination of immunofluorescence and flow cytometry. The essential reagents are fluorescent-dye conjugated antibodies specific for individual cell surface molecules; that is, after interaction with these reagents, only particular cells acquire a fluorescent label. The cells are then passed across a laser beam, one at a time in a stream, and their fluorescence intensity is measured. In fluorescence-activated cell sorting, the stream of cells is broken into droplets, and droplets containing particular types of cells are deflected and collected. Immunofluorescence may also be used to examine tissue sections under a microscope. The results of these tests are used to help diagnose a disease or to evaluate the effectiveness of a treatment. *See* IMMUNOASSAY; IMMUNOFLUORESCENCE.

Clinical microbiology

The adaptation of microbiological techniques to the study of the etiological agents of infectious disease. Some of the most significant scientific advances during the latter half of the nineteenth century and the first few decades of the twentieth century were in medical bacteriology. From the work of Louis Pasteur, Robert Koch, Theobald Smith, and others, it was shown that bacteria were responsible for many diseases of humans. During the early part of the twentieth century, the technology for the growth of bacteria was advanced to the extent that pure cultures of bacteria could be studied from defined environments. Not only did bacteria become models for the study of their own biochemical characteristics, but the same technology enabled bacteriologists to isolate and identify bacteria from patients with infectious disease. This spurred the discovery of most of the bacterial diseases that are currently known.

The role of fungi, protozoa, rickettsias, and viruses in human disease was also elucidated during the first half of the twentieth century. The inhibitory power of materials from a fungus called *Penicillium* was discovered in 1928 by Alexander Fleming. His discovery of penicillin and the contributions of many others marked a great era in the treatment of bacterial diseases. The discovery of penicillin was soon followed by that of streptomycin and tetracycline.

For the first time, bacteriologists could detect and identify bacteria and then test in the laboratory the ability of various antibiotics to kill these isolated bacteria. Such was the birth of contemporary clinical microbiology. *See* ANTIBIOTIC.

Clinical microbiologists determine the nature of infectious disease and test the ability of various antibiotics to inhibit or kill the isolated microorganisms. A contemporary clinical microbiologist is also responsible for a wide range of microscopic and cultural studies in mycology, parasitology, and virology. The consultative skill of the clinical microbiologist is sought by many clinicians. The clinical microbiologist is often the most competent person available to determine the nature and extent of hospital-acquired infections, as well as public-health problems that affect both the hospital and the community. The clinical microbiologist is a valuable resource to the hospital and community. As clinical microbiology encompasses all aspects of infectious disease, the various specialties will be discussed individually. *See* EPIDEMIOLOGY; HOSPITAL INFECTIONS.

Bacteriology. Historically, the diagnosis of bacterial disease has been the primary job of clinical microbiology laboratories. Many of the common ailments of humans are bacterial in nature, such as streptococcal sore throat, diphtheria, and pneumococcal pneumonia. Only rarely, however, in recent decades have new bacterial diseases been described. A prime example is the disease legionellosis caused by a hitherto unknown bacterium, *Legionella pneumophila*. *See* LEGIONNAIRES' DISEASE.

The bacteriology laboratory plays a major role in the diagnosis of bacterial diseases. It accepts specimens of body fluids, such as sputum, urine, blood, and respiratory or genital secretions, and inoculates the specimens onto various solid and liquid growth media. Following incubation at body temperature, the microbiologist examines these agar plates and tubes and makes a determination as to the relative numbers of organisms growing from the specimen and their importance in the disease process. The microbiologist then identifies these alleged causes of disease and determines their pattern of antibiotic susceptibility to a few chosen agents.

Clinical microbiologists also microscopically examine these body fluids. They report on the presence of bacteria in body fluids and the cellular response to infection, such as the numbers of white blood cells observed in the specimen. Sometimes the kinds of white blood cells observed can provide hints for the identity of the disease. Such microscopic evaluations can provide a rapid aid in the diagnosis of infectious disease, as well as an assessment of the quality of the specimen. For example, a specimen called "pus" which does not contain white blood cells may not be pus. *See* MEDICAL BACTERIOLOGY.

Mycology. Mycology is the study of fungi. The applications of mycology in the clinical microbiology laboratory include the isolation of fungi which are known to cause disease. In general, diseases caused by fungi are relatively harmless but annoying, such as ringworm and athlete's foot. However, they can be severe, systemic disorders such as blastomycosis, coccidioidomycosis, and histoplasmosis. Fungi can also cause disease in those people whose immunologic processes have been suppressed by drugs or radiation. The diagnosis of fungal infection differs from bacterial infection because of the relatively slower rate of fungal growth. In general, diagnosis of fungal disease is a function of not only isolating and identifying the causative organism and determining which of three or four antifungal antibiotics might be effective, but also determining the patient's antibody response to the disease. *See* MEDICAL MYCOLOGY.

Parasitology. Parasitic diseases are widespread and of worldwide importance to humans. Such diseases include amebic dysentery, malaria, and Chagas' disease. The clinical microbiologist working in parasitology examines specimens of feces and blood for the presence of parasitic agents. These examinations are primarily microscopic, and the agents are identified on the basis of their characteristic structure. Although antiparasitic agents are available for the treatment of such infection, the parasitologist is usually not involved in the determination of the relative effectiveness of these agents on parasites. *See* MEDICAL PARASITOLOGY.

Virology. Virology is a specialized part of clinical microbiology. Because of the nature of viruses and their proclivity for growth only in living cell cultures or in eggs, few clinical microbiology laboratories have facilities for the isolation and identification of viruses. Most of these procedures are best done in large hospitals or in state departments of health. There is a growing trend, however, for smaller hospitals to develop screening virology laboratories in which specimens are brought to the laboratory, placed in tissue culture, and preliminary identification steps taken in order to provide a rapid diagnosis of viral disease. Although only a few drugs exist that can be used to treat virus infections, the early recognition of viral disease may allow the clinician to discontinue the use of powerful antibiotics that are effective only for bacterial diseases. Common virus diseases include influenza, herpes, chicken pox, the common cold, and many nonspecific respiratory infections. Much of the viral diagnosis that is done in the laboratory is by the determination of a specific antibody response to viral disease. The routine clinical microbiology laboratory usually does not become involved in such procedures. A special procedure for the detection of viruses and other organisms that affect infants is called the TORCH screen. It is a procedure for the detection of antibodies to the parasitic disease toxoplasmosis and the viral diseases rubella, cytomegalovirus, and herpes. These diseases may cause devastating health problems in babies. *See* ANIMAL VIRUS; DISEASE; TISSUE CULTURE; VIRUS.

Richard C. Tilton

Technology. While direct microscopy and culture continue to be methodological mainstays in diagnostic microbiology laboratories, the nonculture methods are growing in the variety of applications and the sophistication of the technology.

Antibodies. Polyclonal antibodies raised in animals such as mice, sheep, goats, and rabbits, and monoclonal antibodies produced by hybridization technology are used to detect bacteria, fungi, parasites, or virus-infected cells by using direct or indirect fluorescent techniques. Additional methods include latex agglutination tests to detect particulate antigens and enzyme immunoassays to detect soluble antigens. Some of these technologies can also be used to detect antibodies rather than antigens, usually using the antigen to capture antibody that is in serum. *See* IMMUNOASSAY; MONOCLONAL ANTIBODIES.

Instrumentation. Instrumentation for identification of bacteria and yeastlike fungi and for antimicrobial susceptibility testing includes a variety of technologies. The systems use either microtiter plates or plastic cards containing dried or frozen substrates or antimicrobial agents. A known concentration of the organism to be tested is introduced into the wells, and the plate is incubated until the instrument reader detects sufficient growth. The pattern of growth and reactivity is compared to patterns of known organisms. The likelihood that the test organism is one of them is reported from information maintained in a database. Because urinary tract infections in outpatients are usually caused by a single organism, some of these systems can be directly inoculated with urine. Generally, however, a pure culture must first be obtained by overnight incubation of inoculated agar plates.

Nonamplified hybridization. Probes for deoxyribonucleic acid (DNA) or messenger ribonucleic acid (mRNA) are available for various applications. There are two advantages in testing for mRNA. (1) It is present only if the gene it represents is expressed (contributing to the phenotypic characteristics of the organism). (2) If the gene is expressed, there will be multiple copies of the mRNA, thus increasing the analytical sensitivity of the test. A drawback is that ubiquitous ribonucleases can render a false negative test. Probes are used for direct detection of organisms in clinical material and for culture confirmation.

Amplification. Further increases in analytical sensitivity have been achieved by nucleic acid amplification techniques. Several methods are currently available to clinical laboratories.

In polymerase chain reaction (PCR), double-stranded DNA is denatured; oligonucleotide probes bind to homologous strands of single-stranded DNA, and the enzyme polymerase extends the probes using deoxyribonucleotides in the milieu. Over 30 cycles, the number of copies increases a millionfold. This product is then detected.

In ligase chain reaction (LCR), the enzyme ligase can fill the 3-nucleotide gap between two probes that attach to homologous, target, single-stranded DNA. By cycling in a manner similar to PCR, a million joined copies can be generated in a short period of time, after which they are detected.

In nucleic acid sequence–based amplification (NASBA), reverse transcriptase is used to make double-stranded complementary DNA (cDNA) and the target RNA is digested by ribonuclease H. Another enzyme, T_7 polymerase, is used to make more RNA target from which more cDNA is made.

Molecular typing. Analysis of lipopolysaccharides and proteins by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) and cellular fatty acid analysis by gas-liquid chromatography have given way to nucleic acid–based methods. Restriction enzymes, which cut DNA at a constant position within a specific recognition site usually composed of four to six base pairs, are used to cut chromosomal DNA; the resulting fragments are compared by pulse field gel electrophoresis (PFGE) or ribotyping. Electrophoresis of isolated plasmid DNA is another method for comparing organisms. DNA sequencing can also compare segments of the DNA of organisms from the same genus and species.

Chip arrays. DNA chip or microarray technology is expected to have a greater effect on medicine than either DNA sequencing or PCR. Over 30,000 small cDNA clones of expressed fragments of individual genes (expressed sequence tags, or ESTs) are spotted onto a thumbnail-sized glass chip. Fluorescein-labeled genomic or cDNA from the sample being evaluated is passed over the chip to allow hybridization. A laser measures the fluorescent emissions and a computer analyzes the data. As an example, relevant cDNA fragments from the bacteria, viruses, and protozoa that are known to cause diarrhea or dysentery could be placed on one chip and a stool specimen could be analyzed for all known pathogens at one time. Genes coding for known antimicrobial resistance mechanisms could also be represented so that an appropriate therapeutic agent could be prescribed. *See* CLINICAL PATHOLOGY. Carol A. Spiegel

Clinical pathology

The discipline in which disease processes are assessed and monitored by the examination of blood, body fluids, secretions, and aspirated specimens. The detection of chemical, morphological, microbiological, and immunological abnormalities in this material is reported as laboratory results. In contrast, anatomical pathology is that branch of pathology dealing with the nature of a disease process through studying the gross and microscopic features of tissues and fluids removed either at postmortem examination (autopsy) or during surgery. However, divisions between anatomical and clinical pathology are somewhat artificial and largely embedded in how pathology evolved in academic practice. Information derived from autopsy examinations, surgical specimens, or clinical laboratory testing provides physicians with the means to confirm a final diagnosis and to evaluate nonsurgical conditions. Such information is used by physicians in diagnosis and in therapy management.

History and Laboratory Administration

Early clinical pathology laboratories were simple, often confined to a single room (**Fig. 1**). A limited number of tests were performed by hand, with visual observation of color changes or turbidity. Microscopes, often monocular, were used primarily to identify abnormal cells in stained smears or blood films, inflammatory cells and atypical crystals in urinary sediment, or foreign particles such as bacteria in direct mounts of clinical specimens. A group of biochemists, working primarily in hospitals in Boston and New York before the outbreak of World War I, soon recognized that quantitative results must be derived from clinical laboratory tests to detect and monitor underlying diseases. Crude instruments such as manometers to measure blood gases, colorimeters to quantify chemical reactions, and fluorometers on which levels of blood electrolytes could be quantified were introduced between the two world wars. During this time, all reagent samples and reagents were dispersed using mouth pipetting, and it was not uncommon to observe lit cigarettes and open caches of food on the workbench, practices that later were strictly forbidden.

Clinical pathology laboratory testing experienced its first transition following WWII. From the late 1950s into the early 1960s, the number of new tests introduced into clinical laboratories multiplied logarithmically, accompanied by ever-increasing sophistication of instrumentation and advances in laboratory organization and administration. A number of new self-operating analytical systems were introduced to replace the laborious and time-consuming hand-operated processes characteristic of early laboratories. Through the advancement of technology, new tests, new procedures, and new reporting systems were made accessible to medical practitioners and their patients. On the other hand, the massive numbers and complexity of tests also placed burdens on those who use this information in patient care. How to determine which tests meet the standards for evidence-based medicine is an ongoing challenge. Testing was made more creditable by instrument testing. The subjective testing by multiple technologists could be standardized to better inform practicing physicians.

In keeping with the continuing increase in the number of laboratory tests and the complexity resulting from the introduction of automation and molecular techniques, nontechnical matters of the organization, administration, and staffing of clinical pathology laboratories has changed dramatically as well. Typically, a laboratory director must oversee the overall operation of the laboratory and relate to physicians and other medical personnel in choosing appropriate diagnostic tests, interpreting laboratory data, and monitoring therapeutic responses. The director also assumes many administrative duties relating to hospital settings and financial affairs. The day-to-day analysis and quality control of test procedures, the review of the accuracy and precision of test results, and the supervision of laboratory personnel are the several activities commonly carried out by clinical scientists and medical technologists with advanced degrees. Materials obtained from patients are commonly assayed by highly trained laboratory scientists and medical technologists. Laboratory assistants and clerical personnel assist in processing specimens and in transcribing, recording, and logging in laboratory test results. Although computer-based

Fig. 1. Clinical pathology laboratory at Christus Santa Rosa Hospital, San Antonio, Texas, 1923.

laboratory information systems are now indispensable, intervention by laboratory personnel is critical to ensure that samples are procured from the correct patient at the correct time and delivered to the correct section in the laboratory.

Role in patient care. Clinical pathology laboratories function as an integral part of the diagnostic cycle beginning as an individual with signs and symptoms suggestive of disease consults a physician.

Specimen collection and processing. After obtaining a clinical history and examining the patient, a physician may order laboratory studies on blood, urine, other body fluids and secretions, or tissue biopsies to establish or confirm a working diagnosis. Specific protocols are followed in the preparation of the patient and in the techniques in collecting a specimen. Specimen collection must be made into a proper container with preservatives or anticoagulants appropriate to the test being requested. Particular attention to proper packaging of the specimen is critical, especially if the delivery time is delayed by transport through long distances.

A visual and/or microscopic examination may be the first evaluation of specimen quality. If unsatisfactory (not meeting a variety of predetermined criteria), particularly misidentifications, the specimen may be rejected with a request for repeat collection. Patient information and test requests are bar-coded into the laboratory information system. The processing and analysis stages follow.

Processing may require centrifugation to separate the cells if the test requested requires an analysis of plasma or serum. Commercially prepared reagent systems and automated or nonautomated electronic instruments have replaced manual testing. Using direct-read instruments and/or special chemical and immunological reagent packages, test results may be obtained within a few minutes. In highly automated laboratories, test results may be transferred directly from the instrument into the hospital computer system, providing clinicians with direct access to results from terminals present on the wards.

Point-of-care testing. On-site or point-of-care laboratory testing has evolved as an alternative testing arrangement to meet the increasing demand for rapid turnaround time of certain test results. Emergency rooms, outpatient clinics, and physician offices, as well as select special-care hospital settings, are particularly served. Rapid-response read-out devices, packaged reaction cassettes that include positive and negative controls, and reagents to perform a variety of "spot" tests are currently available. The license to perform an increasing variety of simple or "waived" tests has been afforded through regulations provided under the Clinical Laboratory Improvement Amendment of 1988 (CLIA-1988).

The menu of waived point-of-care laboratory procedures provides for the immediate assessment of a number of diseases and conditions. Methods for enumerating blood cells, performing a urinalysis, measuring abnormal levels of chemical constituents such as glucose and cholesterol, determining early pregnancy, and detecting several bacterial and viral infections are currently available. Many of these tests can be performed on a small quantity of blood, 25–50 microliters obtained by a simple finger stick precluding the need for a vena puncture. Again, each of these areas of point-of-care testing must be carefully monitored for accuracy and reproducibility of test results under strict administrative supervision and careful quality control. When all such parameters are in place, the availability of test results within 5 min or less provides for the immediate implementation of an appropriate therapeutic regimen.

Quality control. The clinical laboratory generates data that are converted into information that the physician may use to supplement his clinical knowledge of the patient. Laboratory directors and personnel are obligated to have in place systems of quality maintenance for all of its practices in supplying laboratory test information. Established testing standards must be applied to the assay. In practice, a control sample containing a known amount of the substance being tested is treated in exactly the same way as the patient sample.

This known sample interjection concept of quality control was developed from industrial models used in the 1950s. Included within the run of each batch of specimens is a pair of control samples that contain a known concentration of analyte, commonly set at both high- and a low-level readings. The control results must come within a fixed standard deviation before the specimen results can be approved. Thus, observing a drift in the results of the control samples provides a means to detect reagent deterioration, operator errors, or technical problems that may have occurred during analysis. All specimen test results must be checked against the quality control results before a report is issued. Each analytical instrument must be calibrated and paced through test runs, and all storage compartments and heat-controlled devices must be checked daily for temperature maintenance. All quality control data must be posted on daily log charts that are clearly visible and in usable formats.

Laboratory inspection and accreditation. The College of American Pathologists (CAP) in 1961 launched a laboratory inspection program focused initially on hospital laboratories. Standards were developed for technical performance. Meeting these standards, directed toward continuous improvement of laboratory testing in health care, is rewarded by accreditation. The thrust of the quality-improvement efforts remains educational, and the inspections currently are carried out by volunteer pathologists, Ph.D. scientists, and medical technologists. Through collaborative efforts of the CAP with regulatory agencies, such as the state public heath departments, the FDA, the American Association of Blood Banks, the American Association of Clinical Chemists, and the Joint Commission on Hospital Accreditation, among others, a highly sophisticated and integrated system of ongoing laboratory surveillance and regulation has evolved, leading to high-quality performance.

Proficiency standards are monitored by requiring participating laboratories to analyze, in 3- or 4-month cycles, a set of proficiency test samples that are indistinguishable from those obtained from a patient. The analytical results derived from these proficiency samples are then surveyed by independent observers. When aberrations are spotted, corrective actions must be immediately put in place.

Evidence-based medicine. Resource constraints combined with demands by physicians and the public to have the best evidence about medical testing have led to new approaches to medicine in the clinical laboratory. Clinical epidemiology, also known as evidence-based medicine, has grown in importance as an approach to medical treatment as well as testing and diagnosis. Evidence-based medicine focuses on objective measurements of diagnostic and prognostic accuracy and therapeutic effectiveness, and the implementation of best practices based upon those measurements.

Clinical Laboratory Subsections

Evolution of laboratory testing and its complexities has directed the laboratory's functioning into separate sections and disciplines. Although this division varies from laboratory to laboratory, the following sections and subsections are common:

- Chemical pathology
  - General chemistry
  - Spirometry (measurement of lung breathing capacity and blood gases)
  - Toxicology, in particular the monitoring of drugs of abuse
  - Radiometry (measuring minute amounts of radiant energy) and enzyme immunoassay (determination of binding between antigens and antibodies)
  - Medical microscopy/urinalysis
  - Electrophoresis
- Hematology
  - Morphologic hematology, involving glass-slide preparation and microscopy
  - Chemical hematology for the detection of hemoglobinopathies
  - Blood clotting and dissolution (fibrinolysis)
  - Flow cytometry (fluorescence microscopics) for the determination of cell markers
- Immunohematology
  - Transfusion medicine (blood bank)
  - Donor recruitment and service
  - Transfusion preparations (cross matching)
  - Component separation (red cells, white cells, platelets, plasma)
  - Plasmapheresis (separating out directly from the patient certain blood components)
- Microbiology
  - General aerobic bacteriology
  - Anaerobic bacteriology: bacteria that grow only in the absence of oxygen
  - Mycobacteriology: the agents of tuberculosis
  - Mycology: the agents of fungal infections
  - Parasitology: the animal parasites causing disease in humans
  - Virology: minute microorganisms having only a core of nucleic acid and a protein envelope
  - Immunology and serology: the diagnosis of disease by detection of antigens and antibodies
  - Antimicrobial susceptibility testing: determination of the best drug to use in the treatment of infections

Chemical pathology. Chemical pathology, also known as clinical chemistry or clinical biochemistry, encompasses determination of the presence or quantity of chemicals present in blood, serum, plasma, urine, cerebrospinal fluid, or other body fluids.

The age of automation, which has become so much a part of the modern chemical pathology laboratory, began in the late 1950s with the Technicon Autoanalyzer, possessing the following features:

1. A pipetting robot that procured small volumes of sample from tiny cups placed in a rotating carousel.
2. Streams of liquid passed through a series of plastic tubes connected to reagent baths.
3. A peristaltic proportioning pump under which the reagent tubes passed, propelling a measured amount of sample and reagents in air-segmented aliquots, coming together in a mixing coil housed in a constant-temperature water bath.
4. A photometric flow-through cell through which a light beam passed, producing proportional electrical currents from a photovoltaic cell that activated a recording needle that traced quantitative peak-and-valley line grafts on a roll of moving paper.

Upon this foundation has evolved ever-increasing innovations in robotic, electronic, and computer-based technology. Automated instruments now find service in several subsections of the chemical laboratory: blood gas analysis, toxicology and therapeutic drug monitoring, core chemistry, immunoassay, electrophoresis, and urinalysis. The ultimate extension of this technology is the sequential "streaming" of instruments currently utilized in larger reference laboratories, where the specimen is advanced along an automatic hands-off treadmill assembly, passing through a series of stations including centrifugation, sampling, analysis, and computer-based reporting (**Fig. 2**).

Core chemistry. In the core chemistry section of the laboratory are evaluated many different chemicals in blood samples, including electrolytes such as sodium, potassium, calcium, and chloride ions. Quick measurement of these ions often permits doctors to avoid delays in making accurate diagnostic decisions. Other important molecules are also quantified in this laboratory section; for example, creatinine and urea nitrogen are widely employed to evaluate kidney function.

Blood gas analysis. The blood gas analysis section is found in almost all chemical pathology laboratories. Included among the chemicals analyzed are gases that are dissolved or bound to other molecules, ions,

Fig. 2. Overview of a 2005 automated chemical analysis system. Specimen racks are placed on a movable track that moves sequentially through sampling, read-out, and reporting stations in the course of multitest analyses.

small metabolic molecules, and proteins. Establishing the blood pH as well as the quantity of oxygen and carbon dioxide permits physicians to determine rapidly the acid–base status of patients. From these test results a quick diagnosis may be made on patients with drug poisoning, kidney malfunction, and diabetic ketoacidosis—an acute illness in some diabetics.

Toxicology. In the toxicology and therapeutic drug monitoring sections of the laboratory, suspected patient overdose and poisoning are investigated through the analysis of blood, urine, or other samples for the presence of drugs or drug metabolites. Early identification of the cause of patient overdose permits physicians to begin therapy quickly and often makes the difference in patient outcome. Medication drug levels are also evaluated in this section of the laboratory. Physicians are thus able to tailor the medication and dosage to provide the best therapy for patients. *See* TOXICOLOGY.

Immunochemistry. Larger molecules such as proteins are often measured using immunoassays in the immunochemistry section. Immunoassays use antibodies to detect and quantify the specific antibody target. For example, ferritin, a molecule used to evaluate iron deficiency, is typically measured using antiferritin antibodies. Patient antibodies directed against viruses or bacteria such as hepatitis C, human immunodeficiency virus (HIV), cytomegalovirus, and *Helicobacter pylori* are measured in this section of the laboratory. *See* IMMUNOCHEMISTRY.

Electrophoresis. Electrophoresis is the process through which large molecules are separated by exposing them to an electric field through a solid porous medium, such as agarose or polyacrylamide. Such separation can be visualized with certain dyes and evaluated either visually or by instrument densitometry. Serum protein electrophoresis (SPEP) allows pathologists to identify patterns to detect or monitor patients with multiple myeloma. Electrophoresis is also commonly used to assay urine (urine protein electrophoresis, UPEP) and cerebrospinal fluid. The diagnosis of multiple sclerosis is supported by certain findings seen after the electrophoresis of cerebrospinal fluid. *See* ELECTROPHORESIS.

Urinalysis. The urinalysis section of the laboratory is dedicated to measuring chemicals present in urine as well as the microscopic analysis of solid-formed elements in the urine. Such formed elements include red blood cells, white blood cells, crystals, casts, and bacteria. For example, abnormalities detected in the urinalysis laboratory are often some of the earliest signs of kidney failure. *See* URINALYSIS.

Hematology. Blood is an easily accessible source of human material for analysis. Several blood cell types circulate in the serum and become available for study after blood is drawn (phlebotomy) from a patient's vein or artery.

Microscopy. Blood cells may be scrutinized directly by smearing a drop of blood on a glass slide, applying a stain, and examining the cells under the

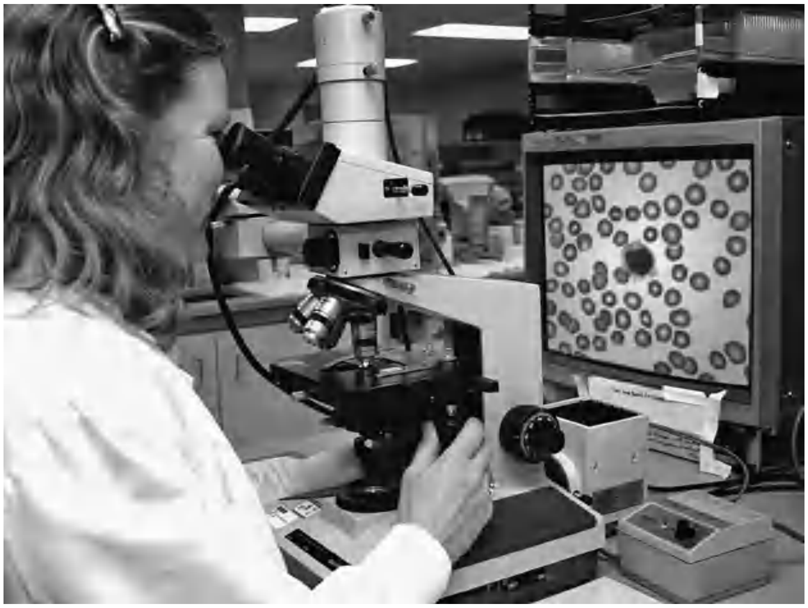

Fig. 3. Microscopic examination of a stained peripheral blood smear. The field of view used for cell identification observed by the microscopist is projected on the monitor screen located behind the microscope.

microscope. Valuable information is there before the eyes of the microscopist, and key observations may point immediately to a diagnosis or direct the physician to additional testing (**Fig. 3**). *See* MICROSCOPE.

Automatic counting. Examinations of the blood are facilitated by the use of automated counting instruments. Among these is the Coulter Counter, introduced in the 1960s. The major features of its operation include:

1. The aspiration of a small sample of blood by negative vacuum pressure into a fine-bore tube that channels the test specimen into the reading chamber of the instrument.
2. The tube is of such small diameter that the individual blood cells are partitioned out in single file.
3. Each cell in turn passes through a reading device, by which its diameter, color, nuclear density, and light transmission properties are measured.
4. This information is electronically captured to produce a multidot graph called a histogram by which the several cell types can be separated and enumerated.
5. Either red cell or differential white cell counts can be automatically generated depending on how the sample was processed before aspiration into the instrument.

Thus, cellular components are separated into red cells (blood), white cells (granulocytes, lymphocytes, and monocytes), and platelets. These different cell types are categorized and sorted electronically, resulting in computer-generated reports. Problems in relationship of cells or cells out of the range of size, shape, and content are flagged for review by the technologist or hematologist. An extension of this technology is the three-part and five-part automated differential counters by which the percentage of these white cells is displayed and printed out on a multicolored histogram, eliminating manual cell counting.

Molecular targeting. As with most testing procedures in the clinical laboratory, technology in hematology has advanced far beyond the counting and visual categorization of cells. Rapid developments in genomics and proteomics, as applied to hematologic disorders, have supplanted the simple hands-on, glass-slide examination of blood cells and test-tube shaking for the observation of clotting, practices that now have limited usefulness in defining a clinical problem. Basic knowledge in molecular and cellular biology, molecular immunology, and genetics have been translated into specific diagnostic and therapeutic testing methods. In further similar developments, clinicians look forward to these same reactions of specific molecular targeting for therapy of hematologic and coagulation disorders. *See* BLOOD; HEMATOLOGIC DISORDERS.

Flow cytometry. In a sense, flow cytometers are specialized fluorescence microscopes attached to a computer that translates signals to data. Specific bands of fluorescence are measured through a series of optic beam splitters and filters, as a flow of single cells passes through a light source. Through this method cells, such as blood cells, are analyzed and sorted. Physical characteristics of cells such as size, shape, and internal complexity can be measured. Any component or fraction that can be detectable by fluorescence is opened for examination. Fluorescence technology with high speeds (1000 cells per second or more) combined with the capability of correlating quantitative dots from simultaneous measurements on each cell has led to widespread use in the biological and medical fields.

In medicine, flow cytometry is used to identify lymphocyte subsets in conditions of immunodeficiency, and in immunophenotyping for leukemia and lymphoma. One common use is immunophenotyping of peripheral blood, lymph node, and bone marrow samples to establish the presence of clonality or leukemia. A wide range of cell surface antigens are present on hematopoetic cells. Flow cytometry is geared to their identification and allows the sorting of these cells into normal or abnormal expression patterns. *See* LEUKEMIA.

Microbiology. The implementation of automation in the clinical microbiology laboratory progressed more slowly than in other sections of the clinical laboratory. The tried and true conventional culture recovery methods of Robert Koch and making bacterial identifications by visually observing color reactions in reaction tubes are still used to varying degrees. As a prelude to automation, several laboratory supply companies introduced packaged kits in the 1960s, in which a series of dehydrated biochemical substrates were contained within miniaturized cupules embedded in a plastic strip. First was the Roche Enterotube, a pencil-shaped plastic tube containing 12 chambers with slants of differential culture media. Then followed the API 20E strip, containing 20 cupules containing dehydrated substrates, which is still used today. The color reactions within the reagent chambers of each of these systems is read visually, from which a biocode number linked to a bacterial identification is derived. *See* MEDICAL BACTERIOLOGY.

Automated bacterial identification. The impetus for the automation of bacterial identifications came in the mid-1970s as part of the NASA space program. The challenge was to design a small instrument that would be capable of identifying bacterial species encountered in space flights, particularly from environmental samples collected from the Moon. The outcome was the AMS bacterial identification system, since marketed under the name VITEK® (bioMerieux, Inc). The key feature of this system is a multiwell reagent card that, after inoculation of a bacterial suspension, is inserted into the incubation chamber of the instrument. The results of 30 biochemical reactions are provided by the instrument, available as soon as 4 h for biochemically active bacterial species. Competitive systems are also available for use in microbiology laboratories. Each of these widely used systems also has cards for the determination of antimicrobial susceptibility test results, replacing in many laboratories the time-honored method of measuring the zones of inhibition surrounding antibiotic-impregnated filter paper disks (**Fig. 4**).

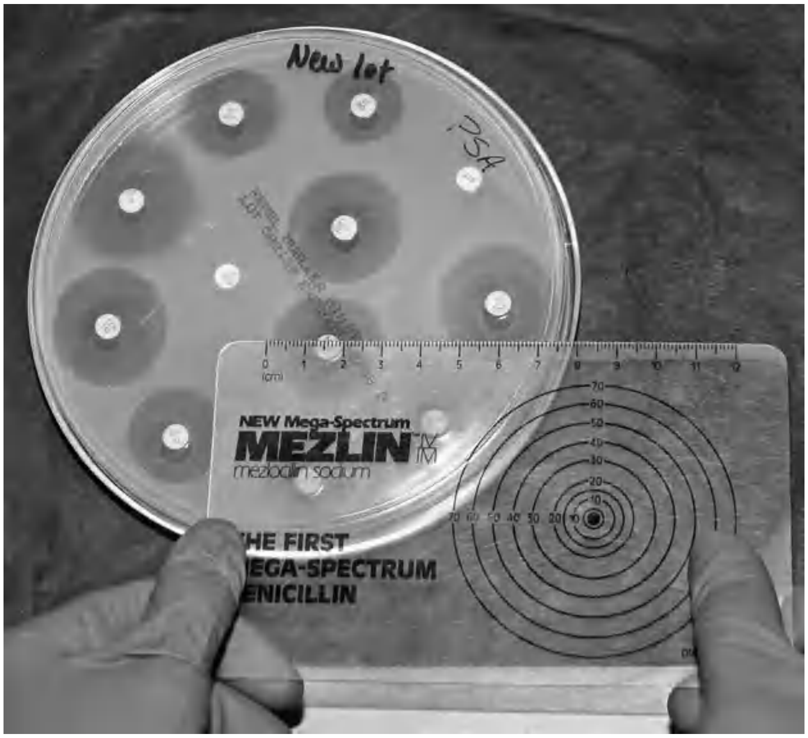

Fig. 4. Disk diffusion antimicrobial susceptibility plate illustrating assessment of antibiotic action by measuring zones of inhibition surrounding antibiotic-impregnated filter paper disks.

Continuous-read blood culture systems. The recent introduction of automated continuous-read blood culture systems has been a major breakthrough in providing the more timely detection of bloodborne infections. Previously, blood cultures were prepared by injecting a given volume of venous blood into bottles containing an enriched culture medium. The inoculated bottles were placed into a 35°C incubator. After 24–48 h of incubation, each bottle was visually observed against a strong transmitted light source for the detection of turbidity as a signal for bacterial growth. Subcultures were made of any turbid bottle to identify the organism.

In continuous-read systems, culture bottles are placed in a holding chamber within the instrument. Located in the bottom of each bottle is a pH-sensitive plastic disk that undergoes a color change when acid is produced by growing bacteria in the culture broth. As a threshold color change is achieved, the system automatically produces both a visual and an audio “alert.” The distinct advantage of this system, in addition to being more labor-saving, is the detection of positive blood cultures in as short a time as 4 h after collection.

Immunoassay. The introduction of immunoassays in the late 1960s has impacted in microbiology as well. Using a technology developed by the 1975 Nobel Prize winners George Köhler and César Milstein, monoclonal antibodies are now produced by hybridizing “immortal” antibody-secreting cancer cells (myeloma cells) from mice with a genetically equivalent cell producing a specific antibody. These specific antibodies can be used to detect the complementary antigens on bacterial cell walls, by which species identifications can often be directly made without the need for culture. Immunoassay can also be used to detect cell-surface antigens using monoclonal antibodies labeled with fluorescent dyes. Using this technology, more than 140 different antigens and adhesion molecules have been demonstrated on the surfaces of bacteria, white blood cells, platelets, and lymphocytes. *See* IMMUNOASSAY.

Blood banking and transfusion medicine. The blood bank and the transfusion service are sections of the laboratory dedicated to preparing, storing, and dispensing blood products as well as testing those who donate blood and those who will receive blood products. One hundred years ago, transfusions posed a significant risk to both the donor and recipient. Advances in laboratory testing for blood antigens and infectious disease has made the blood supply and the transfusion process relatively safe. Blood products are critical for treating trauma patients in the emergency department, surgical patients in the operating room, and patients with bleeding or clotting disorders.

Processing of blood for transfusion begins with the blood donor. Most blood donors are individuals who voluntarily give about $^1/_2$ liter of blood in a procurement procedure lasting about 20–30 min. Other donors selectively donate platelets, plasma, or red blood cells, using apheresis technology, a process that typically requires between 45 and 90 min. Patient donors are screened for many infectious diseases to maximize the safety of the blood supply. After a donation, patient blood is processed into components such as platelet concentrate, fresh frozen plasma, red blood cell concentrate, or cryoprecipitate. These components are then stored at the appropriate temperature until used.

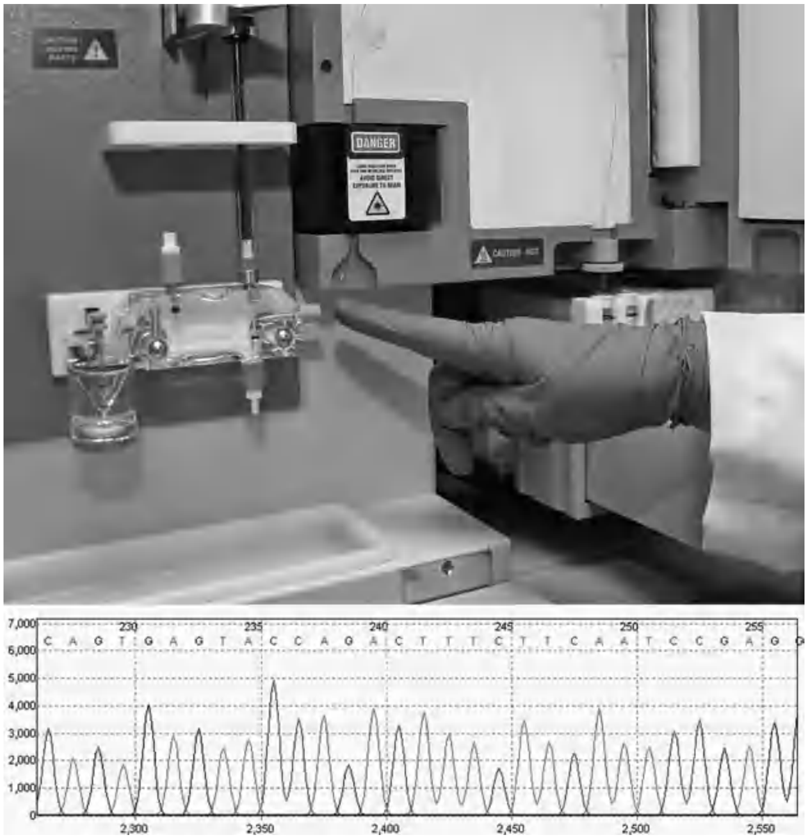

Fig. 5. Capillary electrophoresis is used for DNA sequencing. Data are processed by a computer which then converts the findings into a graphic display. This information is converted to identification of mutations, deletions, and insertions relating to human disease.

Prospective blood recipients are tested to determine their blood type and to detect the presence of antibodies and blood antigens. Using blood type and antibody screening information, blood products are selected that minimize the probability of any adverse transfusion reaction between donor and recipient blood. Many uses for blood products have evolved. For example, red blood cell concentrates are used to treat severe bleeding and anemia. Platelet concentrates are used to treat patients who are bleeding or at risk of bleeding due to lack of platelets. Fresh frozen plasma is used to replenish clotting factors in those with deficiencies or to avert severe bleeding.

The clinical pathologist is trained in blood banking and transfusion medicine and provides advice to other physicians about the best products to use in treating individual patients. In addition, the clinical pathologist oversees the collection of donor blood and the testing of recipients. The clinical pathologist also uses apheresis technology to treat patients. For example, apheresis is often employed to remove harmful antibodies or cells from patients with a wide variety of diseases such as Guillain-Barre syndrome or thrombotic thrombocytopenic purpura. *See* TRANSFUSION.

Recent Advances

A transition in the clinical pathology laboratory began in the early 1990s and is still progressing—the introduction of molecular biology and genetics.

Molecular and genetic biology. This technology, based on the direct amplification and analysis of DNA from a variety of biological cells, facilitates the diagnosis of diseases associated with defects and alterations in genes, including many hereditary diseases and cancers known to have a genetic association. These techniques have also allowed the direct and rapid identification of a variety of microorganisms that cause infectious diseases. For example, the detection of certain DNA sequences in *Mycobacterium tuberculosis*, the cause of tuberculosis, extracted directly either from infected body secretions or from bacterial cells recovered in culture, can lead to a diagnosis within hours, in contrast to the 2 to 3 weeks previously required. As part of forensic examinations, human beings, both alive and postmortem, can be identified based on direct molecular analysis of shed cells, aspirated body fluids, and/or autopsy specimens. The working parts of a nucleic acid sequencing instrument with the resultant printout of the graph depicting the peaks of the individual nucleotides are illustrated in **Fig. 5**. An analysis of the individual presence and sequence of these nucleotides provides information about gene defects and hereditary diseases. *See* DEOXYRIBONUCLEIC ACID (DNA); GENE.

Molecular pathology-laboratory. The molecular pathology laboratory is one of the newest additions to clinical laboratories. Its creation follows advances in molecular biology over the past 30 years such as the polymerase chain reaction, nucleic acid hybridization, and DNA sequencing. The term "molecular pathology" may be a bit misleading since all other laboratory areas also measure molecules in some form. The term, however, is reserved at present for the measurement of molecules using the most advanced technologies. Molecular pathology laboratories include tests for the detection of DNA fragments related to infectious disease, certain types of cancer, and genetic disease (**Fig. 6**).

Most cases of chlamydia and gonorrhea are diagnosed using nucleic acid testing for the organism responsible for each disease. Other organisms such as

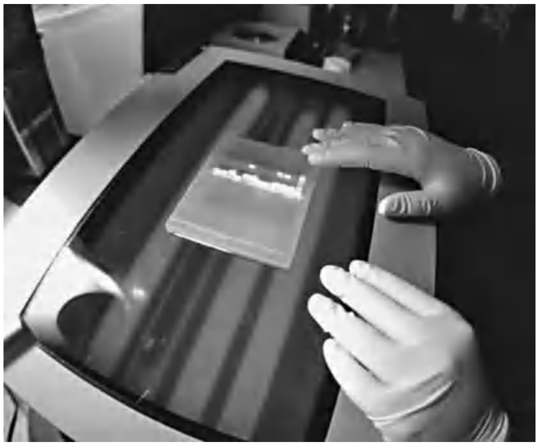

Fig. 6. Examination of an agarose gel with an ultraviolet light source to identify diagnostic fragments of DNA (orange-yellow fluorescent bands in the gel).

human papilloma virus (HPV) are also detected using DNA probes or polymerase chain reaction technology. In addition to detection of infectious diseases, treatment for patients with hepatitis C is monitored increasingly with viral load testing, in which the RNA from the virus is measured as treatment progresses. Patients with HIV infections are monitored the same way. In the workup of hematologic malignancies, the type of malignant cells can be detected by molecular analysis.

Molecular pathology techniques such as immunoglobulin and T-cell receptor gene rearrangements are often employed to help in the diagnosis of a specific type of leukemia or lymphoma. In addition, several types of cancer have characteristic chromosomal translocations. These translocations are usually detected using cytogenetics; however, in some cases DNA-based techniques are used to detect translocations of chromosomal material.

In addition to diagnosis and monitoring the therapy of infectious diseases and cancer, molecular pathology is often the only method by which genetic diseases may be detected prior to the development of symptoms. It is also the most powerful method for identifying patients who are carriers of genetic mutations. Several tests for genetic mutation analysis are commonly used for identifying Huntington's disease, factor V Leiden mutation, muscular dystrophy, and many other conditions. *See* HUMAN GENETICS; MUTATION.

The molecular pathology laboratory is likely to see expansion in both scale and scope. For example, methods to quickly measure large numbers of genes, messenger RNAs, proteins, and small metabolic molecules simultaneously have been developed. These advancements have led to the formation of several new disciplines: genomics, transcriptomics, proteomics, and metabolomics. The clinical pathologist as a laboratory physician becomes responsible for developing these sophisticated testing methods and interpreting results for other physicians.

Clock (mechanical)

A mechanical device for indicating the passage of time. Most clocks contain a means for producing a regularly recurring action, such as the swing of a pendulum, the oscillation of a spiral spring and balance wheel, the vibration of a tuning fork, the oscillation of a piezoelectric crystal, or the comparison of a high-frequency signal with the radiation from the hyperfine structure of the ground state of atoms. This article describes the refinements of mechanical clocks. *See* ATOMIC CLOCK; QUARTZ CLOCK; WATCH.

Basic movement. The recurring action of a mechanical clock depends on the swing of a pendulum, or the oscillation of a balance wheel and balance spring or hairspring, or the vibration of a tuning fork, mechanisms capable of repeating their cyclic movements with great regularity. A counting mechanism, consisting of a gear train with calibrated dial and indicating hands, sometimes with a striking mechanism, marks the number of oscillations that have occurred, although the graduations are in seconds, minutes, and hours. A weight or spring ordinarily supplies power to operate the oscillating and the counting mechanisms. However, temperature changes, accelerations, automatic windings, or electricity may provide the power. (The conventional electric clock is not an independent timepiece but is a repeater whose accuracy depends on a remote primary clock.) Usually an escapement transmits power from the counting mechanism to the oscillating mechanism. The accuracy of a clock depends primarily on the escapement.

Escapements. Figure 1 depicts an anchor or recoil escapement. Anchor A is connected loosely to the pendulum and swings about C. At some time after midswing, a tooth of the wheel escapes from pallet P_1 or P_2, giving the pallet a push to maintain oscillation. The other pallet then checks another tooth, the curve of the pallet forcing the wheel slightly backward. The reaction helps to reverse the pendulum swing and to correct for circular error.

Figure 2 shows a deadbeat escapement. Faces F are circles about C so that the wheel is stationary

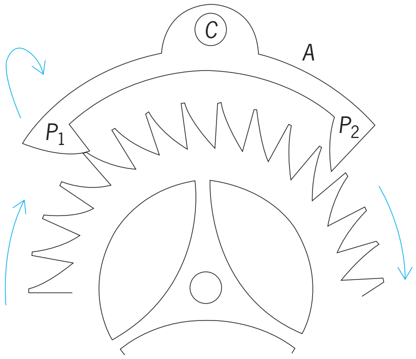

Fig. 1. Anchor escapement. Common in domestic pendulum clocks, this escapement tends to compensate for changes in amplitude of the swing because of irregularly cut gears and varying lubrication.

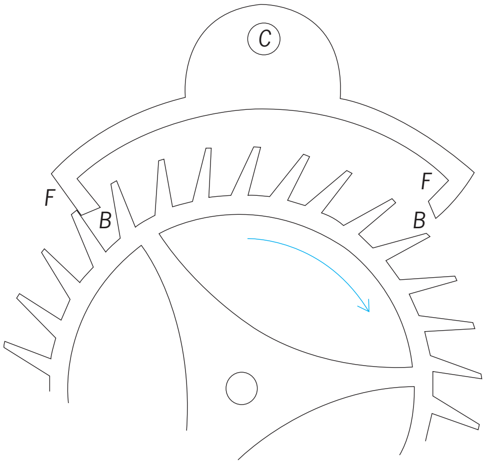

Fig. 2. Deadbeat escapement. Although lacking the corrective feature of the recoil type, this escapement gives better performance if well made.

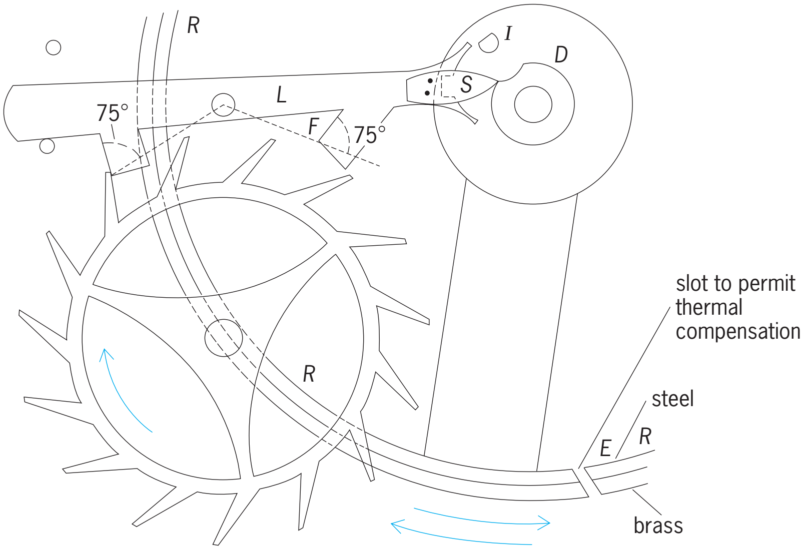

Fig. 3. Lever escapement. Used in good spring clocks and watches, it is detached from the balance wheel during most of a cycle, thus promoting accurate timekeeping.

except near midswing when a thrust on *B* allows a tooth to escape. **Figure 3** shows a lever escapement in which a balance wheel swings through a much larger angle than does a pendulum. Balance wheel and escapement are connected only while impulse pallet *I* is in a notch of lever *L*. As *I* enters a notch, it pushes the lever and then receives an impulse from it. Disk *D* and safety pallet *S* prevent the lever from moving accidentally before *I* returns; thus the mechanism tolerates appreciable vibration. The escapement pallets are similar to those of Fig. 2, but faces *F* are drawn or inclined so that the escape wheel moves slightly forward after each tooth locks; this motion pulls *S* clear of *D*, leaving the balance wheel completely detached. *See* ESCAPEMENT.

In the escapement of **Fig. 4**, the balance wheel is completely detached except for three brief action periods: (1) when pallet *P* presses detent *D* to unlock catch *L*, (2) when an impulse is being given to pallet *I*, and (3) when *P* lifts gold spring *G* on its return half swing. *See* CHRONOMETER.

Power supply. A weight gives uniform power, but a spring develops less force as it runs down. A fuzee by which a cord or chain is unwrapped from an increasing spiral on the first gear provides uniform force from a spring. Alternatively, there may be a remontoir with a small secondary spring driving the clock and being rewound frequently by the mainspring or by an electric motor.

Wind and snow apply large force to the hands of outdoor turret clocks. A gravity escapement isolates the pendulum from such forces. In this design, first used on the Great Westminster Clock (Big Ben), which has run since the mid-1800s with nearly chronometric accuracy, the escape wheel alternately lifts two weighted arms away from the pendulum as it swings out and releases them alternately against the pendulum as it swings back. The maintaining pushes come from the weighted arms rather than directly from the driving power.

Temperature compensation. The rate of a pendulum or balance wheel decreases if it expands with rising temperature. Expansion is counteracted by using two metals of different expansion coefficients. In a compensated balance wheel, rim *R* is of brass and steel fused together and cut (Fig. 3). Small screw weights added near free end *E* increase the effect; near the spoke they counteract it. Alternatively, the hairspring can be of an alloy that changes in stiffness with temperature.

Shortt clock. For still greater accuracy, in the Shortt or free-pendulum clock, a master pendulum is enclosed in an airtight and nearly evacuated case in a constant-temperature cellar. This pendulum swings freely for about 30 s until wheel *W* is released by electromagnet *E* and rolls along arm *A* attached to the pendulum rod (**Fig. 5**). Near the end of the swing, wheel *W* rides down slope *B*, giving the pendulum the slight impulse needed to maintain oscillation for another 30 s. In falling off, wheel *W* triggers the circuit and is reset by electromagnet *F*. The trigger

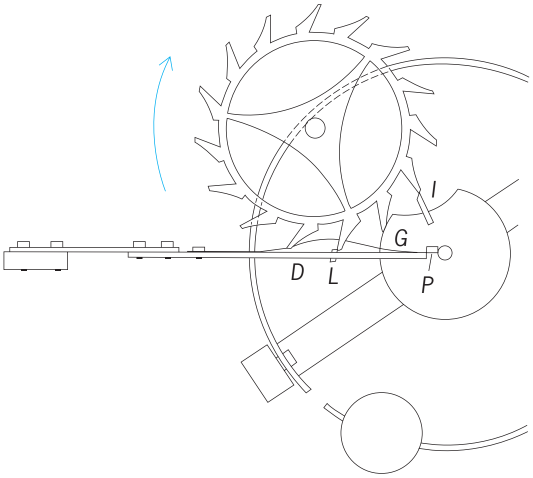

Fig. 4. Escapement used in ships' chronometers. It is sensitive to sudden movements but otherwise can keep within 1 s/day; pallets need no oil.

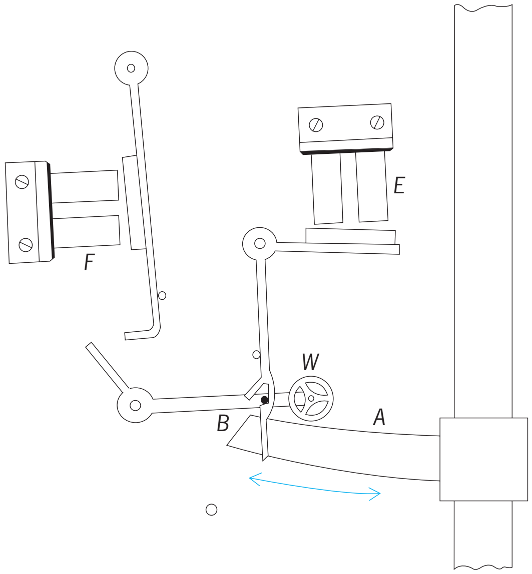

Fig. 5. Shortt free-pendulum clock. The master has only a pendulum and impulse giver; escapement and counting gears are in a separate slave clock (not shown).

pulse also serves as a synchronizing signal to a slave clock which is a complete clock with pendulum and indicating mechanism. If the slave is slow, the pulse accelerates one swing of its pendulum. *See* HOROLOGY; TIME.

Robert D'E. Atkinson

Tuning-fork mechanism. In the Accutron design the balance wheel and hairspring are replaced by a precision tuning fork which is driven with energy from a tiny battery. A permanent magnet and a surrounding magnetic cup are mounted on each tine of the tuning fork, which vibrates 360 times per second. Fixed coils of wire extend into the area between each magnet and cup, lying inside the magnetic field but not in contact with the moving parts of the tuning fork. Passing a current through one of these coils causes it to become an electromagnet which, depending on the polarities involved, will either repel or attract the corresponding magnet and cup assembly. Conversely, motion of the magnet and cup assembly within its electromagnetic coil causes a voltage to be induced, the polarity being determined by the direction of motion. This electromagnetic system serves three purposes: (1) It drives the tuning fork by converting electrical energy into mechanical impulses, (2) allows a determination of the tuning-fork amplitude by measuring the induced voltage, and (3) permits the accurate determination of the point within each tuning-fork cycle when the driving impulse should be applied. Conversion of the vibrational motion of the tuning fork to rotary motion is achieved by a simple ratchet and pawl mechanism.

Clock paradox

The phenomenon occurring in the special theory of relativity wherein two observers who start together with identical clocks and then undergo different motions can have different total elapsed time on their clocks when they rejoin later. This effect is a well-defined, mathematically consistent prediction of special relativity which has been verified by experiment but, historically, it has been referred to as a paradox because of erroneous reasoning in the manner in which the effect is commonly analyzed. The clock-paradox phenomenon arises because there is no notion of absolute simultaneity in the theory of special relativity.

The clock-paradox effect is illustrated by the following hypothetical example. (In the context of the example the effect usually is referred to as the twin paradox.) Two identical twins are separated as young adults. One of the twins remains on Earth and, for the purposes of the discussion, is assumed to undergo inertial motion. (In fact, in the context of general relativity, the twin on Earth would be viewed as accelerating—only freely falling observers would be viewed as inertial—but in this example the corrections made to the effect by performing a proper, general-relativistic analysis would be negligible.) The other twin is placed in a rocket ship which accelerates very rapidly away from Earth until it is receding from Earth at nearly the speed of light. After coasting for a while at this speed, the rocket ship turns around and accelerates very rapidly back toward Earth, so that it soon is traveling at nearly the speed of light. The rocket ship then lands on Earth and the twins rejoin. The twin on Earth is old (and everything else on Earth has aged considerably), but the twin in the rocket ship (and everything else therein) has barely aged at all.

Comparison of path lengths. To explain the nature of this prediction of special relativity and why it has been thought to be paradoxical, it is useful to consider the following elementary phenomenon in ordinary euclidean plane geometry, which is mathematically very closely related to the clock paradox. In particular, two points A and B (**Fig. 1***a*) and the straight line segment AB connecting these points are considered, as well as a third point C and the path ACB comprising the straight line segments AC and CB. Then, although both paths AB and ACB start at A and end at B, they have different total lengths. Indeed, in the simple case where C is equidistant from A and B, by the pythagorean theorem, the lengths of the two paths are related by Eq. (1), where L' denotes

$$L' = L\sqrt{1 + \left(\frac{2d}{L}\right)^2} \qquad (1)$$

the length of the path ACB, L denotes the length of AB, and d denotes the perpendicular distance of C from AB.

It is possible to use the following method to calculate the increased length of the path ACB given by Eq. (1). A series of closely spaced lines is drawn

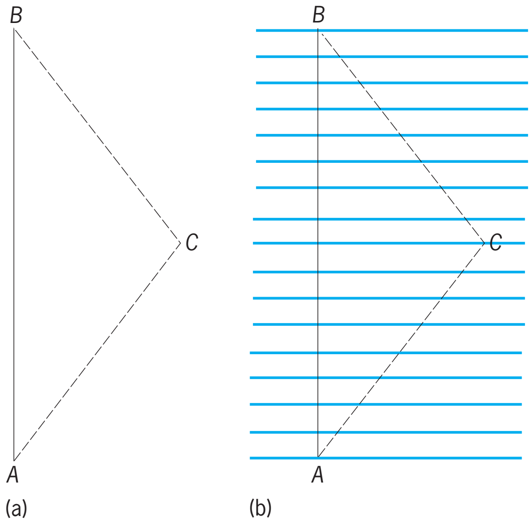

Fig. 1. Comparison of path lengths and elapsed times. (*a*) Straight line *AB* and broken straight line *ACB* connecting points *A* and *B* in euclidean plane geometry. This figure can also represent the world lines of an inertial observer and a "twin." (*b*) Method for comparing the lengths of *AB* and *ACB* in euclidean plane geometry. It can also be used to compare the elapsed time on clocks carried by an inertial observer and a "twin."

perpendicular to AB (Fig. 1*b*). An adjacent pair of such lines is considered, both of which intersect AC. Then it can be seen that the length of the portion of AC lying between these two lines is greater than the corresponding portion of AB by the factor $\sqrt{1+(2d/L)^2}$. The same result holds if two adjacent lines are considered which intersect CB rather than AC. However, the total length of AB can be obtained by summing the lengths of all of the portions of AB lying between adjacent perpendicular lines. By doing the sum, it is possible to correctly rederive the result that ACB is longer than AB by the factor $\sqrt{1+(2d/L)^2}$.

However, an apparent distance paradox arises from an attempt to redo this calculation as follows. A series of lines is drawn perpendicular to AC (**Fig. 2***a*).

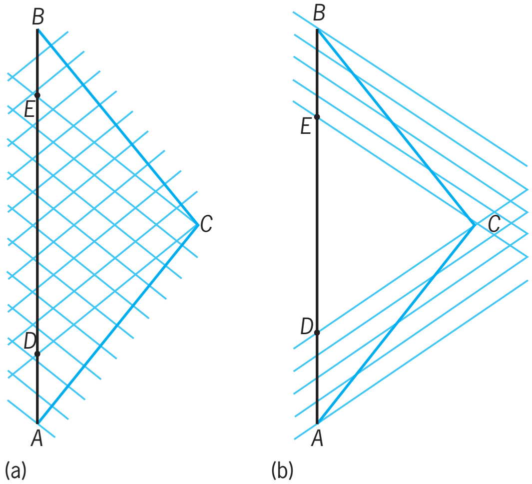

Fig. 2. Alternate methods for comparing (*a*) the lengths of *AB* and *ACB* in euclidean plane geometry, and (*b*) the elapsed times on the clocks carried by an inertial observer (world line *AB*) and a "twin" (world line *ACB*).

The portion of AC lying between adjacent lines now will be shorter than the corresponding portion of AB by the factor $\sqrt{1+(2d/L)^2}$. The same will be true for a similar calculation for the segment CB. Therefore, it might also seem possible to derive the manifestly false conclusion that the path ACB is shorter than the straight line AB by the factor $\sqrt{1+(2d/L)^2}$.

It is not difficult to spot the fallacy in this latter argument. When the series of lines is drawn perpendicular to CB, they will intersect the lines perpendicular to AC (Fig. 2*a*). As a consequence, this argument implicitly double counts a portion, DE, of AB. When a correction is made for this double counting, the correct conclusion that ACB is longer than AB by the factor $\sqrt{1+(2d/L)^2}$ is restored.

Comparison of elapsed times. The original diagram (Fig. 1*a*) may also be used to represent the twin-paradox phenomenon if it is now viewed as a space-time diagram with the vertical axis corresponding to time t and the horizontal axis corresponding to the spatial dimension x, so that "forward in time" corresponds to "upward" in the diagram. At event A, the twins separate, and the first twin undergoes inertial motion in space-time represented by the straight line AB. The segment AC represents the portion of the world line of the second twin while rapidly receding from the first twin, whereas CB represents the portion of the second twin's world line during the return. The comparison of the elapsed time T along the world line AB with the elapsed time T' along the world line ACB differs from the previous distance calculation only in that lorentzean geometry rather than euclidean geometry must be used in the analysis. Taking account of the sign change occurring in the lorentzean analog of the pythagorean theorem, the elapsed times are related by Eq. (2), where

$$T' = T\sqrt{1-\left(\frac{2d}{cT}\right)^2} = T\sqrt{1-\left(\frac{v}{c}\right)^2} \qquad (2)$$

$v = 2d/T$ is the magnitude of the relative velocity of the twins, and c is the velocity of light. In special relativity, the "straight line" (that is, inertial motion) AB has longer elapsed time than the motion represented by the world line ACB or, indeed, any other noninertial motion between A and B. *See* LORENTZ TRANSFORMATIONS.

The ratio of T' to T also can be calculated by the analog of the method of drawing lines perpendicular to AB (Fig. 1*b*), and this method correctly reproduces Eq. (2). There is also a calculation analogous to that of drawing lines perpendicular to AC and CB (Fig. 2*a*), where the lines are perpendicular to AC and CB in the lorentzean geometry of space-time (Fig. 2*b*). A careless use of this method yields the conclusion that T' is longer than T, resulting in the clock paradox. This paradox is easily resolved by noting that this method fails to count the portion DE of AB.

Experimental verification. The clock-paradox phenomenon has been observed directly in an experiment performed in 1971 by J. C. Hafele and R. E. Keating, who observed differences in elapsed times of atomically stabilized clocks flown in airplanes as compared with ones on the ground. In this experiment the special relativistic effect is so small, since the velocities achieved by airplanes are much smaller than *c*, that the tiny corrections due to general relativity cannot be neglected, so the experiment actually must be viewed as verifying the analogous clock effect in general relativity rather than purely the clock effect of special relativity described here. *See* RELATIVITY; SPACE-TIME.

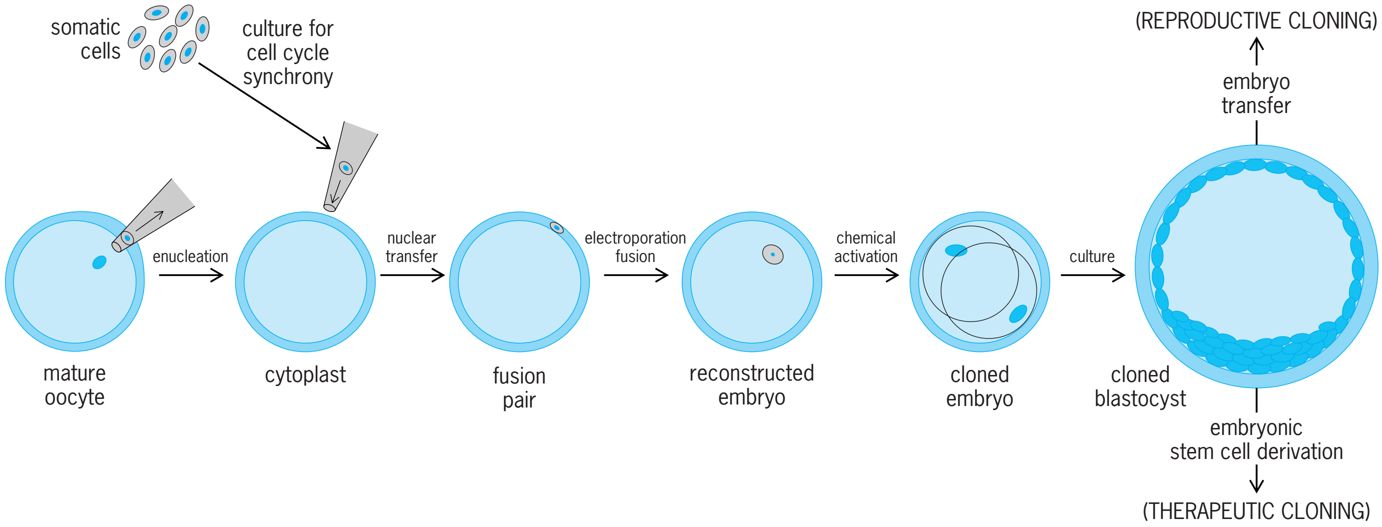
Cloning

The asexual creation of a genetic copy, a capability possessed by plants but not by most animals. Thus, plants generate genetic copies spontaneously, and rooting "cuttings" is widely used by horticulturists to propagate millions of clones annually. In animals, only some lower invertebrates can be cloned by "cutting"; for example, earthworms when bisected will regenerate the missing half, resulting in two whole, genetically identical individuals. However, asexual reproduction and cloning do not normally occur in vertebrates except for the special case of identical twinning. This is despite the fact that individual cells, called blastomeres, within the very early embryo are totipotent; that is, each is capable, if evaluated on its own, of developing into a viable term pregnancy and infant.

A major scientific interest in cloning revolves around the question of whether the hereditary material in the nucleus of each cell remains intact throughout development, regardless of the cell's fate. On a more practical level, the production of genetic copies of mammals could support the rapid improvement of livestock herds by propagation of valuable founder animals, the creation and production of disease models or transgenic animals for biomedical research, and the preservation of the genetic contribution of a particularly valuable animal, even after death. Therapeutic cloning, a variation that involves the isolation of embryonic stem cells, may provide new cell-based medical approaches to the treatment of human diseases or degenerative conditions.

Reproductive cloning. Scientific inquiry into reproductive cloning in animals began with a "fantastical experiment" suggested by Hans Spemann in 1938 that involved the insertion of a nucleus into an ovum bereft of its own genetic material. This experiment was eventually conducted in 1952 by Robert Briggs and Thomas King in an amphibian, the northern leopard frog, and the technology was quickly extended to a number of other lower vertebrates and invertebrates, and eventually to mammals. The first step in mammalian reproductive cloning is removal of the genetic material from an egg by micromanipulation to create an enucleated egg called a cytoplast. Then genetic material from a donor cell is added, in the form of an intact cell or an isolated nucleus, to produce a diploid, reconstructed embryo. The cell cycle of the nuclear donor cell may be temporarily slowed or stopped in advance of nuclear transfer. Development of the nuclear transfer embryo is triggered chemically, and the cloned embryo is subsequently transferred into a host mother in order to establish a pregnancy (see **illustration**).



Mammalian somatic cell cloning. The starting requirements include a cohort of mature fertile eggs and a nuclear donor source. Reproductive cloning in mammals involves the transfer of a nucleus or an entire donor cell into an enucleated egg or cytoplast, followed by the subsequent reprogramming of that nucleus by the egg, to the degree that the events of development are recapitulated in the cloned embryo. Therapeutic cloning is accomplished by conducting nuclear transfer with a nuclear donor cell derived from the patient, a skin fibroblast perhaps, transferred into a cytoplast. The resulting nuclear transfer embryo, after culture to the blastocyst stage, would then provide a source of inner-cell-mass cells from which an embryonic stem cell line could be derived.

When the nuclear donor cell originates from an embryo, the process is called embryonic cloning, first reported in cattle and sheep in 1986 and in primates in 1997. When the donor nucleus is derived from a fetus or a juvenile or adult animal and is not a germ cell, the process is called somatic cell cloning. This form of cloning was thought to be impossible in mammals even as recently as 1995, when scientists in Scotland cloned sheep from differentiating embryonic cells. In 1996, the birth of Dolly, a cloned sheep, was the first successful generation of a viable mammal derived from the transfer of an adult cell (a mammary gland cell).

Successful somatic cell cloning in other species (including the cow, mouse, goat, pig, rabbit, cat, horse, mule, and rat) quickly followed. A wide variety of somatic cells—even those that are unequivocally, terminally differentiated—have been used as nuclear donors. It now appears logical that cloning will be possible in all mammals, given an adequate opportunity to define the unique conditions required by each species.

While dramatic progress has been realized in somatic cell cloning, virtually nothing is known about how the process works, and significant limitations continue to undermine efforts to produce viable offspring. Thus, somatic cell cloning is characterized by high fetal and neonatal wastage, along with age-onset health problems (including obesity, hepatic and immune impairment, and premature death) in surviving clones. It is in fact amazing that somatic cell cloning works at all, given that over the course of normal development as a cell specializes, some genes are silenced temporarily or in some cases permanently. In order for the events of development to be accurately recapitulated following nuclear transfer of a differentiated cell, the donor nucleus must be reprogrammed so that it ceases to express genes of importance to a differentiated or somatic cell in favor of those important to a young embryonic cell; reprogramming is a responsibility of the cytoplast that must occur in a timely manner following nuclear transfer, perhaps along with dramatic remodeling of chromosomal architecture. In addition, nuclear reprogramming must ensure retention of the pattern of expression of imprinted genes, that is, those genes that are differentially expressed depending on their maternal or paternal origin. The inappropriate or abnormal expression of imprinted genes, as regulated by epigenetic changes (factors that alter the expression of genes rather than the genes themselves) such as DNA methylation, can impact placental development and fetal wastage.

Other possible explanations for the losses associated with somatic cell cloning are that clones age prematurely because the nuclear donor cells have shortened telomeres (chromosome tips) and because of heteroplasmy, the presence of more than one type of mitochondrial DNA in a cell. Since mitochondrial DNA is contributed by both the cytoplast and by the injection of a donor cell or nucleus preparation, clones are not exact genetic copies; indeed, they can be phenotypically quite different from one another. Fetal exposure to unique environments is another factor that results in phenotypic differences. *See* CELL DIFFERENTIATION; CELL DIVISION; GENE; SOMATIC CELL GENETICS.

Therapeutic cloning. In therapeutic cloning, embryos are produced by nuclear transfer, as in reproductive cloning, but with the intent of isolating embryonic stem cells rather than transferring cloned embryos into a host to produce a pregnancy. Embryonic stem cells are undifferentiated cells present in the embryo that are pluripotent; that is, they are capable of giving rise to all of the major cell lineages in the adult body but unable to generate a functioning organism. Adult stem cells exist and can be recovered in limited numbers from a host of different tissues or organs. They can, in theory, be used in cell-based therapies to treat human disease, but their low numbers and limited developmental potential are drawbacks. It is now clear that the pre-implantation-stage embryo contains a cohort of stem cells confined to the inner cell mass at the blastocyst stage, and these embryonic stem cells can be harvested, propagated, and established as permanent cell lines. These embryonic stem cells could be stored frozen until needed and then thawed and used directly for transplantation into the patient, or after their fate was directed into the desirable cell type in vitro by exposure to the appropriate chemical signals (see illustration).

Embryonic stem cells are the most primitive, most mitotically capable stem cells, and they hold virtually unlimited promise in the treatment of diseases attributable to the loss or dysfunction of known cell types. This cell-based therapy, as envisioned, would involve the transplantation of embryonic stem-cell-derived progeny that had been induced to differentiate into the missing or dysfunctional cells. Transplantation of allogeneic stem cells (stem cells from another individual of the same species) or their progeny, however, is complicated by the likelihood of host-graft rejection. As an alternative to overcome this problem, the patient could generate his or her own embryonic stem cells by contributing the donor nucleus or cell in somatic cell cloning, thereby creating self-cells transparent to the immune system such that their transplantation would not elicit an immune response. Proof-of-principle experimentation with adult cells in therapeutic cloning has now been reported in both mice and humans. *See* STEM CELLS.

Future research. An immediate focus of cloning research is to overcome the low success rates with somatic cell cloning in order to extend this technology to other nonhuman species. Undoubtedly, improvements will be realized with additional experience and increased surveillance at birth, with cloned pregnancies treated as high risk. This is already happening with cattle as substantial financial incentive exists in the cattle industry to produce cloned animals, and with mice due to their amenability to laboratory experimentation. Scientists are asking what kinds of cells make the best donors, what environments are most conducive to early development of the cloned embryo, what cell cycle stages are optimal for reprogramming, and how reprogramming can be initiated in the test tube. It seems reckless to extend reproductive cloning to humans at present because of the unacceptable risks imposed on the embryo, fetus, and neonate. Additional ethical considerations have been addressed extensively, for instance, in a United States National Bioethics Advisory Commission report issued in 1997. Therapeutic cloning in humans is less controversial, since it is not associated with efforts to produce cloned children and may represent a viable approach to treat human disease. Clearly, though, ethical concerns do persist with therapeutic cloning, based on the requirement to recruit egg donors in order to create a cloned embryo and then the need to destroy the embryo in the process of deriving embryonic stem cell lines. An alternative to creating individual embryonic stem cell lines by therapeutic cloning may ultimately be the development of stem cell banks that can be used to match the needs of all patients.

While many challenges lie ahead for somatic cell cloning, the mere demonstration that this process is possible in mammals is a highly significant beginning. Ongoing research efforts will lead to a better understanding of the molecular correlates to reprogramming, information that in turn will allow the development of in vitro conditions for reprogramming (for instance, the use of readily available cytoplasm as might be harvested from amphibian eggs). Ultimately, reprogramming will be accomplished with chemically defined reagents and, in the process, we will have developed profound new insights into the events underlying development in mammals, humans included. *See* GENETIC ENGINEERING.

Closed-caption television

A service, primarily for deaf people, that allows individual viewers to display the dialog of a television program in a readable form on the television screen. In the United Kingdom the service is called subtitling. Closed-caption television was introduced in the United States in 1980.

Caption preparation. Captions for television programs can be prepared in three ways. (1) Off-line captioning is used when the television program has been prerecorded. This is the preferred method for creating captions in that they can be caused to appear on different parts of the home television screen, for example, under the individual speaking, and they can be displayed in close synchronism with the dialog. Also, the caption display can be edited if necessary to a comfortable reading rate of about 125 words per minute. (2) Live television broadcasts that are scripted in advance, such as presidential State of the Union speeches, employ a live display captioning method. Here the script is stored in a computer in advance of the broadcast. During the broadcast the script appears as roll-up captions at the bottom of the screen. (3) In live broadcasts, where a script is not available, real-time captions have to be generated during the broadcast. This is by far the most difficult way to caption a television program. Highly skilled court reporters using a stenograph keyboard and an associated computer create the captions, often at instantaneous rates of 200–250 words per minute. In this method, inevitably, typographical errors are often generated.

Caption transmission. Prior to being broadcast, the captions are digitally encoded and inserted into the vertical blanking interval (VBI) of the television picture. In the United States and Canada, a single VBI line is allocated exclusively for the captioning service. In other countries such as the United Kingdom and Australia, the captions are integrated with other text material on a series of VBI lines that are used to deliver Teletext service to a more general audience. As the Teletext transmission data rate is about ten times the caption-only service data rate, it cannot be used in videocassette recorder (VCR) applications. This led to the caption-only system being introduced in home-television movies in the United Kingdom in the early 1990s.

Digital television. The world's terrestrial television systems are in the process of converting from analog to digital broadcasting. In the United States, the Federal Communication Commission (FCC) has adopted the Advanced Television Standards Committee (ATSC) system. Europe has adopted the Digital Video Broadcasting–Terrestrial (DVB-T) system. Elsewhere in the world, those countries that previously adopted the United States or European analog television standards are typically adopting the respective digital television standards. However, the International Telecommunications Union (ITU) recommendation on a digital video, audio, and ancillary data multiplex model has been adopted worldwide. Captions have been classified as an ancillary service and will be multiplexed with other ancillary services such as text services.

Captioned program service growth. Legislative and regulatory actions are spurring the worldwide introduction and growth of captioned television service. In many countries, specific goals have been set as to the percentage of television programs that must be captioned by the broadcasters. In the United States, it is illegal to sell a television set with a screen size 12 in. (30 cm) or larger that does not contain caption decoder circuitry built in by the manufacturer. *See* TELEVISION. John E. D. Ball

Closed-circuit television

Television transmitted to a particular audience at specific locations via coaxial cables, telephone wires, fiber-optic strands, microwave radio systems, or communications satellites, as compared to open-circuit (broadcast) television intended for the general public. *See* COAXIAL CABLE; COMMUNICATIONS CABLE; COMMUNICATIONS SATELLITE; MICROWAVE; OPTICAL COMMUNICATIONS; TELEPHONE SERVICE.

The usual closed-circuit television picture display device is a television receiver. Most receivers use a cathode-ray tube to produce the visible image, although other devices such as flat-panel displays have become common. *See* CATHODE-RAY TUBE; ELECTRONIC DISPLAY; FLAT-PANEL DISPLAY DEVICE; LIQUID CRYSTALS; TELEVISION RECEIVER.

Applications. Closed-circuit television applications include information display, remote monitoring, instruction, cable television programming, and teleconferences and special events.

Information display. Flight times in airports are displayed by closed-circuit television, typically on large cathode-ray-tube video screens. A video screen may be used to display an image of the sales floor to a cashier at the front of a store; this setup is frequently installed for security reasons. In both examples, closed-circuit television provides information, but different methods are used for generating the video. The airport display usually shows text produced by a computer. The store screen shows the image of the sales floor produced by a video camera. These applications exemplify simple forms of closed-circuit television used to connect a source of information to a restricted group of viewing locations.

Remote monitoring. Many types of closed-circuit television systems produce pictures intended for distant viewing. These images may include those taken from a space probe passing close to a distant planet, or pictures of blast furnaces or other industrial operations that could be hazardous to human observers. At the opposite extreme, the low cost of modern video equipment makes practical the use of small cameras to observe sleeping children at home and to enjoy video images of people far away while chatting with them on the Internet.

Parking lots at shopping centers, store cashier locations, bank and hotel lobbies, and other public places are often equipped with closed-circuit television surveillance cameras and displays. These systems may be designed to function in nearly total darkness to detect suspicious activities or in brilliant surroundings to watch for hot spots in factory processes. Medical and scientific equipment and industrial robots often incorporate specialized closed-circuit television systems. Modern closed-circuit television cameras used for remote monitoring are sensitive, rugged, relatively inexpensive, and durable, with long service lives. Most modern solid-state designs use charge-coupled imaging devices. Video signals are often recorded on magnetic tape for future use. *See* CHARGE-COUPLED DEVICES.

Instruction. Closed-circuit television has been available for many years for educational uses. Many universities and school systems employ television for teaching. Classrooms may be equipped with closed-circuit television cameras, recorders, and receivers. Lesson material is often presented via video tape recordings, CD-ROMs, or DVD recordings. In other cases, classroom receivers are supplied with signals from specially reserved broadcast channels (called ITFS channels, for Instructional Television Fixed Service), cable television channels, or satellite channels. Audio circuits installed at viewing locations sometimes allow two-way conversations between lecturer and students. *See* COMPACT DISK; MAGNETIC RECORDING.

Cable television. Cable television was originally developed to improve broadcast reception in difficult receiving situations—for example, to bring distant signals from broadcast television stations to residents of mountain valleys or to serve viewers in cities where large buildings prevent satisfactory reception of broadcast signals. Contemporary cable systems continue to distribute signals from local and distant television stations, but they now offer additional television services not available from broadcast stations, such as satellite-distributed news, music, movies, weather information, and locally originated community-based programming. Cable systems offer services to an estimated 65 million households in the United States (75% of the total) using either coaxial cables or fiber-optic strands for signal delivery. *See* CABLE TELEVISION SYSTEM.

Wider availability has reduced the cost of using fiber-optic strands for high-speed signal transmission. High-speed interconnections enable closed-circuit television systems to utilize important new kinds of digitally based services. For example, many telephone and cable television companies provide fiber-optic connections to schools and classrooms. These permit relatively inexpensive two-way video and audio connections between schools and among school systems, enabling great flexibility in system design and utilization.

Teleconferences and special events. Closed-circuit television is used to conduct conferences among geographically separated groups of people. Signals from television-equipped meeting rooms or studios are distributed by fiber-optic circuits, communications satellites, or the Internet to convention centers, school or university classrooms, motels, hotels, or corporate locations. Two-way audio is typically provided, and conferences may involve many hundreds or thousands of people. Sports or musical events may also be televised and distributed in this fashion for viewing in suitably equipped theaters or auditoriums. *See* TELECONFERENCING.

Technology. Closed-circuit television systems frequently utilize equipment that produces signals based on broadcasting industry specifications. However, in contrast to the many possible designs for closed-circuit television systems, broadcast television is always limited to the use of standardized signals for its transmissions. The standardized television broadcast system used at present in the United States, Canada, Mexico, Japan, and some other countries was devised in the 1950s by the National Television Systems Committee (NTSC). NTSC systems display 30 complete television pictures (frames) per second, and each frame is composed of 525 horizontal scanning lines arranged from top to bottom. *See* TELEVISION STANDARDS.

Video cameras, television receivers, videocassette recorders, and accessories are produced in large quantities for NTSC broadcast applications. The NTSC system is well suited for home entertainment, but its signal structure is technically limited by the requirement for simple, inexpensive home receivers and video tape recorders. Inauguration of improved kinds of advanced television systems, most of them digital, is under way in many countries. Such technologies will eventually permit higher picture quality and the mass production of affordable receivers with new features. These features will eventually also become available for closed-circuit applications.

Special requirements. Closed-circuit television systems are not required to use NTSC signals, but many do, mainly for economic reasons. In many applications, normal NTSC-based closed-circuit television equipment is satisfactory. If the transmission path to the viewer is of low quality, however, special steps must be taken. In such cases, the signal can be modified to meet more closely the characteristics of the transmission system. For example, channel bandwidth can be reduced without loss of image resolution if the user accepts reduced quality in the representation of image motion. In that case, a rate lower than the normal 30 frames per second can be chosen. This is called slow-scan closed-circuit television.

Still-frame video images sometimes suffice. A high-quality still frame can be transmitted with picture elements being stored for seconds or even minutes in a memory system and then assembled for display after receipt of all data. This allows use of transmission channels having limited bandwidth. Most video pictures from space are transmitted at low frame rates over narrow-bandwidth communications channels, and complete reception requires several seconds. Narrow-band channels are also found on the Internet, where both slow-scan and still images are often used. *See* INTERNET; REMOTE SENSING.

NTSC broadcast signal characteristics may also be poorly suited to other kinds of specialized closed-circuit television applications. Some applications require high image resolution, great sensitivity to light, the ability to respond to infrared or ultraviolet light, or very rugged system components. Closed-circuit television requirements for high-resolution display can be satisfied by increasing the number of image scanning lines and the overall video channel bandwidth. Industrial standards exist for high-resolution closed-circuit systems. Cameras and monitors are available to meet other specialized requirements.

Advanced developments. The digital revolution has affected the design of all kinds of television equipment. Video signals can be converted into digital form and processed by specialized computers, called digital signal processors. Visual special effects are often seen on entertainment television, including slow motion, still frames, rotations, inversions, and picture shape changes. They are accomplished by use of digital signal processing systems. In closed-circuit television applications, digital processing can make transmission via the Internet practical and can also provide image enhancement. The excellent pictures from weather and surveillance satellite imaging systems are obtained with digital signal processing and enhancement. High-performance solid-state camera sensors and the digital processing of video signals, taken together, have extended the applications of closed-circuit television systems. The advanced television systems now entering service make use of the advantages of digital signal processing to provide high-quality images to the home, to the class-room, and to industrial locations. *See* DATA COMPRESSION; IMAGE PROCESSING; TELEVISION. Clostridium

A genus of bacteria comprising large anaerobic spore-forming rods that usually stain gram-positive. Most species are anaerobes, but a few will grow minimally in air at atmospheric pressure.

The clostridia are widely distributed in nature, and are present in the soil and in the intestinal tracts of humans and animals. They usually live a saprophytic existence, and play a major role in the degradation of organic material in the soil and other natural environments. A number of clostridia release potent exotoxins and are pathogenic for humans and animals. Among the human pathogens are the causative agents of botulism (*Clostridium botulinum*), tetanus (*C. tetani*), gas gangrene (*C. perfringens*), and an antibiotic-associated enterocolitis (*C. difficile*). *See* ANAEROBIC INFECTION; TOXIN.

Characteristics. Clostridial cells are straight or slightly curved rods, 0.3–1.6 micrometers wide and 1–14 μm long. They may occur singly, in pairs, in short or long chains, or in helical coils. The length of the cells of the individual species varies according to the stage of growth and growth conditions. Young cultures of most species of *Clostridium* are gram-positive and stain readily with the usual aniline dyes, but in older cultures and clinical specimens the organisms frequently stain gram-negative. Most clostridia are motile with a uniform arrangement of flagella. *See* CILIA AND FLAGELLA.

The endospores produced by clostridia are dormant structures capable of surviving for prolonged periods of time, and have the ability to reestablish vegetative growth when appropriate environmental conditions are provided. The spores of most clostridia are resistant to heat, chemical agents, and radiation and thus provide the organism with a selective advantage in its native habitat, enabling it to survive under the most adverse environmental conditions. The spores of clostridia are oval or spherical and are wider than the vegetative bacterial cell. Among the distinctive forms are spindle-shaped organisms, club-shaped forms, and tennis racket–shaped structures.

Clostridia are obligate anaerobes: they are unable to use molecular oxygen as a final electron acceptor and generate their energy solely by fermentation. Clostridia exhibit varying degrees of intolerance to oxygen. Some species are sensitive to oxygen concentrations as low as 0.5%, but most species can tolerate concentrations of 3–5%. The sensitivity of clostridia to oxygen restricts their habitat to anaerobic environments; habitats that contain large amounts of organic matter provide optimal conditions for their growth and survival.

A primary property of all species of *Clostridium* is their inability to carry out a dissimilatory reduction of sulfate. Most species are chemoorganotrophic. The substrate spectrum for the genus as a whole is very broad and includes a wide range of naturally occurring compounds. Extracellular enzymes are secreted by many species, enabling the organism to utilize a wide variety of complex natural substrates in the environment. Four nutritional groups are recognized: saccharolytic species (species that break down sugars), proteolytic species (species that hydrolyze proteins and peptides), species that are both saccharolytic and proteolytic, and species that are neither but are specialized on one or a few substrates. A number of saccharolytic species ferment carbohydrates, with the production of such compounds as butyric acid, butanol, isopropanol, and acetone. Proteolytic species metabolize proteins, often with the production of foul-smelling amines.

Pathogens. Species of *Clostridium* associated with human disease are divided into four major groups on the basis of the types of diseases: histotoxic clostridia cause a wide variety of tissue infections; enterotoxigenic clostridia produce gastrointestinal disorders; *C. tetani* is the etiologic agent of tetanus; and *C. botulinum* is the etiologic agent of botulism. In all clostridial diseases, pathogenesis is attributable to potent exotoxins released by the organism.

Histotoxic forms. *Clostridium perfringens* is the most important of the histotoxic clostridia that cause tissue infections in humans, especially of the muscle tissue (clostridial myonecrosis, or gas gangrene). This short, plump, nonmotile rod (2–4 μm wide) is more aerotolerant than most other anaerobes. Its strains produce at least 12 different toxins and enzymes, many of which have lethal, cell-destroying, and hemolytic (red blood cell–destroying) properties. A number of nonlethal enzymes are also produced, and apparently contribute to the invasiveness of the organism. These include collagenase, deoxyribonuclease, and hyaluronidase. *See* GANGRENE.

Other histotoxic clostridia include *C. novyi* and *C. septicum*. More than 30 additional species have been isolated from human clinical specimens, but most of these are considered to be nonpathogenic opportunistic organisms.

In individuals with malignancies of the cecum or with leukemia, invasion of the bloodstream by *C. septicum* or *C. perfringens* may lead to a life-threatening fulminating septicemia. *Clostridium perfringens* can also cause food poisoning if large numbers of an enterotoxin-producing strain are ingested. A more severe form of food poisoning, called enteritis necroticans, is caused by type C strains of *C. perfringens*. It is seen most often in malnourished children in the less developed countries. *See* FOOD POISONING.

Enterotoxigenic forms. *Clostridium difficile* causes pseudomembranous colitis, a severe disease associated with the administration of antibiotics. The antibiotics most often involved include clindamycin, ampicillin, and the cephalosporins. *Clostridium difficile* is widespread in the environment and is part of the normal intestinal flora of about 3% of healthy adults. When antibiotic-sensitive organisms are eliminated from the intestine, there is an overgrowth of *C. difficile*, severe intestinal mucosa damage, and resultant clinical disease.

Clostridium tetani. This species is the causative agent of tetanus. It is a long, thin rod that forms a round terminal spore that gives the sporulating organism a characteristic drumstick appearance. The organisms are widely distributed in the soil and in the gastrointestinal tracts of humans and other animals. The spores remain viable in the soil for many years and provide the primary source of infection. Often after a simple puncture wound from a nail or splinter contaminated with soil containing the organisms, they multiply locally at the site and elaborate a potent neurotoxin (tetanospasmin) which is responsible for all of the symptoms of tetanus. *See* TETANUS.

Clostridium botulinum. The most common form of botulism is an intoxication that usually follows the ingestion of a preformed toxin produced by *C. botulinum*. There are seven types (A to G) of *C. botulinum* based on the immunologically distinct type of toxin produced. The production of a specific type of botulinum toxin is determined by the specific bacteriophage carried by the organism. Types A, B, and E are responsible for most cases of human botulism. The toxins are neurotoxins and are among the most toxic compounds known. They act on neuromuscular junctions by inhibiting the release of acetylcholine. *See* ACETYLCHOLINE.

The spores of *C. botulinum* are widely distributed in soils, lake sediments, and decaying vegetation in many parts of the world. They are very resistant to heat and can withstand 212°F (100°C) for 3–5 h; moist heat at 250°F (121°C) will kill them in 15 min. In the canning of food (especially vegetables), if the spores on contaminated food are not killed, they will germinate and release toxins when conditions become sufficiently anaerobic. *See* BOTULISM; FOOD PRESERVATION.

Disease in animals. A number of diseases in mammals and birds are caused by the ingestion of toxins elaborated by toxinogenic species of *Clostridium. Clostridium botulinum* causes grass or fodder sickness of horses, silage disease in cattle, limberneck in chickens, lamziekte in cattle, and dust sickness in wild birds. Type C botulinum toxin causes large epidemics of botulism in aquatic birds. In the western United States, the disease is the major natural cause of death of wild ducks. Other species of clostridia associated with major diseases in animals are *C. chauvoei*, *C. haemolyticum*, *C. novyi* type B, *C. septicum*, and *C. tetani*. *See* MEDICAL BACTERIOLOGY.

Cloud

A suspension of minute droplets or ice crystals produced by the condensation of water vapor. This article presents an outline of cloud formation upon which to base an understanding of cloud classifications. For a more technical consideration of the physical character of atmospheric clouds, including the condensation and precipitation of water vapor, *see* CLOUD PHYSICS; FOG.

Rudiments of cloud formation. A grasp of a few physical and meteorological relationships aids in an understanding of clouds. First, if water vapor is cooled sufficiently, it becomes saturated and is in equilibrium with a plane surface of liquid water (or ice) at the same temperature. Further cooling in the presence of such a surface causes condensation upon it; in the absence of any surfaces, no condensation occurs until a substantial further cooling provokes condensation upon ions or random large aggregates of water molecules. In the atmosphere, even in the apparent absence of any surfaces, nuclei always exist upon which condensation proceeds at barely appreciable cooling beyond the state of saturation. Consequently, when atmospheric water vapor is cooled sufficiently, condensation nuclei swell into minute water droplets and form a visible cloud. The total concentration of liquid in the cloud is controlled by its temperature and the degree of cooling beyond the state in which saturation occurred, and in most clouds approximates to 1 g/m^3 (0.001 oz/ft^3) of air. The concentration of droplets is controlled by the concentrations and properties of the nuclei and the speed of the cooling at the beginning of the condensation. In the atmosphere these are such that there are usually about 100,000,000 droplets/m^3 (2,800,000 droplets/ft^3). Because the cloud water is at first fairly evenly shared among them, these droplets are necessarily of microscopic size, and an important part of the study of clouds concerns the ways in which they become aggregated into drops large enough to fall as rain.

The cooling which produces clouds is almost always associated with the upward movements of air which carry heat from the Earth's surface and restore to the atmosphere that heat lost by radiation into space. These movements are most pronounced in storms, which are accompanied by thick, dense clouds, but also take place on a smaller scale in fair weather, producing scattered clouds or dappled skies. *See* STORM.

Rising air cools by as much as 10°C for each kilometer of ascent, so that even over equatorial regions temperatures below 0°C (32°F) are encountered a few kilometers above the ground, and clouds of frozen particles prevail at higher levels. Of the abundant nuclei which facilitate droplet condensation, very few cause direct condensation into ice crystals or stimulate the freezing of droplets, and especially at temperatures near 0°C (32°F) their numbers may be vanishingly small. Consequently, at these temperatures, clouds of unfrozen droplets are not infrequently encountered (supercooled clouds). In general, however, ice crystals occur in very much smaller concentrations than the droplets of liquid clouds, and may by condensation alone become large enough to fall from their parent cloud. Such ice nuclei are particles of clay, or sometimes bacteria,

mixed upward from the Earth's surface. All cloud droplets freeze by self-nucleation (ice crystal formation by random motion of the water molecules) at temperatures below −35 to −40°C (−31 to −40°F). Even small high clouds may produce or become trails of snow crystals, whereas droplet clouds are characteristically compact in appearance with well-defined edges, and produce rain only when well developed vertically (2 km or 1.5 mi, or more, thick).

Clouds play a major role in the heat balance of the Earth by scattering back sunlight to space. The heat balance is also affected by clouds' absorbing and scattering thermal radiation from regions partly above the cloud. Changes in cloud particle size and concentration by anthropogenic effects—air pollution from various sources—may influence the heat balance, thus offsetting the effects of carbon dioxide warming. *See* CLIMATE MODIFICATION.

Nacreous and noctilucent clouds. Clouds sometimes occur at much higher levels in the atmosphere, particularly when the temperature falls below −90 to −95°C (−130 to −139°F). Nacreous clouds (or polar stratospheric clouds) occur at heights near 25 km (17 mi) in the Arctic and Antarctic winter or early spring. They are visible when their level is illuminated by the Sun from some 20° below the horizon, so that the observer is on the surface in darkness. Such low temperatures occur preferentially in wave disturbances propagating upward and downstream of surface mountain ranges. Particles are composed of sulfuric acid (possibly injected by extreme volcanic events) and nitric acid, water ice, and combinations thereof as hydrates, usually some 1–5 micrometers in diameter. Such clouds are sometimes colored (particularly when particles are unfrozen supercooled or saturated droplets), a phenomenon

which also occurs in lower-level clouds because of sunlight diffraction from regions containing particles of near-uniform size; hence the alternative name, mother of pearl clouds. At higher levels, near 80 km (50 mi), at the temperature minimum near −80°C (−112°F), noctilucent clouds form and can be viewed under similar circumstances, with viewing time extended for an even lower Sun because of the additional height. The particles tend to be smaller (by about one-tenth); however, these clouds show a much more fibrous structure than nacreous clouds and are not colored. Observation of these clouds is associated with north-south-oriented mountains which give rise to gravity waves in easterly circumpolar flow, being more frequent in Scandinavia, Alaska, and northern Canada. Particles making up these clouds may form the substrate for chemical reactions leading to destruction of ozone.

Classification of clouds. The contrast in cloud forms mentioned above was recognized in the first widely accepted classification, as well as in several succeeding classifications. The first was that of L. Howard in 1803, recognizing three fundamental types: the stratiform (layer), cumuliform (heap), and cirriform (fibrous). The first two are indeed fundamental, representing clouds formed respectively in stable and in convectively unstable atmospheres, whereas the clouds of the third type are the ice clouds which are in general higher and more tenuous and less clearly reveal the kind of air motion which led to their formation. Succeeding classifications continued to be based upon the visual appearance or form of the clouds, differentiating relatively minor features, but later in the nineteenth century increasing importance was attached to cloud height, because direct measurements of winds above the ground were then very difficult, and it was hoped to obtain wind data on a great scale by combining observations of apparent cloud motion with reasonably accurate estimates of cloud height, based solely on their form. With the advent of satellite and rocket observations in the 1970s, a broader perspective became available for examination of clouds on a global basis. Such pictures readily show the distribution of clouds from systems as a midlatitude cyclone, hurricane, or the intertropical convergence zone; they show the influence of land and ocean in initiating convective motion; examples are given in **Fig. 1**. *See* METEOROLOGICAL ROCKET; METEOROLOGICAL SATELLITES; SATELLITE METEOROLOGY.

WMO cloud classification. The World Meteorological Organization (WMO) uses a classification which, with minor modifications, dates from 1894 and represents a choice made at that time from a number of competing classifications. It divides clouds into low-level (base below about 2 km or 1.5 mi), middle-level (about 2 to 7 km or approximately 1 to 4.5 mi), and high-level (between roughly 7 and 14 km or approximately 4 to 8.5 mi) forms within

Fig. 7. Altocumulus, which occurs at intermediate levels. (*G. A. Lott*, *U.S. Weather Bureau*)

Fig. 8. Altostratus, a middle-level layer cloud. Thick layers of such clouds, with bases extending down to low levels, produce prolonged rain or snow, and are then called nimbostratus. (*C. F. Brooks*, *U.S. Weather Bureau*)

Fig. 9. Cumulonimbus clouds photographed over the upland adjoining the upper Colorado River valley. (*Lt. B. H. Wyatt, U.S.N., U.S. Weather Bureau*)

the middle latitudes. The names of the three basic forms of clouds are used in combination to define 10 main characteristic forms, or genera.

1. Cirrus are high white clouds with a silken or fibrous appearance (**Fig. 2**).
2. Cumulus are detached dense clouds which rise in domes or towers from a level low base (**Fig. 3**).
3. Stratus are extensive layers or flat patches of low clouds without detail (**Fig. 4**).
4. Cirrostratus forms from an abundance of cirrus as a layer, well above and distinct from the lower layer cloud (**Fig. 5**).
5. Cirrocumulus is formed of high clouds broken into a delicate wavy or dappled pattern (**Fig. 6**).
6. Stratocumulus is a low-level layer cloud having a dappled, lumpy, or wavy structure. See the foreground of Fig. 5.
7. Altocumulus is similar to stratocumulus but lies at intermediate levels (**Fig. 7**).
8. Altostratus is a thick, extensive, layer cloud at intermediate levels (**Fig. 8**).
9. Nimbostratus is a dark, widespread cloud with a low base from which prolonged rain or snow falls.
10. Cumulonimbus is a large cumulus which produces a rain or snow shower (Fig. 1*a*; **Fig. 9**).

Classification by air motion. Modern studies of clouds have been stimulated by the need to know their composition from the viewpoint of aircraft and rocket penetration, which gives rise to icing, turbulence, and lightning hazards, and by the discovery that seeding of supercooled clouds could, on occasion, give rise to enhanced precipitation. *See* WEATHER MODIFICATION.

These studies show that the external form of clouds gives only indirect and incomplete clues to the physical properties which determine their evolution. Throughout this evolution the most important properties appear to be the air motion and the size-distribution spectrum of all the cloud particles, including the condensation and ice-forming nuclei. These properties vary significantly with time and position within the cloud, so that cloud studies demand the intensive examination of individual clouds with aircraft, radar, and satellites. Nevertheless, the overall cloud shape does give information on the formation process. Lenticular clouds with smooth tops may form from smooth air flow with little environmental mixing (**Fig. 10**); clouds with irregular tops (Figs. 3

Cloud classification based on air motion and associated physical characteristics

Kind of motion	Typical vertical speeds, cm/s*	Kind of cloud	Name	Characteristic dimensions, km†		Characteristic precipitation
				Horizontal	Vertical	
Widespread slow ascent, associated with cyclones (stable atmosphere)	1–10	Thick layers	Cirrus, later becoming: cirrostratus altostratus altocumulus	10^3	1–2	Snow trails
			nimbostratus	10^3	10	Prolonged moderate rain or snow
Convection, due to passage over warm surface (unstable atmosphere)	10^2	Small heap cloud	Cumulus	1	1	None
	10^3	Shower- and thundercloud	Cumulonimbus	10	10	Intense showers of rain or hail
Irregular stirring causing cooling during passage over cold surface (stable atmosphere)	$10–10^2$	Shallow low layer clouds, fogs	Stratus Stratocumulus	$<10^2$ $<10^3$	<1	None, or slight drizzle or snow

*1 cm = 0.4 in. †1 km = 0.62 mi.

and 9) show that mixing is strong. The former has nonturbulent, laminar air motions and give a smooth flight; the mixing clouds give modest to strong turbulence and a bumpy flight. An observer of clouds can readily see motions of convective clouds; motions in other systems can be viewed by time-lapse photography at 5–50-s intervals, or sequential satellite pictures at intervals of several hours. From a general meteorological point of view, a classification can be based upon the kind of air motion associated with the cloud, as shown in the **table**.

Frank H. Ludlam; John Hallett

Cloud physics

The study of the physical and dynamical processes governing the structure and development of clouds and the release from them of snow, rain, and hail (collectively known as precipitation). *See* PRECIPITATION (METEOROLOGY).

The factors of prime importance are the motion of the air, its water-vapor content, and the number and properties of the particles in the air which act as centers of condensation and freezing. Because of the complexity of atmospheric motions and the enormous variability in vapor and particle content of the air, it seems impossible to construct a detailed, general theory of the manner in which clouds and precipitation develop. However, calculations based on the present conception of laws governing the growth and aggregation of cloud particles and on simple models of air motion provide reasonable explanations for the observed formation of precipitation in different kinds of clouds.

Cloud formation. Clouds are formed by the lifting of damp air which cools by expansion under continuously falling pressure. The relative humidity increases until the air approaches saturation. Then condensation occurs (**Fig. 1**) on some of the wide variety of aerosol particles present; these exist in concentrations ranging from less than 2000 particles/in.^{3} (100/cm^3) in clean, maritime air to perhaps 10^7/in.^{3} (10^6/cm^3) in the highly polluted air of an industrial city. A portion of these particles are hygroscopic and promote condensation at relative humidities below 100%; but for continued condensation leading to the formation of cloud droplets, the air must be slightly supersaturated. Among the highly efficient condensation nuclei are the salt particles produced by the evaporation of sea spray, but it appears that particles produced by human-made fires and by natural combustion (for example, forest fires) also make a major contribution. Condensation onto the nuclei continues as rapidly as the water vapor is made available by cooling of the air and gives rise to droplets of the order of 0.0004 in. (0.01 mm) in diameter. These droplets, usually present in concentrations of several thousand per cubic inch, constitute a nonprecipitating water cloud.

Mechanisms of precipitation release. Growing clouds are sustained by upward air currents, which may vary in strength from about an inch per second to several yards per second. Considerable growth of the cloud droplets (with falling speeds of only about 0.4 in./s or 1 cm/s) is therefore necessary if they are to fall through the cloud, survive evaporation in the unsaturated air beneath, and reach the ground as drizzle or rain. Drizzle drops have radii exceeding 0.004 in. (0.1 mm), while the largest raindrops are about 0.24 in. (6 mm) across and fall at nearly 30 ft/s (10 m/s). The production of a relatively few large particles from a large population of much smaller ones may be achieved in one of two ways.

Coalescence process. Cloud droplets are seldom of uniform size for several reasons. Droplets arise on nuclei of various sizes and grow under slightly different conditions of temperature and supersaturation in different parts of the cloud. Some small drops may remain inside the cloud for longer than others before being carried into the drier air outside.

A droplet appreciably larger than average will fall faster than the smaller ones, and so will collide and fuse (coalesce) with some of those which it overtakes (**Fig. 2**). Calculations show that, in a deep cloud containing strong upward air currents and

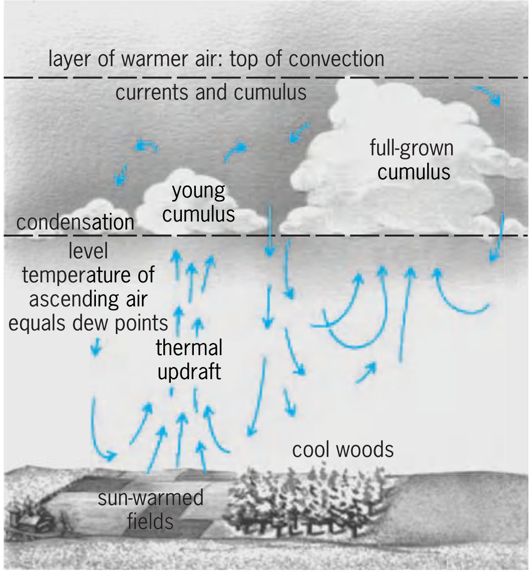

Fig. 1. Conditions leading to birth of a cumulus cloud.

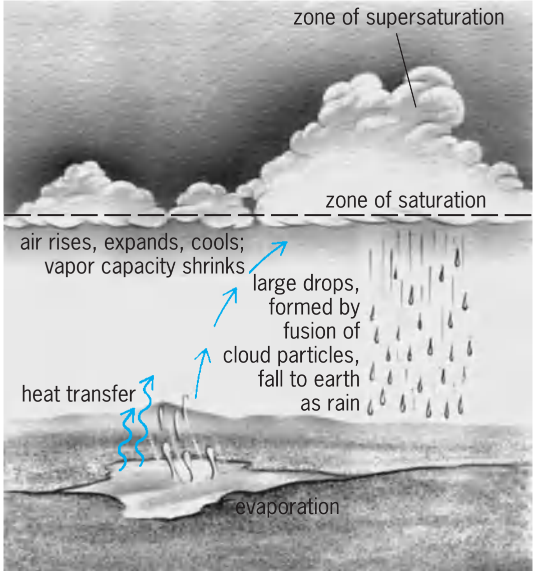

Fig. 2. Diagram of the steps in the formation of rain.

high concentrations of liquid water, such a droplet will have a sufficiently long journey among its smaller neighbors to grow to raindrop size. This coalescence mechanism is responsible for the showers that fall in tropical and subtropical regions from clouds whose tops do not reach the 32°F (0°C) level and therefore cannot contain ice crystals which are responsible for most precipitation. Radar evidence also suggests that showers in temperate latitudes may sometimes be initiated by the coalescence of waterdrops, although the clouds may later reach to heights at which ice crystals may form in their upper parts.

Initiation of the coalescence mechanism requires the presence of some droplets exceeding 20 micrometers in diameter. Over the oceans and in adjacent land areas they may well be supplied as droplets of sea spray, but in the interiors of continents, where so-called giant salt particles of marine origin are probably scarce, it may be harder for the coalescence mechanism to begin.

Ice crystal process. The second method of releasing precipitation can operate only if the cloud top reaches elevations where temperatures are below 32°F (0°C) and the droplets in the upper cloud regions become supercooled. At temperatures below −40°F (−40°C) the droplets freeze automatically or spontaneously; at higher temperatures they can freeze only if they are infected with special, minute particles called ice nuclei. As the temperature falls below 32°F (0°C), more and more ice nuclei become active, and ice crystals appear in increasing numbers among the supercooled droplets. But such a mixture of supercooled droplets and ice crystals is unstable. The cloudy air, being usually only slightly supersaturated with water vapor as far as the droplets are concerned, is strongly oversaturated for the ice crystals, which therefore grow more rapidly than the droplets. After several minutes the growing crystals will acquire definite falling speeds, and several of them may become joined together to form a snowflake. In falling into the warmer regions of the cloud, however, the snowflake may melt and reach the ground as a raindrop.

Precipitation from layer-cloud systems. The deep, extensive, multilayer-cloud systems, from which precipitation of a usually widespread, persistent character falls, are generally formed in cyclonic depressions (lows) and near fronts. Such cloud systems are associated with feeble upcurrents of only a few centimeters per second, which last for at least several hours. Although the structure of these great raincloud systems, which are being explored by aircraft and radar, is not yet well understood, it appears that they rarely produce rain as distinct from drizzle, unless their tops are colder than about 10°F (−12°C). This suggests that ice crystals may be responsible. Such a view is supported by the fact that the radar signals from these clouds usually take a characteristic form which has been clearly identified with the melting of snowflakes.

Production of showers. Precipitation from shower clouds and thunderstorms, whether in the form of raindrops, pellets of soft hail, or true hailstones, is generally of greater intensity and shorter duration than that from layer clouds and is usually composed of larger particles. The clouds themselves are characterized by their large vertical depth, strong vertical air currents, and high concentrations of liquid water, all these factors favoring the rapid growth of precipitation elements by accretion.

In a cloud composed wholly of liquid water, raindrops may grow by coalescence with small droplets. For example, a droplet being carried up from the cloud base would grow as it ascends by sweeping up smaller droplets. When it becomes too heavy to be supported by the vertical upcurrents, the droplet will then fall, continuing to grow by the same process on its downward journey. Finally, if the cloud is sufficiently deep, the droplet will emerge from its base as a raindrop.

In a dense, vigorous cloud several kilometers deep, the drop may attain its limiting stable diameter (about 0.2 in. or 5 mm) before reaching the cloud base and thus will break up into several large fragments. Each of these may continue to grow and attain breakup size. The number of raindrops may increase so rapidly in this manner that after a few minutes the accumulated mass of water can no longer be supported by the upcurrents and falls out as a heavy shower. The conditions which favor this rapid multiplication of raindrops occur more readily in tropical regions.

The ice crystals grow initially by sublimation of vapor in much the same way as in layer clouds, but when their diameters exceed about 0.004 in. (0.1 mm), growth by collision with supercooled droplets will usually predominate. At low temperatures the impacting droplets tend to freeze individually and quickly to produce pellets of soft hail. The air spaces between the frozen droplets give the ice a relatively low density; the frozen droplets contain large numbers of tiny air bubbles, which give the pellets an opaque, white appearance. However, when the growing pellet traverses a region of relatively high air temperature or high concentration of liquid water or both, the transfer of latent heat of fusion from the hailstone to the air cannot occur sufficiently rapidly to allow all the deposited water to freeze immediately. There then forms a wet coating of slushy ice, which may later freeze to form a layer of compact, relatively transparent ice. Alternate layers of opaque and clear ice are characteristic of large hailstones, but their formation and detailed structure are determined by many factors such as the number concentration, size and impact velocity of the supercooled cloud droplets, the temperature of the air and hailstone surface, and the size, shape, and aerodynamic behavior of the hailstone. Giant hailstones, up to 4 in. (10 cm) in diameter, which cause enormous damage to crops, buildings, and livestock, most frequently fall not from the large tropical thunderstorms, but from storms in the continental interiors of temperate latitudes. An example is the Nebraska-Wyoming area of the United States, where the organization of larger-scale wind patterns is particularly favorable for the growth of severe storms. *See* HAIL.

The development of precipitation in convective clouds is accompanied by electrical effects culminating in lightning. The mechanism by which the electric charge dissipated in lightning flashes is generated and separated within the thunderstorm has been debated for more than 200 years, but there is still no universally accepted theory. However, the majority opinion holds that lightning is closely associated with the appearance of the ice phase, and the most promising theory suggests that the charge is produced by the rebound of a small fraction of the supercooled cloud droplets that collide with the falling hail pellets. *See* LIGHTNING.

Basic aspects of cloud physics. The various stages of the precipitation mechanisms raise a number of interesting and fundamental problems in classical physics. Worthy of mention are the supercooling and freezing of water; the nature, origin, and mode of action of the ice nuclei; and the mechanism of ice-crystal growth which produces the various snow crystal forms.

It has been established how the maximum degree to which a sample of water may be supercooled depends on its purity, volume, and rate of cooling. The freezing temperatures of waterdrops containing foreign particles vary linearly as the logarithm of the droplet volumes for a constant rate of cooling. This relationship, which has been established for drops varying between 0.0004 and 0.4 in. (10 μm and 1 cm) in diameter, characterizes the heterogeneous nucleation of waterdrops and is probably a consequence of the fact that the ice-nucleating ability of atmospheric aerosol increases logarithmically with decreasing temperature.

When extreme precautions are taken to purify the water and to exclude all solid particles, small droplets, about 0.00004 in. (1 μm) in diameter, may be supercooled to −40°F (−40°C) and drops of 0.04 in. (1 mm) diameter to −31°F (−35°C). Under these conditions freezing occurs spontaneously without the aid of foreign nuclei.

The nature and origin of the ice nuclei, which are necessary to induce freezing of cloud droplets at temperatures about −40°F (−40°C), are still not clear. Measurements made with large cloud chambers on aircraft indicate that the most efficient nuclei, active at temperatures above 14°F (−10°C), are present in concentrations of only about 30/ft^3 (10/m^3) of air, but as the temperature is lowered, the number of ice crystals increases logarithmically to reach concentrations of about 25/ft^3 (1/liter) at −4°F (−20°C) and 2500/ft^3 (100/liter) at −22°F (−30°C). Since these measured concentrations of nuclei are less than one-hundredth of the number that apparently is consumed in the production of snow, it seems that there must exist processes by which the original number of ice crystals are rapidly multiplied. Laboratory experiments suggest the fragmentation of the delicate snow crystals and the ejection of ice splinters from freezing droplets as probable mechanisms.

The most likely source of atmospheric ice nuclei is provided by the soil and mineral-dust particles carried aloft by the wind. Laboratory tests have shown that, although most common minerals are relatively inactive, a number of silicate minerals of the clay family produce ice crystals in a supercooled cloud at temperatures above −0.4°F (−18°C). A major constituent of some clays, kaolinite, which is active below 16°F (−9°C), is probably the main source of highly efficient nuclei.

The fact that there may often be a deficiency of efficient ice nuclei in the atmosphere has led to a search for artificial nuclei which might be introduced into supercooled clouds in large numbers. Silver iodide is a most effective substance, being active at 25°F (−4°C), while lead iodide and cupric sulfide have threshold temperatures of 21°F (−6°C) for freezing nuclei.

In general, the most effective ice-nucleating substances, both natural and artificial, are hexagonal crystals in which spacings between adjacent rows of atoms differ from those of ice by less than 16%. The detailed surface structure of the nucleus, which is determined only in part by the crystal geometry, is of even greater importance. This is strongly indicated by the discovery that several complex organic substances, notably steroid compounds, which have apparently little structural resemblance to ice, may act as nucleators for ice at temperatures as high as 30°F (−1°C).

The collection of snow crystals from clouds at different temperatures has revealed their great variety of shape and form. By growing the ice crystals on a fine fiber in a cloud chamber, it has been possible to reproduce all the naturally occurring forms and to show how these are correlated with the temperature and supersaturation of the environment. With the air temperature along the length of a fiber ranging from 32 to −13°F (0 to −25°C), the following clear-cut changes of crystal habit are observed (**Fig. 3**): hexagonal plates–needles–hollow prisms–plates–stellar dendrites–plates–prisms. This multiple change of habit over such a small

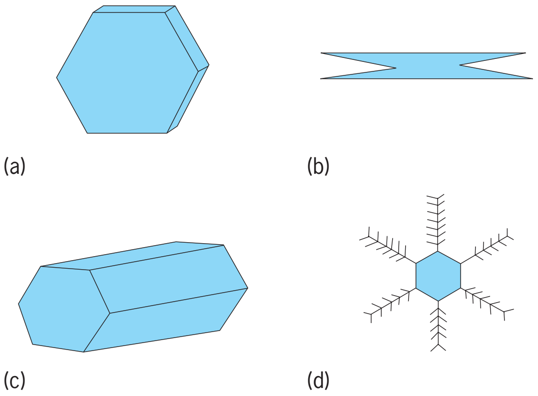

Fig. 3. Ice crystal types formed in various temperature ranges: (*a*) Thin hexagonal plate at 32 to 27°F (0 to −3°C), 18 to 10°F (−8 to −12°C), 3 to −13°F (−16 to −25°C). (*b*) Needles at 27 to 23°F (−3 to −5°C). (*c*) Hexagonal prismatic column at 23 to 18°F (−5 to −8°C), below −13°F (−25°C). (*d*) Dendritic star-shaped crystal at 10 to 3°F (−12 to −16°C).

temperature range is remarkable and is thought to be associated with the fact that water molecules apparently migrate between neighboring faces on an ice crystal in a manner which is very sensitive to the temperature. Certainly the temperature rather than the supersaturation of the environment is primarily responsible for determining the basic shape of the crystal, though the supersaturation governs the growth rates of the crystals, the ratio of their linear dimensions, and the development of dendritic forms. *See* SNOW.

Artificial stimulation of rain. The presence of either ice crystals or some comparatively large waterdroplets (to initiate the coalescence mechanism) appears essential to the natural release of precipitation. Rainmaking experiments are conducted on the assumption that some clouds precipitate inefficiently, or not at all, because they are deficient in natural nuclei; and that this deficiency can be remedied by seeding the clouds artificially with dry ice or silver iodide to produce ice crystals, or by introducing waterdroplets or large hygroscopic nuclei. In the dry-ice method, pellets of about 0.4-in. (1-cm) diameter are dropped from an aircraft into the top of a supercooled cloud. Each pellet chills a thin sheath of air near its surface to well below −40°F (−40°C) and produces perhaps 10^{12} minute ice crystals, which subsequently spread through the cloud, grow, and aggregate into snowflakes. Only a few pounds of dry ice are required to seed a large cumulus cloud. Some hundreds of experiments, carried out mainly in Australia, Canada, South Africa, and the United States, have shown that cumulus clouds in a suitable state of development may be induced to rain by seeding them with dry ice on occasions when neighboring clouds, untreated, do not precipitate. However, the amounts of rain produced have usually been rather small.

For large-scale trials designed to modify the rainfall from widespread cloud systems over large areas, the cost of aircraft is usually prohibitive. The technique in this case is to release a silver iodide smoke from the ground and rely on the air currents to carry it up into the supercooled regions of the cloud. In this method, with no control over the subsequent transport of the smoke, it is not possible to make a reliable estimate of the concentrations of ice nuclei reaching cloud level, nor is it known for how long silver iodide retains its nucleating ability in the atmosphere. It is usually these unknown factors which, together with the impossibility of estimating accurately what would have been the natural rainfall in the absence of seeding activities, make the design and evaluation of a large-scale operation so difficult.

Little convincing evidence can be found that large increases in rainfall have been produced consistently over large areas. Indeed, in temperate latitudes most rain falls from deep layer-cloud systems whose tops usually reach to levels at which there are abundant natural ice nuclei and in which the natural precipitation processes have plenty of time to operate. It is therefore not obvious that seeding of these clouds would produce a significant increase in rainfall, although it is possible that by forestalling natural processes some redistribution might be effected.

Perhaps more promising as additional sources of rain or snow are the persistent supercooled clouds produced by the ascent of damp air over large mountain barriers. The continuous generation of an appropriate concentration of ice crystals near the windward edge might well produce a persistent light snowfall to the leeward, since water vapor is continually being made available for crystal growth by lifting of the air. The condensed water, once converted into snow crystals, has a much greater opportunity of reaching the mountain surface without evaporating, and might accumulate in appreciable amounts if seeding were maintained for many hours.

Trials carried out in favorable locations in the United States and Australia suggest that in some cases seeding has been followed by seasonal precipitation increases of about 10%, but rarely have the effects been reproduced from one season to the next, and overall the evidence for consistent and statistically significant increases of rainfall is not impressive. Indeed, as the experiments have been subjected to stricter statistical design and evaluation, the claims have steadily became more modest, and the difficulty of improving on natural processes has become increasingly apparent.

During the 1960s and 1970s, remaining trials were carried out in some 75 countries, and at one time about 25% of the land area of the United States was being seeded. However, by the late 1980s the activity was much reduced and had virtually ceased in Australia and many other countries. Nevertheless, China and Israel persevered. The Israeli experiments were unique in that they appeared to have produced rainfall increases on the order of 15% year after year for about 15 years. No convincing explanation for this has yet emerged. *See* CLOUD; WEATHER MODIFICATION.

Clove

The unopened flower bud (see **illus.**) of a small, conical, symmetrical, evergreen tree, *Eugenia caryophyllata*, of the myrtle family (Myrtaceae). The cloves are picked by hand and dried in the sun or by artificial means. The crop is uncertain and difficult to grow. Cloves, one of the most important and useful spices, are strongly aromatic and have a pungent flavor. They are used as a culinary spice for flavoring pickles, ketchup, and sauces, in medicine, and for perfuming the breath and the air in rooms. The essential oil distilled from cloves by water or steam has even more uses. The chief clove-producing countries are Tanzania with 90% of the total output, Indonesia, Mauritius, and the West Indies. *See* MYRTALES; SPICE AND FLAVORING.

Clover

A common name used loosely to designate the true clovers, sweet clovers, and other members of the plant family Leguminosa. This article discusses true clovers, sweet clover, and clover diseases.

True Clovers

The true clovers are plants of the genus *Trifolium*, order Rosales. There are approximately 250 species in the world. Collectively they represent the most important genus of forage legumes in agriculture. Different species constitute one or more crops on every continent. As indicated by the number of species and their ecotypes (subspecies) that have been collected and described, the center of origin appears to be southeastern Europe and southwestern Asia Minor. Many species are found in countries that border the Mediterranean Sea. About 80 species are native to the United States, most of them occurring in the general regions of the Rocky and Cascade mountains and the Sierra Nevada. Although these native clovers are not used as crop plants, they contribute to the range for grazing and wild hay and also supply nitrogen to associated grasses. Of those that are now named, it is possible that many are variants of other species. Only a few are native to the humid Eastern states. Most clovers are highly palatable and nutritious to livestock. The name clover is often applied to members of legume genera other than *Trifolium*. *See* ROSALES.

Characteristics. The true clovers are herbaceous annual or perennial plants. However, many perennial species behave as biennials or annuals under attacks of disease or insects, unfavorable climatic or soil conditions, or improper management. In general, clovers thrive under cool, moist conditions although one native species, desert clover (*T. gymnocarpum*), tolerates semiarid conditions. Annual species usually behave as winter annuals where winter conditions are not severe, and as summer annuals at northern latitudes and high altitudes.

Clovers grow best in areas where adequate supplies of calcium, phosphorus, and potassium are naturally present in the soil or where these elements are applied in limestone and fertilizers. They grow from a few inches to several feet tall, depending on the species and the environmental conditions. The leaves have three to five roundish to spearlike leaflets. The florets, ranging from 5 to 200 in number, are borne in heads. Colors include white, pink, red, purple, and yellow, and various mixtures. The basic haploid chromosome numbers of the species are 6, 7, and 8. Somatic chromosomes range from 12 to about 130, forming diploids, tetraploids, and polyploids. The flowers of some species are self-sterile and must be cross-pollinated before seed will form; the flowers of other species may be self-fertile and capable of self-pollination; others are self-fertile but do not set seed unless the flowers are tripped and the pollen scattered onto the stigma. Cross-pollination and tripping of flowers are effected principally by bees that visit the flowers for nectar and pollen. Seed color ranges from yellow to deep purple, some being bicolored. There are approximately 60,000–700,000 seeds per pound.

Uses. Clovers are used for hay, pasture, silage, and soil improvement. Certain kinds may be used for all purposes whereas others, because of their low growth, are best suited for grazing. All kinds, when well grown in thick stands, are good for soil improvement. Thoroughly inoculated plants add 50–200 lb of nitrogen per acre (56–222 kg per hectare) when plowed under for soil improvement, the amount added depending on growth, thickness of stand, and length of growing season. Clovers may be grown alone, in combination with grasses and other legumes, or with small grains. In the humid states, or where irrigated, clovers are sown most

frequently with small-grain companion crops. In the Corn Belt they are generally spring-seeded, whereas in the Southern states and in the West Coast region they should be seeded in the fall for best results.

Important species. All the clover species of agricultural importance in the United States are introduced (exotic) plants. **Figure 1** shows some of the species most widely used: red clover (*T. pratense*), alsike clover (*T. hybridum*), white clover (*T. repens*), crimson clover (*T. incarnatum*), subclover (*T. subterraneum*), strawberry clover (*T. fragiferum*), persian clover (*T. resupinatum*), and large hop clover (*T. campestre*, or *procumbens*). Other clovers of regional importance, mostly adapted to specific environmental conditions, are rose clover (*T. hirtum*), berseem clover (*T. alexandrinum*), ball clover (*T. nigrescens*), lappa clover (*T. lappaceum*), big-flower clover (*T. michelianum*), and arrowleaf clover (*T. vesiculosum*).

Species characteristics. The following sections discuss the characteristics of the most important species.

Red clover. Red clover is composed of two forms, medium and mammoth, producing two and one hay cuts, respectively. The large purplish-red flower heads are round. An upright-growing perennial, red clover generally persists for 2 years in the northern United States, but behaves as a winter annual in the South. When planted alone or with small grain, seeding rates are 10–15 lb/acre (11–17 kg/hectare). When seeded with grass and other mixtures, 4–8 lb/acre (4.9–9.0 kg/ha) is sufficient. Under favorable growth conditions, seed yields average 70 lb/acre (79 kg/ha); in the West under irrigation they may reach 600–800 lb/acre (675–900 kg/ha). There are several varieties and strains of red clover such as Kenland, Pennscott, Lakeland, Dollard, and Chesapeake. These produce higher yields of forage and are more persistent than common red clover.

Alsike clover. Alsike clover is an upright-growing species that behaves like a biennial. The growth pattern, seeding methods, mixtures, and uses are similar to those of red clover. The flower heads are much like those of white clover in shape and size, but are slightly more pinkish. Alsike clover is more tolerant of wet, poorly drained soils than red clover and occurs widely in mountain meadows of the West.

White clover. White clover, an inhabitant of lawns and closely grazed pastures, is the most important pasture legume in the humid states. The flowers are generally white, but sometimes they are tinged with pink. The stems grow on the soil surface and root at the joints (nodes) as the plant spreads. There are three main types, large, intermediate, and small, with all gradations between. Ladino is the best-known and most widely seeded variety of the large type, and Louisiana Sl represents the intermediate type. The small type is found principally in pastures that are continuously and closely grazed. All types are nutritious and are relished by all classes of livestock and poultry. The protein content ranges from 15 to 30%, depending on plant age and the succulence of growth. Ladino white clover is sometimes used for silage and hay. White clover is mainly grown with low-growing grasses, not being tolerant of the tall-growing kinds. Seeding rates vary from $^1/_2$ to 2 lb/acre (0.6 to 2.3 kg/ha) depending on the seed mixture. For successful growth, it is important to use the variety or strain best adapted to the particular climatic and soil conditions. Limestone and fertilizer must usually be used to get a thick stand and good growth. Spring seeding is recommended for the Northern states and fall seeding for regions having mild winters. For best growth of the clover, grass-clover mixtures should be grazed or cut frequently.

Crimson clover. Crimson clover is used principally as a winter annual for pasture and as a soil-improving crop from the latitude of the Ohio River southward, and along the West Coast. The yellow seed, approximately 120,000 per pound (260,000 per kilogram), are planted at the rate of 15–20 lb/acre (17–22 kg/ha) during the late summer and fall months in a prepared seedbed or on grass which is closely grazed or cut. The seedlings make a rosette of leafy growth during the winter months. With the advent of spring, growth is rapid; the plant reaches $1^1/_2$–3 ft (0.4–0.9 m) in height and the flower stems elongate, terminating with pointed crimson flower heads in late spring or early summer. The plant dies when the seed matures. Seed yields average about 250 lb/acre (280 kg/ha) even though large quantities are lost by shattering. Crimson clover is seeded alone, with small grains and grasses, or on grass turf. During the winter it may be grazed when growth reaches 4 in. (10 cm), although if it is too heavily grazed, regrowth is slow. The greatest return for soil improvement is obtained when the largest growth is plowed under. There are several varieties of crimson clover, including Dixie, Auburn, Autauga, Chief, Talladega, and many local strains. When conditions are favorable, all of these will reseed, forming volunteer stands in the fall from seed shattered the previous spring. Common crimson clover does not reseed. When used with Bermuda or other perennial summer-growing grasses, the tall growth of the grass must be closely grazed or clipped.

Subclover. Subclover, a winter annual extensively used for grazing in the coastal sections of the Western states, is the basic pasture crop of the sheep and cattle industry of Australia. The seed are blue-black and the largest of any clover species (about 60,000 per pound or 132,000 per kilogram). The flower heads on decumbent stems are inconspicuous. As the seed develop, fishhook-shaped appendages are produced which, by their twisting action, pull them into the soil, and hence the name subclover. Seed production is large, but the seed are difficult to harvest. When once established, fall stands develop from seed produced the preceding months. The Australian varieties Mount Barker, Tallarook, and Nangeela have proved to be best adapted to most conditions in the United States. Subclover appears to have considerable promise as a pasture legume under many conditions in the southern United States, but better adapted varieties are needed. Eugene A. Hollowell

Berseem clover. Berseem, or Egyptian clover (*T. alexandrinum*), is used as a cool-season annual forage crop in the states of Washington, Oregon, California, and Arizona and in the southeastern United States, and as a summer annual in northern areas. It is an upright-growing legume with oblong leaflets and hollow stems. It produces yellowish-white florets in heads and has short tap roots. In southern Florida, plants may obtain a height of 18–24 in. (45–60 cm) during a growing season from October to May and heights of 34–42 in.

(19–105 cm) in Arizona. Berseem clover's greatest potential is probably as green-chopped forage or pasture. It provides high-quality forage with a crude protein concentration of 20–24% on a dry-weight basis. Berseem clover produces an abundance of seed with yields exceeding 990 lb/acre (1100 kg/ha). Berseem flowers are essentially self-sterile, with cross pollination being accomplished by honeybees.

Cultivars of berseem clover are classified according to their branching behavior; branching influences the number of cuttings that can be made. The cultivars Miscawi and Kahdrawi, which exhibit basal branching, can yield four cuttings per growing season, whereas the Saidi produces both basal and apical branching and can be cut twice. The Fahl cultivar exhibits apical branching and can be cut only once; Nile and Hustler cultivars were developed in the United States and are equal to or superior to Miscawi. A somewhat hardier cultivar Multicut, which tolerates temperatures down to 23°F (−5°C), was released in 1988 for use in parts of California and Mexico; it produces five or six cuttings under irrigation. The release in 1984 of the winter-hardy, reseeding cultivar Bigbee, extended the range of adaptation of berseem clover to Tennessee and Oklahoma and enabled producers to obtain reseeding stands. Prior to the release of Bigbee, berseem clover was considered to be a nonwinter-hardy, nonreseeding annual forage legume. W. E. Knight

Other clovers. Strawberry clover, a perennial, is a nutritious pasture plant similar in growth habit to white clover, for which it is frequently mistaken. The pinkish flower head looks like a strawberry, and hence the common name. It is highly tolerant of the wet, salty soil common to the Western states.

Persian clover is a winter annual used mostly for pasture and soil improvement but is also an excellent silage plant. It is particularly adapted to the wet, heavy soils of the lower southern part of the United States. The flowers are light purple, and the mature seed are enclosed in balloonlike capsules that shatter easily, float on water, and are readily blown about by the wind. Persian clover is relished by all classes of livestock.

Large hop clover and small hop clover, widely distributed as winter annuals in the Southern states, are used in pastures. They are more tolerant of low soil fertility than the other species and less productive, but are highly palatable to livestock. The flower heads are bright yellow and, when mature, look like the flowers of the hop plant. The two species are similar.

Rose clover is a relatively new winter annual and appears to be best adapted to the foothill rangelands of California.

Other species are ball clover, lappa clover, bigflower clover, and arrowleaf clover, all winter annuals. Lappa clover grows best in the heavy dark marl soils of the South, whereas ball, big-flower, and arrowleaf clovers appear to be more widely adapted. All are used for pasture, although bigflower and arrowleaf clovers may also be used for hay.

Seaside clover (*T. willdenovii*), white-tipped clover (*T. variegatum*), and long-stalked clover (*T. longipes*) are the most widely distributed of the native western species. All produce thick stands and good growth under varying conditions. *See* GENETICS; LEGUME FORAGES; REPRODUCTION (PLANT).

Sweet Clover

Sweet clover is the common name applied to all but one species of legumes of the genus *Melilotus*, order Rosales. The exception is sour clover (*M. indica*).

Origin and distribution. There are approximately 20 species of sweet clover. Some of the biennial species have an annual form. The roots of the biennials develop crown buds from which the second-year growth arises; the roots of annuals do not develop crown buds. Sweet clovers are native to the Mediterranean region and adjacent countries, but several are widely scattered throughout the world, generally by chance introduction. None is indigenous to the United States. White sweet clover (*M. alba*) and yellow sweet clover (*M. officinalis*) are important forage and soil-improvement plants in the United States and Canada and are found growing along roadsides and in waste places in every state (**Fig. 2**). Sour clover, a yellow-flowered winter annual, is of some value for soil improvement only along the Gulf Coast and in southern New Mexico, Arizona, and California. Improved varieties of white and yellow sweet clovers are available for farm use.

Uses. Sweet clover is used as a field crop in regions of the United States and Canada where the rainfall is 17 in. (42 cm) or more during the growing season, where the soil is neutral, or where

Fig. 2. White sweet clover (*Melilotus alba*). (*USDA*)

limestone and other needed minerals are applied. It is most extensively grown in the Great Plains and Corn Belt, either alone or in rotations with small grains and corn, and is used for grazing, soil improvement, and hay.

Except for those of certain improved varieties, the plants are somewhat bitter because of the presence of coumarin. External and internal bleeding of animals may result from feeding spoiled sweetclover hay or improperly preserved silage containing sweet clover, a decomposition product of coumarin (4-hydroxycoumarin, commonly called dicumarol), which develops during spoilage, being the toxic principle. Research has led to its use in medicine and for making warfarin, a rodenticide.

Eugene A. Hollowell

Diseases

Diseases of clovers are caused by bacteria, fungi, nematodes, viruses, a mycoplasma, and air pollutants. These diseases reduce forage yield, quality, and stand. Frequently, perennial clovers are productive for only 1 or 2 years because of diseases. Crop losses are best minimized by growing adapted cultivars that are tolerant of or resistant to one or more of the major diseases. Fungi and viruses are the most important pathogens.

Fig. 3. Red clover roots cut longitudinally to show type of injury caused by crown and root rot organisms.

Fig. 4. Typical petiole and stem lesions of northern anthracnose disease of red clover, caused by the fungus *Kabatiella caulivora*.

Fungal diseases. Fungi, including *Pythium, Fusarium*, and *Sclerotinia*, cause root and crown rots that reduce stand establishment and persistence (**Fig. 3**). These pathogens can attack clover plants at any developmental stage. Plants not killed are weakened, and are thus predisposed to further injury from physical and biological stress.

Fungi, including *Stemphylium, Colletotrichum*, and *Kabatiella*, cause leaf and stem diseases, which usually do not kill the plants but reduce their productive and competitive capabilities (**Fig. 4**).

Viral diseases. Most clovers are susceptible to destructive viruses that cause leaf mottling and distortion and reduced plant vigor. Viruses may be seed-borne or spread by insects and mowing. *See* PLANT PATHOLOGY; PLANT VIRUSES AND VIROIDS.

Clupeiformes

The single order of the teleost fishes in the subdivision Clupeomorpha. Clupeiforms, including anchovies, herrings, sardines, shads, and allies, are classified in two suborders, five families, 83 genera, and about 357 species. A unique feature of clupeiforms is the ear–swim bladder connection (otophysic connection) composed of a pair of anterior extensions of the swim bladder that enter the skull to connect with the utriculus of the inner ear. They are further distinguished by a series of median scutes (keel-like scales) along the abdomen before and behind the pelvic fin (some species have predorsal scutes as well as ventral scutes), and a single scute is present at the insertion of the pelvic fins. The body is compressed in most species; fin spines are lacking, as are an adipose fin and gular plate; the jaws are not protractile; the pelvic fins are abdominal in position and free from the shoulder girdle; the pectoral fin is placed low on the side; and a mesocoracoid arch is present; the upper jaw is bordered by premaxillae and maxillae, but the detention is usually feeble; the cycloid scales are usually thin and loosely attached, especially in anchovies; the air bladder is connected to the gut (physostomous); and there is no leptocephalus larva.

Clupeiforms are mostly silvery and typically occur in large schools, feeding on plankton that is strained from the water by numerous long gill rakers. A notable exception is the wolf herring (*Chirocentrus*) of the Indo-Pacific, which is a predator with strong teeth.

Some of the great fisheries of the world are based on the conversion of plankton by clupeiform fishes. These include the tremendous anchovy fishery off western South America, the California fisheries for anchovy and (until depleted) Pacific sardine, the menhaden fisheries of the western Atlantic, and the herring and sardine fisheries of northern seas. The catch is processed variously into oil, fertilizer, or fish meal or is prepared directly for human consumption. Indirectly, clupeiforms are of tremendous importance in the food cycles of piscivorous fishes and of some sea birds which depend on them as dietary staples.

Clupeiform fishes have left a rich fossil record, especially from the Upper Cretaceous to the early Tertiary, but appeared first in the Upper Jurassic.

Denticipitidae. This family, in the suborder Denticipitoidei, comprises one fossil species, probably from the Miocene, and one extant species, *Denticeps clupeoides* (denticle herring), known from the coastal rivers of Nigeria and Cameroon. It differs from other clupeiforms in having a complete lateral line, denticles variously placed on the skull and branchiostegal rays, and 16 principal caudal fin rays.

Commerson's anchovy (*Stolephorus commersonnii*). Maximum size approximately 10 cm (4 in.). (*Photo © by John E. Randall*)

Clupeoidei. This suborder comprises the remainder of the clupeiforms and is distinguished by the lateral line not extending onto the body, but essentially limited to a cephalic canal system extending onto the operculum; and 19 principal caudal fin rays.

Engraulidae. Anchovies, which make up this family, are for the most part small, delicate fishes that have a conical snout overhanging a large mouth (see **illustration**). The maxilla is extremely long, reaching beyond the large eye and often to the margin of the operculum. Gill rakers are long and numerous; teeth are absent in jaws of most species—however, the large piscivorous species have large jaw teeth. Scales are thin and cycloid and usually deciduous, even when carefully handled. There are 16 genera and 139 species, with about 17 species occurring in freshwater and the rest in the Atlantic, Indian, and Pacific oceans. Thirty species occur in North American waters, 23 of which are in the genus *Anchoa*. Most of the freshwater species are from South America.

Pristigasteridae. In this family the mouth is superior in most species, otherwise it is terminal; jaw teeth are small (one genus has canine teeth); abdominal scutes are present; and the anal fin is long, with 30 to 92 rays. This family comprises nine genera and 34 species. Four species are freshwater and the rest occur in tropical and subtropical Atlantic, Indian, and Pacific oceans. Five species occur on the Pacific coast of Mexico.

Chirocentridae (wolf herring). This family consists of only one genus and two species that are characterized by an elongate, highly compressed body and fanglike jaw teeth. It has a spiral valve in the intestine, an uncommon feature for a teleost fish. The pelvic fin is small, the scales are small; the pelvic scute is reduced; and abdominal scutes are absent. These fishes occur in the western Pacific and the western Indian oceans to South Africa and the Red Sea.

Clupeidae. This family includes herrings, shads, sardines, sprats, pilchards, and menhadens. Two long, rodlike postcleithra distinguish most members of this family from other clupeiforms. In addition, the mouth is terminal and abdominal scutes are present, except in the subfamily Dussumieriinae (round herrings). The family is composed of five subfamilies, 50 genera, and 181 species, 50 of which occur in freshwater, some of which are anadromous. The rest are marine species that occur worldwide, mostly in tropical waters. Eleven genera and 33 species occur in North American waters.

Distribution and ecology. Some herrings and a few anchovies live in lowland rivers and lakes, and others such as the shad and alewife enter rivers to reproduce; but the majority of clupeiforms occur in bays or shore waters of tropical, temperate, or even northern seas, where they commonly make up enormous schools. None inhabits deep water. Most clupeiforms feed on plankton or other minute organisms, thus they are efficient converters from the base of the food chain to fish flesh.

Clutch

A coupling device which permits the engagement and disengagement of coupled shafts during rotation. There are four major types: positive, friction, hydraulic, and electromagnetic.

Positive clutch. This type of clutch is designed to transmit torque without slip. It is the simplest of all shaft connectors, sliding on a keyed shaft section or a splined portion and operating with a shift lever on a collar element. The jaw clutch is the most common type of positive clutch. This is made with square jaws (**Fig. 1***a*) for driving in both directions, or spiral jaws (Fig. 1*b*) for unidirectional drive. Engagement speed should be limited to 10 revolutions per minute (rpm) for a square-jaw clutch and 150 rpm for a spiral-jaw clutch. If desengagement under load is required, the jaws should be finish-machined and lubricated. *See* MACHINE KEY; SPLINES.

Friction clutch. This type of clutch is designed to reduce coupling shock by slipping during the engagement period. It also serves as a safety device by slipping when the torque exceeds its maximum rating. The three common designs for friction clutches are cone, disk, and rim, according to the direction of contact pressure. *See* FRICTION; TORQUE.

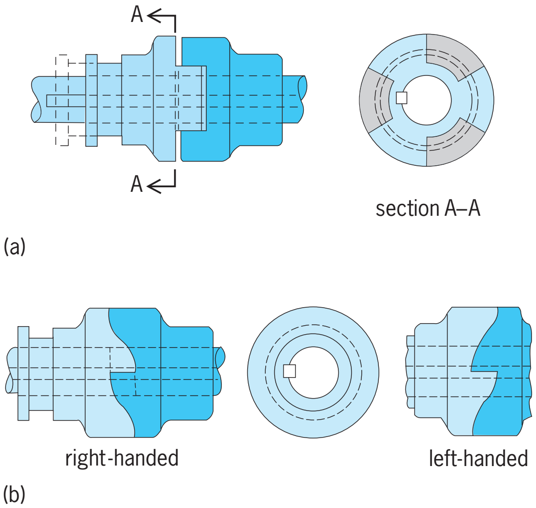

Fig. 1. Positive clutches. (*a*) Square-jaw clutch. (*b*) Spiral-jaw clutch. (*After E. A. Avallone and T. Baumeister III, eds., Marks' Standard Handbook for Mechanical Engineers*, 9th ed., McGraw-Hill, *1987*)

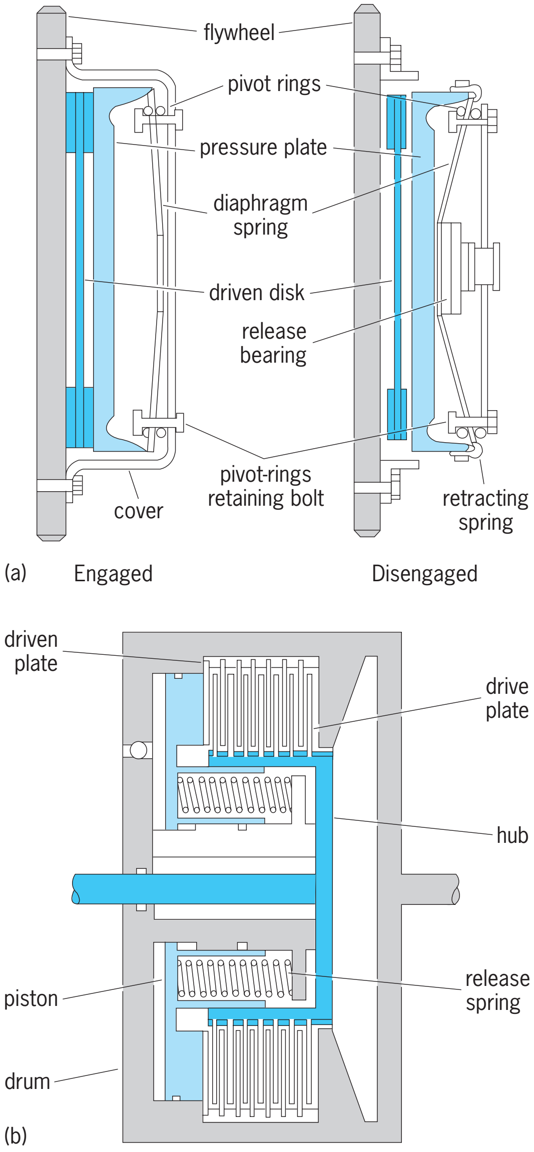

Fig. 2. Friction clutches. (*a*) Plate clutch. (*b*) Multidisk clutch. (*After E. A. Avallone and T. Baumeister III, eds., Marks' Standard Handbook for Mechanical Engineers*, 9th ed., McGraw-Hill, *1987*)

Cone clutch. This is an axial type clutch. The surfaces of the cone clutch are sections of a pair of cones. This shape uses the wedging action of the mating surfaces under relatively small axial forces to transmit the friction torque. These forces may be established by the compression of axial springs or by the outward displacement of bell-crank levers to apply axial thrust to the conical surfaces.

Disk clutch. This is also an axial-type clutch. The disk clutch may consist of a single plate or multiple disks (**Fig. 2**). With the development of improved friction material, disk clutches have become more common than cone clutches, with wide applications in the industrial and automotive fields. Disk clutches are not subjected to centrifugal effects, present a large

Friction materials for clutches and design data*

†The friction coefficient can be maintained within ± 5% for specific materials in this group.

friction area in a small space, establish uniform pressure distribution for effective torque transmission, and are capable of effectively dissipating the generated heat to the external housing. The disk clutch may be operated dry, as in most automobile drives, or wet by flooding it with a liquid, as in heavier automotive power equipment and in industrial engines. The advantage of wet operation is the ability to remove heat by circulating the liquid enclosed in the clutch housing. Typical friction materials for clutches and design data are shown in the **table**.

Rim clutch. This is another form of frictional contact clutch that has surface elements applying pressure to the rim either externally or internally. Rim clutches may be subdivided into two groups: those employing either a frictional band or block (**Fig. 3**) to make contact with the rim; and the overrunning clutch (**Fig. 4**), employing the wedging action of a roller or ball. The clutches of the former type may have hinged shoes connected by an expanding or contracting kinematic mechanism on a hub fixed to one shaft and riding of a drum or rim attached to a hub on a second shaft. They have expansion rings or external bands that, when displaced, are capable of transmitting torque to the clutch rim. The rim may be grooved to increase the surface area; the clutch may have a double grip, internal and external; or pneumatically expanding flexible tubes may set the friction surfaces against the rim (**Fig. 5**). Because the clutch rotates with the shaft when it is engaged, its balancing must be considered.

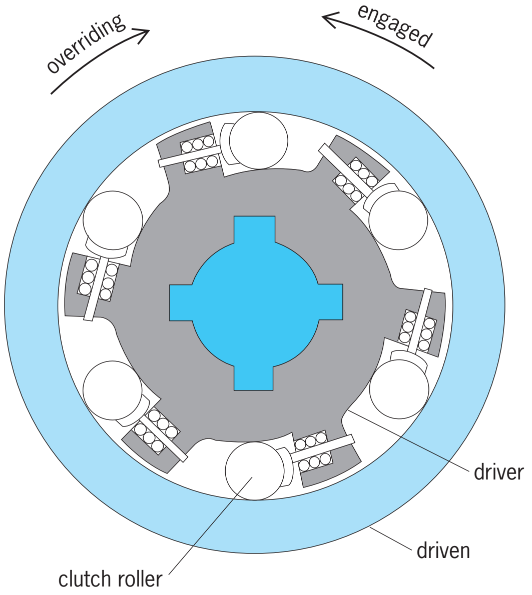

Fig. 4. Overrunning clutch. (*After E. A. Avallone and T. Baumeister III*, *eds.*, *Marks' Standard Handbook for Mechanical Engineers*, *9th ed.*, *McGraw-Hill*, *1987*)

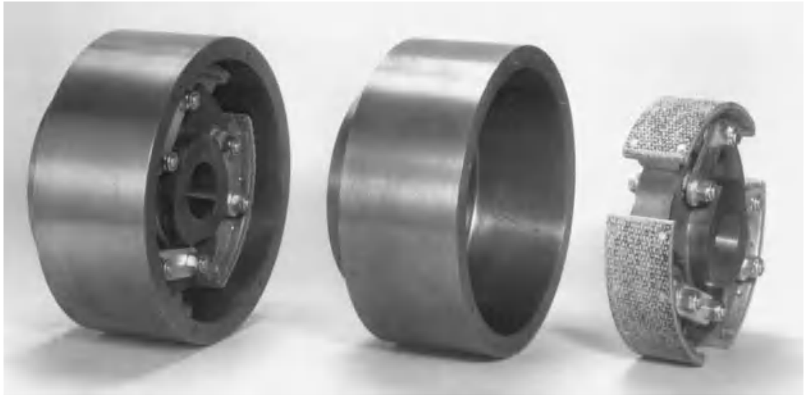

Fig. 3. Internal-expanding centrifugal-acting rim clutch. (*Hilliard Corp.*)

For overrunning clutches, the driven shaft can run faster than the driving shaft. This action permits freewheeling as the driving shaft slows down or another source of power is applied. Effectively this is a friction pawl-and-ratchet drive, wherein balls or rollers become wedged between the sleeve and recessed pockets machined in the hub. The clutch does not slip when the second shaft is driven, and is released automatically when the second shaft runs faster than the driver. Specially shaped struts or sprags may replace the balls; springs may be used to hold the pawl elements in position. Mechanisms have been devised to reverse the direction of operation. *See* PAWL; RATCHET.

Hydraulic clutch. Clutch action is also produced by hydraulic couplings, with a smoothness not possible

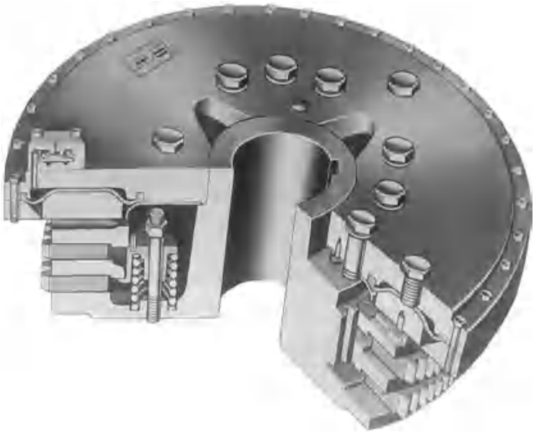

Fig. 5. External-contracting clutch that is engaged by expanding the flexible tube with compressed air. (*Twin Disc, Inc.*)

when using a mechanical clutch. Automatic transmissions in automobiles represent a fundamental use of hydraulic clutches. *See* AUTOMOTIVE TRANSMISSION; FLUID COUPLING; HYDRAULICS.

Electromagnetic clutch. Magnetic coupling between conductors provides a basis for several types of clutches. The magnetic attraction between a current-carrying coil and a ferromagnetic clutch plate serves to actuate a disk-type clutch. Slippage in such a clutch produces heat that must be dissipated, and wear that reduces the life of the clutch plate. Thus the electromagnetically controlled disk clutch is used to engage a load to its driving source. A typical unit 24 in. (61 cm) in diameter and weighing about 600 lb (270 kg) develops 2400 ft-lb (3300 joules) of torque when excited at 2 amperes and 115 dc volts; at a maximum safe speed of 1200 rpm it transmits 540 hp (400 kW). Multiple interleaved disks alternately splined to the driving and driven shafts provide a compact structure (**Fig. 6**). There are three basic types of electromagnetic clutches: magnetic fluid and powder, eddy-current, and hysteresis. *See* ELECTROMAGNET.

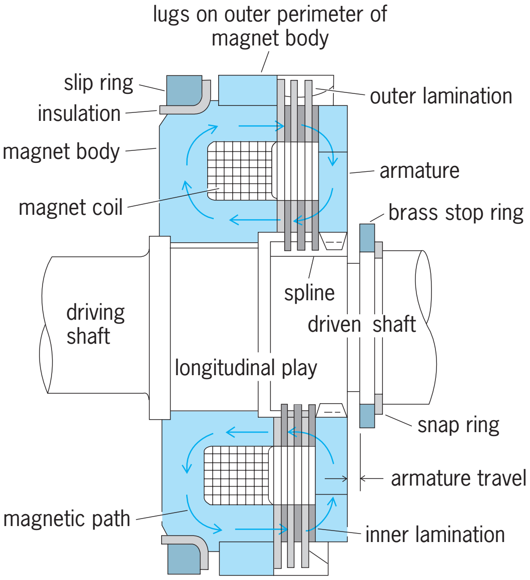

Fig. 6. Electromagnetically activated multiple-disk clutch.

Magnetic fluid and powder clutch. These may use finely divided magnetic particles in an oil carrier or be of the dry can type. Upon the application of a magnetic field, the particles tend to coalesce, thereby creating viscous or friction forces between the clutch members. The wet type provides the smoother operation; the dry type is freer from loss of particles. Torque at a fixed moderate excitation is independent of slip.

Eddy-current clutch. The current that is induced by a magnetic field can serve as the torque-transmitting means. In the eddy-current clutch, a coil-carrying direct current in one rotating member establishes poles that generate currents in the adjacent smooth conductive ring of the mating member. The coupling acts as an untuned damper and therefore does not transmit torsional vibration. An eddy-current clutch consists of a separately excited motor and generator that are combined into a single machine. Clutch action can be obtained by electrically connecting a generator on the driving shaft to a motor on the driver. *See* DYNAMOMETER; EDDY CURRENT; ELECTRIC ROTATING MACHINERY.

Hysteresis clutch. For low-power applications where continuous control with slip is needed, as in instrument servos, a hysteresis clutch may be used. Direct-current excitation of a coil in one part generates a steady flux field that magnetizes an iron ring on the other part, the ring having high magnetic retentivity. The action induces poles in the iron ring. Attraction between the induced poles in the ring and the control field produces a torque that opposes rotation between the two parts of the clutch. Within its load limit the hysteresis clutch transmits rotation without slip. As with the eddy-current clutch, there is no contact surface to wear so that the characteristics are stable and the life is long. *See* HYSTERESIS; SHAFTING; TORQUE CONVERTER.

Bibliography. E. A. Avallone and T. Baumeister III (eds.), *Marks' Standard Handbook for Mechanical Engineers,* 10th ed., 1996; J. E. Shigley and L. D. Mitchell, *Mechanical Engineering Design,* 4th ed., 1993.

Cnidaria

A diverse phylum of aquatic animals that are characterized by the possession of (1) intrinsic nematocysts, (2) a single body space that opens to the external medium, (3) radial or biradial symmetry, (4) tissue level of organization, and (5) diploblastic structure. With few exceptions, a cnidarian also has tentacles surrounding the mouth (the opening of the body cavity to the exterior). Most definitions of the phylum include the feature metagenesis; however, although the life cycle of many cnidarians involves this alternation between an asexually reproducing polyp and a sexually reproducing medusa, this is not true of two entire classes (Anthozoa and Staurozoa) and of some members of class Hydrozoa. The name Coelenterata, which has been used for this phylum, is being supplanted because, as sometimes used, it included the sponges (Porifera) and comb jellies (Ctenophora), as well as the animals now called cnidarians. *See* CTENOPHORA; PORIFERA.

Taxonomy

Cnidarians include jellyfish, corals, sea anemones, the Portuguese man-of-war, hydroids, and the freshwater hydras. For many years, the phylum was divided into three classes, but four are now accepted and a fifth has been proposed: (1) Anthozoa (sea anemones, corals, sea fans, sea pens, and sea pansies), (2) Hydrozoa (hydroids, hydras, and hydromedusae), (3) Scyphozoa ("true" jellyfish), (4) Cubozoa (box jellies; formerly included in Scyphozoa), (5) Staurozoa (the Stauromedusae; formerly included in Scyphozoa) [see **table**]. All except a few hydrozoans are marine (**Fig. 1**). The Hydrozoa, Scyphozoa, Cubozoa, and Staurozoa are collectively referred to as

A classification of the phylum Cnidaria

Subdivision	Characteristics	Representative genera
Class Anthozoa	All marine	
Subclass Octocorallia	Almost exclusively colonial, each polyp with eight tentacles and mesenteries; also called Alcyonaria	
Order: Alcyonacea	Soft corals, sea fans, precious coral; sclerites in most species; thin or thick coenenchyme or stolonic network connects polyps; some with axial skeleton	*Alcyonium, Anthomastus, Clavularia, Corallium, Muricea, Tubipora*
Helioporacea	Blue coral; calcareous skeleton of aragonite; also called Coenothecalia	*Heliopora*
Pennatulacea	Sea pens and pansies; colony retractile, with bilateral symmetry	*Pennatula, Renilla, Virgularia*
Subclass Hexacorallia	Tentacles and mesenteries more or less hexamerously arranged; also called Zoantharia	
Order: Actiniaria	Sea anemones; solitary (may be clonal); live at all depths in all seas	*Actinia, Dactylanthus, Edwardsia, Metridium*
Antipatharia	Thorny or black corals; axial skeleton	*Antipathes, Dendrobranchia*
Ceriantharia	Tube anemones; solitary; lack pedal disc	*Cerianthus*
Corallimorpharia	Resemble corals; lack skeleton; tentacles radially arranged	*Corallimorphus, Corynactis*
Rugosa	Solitary or compound corals; calcareous skeleton; all fossil	*Lambeophyllum, Petraia, Syringaxon*
Scleractinia	True or stony corals; solitary and colonial; half of species reef formers	*Astrangia, Fungia, Porites*
Tabulata	"Honeycomb corals"; colonial, calcareous, tabulate corallites; all fossil	*Favosites*
Zoanthidea	Mat anemones; no skeleton; solitary or colonial, many commensal	*Palythoa, Parazoanthus, Zoanthus*
Class Cubozoa	Velarium present; largely tropical, subtropical	*Carybdea, Tripedalia*
Class Hydrozoa	Most marine; few species fresh-water	
Order: Actinulida	Hydroid generation represented by actinula-like form	*Halamohydra, Otohydra*
Anthoathecata	Athecate hydroids, hydrocorals, chondrophores	*Clava, Hydra, Millepora, Pennaria, Tubularia, Velella*
Limnomedusae	Some species commensal; hydroids naked	*Craspedacusta, Gonionemus*
Leptothecata	Hydroids with a hydrotheca	*Obelia, Plumularia, Sertularia*
Trachymedusae	Polypoid generation absent	*Aglantha, Liriope*
Narcomedusae	Holopelagic; most without polypoid generation; some parasitic	*Aegina, Cunina, Tetraplatia*
Siphonophora	Polymorphic colonies; planktonic	*Abyla, Forskalia, Physalia*
Class Scyphozoa	All marine	
Subclass Scyphomedusae	Tetramerous medusae that are produced through strobilation and grow through ephyra stage	
Order: Coronatae	Coronal furrow; lack ocelli	*Atolla, Linuche, Nausitho, Periphylla*
Semaeostomeae	Pedalia and coronal furrow lacking	*Aurelia, Cyanea, Pelagia*
Rhizostomeae	Numerous small mouths; no marginal tentacles	*Cassiopeia, Cephea, Rhizostoma*
Subclass Conulata	Tetramerous cone-shaped to elongate pyramidal; unattached; tentacles on oral margin; all fossil	
Order Conularida	Characters of subclass	*Conularia, Conulariella, Paraconularia*
Class Staurozoa	Sessile medusae; largely temperate	*Haliclystus, Lucernaria*

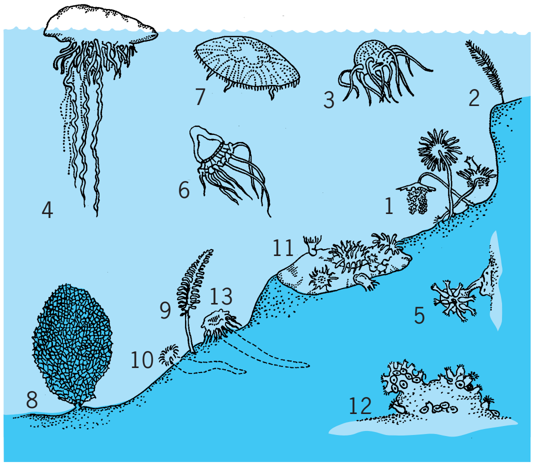

Fig. 1. Marine cnidarians in typical habitats (not to scale): 1, *Tubularia* (solitary hydroid); 2, *Plumularia* (colonial hydroid); 3, *Gonionemus* (hydromedusa); 4, *Physalia* (Portuguese man-of-war); 5, *Haliclystus* (stauromedusa); 6, *Periphylla* (scyphomedusa); 7, *Aurelia* (scyphomedusa); 8, *Gorgonia* (sea fan); 9, *Pennatula* (sea pen); 10, *Edwardsia* (sea anemone); 11, *Epiactis* (sea anemone); 12, *Astrangia* (stony coral); and 13, *Cerianthus* (tube anemone). 1–4 are members of Hydrozoa, 5 is a member of Staurozoa, 6 and 7 are members of Scyphozoa, and 8–13 are members of Anthozoa. (*After T. I. Storer and R. L. Usinger, General Zoology, 3d ed., McGraw-Hill, 1957*)

the Medusozoa because at least some species in each class have a medusa in the life cycle, whereas no anthozoans do. *See* ANTHOZOA; CUBOZOA; HYDROZOA; SCYPHOZOA; STAUROMEDUSAE.

General Morphology

The two basic body forms of cnidarians—the polyp and the medusa—typically live in different habitats (the former benthic, the latter pelagic), and although they appear superficially rather different, they share many features (**Fig. 2**). Of the two epithelial tissue layers, the endoderm (also termed the gastrodermis) lines the single body space, the coelenteron (also termed the gastrovascular cavity), and the ectoderm (also termed the epidermis) forms the external surface. [The name Coelenterata is derived from the term coelenteron (meaning "hollow gut")] Between ectoderm and endoderm is the mesoglea, which varies from a thin, acellular cementing layer to the thick, cellular and fibrous gelatinous layer that is the "jelly" of jellyfishes.

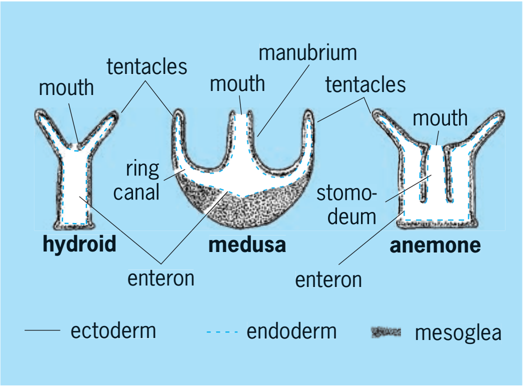

Fig. 2. Comparison of hydrozoan polyp, medusa (inverted), and anthozoan polyp. (*After T. I. Storer and R. L. Usinger, General Zoology, 3d ed., McGraw-Hill, 1957*)

The ectoderm is, in general, a single layer of cells, varying in form from flat and squamous to tall and columnar. It may be ciliated; in its food-gathering mode, the ciliary beat can move material toward the mouth from the surface of the animal and its tentacles, but in its cleaning mode, the direction is reversed. The endoderm may also be ciliated: cilia circulate water through the coelenteron and move food around within it.

Being at the "tissue grade" of construction, cnidarians lack organs and, therefore, organ systems. Their diploblastic structure means that they essentially consist of folded sheets of epithelia—and so have been termed "origami animals." Types of cells in the epithelia (both ectoderm and endoderm) include gland cells (that produce mucus and digestive enzymes), sensory cells, undifferentiated interstitial cells, ciliated cells, and cnidocytes (cells that produce cnidae, including nematocysts). Epitheliomuscular cells, in which the elongated cell base contains contractile fibrils, may constitute the entire musculature of simple polyps, such as most hydroids, but sea anemones and medusae have distinct muscle cells (contrary to many textbooks).

Polyp. A polyp is typically benthic (lives associated with the bottom of an ocean, lake, or stream), sessile, cylindrical, and elongated along the oral-aboral axis. The mouth, at the polyp's free (distal) end, is almost invariably surrounded by few to many hollow or solid tentacles (depending on the taxonomic group) arrayed in whorls or radially (or both). The aboral (proximal) end of a polyp (commonly referred to as the base or pedal disk may be adapted for attachment to a solid substratum or for burrowing into a soft substratum; but in colonial species, it arises from another polyp or the common tissue mass. With strong bilaterality in some taxa, especially Class Anthozoa, the polyp's symmetry is typically tetraradial, hexameral, octameral, or decameral, but it may be otherwise. An anthozoan polyp has sheets of tissue extending radially from the column wall into the coelenteron; some or all of these mesenteries connect with the actinopharynx (or stomodeum), a tube of tissue extending partway into the coelenteron from the mouth (Fig. 2, right). The mesoglea of a polyp may be little more than an adhesive, holding the two cell layers together (as in many hydroids), or it may be thick, spongy, and with many cells (as in some sea anemones). Polyps range in length from 1 mm to 2 m.

Medusa. A medusa is typically pelagic (lives free in the water), with thick mesoglea; its "body" is termed a bell due to its form. The outer (aboral) surface of the bell is termed the exumbrella and the underside (oral part), the subumbrella. The mouth commonly opens at the end of a tube of tissue (the manubrium) that extends from the underside of the bell (Fig. 2, center); there may be some tentaclelike structures immediately around the mouth, but typically the tentacles are located at the margin of the bell. Conventionally portrayed with the tentacles hanging downward and the exumbrella pointing toward the surface of the sea, most medusae spend much of their time in postures other than this. The mouth, commonly via the manubrium, leads to the central coelenteron. Radial canals may run between the cavity and the margin on the subumbrellar side, and they commonly communicate with a ring canal that is continuous around the margin; canals may also run from the ring canal along the tentacles. The mesoglea serves as a type of internal skeleton, against which muscles act, and its elasticity returns the bell to its original shape after each contractile pulse.

Cnidae

The name of phylum Cnidaria is derived from "cnidae," microscopic structures that are the phylum's most distinctive feature, and the most complex secretory product made by any animal. Each is formed within a cell (a cnidocyte) and consists of a capsule and a tubule that is coiled or folded within the capsule. When discharge occurs, the tubule emerges from one end of the capsule; typically, the tubule is many times longer than the capsule. There are three types of cnidae: nematocysts are formed by all cnidarians (and only cnidarians); spirocysts are restricted to the Subclass Hexacorallia of Class Anthozoa; and ptychocysts are restricted to Order Ceriantharia of Subclass Hexacorallia.

Nematocysts. When a nematocyst (a "stinging capsule," not a "stinging cell" as it is sometimes called) is appropriately stimulated, its tubule rapidly everts (turns inside out, like a coat sleeve). Some types are used offensively (they are the means by which the exclusively carnivorous cnidarians capture their food) and some types are used defensively. Some types of hydrozoan nematocysts have a cnidocil (a trigger) that must be stimulated for discharge to occur, but in other cnidarians, it appears that the sensation triggering discharge is received at some distance from the nematocyst, and nerves transfer the impulse that stimulates discharge. Thus, a cnidarian has some control over the use of its nematocysts, although previously nematocysts were thought to discharge upon appropriate stimulation, without any control by the animal. Such control is reasonable; each nematocyst can be used only once, so producing them represents a large portion of the energy budget of a cnidarian.

Approximately 30 morphological types of nematocysts have been identified, differing in capsule shape, tubule length, diameter, and spination. However, all seem to fall into one of three functional categories (**Fig. 3**): a volvent has an unarmed tubule that wraps around and entangles prey; a penetrant has a tubule armed with barbs that penetrates prey and may deliver a toxin; and a glutinant has a sticky tubule that hangs on to prey so that it can be carried to the mouth, or helps to anchor the cnidarian to an object

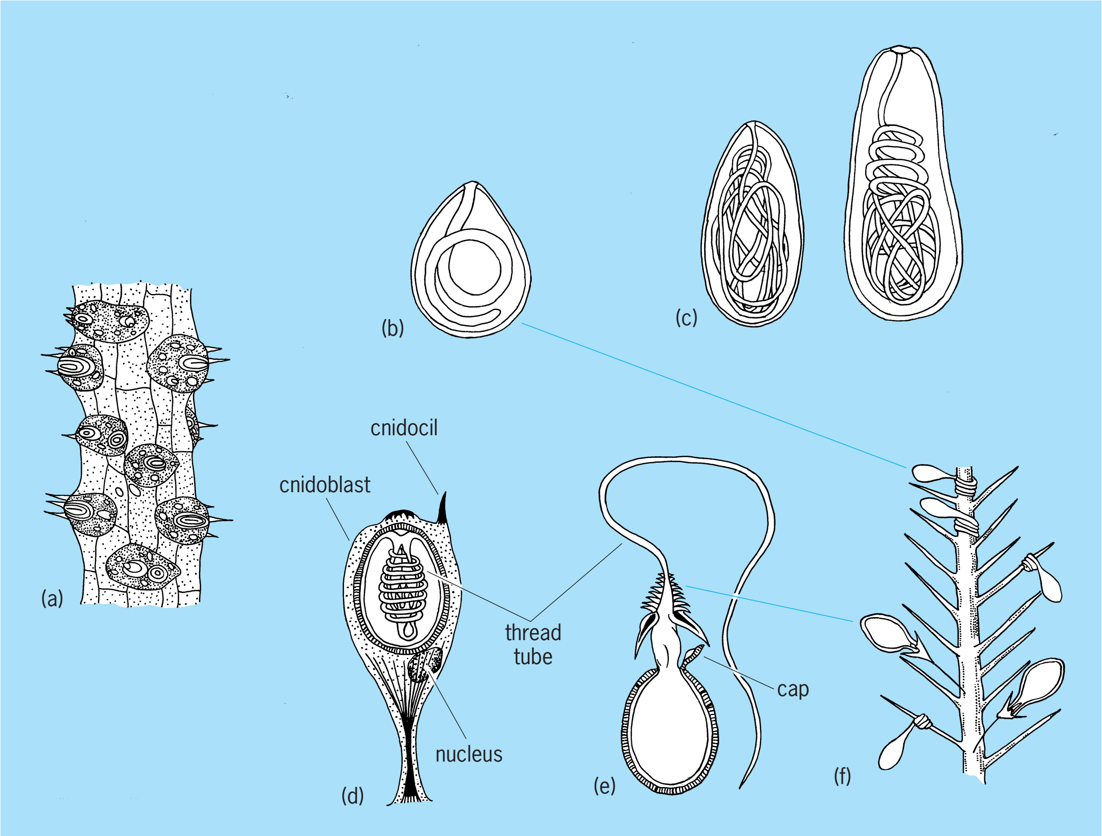

Fig. 3. Nematocysts of Hydra. (*a*) Tentacle with nematocyst batteries. (*b*) Volvent. (*c*) Glutinant. (*d*) Penetrant before discharge. (e) Penetrant discharged. (*f*) Discharged nematocysts on bristle of a crustacean. (*After T. I. Storer and R. L. Usinger, General Zoology, 3d ed., McGraw-Hill, 1957*)

(for example, glutinants appear to be important in attaching its tentacles to the substratum when *Hydra* somersaults).

The double-walled nematocyst capsule is made of collagenous proteins. Nematocysts are typically densest in the tentacles, where types important in prey capture are particularly abundant. Nematocysts are limited to the ectoderm of hydrozoans, whereas in Scyphozoa and Anthozoa, they occur in both ectoderm and endoderm. In sea anemones, certain types are restricted to the filaments on the mesenteries, and they seem to contain digestive enzymes. Some types of nematocysts can be painful to humans, and cubozoan stings may cause vasomotor dysfunction and even death. *See* TOXIN.

Although formed only by cnidarians, nematocysts may occur in other kinds of animals. Some flatworms, comb jellies, and nudibranchs that feed on cnidarians can store the capsules in their own bodies without causing them to discharge. Oriented so the eversible end of the capsule is at the surface of the animal's body, these "kleptocnidae" can be used to defend the cnidarian predator.

Spirocysts and ptychocysts. Spirocysts are especially common in tentacles, where they seem to function in entangling prey. The single-walled spirocyst capsule is thin, and the tubule is long, unarmed, spirally coiled, and of uniform diameter. Spirocysts stain with acid dyes, whereas nematocysts stain with bases. Ptychocysts are larger than either nematocysts or spirocysts (although they, too, are intracellular and therefore microscopic), and the tubule of each is folded within the capsule. Ptychocysts occur largely on the exterior surface of the body of a ceriantheid, where their discharged tubules entangle, forming a feltwork that incorporates mud and organic matter to create the tube that is typical of these "tube anemones."

Functional Morphology

Cnidarians lack organs and therefore organ systems. Because the endoderm and ectoderm are each a single cell thick, all their cells are in contact with either the external medium or the fluid in the coelenteron, allowing gas exchange and excretion to be carried out by individual cells. Other physiological functions are described below.

Nerves and sensory structures. The nerves form a meshwork, with no centralized ganglia. However, the individual nerve cells and the synapses are polarized, like those of other metazoans (previously the system was considered unpolarized). Nerves are situated at the base of the ectoderm and endoderm, with a variable number of connections across the mesoglea, in some animals particularly around the mouth and in the tissue connecting members of a colony. Some medusae have sensory structures such as eyespots or statocysts (which function in balance) along the ring canal, on the tentacle bases, or on marginal structures. Cubozoan eyes are the most highly developed of these sensory structures: they can form images. In other cnidarians that lack discrete sensory structures, there is evidence that at least some nerves are sensitive to particular stimuli. For example, scleractinian corals typically expand at night and contract by day; thus they appear to be able to detect light despite lacking any structure that is recognizably light sensitive.

Functionally, in at least some species, there appear to be nervous pathways specialized for rapid conduction and others for slower, more general spread of impulses. Colonies of some species are functionally integrated by means of nerves, whereas in other species, the members of the colony function more independently. In the former case, stimulation of a single polyp may provoke contraction of many other members of the colony, whereas in the latter case, it will cause contraction only in the area of stimulation. Potentiation is demonstrable in some cnidarians, with a single stimulus causing only a local contraction, and succeeding stimuli at the same location causing a more widespread response. Many cnidarians show simple reflexes, such as righting movements and swallowing.

Swimming contractions of medusae are coordinated by nerves. In species that have them, marginal sensory structures generally regulate these actions. When the structures are removed, swimming movements stop unless the medusa is artificially stimulated; when some of the structures are removed, movement of the medusa is uncoordinated and erratic. In the laboratory, if a preparation constituting a ring from the margin of a medusa is stimulated, a wave of contraction is initiated. *See* NERVOUS SYSTEM (INVERTEBRATE).

Muscles. The column and tentacles of a polyp have an ectodermal longitudinal muscle layer, and an endodermal, circular muscle layer; the contractile elements are located subepithelially. Most small organisms have epitheliomuscular cells (**Fig. 4***c*), but

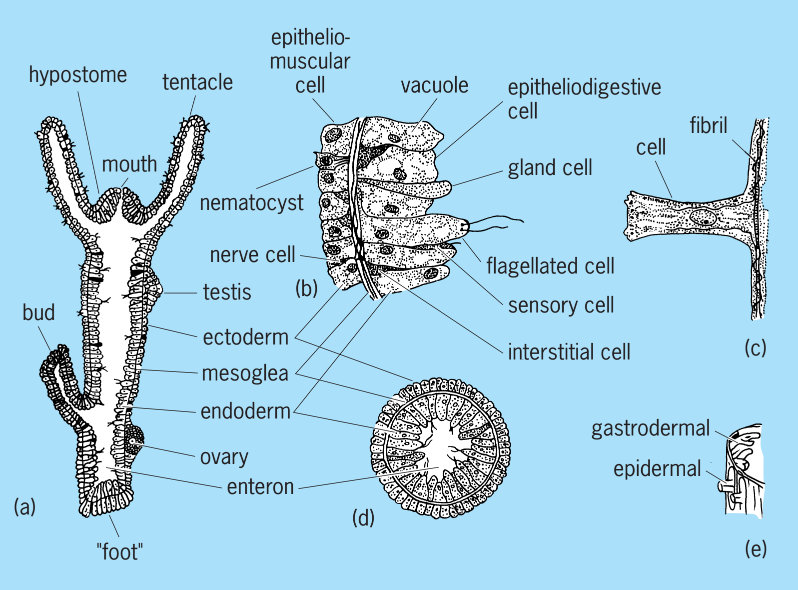

Fig. 4. Histological sections of Hydra. (*a*) Longitudinal section. (*b*) Enlarged cross section through column. (*c*) Epitheliomuscular cell. (*d*) Cross section of tentacle. (*e*) Fibril arrangement of the epitheliomuscular cells. (*After T. I. Storer and R. L. Usinger, General Zoology, 3d ed., McGraw-Hill, 1957*)

many larger ones have discrete muscle cells, which in some medusae are striated. The primary swimming muscles of medusae are large subumbrellar bands, oriented both circularly and radially. In many anthozoans, hypertrophy of the circular muscle at the margin of the oral disk forms a sphincter muscle that allows the animal to close up like a drawstring purse; in some taxa, this muscle is embedded in the mesoglea. In addition to column and tentacle musculature, anthozoan polyps have longitudinal and radial muscles in the mesenteries; the former are the major means by which anthozoan polyps shorten. The muscles work against the hydrostatic skeleton or the mesoglea, depending on the taxon and the part of the body.

Skeleton. The body form of most polyps and some medusae is maintained at least in part by a hydrostatic skeleton, which constitutes water in the coelenteron (and tentacles in the groups with hollow tentacles) maintained under a slight positive pressure through the action of muscles surrounding the cavity and closure of the mouth. By contracting its circular muscles, the polyp or medusa can narrow and extend in length, and by contracting its longitudinal muscles, it can broaden and shorten. When contraction is excessive, some water is expelled through the mouth and, in polyps and some species, through pores at the tentacle tips or in the body wall; expansion can occur again only by pumping water in to reinflate the animal. The mesoglea imparts rigidity and elasticity to the system. Hydrostatic pressure can also be important in supporting colonies (such as those of sea pens), although mechanical support by skeletons made of calcium carbonate and organic materials such as chitin is widespread in the phylum.

The ectoderm of most hydrozoan polyps, some scyphozoan polyps, and all scleractinian corals secretes an exoskeleton, which supports and protects the organism. The hydrozoan skeleton is tubular, surrounding the living tissue. Although typically made of chitin or sclerified protein, and therefore rather flexible, in some taxa it is calcified and rigid. Some hydrozoan skeletons are elaborate, with an ornamented cup into which each polyp may withdraw; others are simple, covering only the column of the polyp. In some colonial pelagic hydrozoans, such as the by-the-wind sailor *Velella*, part of the skeleton may be specialized for flotation. All scleractinians form calcareous exoskeletons, which vary from delicate, branched structures to massive encrusting formations. The living animal tissue overlies the skeletal material, with the polyps occurring in cups or depressions in the skeleton; in colonies, the polyps abut one another or are connected by sheets of living tissue.

Members of several anthozoan groups have an axial skeleton, which is also secreted by ectodermal cells and hidden in life by the polyps and common colony tissue, so it can be seen only after the death of the animals that made it. Composed of sclerified proteins, this tough skeleton is flexible; it is calcified to a greater or lesser extent in some taxa, and flexibility diminishes with calcification. An axial skeleton is characteristic of the hexacoral antipatharians (black corals) and octocoral gorgonians (sea fans and sea whips) and pennatulaceans (sea pens).

Cells of some hydrozoans and anthozoans secrete calcareous sclerites (also known as spicules). Varying in size from microscopic to several millimeters in length, many sclerites are needlelike in form, but others are more globular. In most octocorals, they function to support and strengthen the living tissue in which they are scattered. Some sclerites in some species surround individual polyps or groups of polyps, clearly functioning to protect them. In two groups of octocorals, the sclerites are fused to form solid skeletons. Their morphology is akin to that of hydrozoan corals, with the polyps living in tubes surrounded by protective and supportive skeleton, but, as in scleractinians, the skeleton is covered by tissue in life.

Locomotion. Solitary polyps of many species can creep slowly along the substratum; some can lose contact and be carried by currents. Whether this has functional significance is unclear. A *Hydra* polyp can move in a somersault fashion by alternately attaching the base and tentacles to the substrate. The polyps of a few species of anemones can "swim": some do so by paddling their tentacles—whereas others do so by flexing the column. A few others routinely roll along the sea floor; some of them have suctorial structures on the column that allow them to remain stationary as well. Polyps of *Hydra* and small sea anemones may hang from the surface film of water bodies. One species of sea anemone secretes from its base a chitinous mass that traps air, forming a float from which the anemone hangs as it drifts across the open ocean.

Colonies of polyps can also move about. A sea pansy peduncle anchors the colony in soft substrata and can be released so that the colony can be passively moved by water motion; the peduncle may also function to pull the colony along. The most common examples of motile colonies are the siphonophores and chondrophores, pelagic hydrozoan "superorganisms" (consisting of polyps and/or medusae) such as the Portuguese man-of-war (*Physalia*) and the by-the-wind sailors (*Velella*) that are mistakenly thought by some people to be jellyfish.

A medusa swims by contracting muscles that encircle the edge of the bell, thereby reducing the volume of the subumbrellar space. The water that is forced outward jets the medusa in an aboral direction. In medusae of Class Hydrozoa, a thin sheet of tissue (the velum) extends inward from the margin of the bell, reducing the effective diameter of the subumbrellar aperture, and helping the animal to steer. Cubomedusae have an analogous structure, known as the velarium. Once the circular muscles relax, the resilient and elastic mesoglea returns the umbrella to its original form.

Feeding, digestion, and nutrition. All cnidarians are exclusively carnivorous. (Although there have been claims of phytophagous behavior in some cnidarians such as soft corals, there is no evidence that these animals possess enzymes capable of digesting plant material.) Larger prey items are secured by the tentacles: the tubules of some nematocysts hold onto the prey while the tubules of other types of cnidae deliver toxins to kill it. The tentacles then pass the prey to the mouth, where it is swallowed into the coelenteron. Tiny prey items may be trapped in mucus on the tentacles and oral disk, and carried by ciliary action to the mouth and into the coelenteron.

Gland cells that produce digestive enzymes are abundant in the endoderm. It is likely that in cnidarians that have endodermal nematocysts, the nematocysts also deliver digestive enzymes to prey items. Although some enzymes may be released into the coelenteron, most or all digestion takes place when the prey comes into contact with the endoderm so that the enzymes can be brought directly to the prey. In scyphozoans, gland cells tend to be most abundant on the gastric tentacles, and in anthozoans they are most abundant in the filaments along the free edges of the mesenteries: these structures wrap around the prey, making close contact between it and the gland-rich endoderm. Once the prey is broken into small particles, the particles are engulfed by endodermal cells and digestion is completed in food vacuoles. Thus, digestion in cnidarians is intracellular, although extracellular proteases effect the first stages of food processing.

Distribution of the compounds, in the absence of a circulatory system, depends at least in part on diffusion from the endodermal cells in which digestion occurs. Wandering ameboid cells may also play a role in distributing these materials, particularly to ectodermal cells in animals with a thick mesoglea, because they are more efficient than diffusion at crossing the mesoglea.

Some cnidarians appear to feed seldom or never. Two alternatives to feeding are uptake of dissolved organic matter and acquisition of small organic molecules from photosymbionts. At least some cnidarians can acquire dissolved organic matter directly from seawater, but not all their ectodermal cells have this capability, so this seems to be a specialized type of nutrition. Many cnidarians, particularly polyps, that live in the photic zone contain intracellular photosymbionts, but this is far from universal. In the marine environment, most photosymbionts are dinoflagellates known as zooxanthellae; the photosymbionts of all freshwater and some marine species are green algae known as zoochlorellae. Photosymbionts are generally contained in endodermal cells, but in a small number of species they are ectodermal; a single animal cell may contain several photosynthetic cells. A large proportion of the carbon fixed by the zooxanthellae (and a smaller proportion of that fixed by zoochlorellae) is released to the animal host; reciprocally, the photosymbiont obtains from its animal host carbon dioxide and nitrogenous wastes. Nearly all reef-forming corals contain zooxanthellae; some of these corals can acquire 100% of their required energy from zooxanthellae, but it appears these animals must ingest animal prey to obtain other compounds such as amino acids and vitamins. *See* FEEDING MECHANISMS (INVERTEBRATE).

Reproduction and Development

Cnidarians of all species reproduce sexually, although not all individuals may be capable of sexual reproduction. Cnidarians of many, but not all, species can reproduce asexually through a variety of mechanisms. The capacity to regenerate is widespread, but seems especially characteristic of animals that can propagate asexually. Thus, pieces cut from most medusae or many sea anemones will not survive, and the part that is excised may not be replaced. *See* REGENERATION (BIOLOGY).

Metagenesis. Metagenesis, the alteration between medusa and polyp generations, is commonly considered a characteristic feature of the phylum as a whole (**Fig. 5**). In metagenesis, a medusa is produced asexually by a polyp (which may also asexually produce polyps), and a medusa produces gametes that, through the processes of fertilization and development, result in polyps. Clearly, anthozoans, which are exclusively polypoid, do not undergo metagenesis; this is also true of the groups of hydrozoans that exist only as polyps or medusae. Staurozoa, too, has only one generation (a sedentary medusa or medusa-like polyp).

Many hydrozoans produce free-swimming medusae that have relatively long lives and are carried some distance from their hydroid before forming and releasing gametes. However, in some taxa the medusa is reduced so that it essentially constitutes a package of gametes that lives only long enough to spawn shortly after release from the hydroid; in others, it is not released at all, spawning while still attached to the hydroid. The ultimate reduction involves the disappearance of a morphologically distinct medusa, with gametes formed in structures on the polyps that are remnants of the medusa and essentially constitute a gonad of the hydroid.

Sexual reproduction. Since cnidarians lack organs, they do not have true gonads; rather, gametes are formed in localized areas, which are often referred

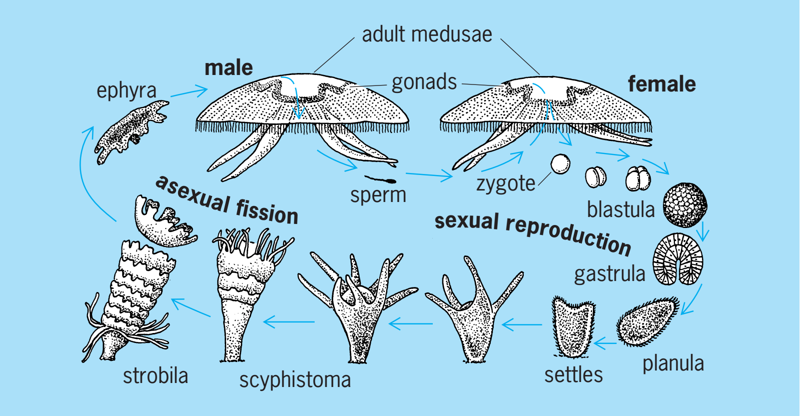

Fig. 5. Life cycle of jellyfish *Aurelia aurita*, class Scyphozoa. (*After T. I. Storer and R. L. Usinger, General Zoology, 3d ed., McGraw-Hill, 1957*)

to as gonads. Thus, there are no accessory sexual structures or ducts to permit the passage of gametes. Gametogenic tissues typically produce gametes only during certain times of the year; at other times, there is no evidence of their existence. Cnidarians lack a germinal cell line, so it is unclear if gametes develop from undifferentiated cells (such as interstitial cells) or if they can develop from cells of any type. In hydrozoans, gametes are produced in the ectoderm, on the manubrium or beneath the radial canals of medusae, and almost anywhere on a hydroid polyp (although in any group or species, gametogenic tissue forms in a characteristic position). Gametes in groups other than Hydrozoa are formed from endodermal cells: in scyphomedusae they develop on the floor of the coelenteron, and in anthozoans they develop in the mesenteries between the filaments and the retractor muscles.

Most cubozoans, hydrozoans, scyphozoans, and staurozoans are gonochoric (have separate sexes); hermaphroditism is widespread in Anthozoa, although most anthozoans are gonochoric. Hermaphroditic species may be self-fertile, but most cross-fertilize. Typically, a cnidarian sheds its gametes into the water surrounding the animal, where fertilization occurs and the embryo develops. However, in some cnidarians, the eggs are fertilized within the body; the developing embryo may be retained in the body or on its surface for its entire duration or for only a part of it.

The first stage of embryogenesis results in the formation of a ciliated blastula (Fig. 5). Gastrulation produces a gastrula that elongates into the typical larva of the phylum, the planula, which is free-swimming, ciliated, mouthless, and pear-shaped (the anterior is the broad end) and has an elongate anterior tuft of sensory cilia. At metamorphosis, if the planula is destined to become a polyp, it attaches by its anterior end, developing a mouth and tentacles at its posterior end. If the the planula is to become a medusa, the anterior end becomes the exumbrellar surface of the bell, and the mouth develops from the posterior end. In some hydrozoans, the planula develops a mouth and tentacles while still swimming; the animal at this stage is termed an actinula. The actinula of some species may attach and develop into a polyp, whereas in others it metamorphoses into a medusa. *See* INVERTEBRATE EMBRYOLOGY; REPRODUCTION (ANIMAL).

Asexual reproduction. If the individuals produced by asexual means separate, they are collectively termed a clone. If the individuals remain attached to one other, they collectively constitute a colony (although it is true that the elements, being genetically identical, are clonal).

One mode of asexual reproduction is budding (a term that is incorrectly applied to any mode of vegetative propagation). Budding involves the creation of a new individual from an outgrowth of an existing organism or the living tissue between individuals (as in Fig. 4*a*). This is the typical mode of formation of hydroid and many scleractinian colonies. Budding is also the means by which hydromedusae are produced by a hydroid colony. Budding is very rare in sea anemones.

Some scleractinian colonies are created by longitudinal fission of existing polyps. In the few medusae that normally propagate asexually, most (or all) do so by binary fission. Some individual sea anemones propagate asexually through longitudinal fission, and others through transverse fission. Transverse fission is the means by which a scyphozoan polyp (at the stage known as a scyphistoma) forms medusae: the distal end develops into an incipient medusa (the ephyra). In some species, these form one at a time, whereas in others, several form simultaneously like a stack of dinner plates of diminishing maturity proximally. When mature, the ephyra pops off the top of the polyp and swims away (Fig. 5).

Small pieces of hydroids may detach and wander about as undifferentiated, elongated entities called frustules, each of which can attach and develop into a new polyp and, ultimately, a colony. Basal bits of sea anemones can also detach and move off and are each capable of developing into a whole anemone. A few species of anemones can even regenerate a whole individual from a cast-off tentacle.

Asexual progeny are genetically identical, at least initially, but may differ morphologically. The most dramatic example of this is a polyp giving rise to a medusa. Even among polyps, in a hydrozoan or octocoral colony, individuals can be very different morphologically. Polymorphic colonies may contain individuals specialized to feed; others specialized to reproduce; and others to protect, propel, or support the colony. In hydrozoan Class Siphonophora, which constitutes the acme of polymorphism, the colony is also highly integrated neurologically and behaviorally. Polymorphism does not occur in scleractinian coral colonies.

Somatic mutation will cause members of a clone or colony to diverge genetically. In colonies that live decades or centuries (like those of some scleractinians), considerable genetic diversity can accumulate.

Ecology

Hydra, the animal used as an exemplar of the phylum, could hardly be less typical—a solitary hydrozoan that lacks a medusa, makes no skeleton, and lives in freshwater. Only a few hydrozoans besides it occur in freshwater. The other 10,000 or so species of cnidarians occur in all oceans and from the highest intertidal to the greatest hadal depths. Medusae are important predators in the pelagic realm, as sea anemones can be in some benthic environments; scleractinians are the primary constructors of one of the most important ecosystems in shallow tropical waters—coral reefs. Calcifying cnidarians do not occur below about 5 km (3 mi) depth, and those at high latitudes do not form large colonies. Both limitations seem due to the saturation state of calcium carbonate in the sea, which is greatest in shallow tropical waters and declines with latitude and depth. Moreover, for reasons that are not entirely understood, the robust skeletons that are important in reef formation are deposited only by corals that possess zooxanthellae (mostly scleractinians, but also a few species of hydrozoans and octocorals).

Only about half the approximately 1500 species of scleractinians participate in forming coral reefs; the others live at high latitudes and below the photic zone. The so-called deep-sea coral reefs are species-rich areas physically structured by skeletons of scleractinian corals, like their shallow counterparts. The diversity of corals, however, is low, and their skeletons are relatively delicate—they would be easily broken in many of the habitats where tropical shallow reefs thrive. *See* ECOLOGY; OCTOCORALLIA (ALCYONARIA); REEF; SCLERACTINIA. Daphne G. Fautin

Fossils and Phylogeny

Cnidaria has a long and impressive fossil record stretching back to the Precambrian, about 700 million years ago. Thus, the known duration of this phylum equals or exceeds that of other animal phyla. Forms with skeletons (primarily the Conulata, Tabulata, Rugosa, and Scleractinia) have left fairly complete fossil records, whereas primarily soft-bodied forms, such as most hydrozoans, scyphozoans, alcyonarians, and anemone-like animals, are represented by few fossils.

Fossils of the earliest-known cnidarians have been found in Late Precambrian rocks on several continents; the Ediacaran is an especially well-preserved fauna known from southern Australia. These early soft-bodied cnidarians were both pelagic medusoid forms and benthic polypoid forms, and seem to represent all the major classes, indicating that cnidarian origins are truly ancient. Appearing in the succeeding Cambrian strata is the extinct group Conulata (**Fig. 6***a*), which possibly belongs in Scyphozoa. These forms are represented in the fossil record by a thin, steep-sided, pyramidal, chitino-phosphatic external skeleton.

Fossils of two of the three major orders of anthozoans with calcium carbonate skeletons, the Rugosa (tetracorals) and the Tabulata (Figs. 6*b*, *c*, and *d*), appear in rocks of the succeeding Ordovician system. Both groups quickly diversified, and include colonial forms that helped form carbonate banks and reefs. In addition, the rugosans are represented by many solitary forms known as horn corals. Rugose corals, especially, were numerous and widespread in the Early Permian, but in the later part of that period their diversity dwindled, the more complex, bank-forming groups disappearing first. Both tabulate and rugose corals disappeared during the great wave of Late Permian extinctions, along with many other marine invertebrates. *See* PERMIAN; RUGOSA; TABULATA.

There are no corals in the Early Triassic, although the last Conulata have been reported from beds of this age. Scleractinians first appear in Middle Triassic strata (Figs. 6*e*, *f*). Scleractinians cannot have evolved from rugosans because they differ in fundamental morphology and there are no transitional forms in the Early Triassic. Thus, it is inferred that all the coral

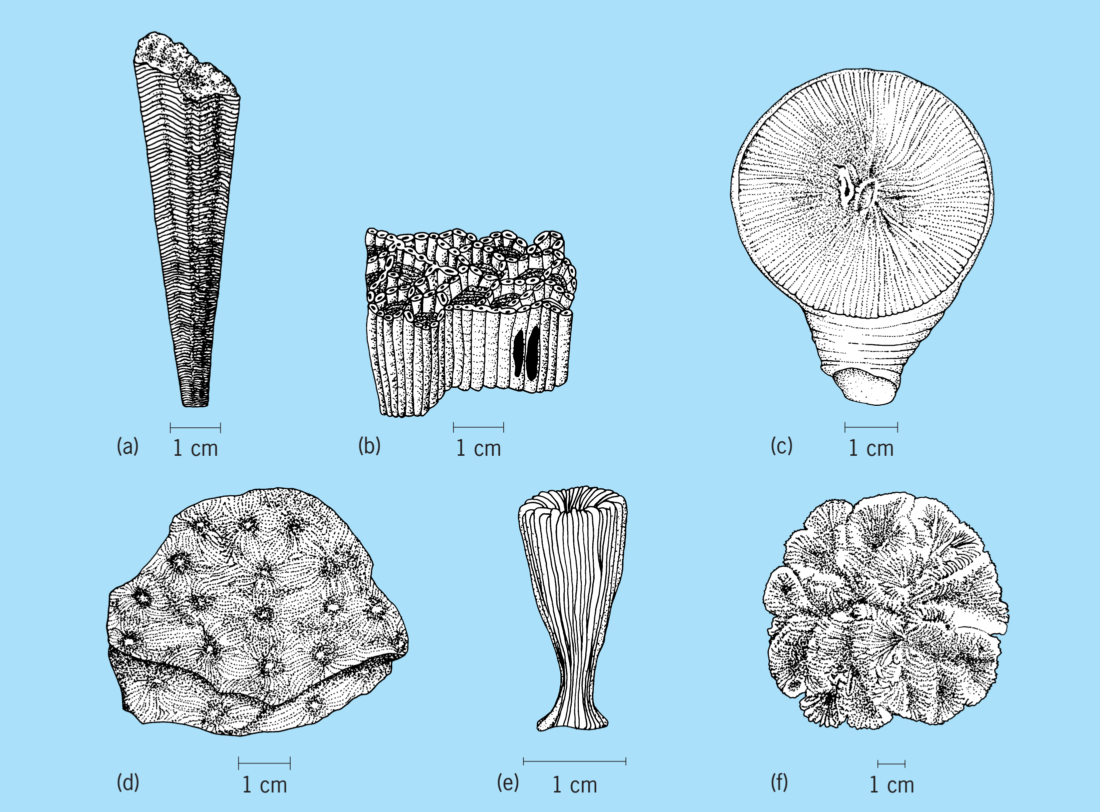

Fig. 6. Cnidarian fossils. (*a*) *Paraconularia*, Middle Paleozoic Conulata. (*b*) *Halysites*, Middle Paleozoic tabulate coral. (*c*) *Bethanyphyllum*, Devonian solitary rugose coral. (*d*) *Billingsastraea*, Devonian colonial rugose coral. (*e*) *Parasmilia*, Late Mesozoic and Cenozoic solitary scleractinian coral. (*f*) *Isophyllia*, Recent colonial scleractinian coral. (*After R. C. Moore, ed., Treatise on Invertebrate Paleontology, pt. F, Geological Society of America and University of Kansas Press, 1956*)

groups arose independently from soft-bodied anthozoans. These coral ancestors are often referred to as "anemones," and sometimes even as Actiniaria, but there is no evidence that those animals had the features characterizing modern sea anemones—or any other currently extant group of naked polyps. The origin of scleractinians is more mysterious because the first fossils of them are remarkably diverse, with many of the modern taxa represented. By the Jurassic, scleractinians had begun to form coral reefs similar to modern reefs of the tropics; it has been hypothesized that the acquisition of zooxanthellae is what allowed this development. However, many died out in the great Cretaceous-Tertiary (K-T) extinction, so that early Tertiary reefs were formed by bivalve mollusks, not corals. It was not until the Oligocene that scleractinians once again became dominant reef formers. *See* CRETACEOUS; TERTIARY.

Molecular evidence is likely to play a large part in understanding cnidarian evolution, since few members of the phylum leave phylogenetically informative fossils (because they are soft-bodied). A longstanding conundrum was whether Anthozoa is the basal group and development of the medusa generation followed or whether Anthozoa is derived from some ancestral cnidarian by loss of the medusa generation. Data that could be used to resolve this debate were problematic until the advent of gene analysis. Molecular analysis revealed that the mitochondrial chromosome in members of the Medusozoa (Cubozoa, Hydrozoa, Scyphozoa, and Staurozoa) is linear, whereas that of Anthozoa is circular, as in all other animals. This is clear evidence that Medusozoa is derived ("advanced"), relative to Anthozoa.

The phylogenetic relationships within each group are beginning to be understood, but many questions remain. *See* ANIMAL EVOLUTION; PHYLOGENY.

Cnidospora

A subphylum of spore-producing Protozoa containing the two classes Myxosporidea and Microsporidea. Myxosporidea contains the three orders Myxosporida, Actinomyxida, and Helicosporida. Microsporida is the only order in the class Microsporidea. Cnidospora are parasites of cells and tissues of invertebrates, fishes, a few amphibians, and turtles. *See* MICROSPORIDEA; MYXOSPORIDEA.

A distinctive structure of this subphylum is the spore, which contains one or more protoplasmic masses called sporoplasms. The spore also contains one or more filaments which lie coiled within the spore proper or within one or more polar capsules. The spore membrane may consist of a single chitinous piece or two or more parts called valves.

When the spore is ingested by a new host, the filaments are extruded and at the same time the sporoplasm is released. The sporoplasm, now called an amebula, reaches the specific site of infection directly through the intestinal wall or by way of the bloodstream. The amebula becomes a trophozoite, a stage in the life cycle, which feeds and grows at the expense of the host. Asexual reproduction by repeated binary fission, multiple fission, internal and external budding, or plasmotomy results in cells which develop into sporonts and eventually into sporoblasts, producing one or more spores. *See* SPOROZOA.

Because of similarity in multinucleated trophozoites, some protozoologists suggest that the Cnidospora have evolved from "slime mold–like" (Mycetozoia) ancestors. *See* PROTOZOA.

Coal

A brown to black combustible rock that originated by accumulation and subsequent physical and chemical alteration of plant material over long periods of time, and that on a moisture-free basis contains no more than 50% mineral matter. The plant debris accumulated in various wet environments, commonly called peat swamps, where dead plants were largely protected from decay by a high water table and oxygen-deficient water. The accumulating spongy, water-saturated, plant-derived organic material known as peat is the precursor of coal. Over time, many changes of the original vegetable matter are brought about by bacteria, fungi, and chemical agents. The process progressively transforms peat into lignite or brown coal, subbituminous coal, bituminous coal, and anthracite. This progression is known as the coalification series. Increasingly deeper burial under hundreds to thousands of feet of younger sediments is required to advance coalification to the bituminous coal and anthracite stages. The pressure exerted by the weight of the overlying sediment and the heat that increases with depth, as well as the length of exposure to them, determine the degree of coalification reached.

The types of plants contributing to peat accumulations vary greatly, depending on when in geologic time the peat was formed, that is, how far plants had evolved at the time, and on the regional and local environments of deposition (for example, water depth and its fluctuations, climate, and flooding by nearby streams or the sea). *See* FOSSIL FUEL; KEROGEN; LIGNITE; PEAT.

Formation

Economic coal deposits originate from accumulations of plant material (peat) in wetlands commonly referred to as moor, swamp, mire, bog, fen, muskeg, or peatland. Most peat-forming plant material accumulates at or close to the place of growth (autochthonous origin), but some organic material may be transported before deposition, for instance, along beaches or in lakes (allochthonous origin). Autochthonous peats often form in various kinds of regionally coexisting depositional environments; low-lying swamps with forested, marshy, and open water environments (low moors) and raised peat bogs (high moors) are common peat-forming environments. Allochthonous plant material may contribute significantly to otherwise autochthonous peat deposits as open water areas develop and disappear in the evolutionary course of a peat swamp. Coal beds commonly are underlain by seat earths, remnants of ancient soils in which the initial swamp plants were rooted (hence the common occurrence of stigmaria in seat earths). *See* BOG; MUSKEG; SWAMP, MARSH, AND BOG.

Peat. Examples of present-day peat accumulation abound both in humid temperate climates and in subtropical to tropical climates. In North America, peat-forming environments are found in the Everglades of Florida, the Okefenokee Swamp of Georgia and Florida, the Dismal Swamp of Virginia, and in numerous depressions with poor drainage that were created during the ice ages in the plains between the Rocky and Appalachian mountains. In the tropics, thick peat deposits are known in the coastal areas of Sumatra and Borneo, for instance. Ultimate preservation of deposits of peat depends on long-term subsidence of the area and on burial under younger sediments. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; SEDIMENTOLOGY.

The nature of a peat deposit depends on the kind of plants composing the accumulation: sedges, reeds, and other herbaceous vegetation; forest trees and bushes; mosses; and so forth. Such differences create different coal facies that can still be identified in highly coalified coal seams. *See* COAL PALEOBOTANY.

Freshly deposited plant material is attacked by microorganisms, fungi, and chemical agents in air and water, enzymes and oxygen in particular. This commonly leads to degradation of the plant material to the point where the original plant structure is no longer recognizable, and new organic compounds are formed. Cellulose, a major constituent of cell walls, and proteins are much less resistant to decomposition than other chemical plant constituents such as lignin, tannins, fats, waxes, and resins. Humic acids and other humic substances are important decomposition products resulting from the peatification process. Fungi and aerobic bacteria depend on the presence of oxygen to degrade the organic material. During burial, as oxygen is consumed, anaerobic bacteria take over degradation. Woody material passes through a plastic, gelatinous stage before it solidifies to huminite and eventually vitrinite. As burial depth increases, overburden pressure causes increasing compaction that reduces the porosity of the mass and expels moisture, while increasing temperature with greater burial promotes chemical changes in the organic components of the coal. Peat is transformed into coal through the process of coalification. Important by-products of the coalification process are water, carbon dioxide, and, especially in the more advanced stages, methane. *See* CELLULOSE; DIAGENESIS; HUMUS; LIGNIN.

Coal seams. Minable coal seams occur in many different shapes and compositions. Some coal seams can be traced over tens, even hundreds, of miles in relatively uniform thickness and structure. The extensively mined Herrin coal bed of the Illinois Basin and the Pittsburgh coal bed of the northern Appalachian Basin are examples. They are 6–8 ft (2–2.5 m) thick over thousands of square miles. These coals originated in peat swamps that developed on vast coastal plains during the Pennsylvanian Period. The German brown coal deposits near Cologne are characterized by very thick coal deposits (300 ft or 100 m). However, their lateral extent is much more limited than are the two examples from the United States. These peat deposits formed in a gradually subsiding structural graben bounded by major faults. Land lay to the south and the sea to the north. Only a relatively small portion of the subsiding graben block provided optimal conditions for peat accumulation over a long period of time. Thus each coal bed has its own depositional history that determined many of its characteristics. *See* CARBONIFEROUS; CRETACEOUS; GRABEN; PENNSYLVANIAN; TERTIARY.

Coal seams are commonly composed of a number of benches of alternating coal and more or less carbonaceous shale. The shale represents periods when the peat accumulation was interrupted by flooding from a river or the sea, or, more rarely, interrupted by volcanic ash deposition (tonsteins). The individual benches of a coal bed vary laterally in thickness and composition, sometimes quite rapidly. The degree of variability is related to the stability of conditions during accumulation. Fluvial and lacustrine depositional environments produce greater lateral variability than deltaic or coastal plain environments. *See* SHALE.

Analyses

Many kinds of chemical, physical, petrological, and technological analyses are commonly performed on coal samples to ascertain characteristics and origin. The selection of analyses depends on the information needed. Many of these analyses have been standardized at both national and international levels [for example, American Society for Testing and Materials (ASTM) and International Standardization Organization (ISO)].

Megascopic coal description. Megascopic descriptions, often with the help of a hand lens, are routinely performed in the field, in mines, and on diamond drill cores. The detail of description varies between merely distinguishing coal from impure coal, carbonaceous shale, and other rocks, and quite detailed descriptions in terms of coal types or lithotypes.

Megascopic descriptions are used primarily during geologic investigations to characterize lateral variations in thickness and structure. Their value in predicting specific coal properties such as ash content or coal rank is limited, and they are generally considered to be only the first step in the characterization of a coal deposit. However, megascopic descriptions are the principal basis for coal resource and reserve determinations.

Proximate analysis. This is probably the most commonly performed type of chemical analysis on coal samples. It involves determination of the ash, moisture, volatile matter, and fixed-carbon contents, which total 100%.

High-temperature ash. Combustion of the organic material at 1290–1380°F (700–750°C) leaves behind the high-temperature ash. At these high temperatures, certain minerals disintegrate, leading to both loss of volatile products and reaction with oxygen from the air to form oxides. Some volatile decomposition products react with the ash before they can escape. Therefore, the weight of the high-temperature ash may differ significantly from the weight of the coal's original mineral matter. High-temperature ash is composed primarily of unaltered, altered, and newly formed oxides and silicates (in particular, unaltered quartz and feldspars, altered clay minerals, and newly formed mullite, hematite, and magnetite).

Moisture content. This term has different meanings depending on when, how, and on what sample type it is determined, for example, as received, surface, air-dried, bed, inherent, and equilibrium moistures. The determination may be made on raw or cleaned coal, on selected grain sizes, and so forth. The moisture content in the fully saturated stage, but without presence of surface moisture, is used for determining coal rank. Bed, inherent, and equilibrium moistures are representative of this type of moisture content.

Volatile matter and fixed carbon. These are derived from a small-scale retorting test which is performed under rigidly controlled conditions at a temperature of 1740 ± 36°F (950 ± 20°C). The process results in the disintegration of coal into volatile matter, a complex mixture of gases (exclusive of water), and a cokelike residue rich in carbon (fixed carbon).

Mineral matter. This term refers to both inorganic constituents that occur as discrete mineral grains and so-called inorganic elements that are more or less homogeneously distributed through coal. Minerals that were present before combustion can be approximated from a chemical analysis of the ash (through a normative analysis). A more accurate way to analyze for mineral matter in coal is by oxidation of the organic matter in a low-temperature asher in which an oxygen plasma, activated by a radio-frequency field, is passed over the coal sample. Because the oxidation occurs at the relatively low temperature of 250–300°F (120–150°C), most minerals remain essentially unaltered and the resulting ash can be subjected to a wide range of analyses (in particular, x-ray diffraction) to determine the minerals present. The Parr formula provides a simple method to estimate the original total amount (but not the composition) of the mineral matter in a given coal; its main purpose is to adjust the ash weight by correcting for the disintegration of iron sulfides and other reactions during combustion (that is, loss of sulfur dioxide, and reaction of iron with oxygen in air). *See* MINERAL; X-RAY DIFFRACTION.

Ultimate (elemental) analysis. The elements carbon, hydrogen, oxygen, sulfur, and nitrogen make up essentially all the organic substance of coal and are determined, along with moisture and ash, by the ultimate analysis. The first four of these so-called organic elements are also present in common inorganic components of coal such as the moisture, and the carbonate, sulfide, sulfate, and oxide minerals, making attribution to either the organic or the inorganic constituents of coal potentially difficult. Ultimate analyses are significantly more involved than proximate analyses. Both analyses are now commonly done on sophisticated computer-controlled instruments.

Calorific or heating value. This parameter is determined by observing temperature changes that result from combustion of a known quantity of coal in an adiabatic bomb calorimeter. In the United States, the calorific value is reported in British thermal units given off per pound of coal burned (Btu/lb); the equivalent SI unit is megajoules per kilogram (MJ/kg) or, until relatively recently, cal/g or kcal/kg (1000 Btu/lb = 2.326 MJ/kg = 560 kcal/kg). The calorific value of a coal is influenced not only by the nature of the organic material of which it is made but also by the proportion of noncombustible material present, primarily mineral matter and moisture. *See* CALORIMETRY; THERMOCHEMISTRY.

Major, minor, and trace elements. Coal contains most elements in the periodic table, at least in trace amounts. Elements not yet identified may be present below detection limits. The total concentrations of the ash-forming elements in whole coals ranges from more than 0.5% for major inorganic elements such as aluminum, calcium, iron, and silicon; to 0.02–0.5% for minor elements such as potassium, magnesium, sodium, titanium, chlorine, and others; to less than 0.02% (200 parts per million) for trace elements such as arsenic, beryllium, cadmium, and mercury. Knowledge of the concentration of these elements is required when evaluating coals for combustion and conversion (for example, relative to corrosion, boiler fouling, and poisoning of catalysts) and to assess potential negative environmental and health impacts resulting from coal use. *See* PERIODIC TABLE.

In the United States, 16 minor and trace elements in coal are included in the list of hazardous air pollutants (HAPs) of the 1990 Amendments to the Clean Air Act (**Table 1**).

Analytical methods that are frequently used to determine minor and trace elements in coal include flame and graphite furnace atomic absorption spectrometry, x-ray fluorescence (XRF) spectrometry, optical emission photographic spectrometry, and neutron activation analysis. Inductively-coupled-plasma (ICP) atomic emission spectrometry and ICP mass spectrometry have been used because of their higher sensitivity for certain elements. To study spatial distribution of trace elements, techniques such as laser ablation ICP mass spectrometry, secondary-ion

TABLE 1. Minor- and trace-element content of cleaned coal shipped by mines in Illinois, in parts per million

Element	Arithmetic mean	Standard deviation
Antimony	0.9	0.7

mass spectrometry, and synchrotron-radiation XRF microprobe have been developed. *See* ACTIVATION ANALYSIS; ATOMIC SPECTROMETRY; MASS SPECTROMETRY; X-RAY FLUORESCENCE ANALYSIS.

Macerals. Macerals are the microscopically recognizable constituents of coal. Microscopic analyses are normally performed on representative crushed coal samples embedded in epoxy and polished for observation under incident light, generally with oil immersion objectives, at a magnification of 400–750×. A sufficiently large number (500–1000) of points evenly distributed over the sample are selected for maceral analysis to determine the percent of macerals in the sample by volume. The measuring spots are only a few micrometers in diameter.

The reflected-light method permits identification of a few nonclay minerals during maceral analysis. However, much more accurate determinations of the amount and composition of mineral matter are accomplished through other analyses, in particular, low-temperature ashing followed by x-ray diffraction analysis of the ash.

Reflectance of vitrinite. The percentage of normally incident light that is reflected from the polished surface of vitrinite under oil immersion has become a commonly used measure of coal rank. A reflected-light microscope equipped with a photomultiplier is used. The small size of the measuring spot, about 5 micrometers in diameter, and the large magnification used (500–1000×) permit selection of highly comparable material for this analysis, in contrast to chemical analyses that test bulk coal with variable mixtures of macerals and minerals. Vitrinite is the preferred material on which to measure reflectance, because of its common occurrence in most coals, its homogeneous appearance, its easy recognition under the microscope, and the considerable range in reflectance exhibited by the maceral, depending on a coal's rank.

Density, porosity, and internal surface area. Because of the large proportion of very small pores (a few angstroms to a few tens of angstroms in diameter) in coal, true values for these parameters are difficult to obtain with standard methods. Only very small molecules or atoms (for example, helium) are able to penetrate these micropores. Determinations with gases or liquids whose molecules are of the same order of magnitude as or larger than the micropores and their entrances yield only apparent values. For example, in one experiment the internal surface area of a sample of bituminous coal was measured separately with nitrogen and then carbon dioxide; the values obtained were 9 and 205 m^2/g, respectively. Another method to estimate the internal surface area is by measuring the heat of wetting with various liquids; but with this method, too, the molecules of the liquids do not necessarily penetrate all pores and thus do not measure the entire internal surface area.

Washability. A large proportion of mined bituminous and higher-rank coal is cleaned before it is used. Washability tests are performed in the laboratory on drill core and test pit samples to predict the cleanability of a given coal when mined. Coal samples are crushed to sizes comparable to those anticipated to be produced by the mine and are subjected to float-sink tests in heavy liquids. The amounts floating and sinking in each gravity fraction are measured, and their ash and sulfur contents as well as other parameters (for example, heating value) are determined. The data are tabulated and plotted to produce washability curves that characterize the coal's cleanability.

The fine fraction of mined coal [<0.3–0.5-mm (0.01–0.02-in.) grain size] is difficult or impossible to clean by the float-sink method. Instead of utilizing the differences in specific gravity of particles of the crushed raw coal, differences in the surface properties of coal and minerals (hydrophobic versus hydrophilic) are employed in the flotation method used to clean coal fines. However, since this method is relatively expensive, fine coal has commonly been discarded (in slurry ponds) without cleaning.

Plastic and coking properties. A significant use of coal is in making coke, which involves heating finely crushed coal in coke ovens in the absence of air. Bituminous coals generally become plastic or fluid during heating as they disintegrate into gases, liquids, and solids (char, coke); certain bituminous coals, commonly blends of several coals of different rank, can form a coke that is strong enough for use in blast furnaces. Several empirical tests have been used widely for many years to characterize the behavior of coal during heating and to predict its coke-forming ability.

Free Swelling Index (FSI). This is probably the most widely used test. It requires rapid heating of 1 g (0.35 oz) of finely ground coal to a temperature of 1508 ± 9°F (820 ± 5°C) in a lid-covered crucible. A coke button is formed, and its shape is compared to standard shapes 1–9 and reported in half-step increments. The FSI test provides a rapid and inexpensive first assessment of the coke-forming behavior of a coal.

Plastometer test. In a Gieseler plastometer, 5 g of finely crushed coal is heated in a retort; a small stirrer submerged in the sample applies constant torque while the temperature is raised at a rate of 5.4°F/min

(3°C/min). As the coal becomes plastic and fluid during heating, the stirrer's rate of rotation is recorded. The temperatures of initial softening, maximum fluidity, and resolidification, as well as the maximum dial movement in dial divisions per minute (ddpm), are recorded. These data differ characteristically for coals of different rank and composition and provide good indicators of a coal's coking properties.

Dilatometer test. This test is widely used outside the United States to characterize the behavior of coal during heating in the range 570–1020°F (300–550°C). A finely ground sample of coal is heated inside a crucible with a piston resting on the sample. The displacement of the piston is recorded as a percentage of the original sample volume. While the sample is heated at a rate of 5.4°F/min (3°C/min), the coal becomes plastic and fluid and releases gas, expands, then solidifies to coke. Volume change is plotted against temperature; the resulting curve reveals much about the coking characteristics of a given coal.

Other tests. The Gray-King and ROGA tests, commonly performed in several European countries, are essentially standardized laboratory-scale coking tests which produce useful index numbers. *See* COKE.

Strength and hardness. Strength and hardness are important coal properties in mine stability, coal winning, and comminution for preparation and utilization. A number of tests are commonly performed in the laboratory to obtain information on a coal's compressive and shearing strengths and hardness; an example is the Hardgrove grindability test. The values thus obtained are only index numbers because of the small size of sample used. They must be translated with caution when full-scale industrial operations are involved.

Ash fusion. During combustion of coal in boilers, the noncombustible portion, such as minerals and inorganic elements, either is volatilized or becomes ash, which forms deposits within the boiler or is removed as fly ash or bottom ash. The ash-fusion test identifies the temperatures at which the ash undergoes major phase changes. In general, for combustion uses of coal, ash that fuses at high temperatures (above 2400°F or 1538°C) is preferred to ash that fuses at low temperatures (below 2000°F or 1093°C). The range of ash-fusion temperatures is about 1600–2800°F (871–1538°C). The properties and relative abundances of minerals present may be critical in the formation of ash deposits in a boiler, as well as in the corrosion of boiler tubes. High alkali and alkali chloride contents are known to cause such problems in boilers. Boilers are designed for certain ash fusion properties.

Classification Schemes

The parameters obtained from coal analyses are used to classify coal for general as well as specific purposes. Both national and international standardization organizations have adopted classification schemes that are used in the coal trade, for statistical purposes, and to compile coal resources and reserves by classification category. One of the most widely used classification systems is the American Society for Testing and Materials (ASTM) Standard Classification of Coals by Rank (**Table 2**).

The European Commission for Europe—UN (UN/ECE) Working Party on Coal developed a new

TABLE 2. American Society for Testing and Materials classification of coals by rank (in box, ASTM standard D 388) and other related coal properties

ASTM class	ASTM group	1000 Btu/ lb[1]	Agglomer-ating[2]	Volatile matter,[3] %	MJ/kg[1]	Maximum reflectance,[4] %	Moisture,[1] %	C,[3] %	O,[3] %	H,[3] %

[1] Moist, mineral-matter-free.

[2] Agglomerating coals form a button of cokelike residue in the standard volatile-matter determination that shows swelling or cell structure or supports a 500-g weight without pulverizing. The residue of nonagglomerating coal lacks these characteristics.

[3] Dry, mineral-matter-free.

[4] Reflectance of vitrinite under oil immersion.

[5] Well suited for rank discrimination in range indicated.

[6] Moderately well suited for rank discrimination.

SOURCE: Modified from H. H. Damberger et al., in B. R. Cooper and W. A. Ellingson (eds.), *The Science and Technology of Coal and Coal Utilization*, 1984.

standard that attempts to incorporate both coal rank and coal facies parameters; this standard is intended for the characterization of coal resources in the ground. Another group of experts of ECE developed a codification system for coals traded. This standard replaces the UN/ECE's 1956 classification scheme for hard coal, which combines rank (class), caking (group), and coking (subgroup) parameters into a three-digit code system; this scheme has not been widely used.

For the purpose of classification, coal analyses must be standardized, through computation, to a common basis, such as ash-free (af), moisture-free (mf) or dry (d), moisture-and-ash-free (maf) or dry ash-free (daf), mineral-matter-free (mmf), dry mineral-matter-free (dmmf), and so forth. Generally, chemical laboratories determine values on an air-dried basis; from these all other bases can be easily computed.

Coal Facies

The coal facies reflects the environments of deposition during accumulation of plant material. The types of plants growing, their preservation, and the kinds and amounts of mineral matter introduced vary with the depositional environments. Coal facies can be recognized both megascopically and microscopically through all or most ranks.

Nonbanded coal. Nonbanded coals are homogeneously fine-granular and devoid of distinct megascopic layers. They have a greasy luster and conchoidal fracture. They formed from subaqueous deposition of finely comminuted plant detritus, commonly with significant amounts of spore or pollen grains, algal remains, wax and resin granules, and various other small plant fragments. Well-known nonbanded coals are cannel coal (composition dominated by spores) and boghead coal (predominance of algae). Transitions exist to oil shales. Their proper identification requires microscopic analysis. *See* OIL SHALE; SAPROPEL; TORBANITE.

Nonbanded coals are relatively rare. They may form entire coal seams or layers within banded coal.

Banded coal. This is the most common coal type. In bituminous coal, recognizable bands are composed of lithotypes such as vitrain, attrital coal, and fusain, and of impure coal. The banding is less pronounced in lower rank (subbituminous, lignitic) coals and may be difficult to discern in anthracites. Most bands are between a fraction of a centimeter to several centimeters thick.

Vitrain. This lithotype, also referred to as bright coal, is highly lustrous in bituminous coals and enhances their banded appearance. Vitrain represents the coalified remains of relatively large fragments of wood and the bark of stems, branches, and roots of trees and bushes. In bituminous coal, it forms bands and lenses of very bright coal, generally a few millimeters to 10 mm thick. In lignite the remains of woody material lack the shiny luster.

Attrital coal. This lithotype represents the fine-grained ground mass of banded coal in which layers of vitrain and fusain are embedded. Attrital coal is highly variable in appearance and composition. It exhibits a finely striated, granulose, or rough texture, much like nonbanded coal. Relatively lustrous attrital coal is often referred to as clarain, dull attrital coal as durain. Dull attrital coal commonly contains relatively high amounts of finely dispersed mineral matter, clays and quartz in particular.

Fusain. In most banded coals fusain represents only a subordinate proportion of the total volume, and it generally occurs in lens-shaped laminae and thin bands that rarely exceed a few centimeters in thickness. Fusain resembles charcoal; it is fibrous, very friable, and has a silky luster. It tends to be concentrated on selected bedding surfaces, forming planes of weakness in coal beds. Its many pores are often filled with secondary mineral matter that strengthens it and reduces its friability.

Impure coal. This type of coal is defined as containing 25–50% of ash by weight on the dry basis. The mineral impurities were introduced either during deposition, mostly as clay or as fine-grained detrital mineral matter (bone coal), or later as secondary mineralization (mineralized coal). Bone coal has a dull appearance; it is commonly finely striated. When scratched with a knife or nail, it forms a brown powder; the scratch mark appears shiny. Pyritized coal is the most common mineralized coal.

Maceral groups. Macerals are the microscopically recognizable organic constituents of coal, equivalent to minerals of other rocks. However, unlike minerals, their chemical and physical properties are not fixed but vary over a wide range depending upon coal rank and facies. Submicroscopic inorganic impurities are considered part of macerals.

Three major groups of macerals are generally recognized: vitrinites, exinites (or liptinites), and inertinites. These maceral groups are divided into maceral subgroups and, depending on the degree of detail desired, even further (**Table 3** and **illus.**). In polished sections, the macerals are distinguished on the basis of their reflectance and morphology, and to some extent on their size and maceral association.

Vitrinite. This is the predominant group of macerals in most coals (commonly 70–85% by volume). The reflectance of vitrinite is intermediate between the darker exinite and brighter inertinite (see illus.).

TABLE 3. Classification of macerals*

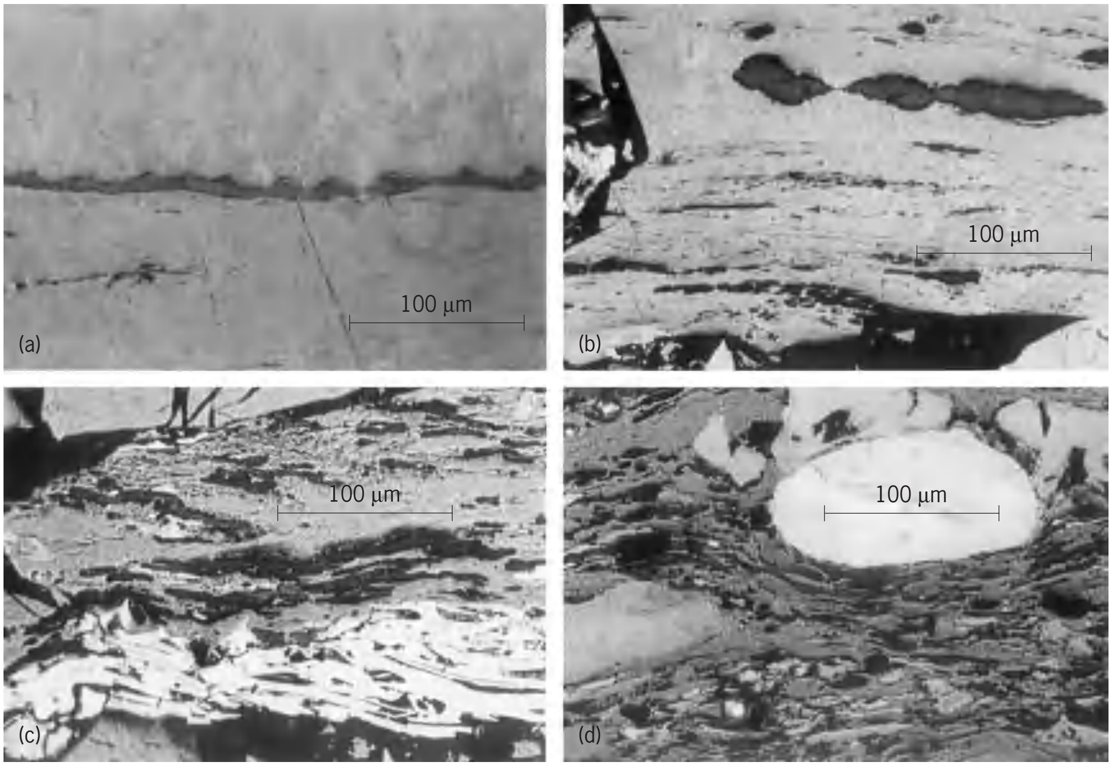
*After American Society for Testing and Materials, standard D 2796.



Macerals in polished surfaces of bituminous coals in reflected light, under oil immersion. (*a*) Thin, "saw-toothed" cutinite (dark) enclosed in vitrinite. (*b*) Elongate globs of resinite (dark) and other, smaller exinite macerals (dark) enclosed in vitrinite. (*c*) Sporinite (dark lenses) in vitrinite (gray) with fusinite (white) on lower part of photo. (*d*) Large grains of macrinite (white), smaller inertodetrinite (light gray), and sporinite and other exinites (dark gray) interlayered with vitrinite (gray).

Vitrinite generally originated from woody plant parts (tree trunks, branches, roots, and bark). The original cellular plant structure is still more or less visible in many vitrinites. The identifiable cell walls are known as telinite, while the structureless vitrinite is known as collinite. These two are sometimes further subdivided into submacerals for very detailed investigations.

The reflectance of vitrinite is a good indicator of coal rank, especially in higher-rank coals. Viewed under oil immersion, reflectance values range from 0.2–0.3% in low-rank lignites to over 4% in anthracites (Table 2).

Exinite (or liptinite). The macerals of the exinite group reflect light distinctly less than vitrinite (see illus.). Their volatile matter and H contents are significantly higher than those of associated vitrinite. These differences in reflectance, volatile matter, and H contents disappear quickly with increasing rank in coals above about 1% R_{oil}, or about 30% volatile matter (dry ash-free), and converge at about 1.4% R_{oil}, or about 20% volatile matter. The origin of the macerals of the exinite group is clearly implied by their names (Table 3); they are derived from algae, spores, cuticles, resins, waxes, fats, and oils of plants.

Inertinite. Inertinites reflect light significantly more than associated vitrinites (see illus.), except in high-rank anthracites. Inertinites do not become plastic during heating, such as in coke making; they react as inert materials. Fusinite is characterized by well-preserved cell wall structure (sometimes broken by compaction, a characteristic known as bogenstructure). Cell cavities commonly are filled with minerals. Fusinite's general appearance suggests origin by rapid charring in the peat stage (for example, in a forest fire). On the other hand, macrinite and micrinite lack visible cell structure. Particle size is greater than 10 μm for macrinite and less than 10 μm, commonly about 1 μm, for micrinite. Micrinite appears to be a solid by-product of the coalification of liptinite macerals in the bituminous rank range. Sclerotinite occurs as high-reflecting round to oval cellular bodies of varying size (20–300 μm) or as interlaced tissues derived from fungal remains. Semifusinite is transitional between fusinite and associated vitrinite in both reflectance and cell structure. Inertodetrinites are small, angular clastic fragments of other inertinites commonly enclosed in vitrinite or associated with mineral matter.

The presence of inertinites indicates oxidative conditions during the peat stage of coal formation. Inertinite contents of 5–15% are the rule for many coals of the eastern United States and Europe. But some coals have inertinite contents in the 30–40% range (for example, the High Splint and Winefrede coal seams of eastern Kentucky), indicating strong oxidizing conditions during peat formation. The mostly Permian-age Gondwana coals of Australia, India, South Africa, and South America are well known for their high inertinite contents, up to 85%. These coals were formed in a relatively cold climate with alternating dry and rainy seasons, providing

ample opportunity for widespread oxidation of the accumulating plant material. In contrast, the Pennsylvanian-age coals of North America and Europe originated in the humid equatorial zone.

Mineral matter. Whether they occur as discrete mineral grains or are disseminated through coal macerals, the inorganic components are referred to collectively as mineral matter. The low-temperature oxygen-plasma ashing technique developed in the mid-1960s has permitted detailed analyses of the minerals found finely dispersed in coal (**Table 4**). Mineral matter occurs in coal seams as discrete layers or partings, as nodules, as fissure fillings, as rock fragments, and as small particles finely disseminated throughout. Genetically, minerals can be classified as inherent (plant-derived), detrital (water- or wind-borne during sedimentation), syngenetic (formed early in the peat stage), and epigenetic (formed during and after lithification and during weathering). There is no sharp boundary between syngenetic and epigenetic origins. Minerals, just as macerals, indicate the environments that prevailed during their incorporation into peat or later during coalification. Similarly, the inorganic major, minor, and trace elements of coal were introduced at various stages of coal formation. Multivariate statistical methods permit attribution of most minor and trace elements to specific mineral phases.

Coal Rank

During burial to greater and greater depth, peat is transformed into brown coal or lignite, subbituminous coal, bituminous coal, and anthracite (coalification series) as a result of increasing overburden pressure and rising temperature. Both physical (pressure, heat) and chemical (biochemical, thermochemical) factors are influential in the transformation of peat into the other members of the coalification series (**Table 5**). The boundaries between the members of the series are transitional and must be chosen somewhat arbitrarily. The term rank is used to identify the stage of coalification reached in the course of coal metamorphism. Rank is a fundamental property of coal, and its determination is essential in the characterization of a coal. Classification of coal by rank generally is based upon the chemical composition of the coal's ash-free or mineral-matter-free organic substance (Table 2), but parameters derived from empirical tests indicative of technological properties, such as agglomerating characteristics (Table 2) or the Free

†1000 Btu/lb = 2.326 MJ/kg.

Swelling Index, as well as the ROGA, Gieseler, and Gray-King tests, are commonly used in several countries outside the United States in addition to coal rank parameters. *See* METAMORPHISM.

Coal rank increases with depth at differing rates from place to place, depending primarily on the rate of temperature increase with depth (geothermal gradient) at the time of coalification. Coal rank also changes laterally, even in the same coal seam, as former depth of burial and thus exposure to different pressure and temperature vary. Originally established vertical and regional coalification patterns can be significantly altered by various kinds of geologic events, such as the intrusion of large magma bodies at depth (plutonism), or renewed subsidence of a region. Volcanic activity may cause significant local anomalies in coal rank, but rarely leads to regional changes in coalification pattern. *See* MAGMA.

The chemical parameters customarily used to rank coal may yield misleading results in coals that are not primarily composed of vitrinite. Coals rich in exinite may have significantly higher contents of volatile matter and coals rich in inertinite may have significantly lower contents of volatile matter than associated so-called normal coals. This problem can be minimized by the use of vitrinite reflectance to indicate rank. Reflectance data have the additional advantage of being applicable to small coaly particles that occur dispersed throughout most sediments, permitting rank measurements in strata devoid of coal beds.

As rank increases during maturation, most coal properties change in tandem. This is reflected in the values given in Tables 2 and 5, but can also be represented graphically in correlation charts.

Occurrence and Resources

During geologic history, coal could not form in economic quantities until vascular land plants evolved during the Devonian Period some 400 million years ago and until they conquered the continents during the Carboniferous Period. The Carboniferous (Mississippian and Pennsylvanian of North America) witnessed an explosive development of vast swamp forests along the Euramerican equatorial coal belt, which extended from the North American midcontinent to Russia. The Atlantic Ocean did not exist then, and the North American and European continents were fused together as part of a continent called Laurasia. Another important coal-forming belt stretched over what was then Gondwana of the Southern Hemisphere. Gondwana subsequently drifted north and broke up into South America, Africa, India, and Australia. Most major coal deposits on Gondwana are of Permian age. They formed in a cool, humid climate. Most of the vast coal deposits of the western United States and Canada, along the eastern margin of the Rocky Mountains, originated during the Cretaceous and Tertiary periods. *See* CARBONIFEROUS.

Not all coal deposits are of economic interest. Governments and private industry need to know how much coal exists in the ground (resources) and what portion may be available for development under current economic and legal conditions (reserves). Various classification schemes have been adopted by national and international agencies for determination of coal resources and reserves on comparable bases. However, no universally accepted standard has yet emerged. An international framework for the classification of reserves/resources for solid fuels and mineral commodities has been developed under the auspices of the United Nations to fill the gap.

Two independent factors generally are considered in these assessments: the degree of economic minability, and the degree of geologic assurance of the existence of a coal deposit of given properties. The World Energy Conference (WEC) has attempted to overcome the lack of standardization between countries by adopting carefully worded definitions of resource and reserve categories, and has asked national organizations to interpret their databases in these terms. **Table 6** is a summary of the worldwide compilation by the World Energy Conference.

TABLE 6. World coal resources and reserves, in 10^9 metric tons*

Continent or country	Proved amount in place	Estimated recoverable reserves	Estimated additional reserves in place	Additional recoverable reserves
Africa	134	62	114	0.1
South Africa	121	55	5	0
North America	455	253	1199	2

Uses

Coal is used primarily for producing steam in electric power plants [87% of coal consumed in the United States in 1997, 67% in countries of the Organization for Economic Cooperation and Development (OECD) in 1996, and 52% in the world in 1996]. Other important uses are by industry for producing steam and heat (9% United States, 12% OECD), and by the steel industry for coke making (3% United States, 7% OECD). Conversion of coal to synthetic liquid or gaseous fuels does not constitute a major use of coal worldwide or in most countries. However, coal conversion has been important under special circumstances in some countries. During World War II, Germany produced a significant amount of liquid fuels from coal, and South Africa, when it became isolated because of its apartheid policy, established a major coal liquefaction industry to reduce its dependence on oil imports. One large coal gasification plant in the United States produces synthetic natural gas from North Dakota lignite; it was built with government support. It will take a significant rise in the price of oil and natural gas to make conversion into synthetic liquid and gaseous hydrocarbons competitive in the future. *See* SYNTHETIC FUEL.

The massive Clean Coal Technology (CCT) cooperative program between the United States government and private industry that began in 1988 included several large-scale projects where coal is gasified, the gas cleaned and then burned on site, first to drive high-temperature gas turbines, and then to generate steam for steam turbines; this makes for very clean and high-efficiency electric power generation. The CCT program has also demonstrated a wide range of other technologies to produce energy from coal cleanly and efficiently. *See* COAL CHEMICALS; COAL GASIFICATION. **Heinz H. Damberger**

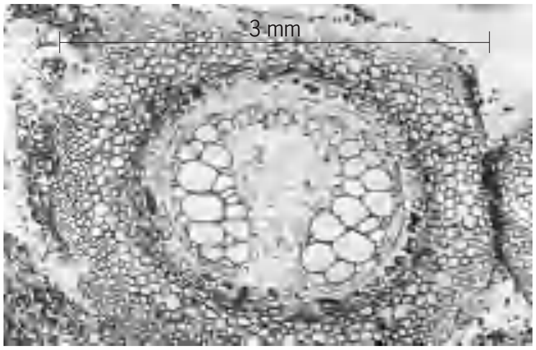
Coal balls

Variously shaped nodules consisting of fossilized peat in which the individual cells and tissue systems of the plant parts are infiltrated by minerals, principally calcium carbonate, along with pyrite, dolomite, and occasionally silica. This type of fossilization, in which the cell walls are filled with minerals, is termed permineralization. Coal balls occur principally in Pennsylvanian (upper Carboniferous) bituminous and anthracite coals, often below black marine shales in North America, but permineralized plants have also been reported in coals from as early as the Devonian and extending well into the Paleocene.

How coal balls formed is not well understood, but some are believed to represent accumulations



Photomicrograph of the peel made from a coal ball containing the petiole of a fern. 1 mm = 0.04 in.

of peat in which the plants were growing in low-lying swampy areas close to the sea. According to this model, seawater provided the high source of calcium carbonate in the permineralization processes. It has also been suggested that the permineralizing fluids were derived from percolating carbonate-rich ground water.

Because the individual plant cells in coal balls have not been crushed, they offer a wealth of information about the structure, morphology, and biology of the plants. Plants are studied by cutting a coal ball with a lapidary saw and then preparing an acetate peel of the surface. That is, the surface is etched with dilute acid that removes mineral material from the cell lumens, and then a thin sheet of acetate is added to the etched surface that has been flooded in acetone. The acetate-acetone mixture flows in and around the cell walls that are standing in relief. When the acetate sheet dries, a thin layer of plant cells can be peeled from the coal ball surface. After lightly grinding the coal ball surface with fine silicon powder, another peel can be prepared. Thus, the paleobotanist can prepare a set of serial sections of a fossil plant organ just as is done in the preparation of living plant and animal tissues. Peels can be observed with a dissecting microscope, or mounted on microscope slides under a cover glass to be examined with a compound microscope (see **illus.**).

Coal balls also contain the reproductive parts of plants. These can be observed on peels, or in the case of pollen grains and spores they can be macerated and studied with scanning and transmission electron microscopy. The preservation is sometimes so good that delicate structures such as nuclei, chromosomes, and membranes can be observed in great detail. *See* COAL PALEOBOTANY; PALEOBOTANY.

Coal chemicals

For about 100 years, chemicals obtained as by-products in the primary processing of coal to metallurgical coke were the main source of aromatic compounds used as intermediates in the synthesis of dyes, drugs, antiseptics, and solvents. However, over 97% of the aromatic hydrocarbons, such as benzene, toluene, and xylenes, are now obtained largely from petroleum. Naphthalene, phenanthrene, heterocyclic hydrocarbons such as pyridines and quinolines, and some phenols are still obtained from coal tar.

Coke oven by-products, as a percentage of the coal used, are gas 18.5, light oil 1.0, and tar 3.5. Coke oven gas is a mixture of methane, carbon monoxide, hydrogen, small amounts of higher hydrocarbons, ammonia, and hydrogen sulfide. Most of the ammonia is recovered as about 20 lb (9 kg) of ammonium sulfate per ton (0.9 metric ton) of coal, but only about 10% of the hydrogen sulfide is recovered as elemental sulfur. Most coke oven gas is used as fuel. The composition of a typical coke oven crude light oil is shown in **Table 1**. The unidentified fractions contain very small amounts of a large number of hydrocarbons, and organic compounds containing oxygen and nitrogen.

Although several hundred chemical compounds have been isolated from coal tar, a relatively small number are present in appreciable amounts. These may be grouped as in **Table 2**.

All the compounds in Table 2 except the monomethylnaphthalenes are of some commercial importance. The amounts recovered and sold, however, are only 5–25% of the totals present in the coal tar.

The direct utilization of coal as a source of bulk organic chemicals has been the objective of much research and development. Oxidation of aqueous alkaline slurries of coal with oxygen under pressure yields a mixture of aromatic carboxylic acids. Because of the presence of nitrogen compounds and hydroxy acids, this mixture is difficult to refine. Hydrogenation of coal at elevated temperatures and pressures yields much larger amounts of tar acids and

Pyridine, picolines, lutidines, quinolines, acridine, and other tar bases	2.3	Drugs, dyes, antioxidants

aromatic hydrocarbons of commercial importance than are obtained by carbonization.

Synthetic fuels may be produced from coal by either direct or indirect methods. In direct liquefaction processes, pulverized coal is suspended in a solvent, the resultant slurry is heated and exposed to gaseous hydrogen under pressure, and the liquids produced are separated from the ash and distilled to obtain the fuel fractions. In the indirect process, the coal is decomposed thermally to yield combustible gases, which are synthesized to yield gasoline, alcohols, and waxes. *See* COAL LIQUEFACTION; COKE; DESTRUCTIVE DISTILLATION; ORGANIC CHEMISTRY; PYROLYSIS.

Coal gasification

The conversion of coal or coal char to gaseous products by reaction with steam, oxygen, air, hydrogen, carbon dioxide, or a mixture of these. Products consist of carbon monoxide, carbon dioxide, hydrogen, methane, and some other gases in proportions dependent upon the specific reactants and conditions (temperatures and pressures) employed within the reactors, and the treatment steps which the gases undergo subsequent to leaving the gasifier. Similar chemistry can also be applied to the gasification of coke derived from petroleum and other sources. The reaction of coal or coal char with air or oxygen to produce heat and carbon dioxide could be called gasification, but it is more properly classified as combustion. The principal purposes of such conversion are the production of synthetic natural gas as a substitute gaseous fuel and synthesis gases for production of chemicals and plastics. *See* COMBUSTION.

Industrial uses. In all cases of commercial interest, gasification with steam, which is endothermic, is an important chemical reaction. The necessary heat input is typically supplied to the gasifier by combusting a portion of the coal with oxygen added along with the steam. From the industrial viewpoint, the final product is either chemical synthesis gas (CSG), medium-Btu gas (MBG), or a substitute natural gas (SNG). Heating values, compositions, and end uses for these gases are compared in the **table**.

Each of the gas types in the table has potential industrial applications. In the chemical industry, synthesis gas from coal is a potential alternative source of hydrogen and carbon monoxide. This mixture is obtained primarily from the steam reforming of natural gas, natural gas liquids, or other petroleum liquids. Fuel users in the industrial sector have studied the feasibility of using medium-Btu gas instead of natural gas or oil for fuel applications. Finally, the natural gas industry is interested in substitute natural gas, which can be distributed in existing pipeline networks. *See* NATURAL GAS.

There has also been some interest by the electric power industry in gasifying coal by using air to provide the necessary heat input. This could produce low-Btu gas (because of the nitrogen present), which can be burned in a combined-cycle power generation system. *See* ELECTRIC POWER GENERATION.

Gasification processes. In nearly all of the processes, the general process-flow diagram is the same (**Fig. 1**). Coal is prepared by crushing and drying, pretreated if necessary to prevent caking, and then gasified with a mixture of air or oxygen and steam. The resulting gas is cooled and cleaned of char fines, hydrogen sulfide, and CO_2 before entering optional processing steps to adjust its composition for the intended end use.

Thermodynamics. In discussions of the thermodynamics of coal gasification, at least one simplifying assumption is usually made, namely, that coal and coal char can be treated as pure carbon. Coal and coal char are really nonhomogeneous solids containing hydrogen, oxygen, sulfur, nitrogen, and mineral matter, but errors associated with this assumption are not likely to be significant.

The basic chemical reactions common to all coal gasification processes are coal and char reactions (1)–(3) and gaseous reactions (4) and (5). Reaction (2) is highly endothermic, requiring 32 kilocalories/mole (134 kilojoules/mole). The principal thermodynamic issue in most practical gasification processes is how to supply the heat for this reaction. Several methods have been considered, but generally

$$\text{Coal} \xrightarrow{\text{heat}} \text{gases } (CO, CO_2, H_2, CH_4) + \text{char} \quad (1)$$

$$C\text{ (char)} + H_2O \rightarrow CO + H_2 \quad \text{(endothermic)} \quad (2)$$

$$2C\text{ (char)} + {}^3/_2\, O_2 \rightarrow CO_2 + CO \quad \text{(exothermic)} \quad (3)$$

$$CO + H_2O \rightarrow H_2 + CO_2 \quad \text{(mildly exothermic)} \quad (4)$$

$$CO + 3H_2 \rightarrow CH_4 + H_2O \quad \text{(exothermic)} \quad (5)$$

Coal gasification products

Product	Higher heating value*	Major constituents	Use
Synthesis gas (CSG)	250–400 Btu/SCF† (9–15 MJ/m^3)	CO, H_2	Chemical feedstock for synthesis of H_2, NH_3, methanol, hydrocarbons, and so forth
Medium–Btu gas (MBG)	300–500 Btu/SCF (11–19 MJ/m^3)	CO, H_2, CH_4	General-purpose fuel for utilities and industries
Substitute natural gas (SNG)	900–1050 Btu/SCF	CH_4	Gaseous fuel

* Based on producing water as a liquid.
†SCF = Standard cubic feet.

heat is supplied by allowing exothermic reactions (3) and (5) to occur in the same vessel as reaction (2). The degree to which one reaction or the other is used depends on the process configuration and the desired product. Reactions (4) and (5) are often carried out in downstream processing blocks in order to tailor the gas composition for particular end uses. In these arrangements it is generally not feasible to return the heat to the gasifier, as the downstream reactions are carried out at much lower temperatures. The heat input methods used in the principal commercial and developing processes are given in the process descriptions below.

Processes. The differences in coal gasification processes principally involve the method of heat input, gasifier type, and ash recovery system. First-generation (commercial) gasifiers include the Lurgi (dry bottom), Koppers-Totzek (K-T), and Winkler gasifiers.

Lurgi. The Lurgi gasifier utilizes a bed of crushed coal moving downward through the reactor with countercurrent flow of gas, and operates at pressures up to 450 lb/in.^{2} gage (3100 kilopascals). Crushed coal, screened to remove fines, is fed to the top of the gasifier through a coal lockhopper, and passes downward through the drying pyrolysis, gasification, and combustion zones. Steam and oxygen are admitted through a revolving grate at the bottom of the gasifier which also removes the ash produced. After burning a portion of the coal to provide the heat required, the hot combustion gas passes upward through the zones of the coal bed. Steam is used as a reactant to gasify the coal, and is also added to keep the temperature below the ash melting point. Although the predominant source of methane (CH_4) is devolatilization, some methane comes from coal hydrogenation, releasing heat which is transferred to the coal and minimizing the oxygen requirements. As the coal moves down through the gasifier, the temperature initially rises slowly. Further down in the gasifier, it rises dramatically as the coal approaches the combustion zone where the temperature exceeds 2200°F (1200°C). The Lurgi reactors commonly used are of the general type shown in **Fig. 2**. Because of the countercurrent flow in the gasifier, high carbon utilization and good heat recovery are obtained.

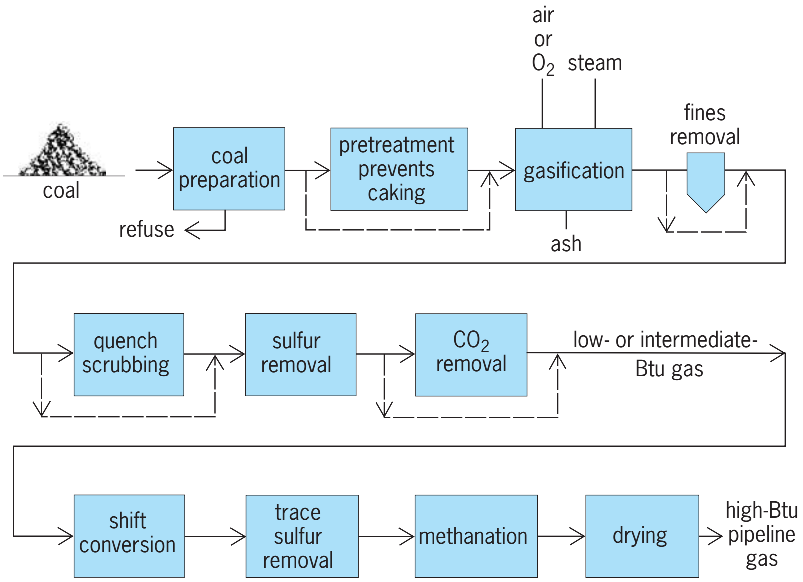

Fig. 1. Schematic representation of the processing steps in coal gasification.

The dry-bottom Lurgi process is generally applicable to subbituminous coals and lignites because the gasifiers operate best with noncaking, nonfriable coals with high reactivity and high ash melting points. The internal design and operating conditions of these reactors may be altered for coals of different caking characteristics and reactivities. Dry-bottom Lurgi gasifiers are used in the Great Plains coal gasification project in North Dakota and also in the world's largest gasification facilities at the SASOL coal-to-oil plants in South Africa.

Koppers-Totzek. The K-T gasifier is an atmospheric, entrained reactor. Dried and pulverized coal is mixed with steam and oxygen and fed to coaxial burners. The pulverized coal is gasified as it is carried in the flow of gas and as a portion of the coal is combusted. Practically every type of coal can be gasified by this technique. The operability of the process is not affected by caking properties of the coal.

The complete entrainment of the feed particles requires high gas velocities to achieve reaction times of only a few seconds; consequently the reaction temperature required is 3300–3500°F (1825–1925°C). At these temperatures, most of the carbon reacts very rapidly with oxygen and steam to produce carbon oxides, hydrogen, and molten slag. Less than 0.1% CH_4 is present in the product gas, and no tars or phenols are produced. More than 50% of the ash flows down the gasifier walls as molten slag into a

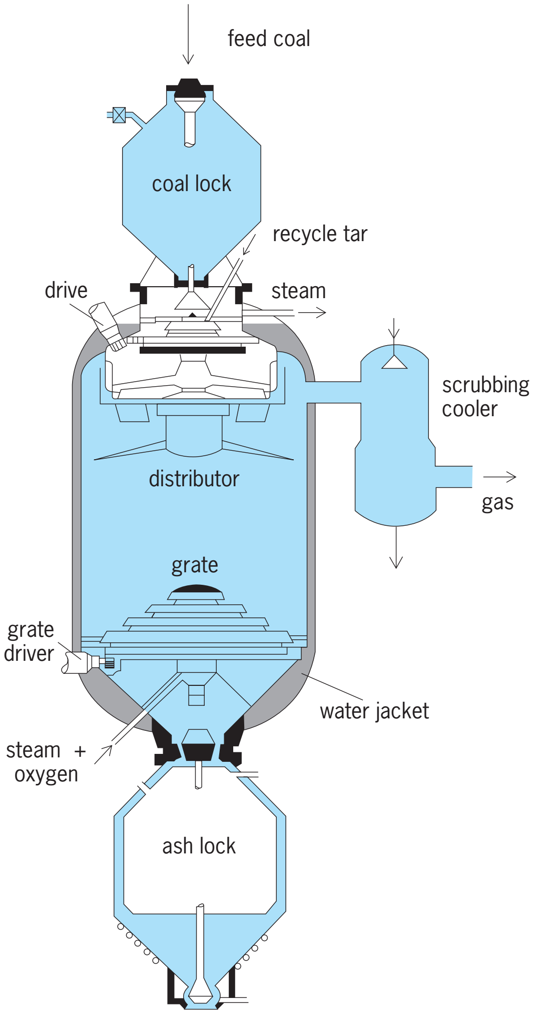

Fig. 2. Diagram of a Lurgi pressure gasifier.

slag quench tank. The rest leaves as entrained fly ash in the exit gas. The gasifier has a double-walled shell and a thin refractory lining. Water is circulated in the vessel jacket to protect the refractory. Most of the operating plants utilizing K-T gasifiers have been for the production of a H_2-rich gas for NH_3 manufacture.

Winkler. The Winkler gasifier is an atmospheric, fluidized-bed reactor that was developed in Germany in the 1920s. The vessel is cylindrical and refractory-lined, with nozzles for injecting a mixture of steam and oxygen at the bottom of the gasifier and above the top of the char bed to control fines. Crushed, dried coal is fed to the gasifier by means of a screw conveyor. The gasification temperature is controlled around 1800–2000°F (1000–1100°C) by adjusting the ratio of oxygen and steam to coal, and thus the portion of the coal being combusted. Gas is removed overhead, cooled, and dedusted. Product gas is low in CH_4 and contains no tars. Heavy char particles, which contain ash, settle to the bottom of the fluidized bed and are withdrawn from the gasifier by a screw conveyor. Most of the Winkler gasifiers that have been built are in eastern Europe and Asia.

Research and development. Most process research and development is directed toward increasing the efficiency of certain process steps, gasifying a wider range of coals or lowering plant costs. Important programs in the United States include work on partial oxidation, gasification with controlled ash agglomeration, and catalytic gasification. Major European efforts include work on the slagging gasifier and partial oxidation.

Slagging gasifier. The British Gas/Lurgi slagging gasifier is a modification of the commercial dry-bottom Lurgi design. It uses less steam and is less coal-sensitive than the dry-bottom Lurgi. These modifications are achieved by incorporating a high-temperature slagging zone at the bottom of a gasifier. Coal is screened and crushed before being introduced via lock-hoppers into the top of the reactor. As the coal moves downward through the reactor as a slowly moving bed, it passes through the drying, pyrolysis, gasification, and combustion zones. The coal ash is melted in the combustion zone and collects in a pool, from which it is tapped and quenched with water before being withdrawn from the gasifier. The oxygen and steam for the reaction are supplied through tuyeres in the bottom of the reactor. Tar, oil, and some of the coal fines produced in the crushing step can also be injected through the tuyeres and gasified. Some quantity of dusty tar can also be distributed at the top of the bed. The gas moving upward countercurrently through the moving bed of coal supplies the heat for the various gasification reactions and for drying the coal. The gas exits the reactor at approximately 1000°F (540°C), and is quenched in a scrubber to remove heavy tars and fines before being cooled in a waste heat boiler. This process is considered to be more attractive than the dry-bottom Lurgi for caking coals, such as bituminous coals of the eastern United States.

Partial oxidation. Both Texaco and Shell have pursued partial-oxidation process development. The Texaco gasifier is a pressurized (up to about 1000 $lb/in.^2$ absolute or 6800 kPa), entrained reactor. Coal is pulverized in a wet mill and slurried (50–70 wt % solids) in water. The slurry is then pumped to pressure and injected with oxygen and steam into the downflow entrained gasifier. The hot gas and slag exit the bottom of the gasifier and pass through a radiant cooler. Most of the ash is collected at the bottom of the radiant section. The gas that contains some fly ash passes through a convective cooler and a scrubber. Both the radiant and convective coolers generate high-pressure, saturated steam. An alternate design involves cooling the hot gas from the reactor by water quench. In this case, no steam is generated, but the gas produced contains sufficient water for subsequent conversion of the carbon monoxide to hydrogen.

The Shell process is similar, but utilizes a dry feed system rather than a water slurry. In this process, ground coal is metered into an entrained gasifier where it reacts with oxygen and steam.

Gasification with controlled agglomeration. Both Westinghouse and the Institute of Gas Technology have pursued gasification under conditions which result in controlled ash agglomeration. The Westinghouse gasifier is a pressurized (about 250 lb/in.^{2} absolute or 1600 kPa), fluidized-bed reactor. Coal is crushed before pressurizing via lockhoppers. The coal is injected with steam and oxygen into the fluid bed through an axial lift pipe. The higher temperature at the outlet of the lift pipe gives controlled ash agglomeration in the fluid bed. Larger particles of ash concentrate at the bottom of the gasifier and are removed and rejected. Steam and recycled gas are also injected in the lower portion of the reactor in order to fluidize the bed and control ash particle size. The resulting gas product is removed overhead, dedusted by cyclones, and cooled in waste heat boilers. The cooled gas is scrubbed to remove fines, and a portion is recycled to provide fluidization gas.

Catalytic coal gasification. The Exxon catalytic coal gasification process is intended for substitute natural gas production, and differs significantly from other gasification methods in that it uses a potassium catalyst to accomplish steam gasification [reaction (2)] and methanation [reaction (5)] in the same vessel. The catalyst enables the gasifier to operate at mild process conditions of 1300°F (700°C) and 500 lb/in.^{2} gage (3550 kPa). A major advantage of this "one-step" approach is that the overall reaction is almost thermally neutral. The gasification heat requirement is essentially supplied by the methanation heat release. Therefore, the catalytic coal gasifier does not require a large heat input by means of oxygen or other methods. The gasifier off-gas is treated by commercially available acid-gas–removal technology, and the methane product is cryogenically separated, with H_2 and CO recycled to the gasifier. The catalyst-char-ash material which is removed from the gasifier is washed countercurrently with water to recover most of the potassium catalyst for reuse. *See* HETEROGENEOUS CATALYSIS.

Underground gasification. Only about one-fifth of the total coal in the ground can be recovered by mining. The remainder is either too deep or in seams that are too thin to be mined. Long-term underground gasification is a promising possibility for utilizing this unminable coal. This process involves drilling wells into coal deposits, preparing a rubbled bed of coal through which gas can flow, and initiating gasification in the bed by using steam and air or oxygen. Such underground field tests have been conducted in the United States, but problems with underground gasification include process control, land subsidence, and ground-water pollution. *See* COAL MINING.

Several organizations have been active in this field, emphasizing work on the nature and direction of subsurface fracture systems, the means to calculate fluid movement underground, and environmental impacts. Directional drilling techniques and fracturing of the underground formations with chemical explosives have been studied. *See* COAL. W. R. Epperly

Coal liquefaction

The conversion of most types of coal (with the exception of anthracite) primarily to petroleumlike hydrocarbon liquids which can be substituted for the standard liquid or solid fuels used to meet transportation, residential, commercial, and industrial fuel requirements. Coal liquids contain less sulfur, nitrogen, and ash, and are easier to transport and use than the parent (solid) coal. These liquids are suitable refinery feedstocks for the manufacture of gasoline, heating oil, diesel fuel, jet fuel, turbine fuel, fuel oil, and petrochemicals.

Liquefying coal involves increasing the ratio of hydrogen to carbon atoms (H:C) considerably—from about 0.8 to 1.5–2.0. This can be done in two ways: (1) indirectly, by first gasifying the coal to produce a synthesis gas (carbon monoxide and hydrogen) and then reconstructing liquid molecules by Fischer-Tropsch or methanol synthesis reactions; or (2) directly, by chemically adding hydrogen to the coal matrix under conditions of high pressure and temperature. In either case (with the exception of methanol synthesis), a wide range of products is obtained, from light hydrocarbon gases to heavy liquids. Even waxes, which are solid at room temperature, may be produced, depending on the specific conditions employed. **Table 1** lists potential uses for coal liquefaction products and indicates the additional processing which would likely be required.

Indirect liquefaction. Indirect coal liquefaction consists of three important steps: first, the coal is gasified; second, the composition of the resulting gas is adjusted (shifted, if necessary, to increase H_2 content; and H_2S and CO_2 are removed); and third, the CO and H_2 in the resulting synthesis gas are catalytically reacted to form the liquids. Commercial processes for catalytically reacting CO and H_2 to form the indirect coal liquids include Fischer-Tropsch synthesis and methanol synthesis. In addition, a Mobil process for conversion of methanol to gasoline is expected to be an important commercial operation.

Fischer-Tropsch synthesis. The synthesis processes based on the Fischer-Tropsch chemistry are represented by reaction (1). This reaction represents a

$$2nH_2 + nCO \rightarrow (\text{—}CH_2\text{—})_n + nH_2O \qquad (1)$$

polymeric addition of methylene (—CH_2—) groups to form a distribution of linear paraffins. In practice, a broad range of molecular weights is produced, and the product includes branched, olefinic, and oxygenated compounds, depending on reactor type,

TABLE 1. Potential uses for coal liquefaction products

Product	Commercial uses	Additional processing required
Light hydrocarbons		
Methane and ethane	Pipeline gas	None
C_3–C_4 hydrocarbons	Liquefied petroleum gas (LPG)	None
C_2–C_4 hydrocarbons	Ethylene and propylene manufacture	Steam cracking
Naphtha		
C_4–160°F (71°C) naphtha	Motor gasoline	Hydrotreating
160–350°F (71–180°C) naphtha	Motor gasoline	Hydrotreating and reforming
	Chemicals (benzene, toluene, xylene)	Extraction
350–430°F (180–220°C) naphtha	Motor gasoline	Hydrotreating
Middle distillate	Turbine fuel	Direct use or hydrotreating
350–650°F (180–340°C) or 430–650°F (220–340°C)	Low- or medium-speed diesel fuel	Direct use
	No. 6 fuel oil blendstock	Direct use
	Home heating oil	Direct use (with burner adjustment) or hydrotreating
	Auto diesel blendstock	Moderate hydrotreating
	Jet, auto diesel, No. 2 fuel oil	Severe hydrotreating or hydroconversion
Heavy distillate		
650–1000°F (340–540°C) vacuum	Fuel oil blendstock	Direct use or hydrotreating
Gas oil	Fluid catalytic cracking or hydroconversion feed	Hydrotreating
Other products		
Solvent refined coal (solid)	Boiler fuel	Direct use
Methanol	Motor fuel, distillate fuel	Direct use (with special distribution system)
Fischer-Tropsch liquids	Gasoline, diesel oil, jet fuel, wax	Hydrotreating, reforming, isomerization, polymerization

operating conditions, and catalyst type. The average molecular weight of the product mixture can be adjusted to some extent by the selection of process conditions.

Two synthesis processes (ARGE and Synthol) are used in the commercial coal liquefaction plants of the South African Coal, Oil, and Gas Company (Sasol) in the Republic of South Africa. The ARGE process utilizes a fixed-bed reactor and a precipitated-iron catalyst to produce a high-boiling, linear paraffin product, including a range of waxes. The Synthol process uses an entrained-bed reactor and a fused-iron catalyst to produce a somewhat lower-boiling hydrocarbon product which contains more isoparaffins and olefins.

The Sasol I commercial coal liquefaction plant started operations in 1955 and utilizes both the ARGE fixed-bed and the Synthol entrained-bed processes. Sasol II operation was initiated in 1980, when a site was also prepared for Sasol III. Both Sasol II and Sasol III are modified and enlarged versions of Sasol I. Each is designed to include seven of the Synthol entrained-bed reactors. Production of nonfuel products will be minimized in Sasol III.

Modified process techniques and conditions can have a significant impact on the Fischer-Tropsch product distribution. New catalyst formulations can improve activity and tailor the product distribution to meet fuel and chemical product demands. Engineering research to define better reactor designs and optimum operating conditions for more economic processes have also been undertaken. *See* FISCHER-TROPSCH PROCESS.

Methanol synthesis. The methanol synthesis processes are based on the chemistry represented by reactions (2) and (3).

$$CO + 2H_2 \rightarrow CH_3OH \qquad (2)$$

$$CO_2 + 3H_2 \rightarrow CH_3OH + H_2O \qquad (3)$$

Commercial processes use copper- and zinc-based catalysts and fixed-bed reactors operating at high pressure (100 atm or 10 megapascals) and low conversion per pass with high recycle ratios. Crude methanol can be utilized in three ways: as a neat fuel in fleet applications, as a gasoline blendstock, or as a feed to the Mobil methanol-to-gasoline process. *See* METHANOL.

Mobil methanol-to-gasoline process. In the Mobil process, a complex sequence of reactions occurs over a zeolite catalyst. Methanol is the first dehydrated to an equilibrium mixture of dimethyl ether, methanol, and water. This mixture is then fed to catalytic reactors where the remaining methanol is dehydrated to dimethyl ether, which reacts to form olefins that polymerize to form aromatic gasoline components. A fixed-bed version of this process is commercially available and has been applied in a New Zealand natural gas-to-gasoline project. A fluid-bed version of the methanol-to-gasoline process is used in a pilot plant in Germany, which started up in late 1982. *See* ZEOLITE.

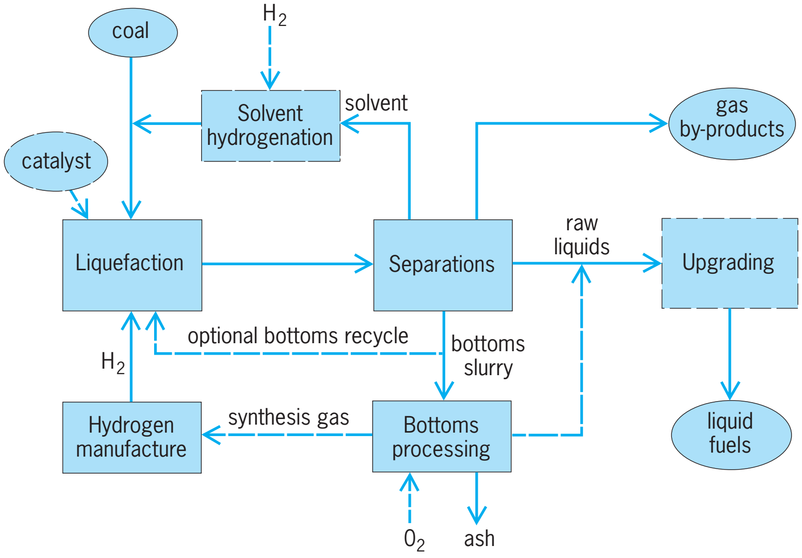
TABLE 2. Leading direct coal liquefaction technologies*

	EDS	H-Coal	SCR II	Modified Bergius-Pier
Demonstration plant	250 tons/day (230 Mg/day), Baytown, Texas	200 tons/day (180 Mg/day), Catlettsburg, Kentucky	35 tons/day (32 Mg/day), Fort Lewis, Washington	220 tons/day (200 Mg/day), Bottrop, Germany
Recycle solvent	Hydrogenated distillate	Distillate	Product slurry	Distillate
Pressure, atm (MPa)	140–170 (14–17)	210 (21)	140 (14)	300 (30)
Bottoms recycle	Optional	No	Essential	No
Catalyst	Ni-Mo in solvent hydrotreater (none in liquefaction)	Co-Mo (in ebullating bed reactor)	None (relies on catalytic activity in recycled coal ash)	$FeSO_4$ as red mud
Types of coal	Bituminous Subbituminous Lignite	Bituminous Subbituminous	Bituminous	Bituminous

*Mg = megagrams.

Direct liquefaction. Direct liquefaction or hydrogenation of coal was developed in Germany in the 1920s by F. Bergius, who received the Nobel Prize in chemistry for his work. This technology was later modified by M. Pier and commercially proved during World War II. However, this technology operated at extremely high pressure (almost 700 atm or 70 MPa) and in small reactors (3-ft or 1-m diameter) and was too costly to be economically justified in peacetime.

Since the war, interest in direct coal liquefaction has periodically been revived, generally in response to projected shortages of petroleum, but no commercial plants have been built. However, four second-generation liquefaction technologies have been demonstrated in large pilot plants, and these are compared in **Table 2**. These technologies were an outgrowth of the Bergius-Pier process, but operate at much lower pressure (140–300 atm or 14–30 MPa). Other technologies have also benefited from major advances in reactor design since the 1940s, which will allow much larger (and therefore more economical) plants to be built. However, notwithstanding the technical improvements which have been made, the basic processing steps in coal liquefaction (see **illus.**) have not changed conceptually.



Processing steps in direct coal liquefaction. Broken lines represent optional steps or flow streams.

Coal is first crushed and slurried in a process-derived solvent and then heated and pumped to typical reaction conditions, in the range of 800–930°F (425–500°C) and 140–300 atm (14–30 MPa). Depending on the process, a catalyst may be added to the liquefaction step, or the solvent may be hydrogenated to improve hydrogen transfer to the coal. As the coal is heated to reaction temperatures and held there for 40–80 min nominal residence time, thermal cracking (thermolysis) occurs. At liquefaction temperature, chemical bonds are broken, that is, cracked, generating free-radical fragments which can participate in secondary reactions—combining with hydrogen to produce stable liquids, reacting further to form lighter liquids, or polymerizing to form high-molecular weight, high-boiling-point bottoms. Control of these secondary reactions is important in achieving high conversions and good selectivity to distillable liquid products. During liquefaction, heteroatoms in the coal (oxygen, nitrogen, and sulfur) are also liberated, principally as carbon oxides, water, ammonia, and hydrogen sulfide.

After liquefaction, products must be separated from bottoms (ash, heavy coal liquids, and unconverted coal) and solvent recovered. The most common technique for separation is distillation, although hydroclones, which separate by centrifugal force, have been used in Hydrocarbon Research's H-Coal and extraction in Gulf solvent-refined coal (SRC) for removal of ash and coal residues. Gulf's SRC II process, which evolved from SRC, recycles bottoms to increase the ash level in the liquifaction reactor and improve conversion. The EDS process has operated with and without bottoms recycling, and employs recycling to increase conversion and produce a lower-molecular-weight product slate. Product slate refers to the end products that are actually sent to the market from the plant. It has been shown that the bottoms contain high-boiling asphaltenes and preasphaltenes which can be readily converted to lighter products through recycling.

The net bottoms product is sent to a bottoms processing step, where the carbon is utilized and coal ash is separated. Carbon utilization can involve recovery of additional liquids by coking or extraction, partial oxidation to produce plant fuel or hydrogen, or combustion to provide plant heat. Hydrogen generation is frequently the preferred bottoms-processing step. In this case, bottoms would be sent to a partial oxidation unit and gasified with oxygen to produce a synthesis gas for hydrogen production. Alternatively, hydrogen could be produced by partial oxidation of coal or by conventional steam reforming of light gases as in present-day petroleum refineries and chemical plants. *See* COAL GASIFICATION; PETROLEUM PROCESSING AND REFINING; SOLVENT EXTRACTION.

Upgrading of coal liquids. In most cases, coal liquids require upgrading prior to use. The type and severity of upgrading depends on the initial characteristics of the liquids and the desired product properties (Table 1). In general, however, the upgrading processes are similar to those employed for petroleum liquids. Hydrotreating (mild hydrogenation) is commonly selected for removal of nitrogen, sulfur, or oxygen in coal liquids. Direct coal liquids are rich in cycloparaffins and aromatics. In the gasoline fraction, the cycloparaffins can be dehydrogenated by catalytic reforming to aromatics, which have a high octane rating. In the middle distillate fraction, the aromatics can be hydrogenated to cycloparaffins, which have improved performance in diesel and jet engines. In addition, catalytic cracking or hydroconversion of heavy distillates can be used to increase the yield of gasoline and middle distillate.

Indirect coal liquids are primarily paraffins and olefins. Polymerization of the propane-butane fraction can be used to increase the yield of gasoline. Reforming of the gasoline fraction increases octane rating by producing aromatics via cyclization of paraffins and subsequent dehydrogenation. Isomerization of linear paraffins also increases octane. Heavy, waxy streams can be cracked to gasoline and middle distillate. *See* HYDROCRACKING.

The severity of product upgrading typically decreases with increasing severity of direct liquefaction. The reason for this lies in the basic chemistry of converting high-carbon coal (H:C atomic ratio of about 0.8) into naphtha and light distillate (H:C of 1.2–1.9). Since the overall reaction involves hydrogen addition, it can be seen that a low level of hydrogenation in the liquefaction section would yield a high percentage of high-boiling components which require extensive hydrotreating to produce salable products. On the other hand, a liquefaction process of relatively high severity would yield liquids which require less extensive treatment to achieve the same salable products. As a result, yield comparisons of different coal liquefaction processes are usually closer on a finished product basis than on an intermediate product basis. It is generally agreed that a commercial coal liquefaction plant will produce approximately 3 barrels (0.5 m^3) of liquid product for every ton (0.9 metric ton) of dry, ash-free coal feed.

Continuing research. Research on improving coal liquefaction processes is concentrated in the general areas of staged liquefaction and catalysis. The principal goal of this work is to increase the yield of distillate products while reducing the amount of gas produced. In staged processes, the conditions in each stage are selected to optimize production of the desired liquid products. In catalytic processes, a catalyst which promotes formation of the desired molecular species is selected. Most emerging technologies incorporate elements of both staging and catalysis to obtain the advantages of each approach.

Staged liquefaction processes utilize two or more distinct stages to promote coal conversion or to improve the product slate. Though processes with many stages are theoretically possible, all of the staged liquefaction concepts use only two stages. Their essential features include a coal dissolver section (first stage), a deashing section to remove solids, and a catalytic hydroconversion section (second stage) to upgrade the heavy liquids. The dissolver section could range between a plug-flow reactor and a short-contact-time preheater. Deashing may be accomplished with hydroclones or by using proprietary antisolvent or critical-solvent deashing techniques. The hydroconversion section is typically operated at a lower temperature than the dissolver section (to prevent thermal cracking of liquids into gases) and contains catalyst in either a fixed bed, expanded bed, or ebullating bed.

In addition to these process differences, several variations in processing sequence are possible improvements to the two-stage technology. For example, the degree to which process streams from the hydroconversion section are recycled to the dissolver section may be adjusted to yield an integrated, partially integrated, or nonintegrated operation. Another option is placement of the second stage; since some hydroconversion processes are less sensitive to solids concentration, it may be possible to locate the deashing section downstream of both liquefaction stages. Finally, within the framework of any given processing sequence, the number of recycle streams, the cut points of these streams, and the severity of hydrotreating can also be changed.

The major two-stage liquefaction processes employ catalysts for additional conversion of heavy liquids. The two-stage process of the Electric Power Research Institute and the U.S. Department of Energy and the integrated two-stage liquefaction (ITSL) process of Lummus, both have high-temperature, plug-flow first stages and solvent-extraction deashing followed by lower-temperature, catalytic hydroconversion. In addition, ITSL uses a short-contact time preheater. The Chevron Coal Liquefaction process uses the same process sections but employs solids separation after both of the liquefaction stages. Overall, direct liquefaction is a fertile area for continuing research. *See* CATALYSIS; COAL; HETEROGENEOUS CATALYSIS.

Coal mining

The technical and mechanical activities involved in removing coal from the earth and preparing it for market. Coal mining in the industrialized countries is characterized by the integration of a number of complex systems into a production methodology that varies for surface versus underground mining. *See* COAL.

The basic systems of the production methodology are the following. (1) Extraction systems: the methods and techniques used to break out or "win" the coal. (2) Materials-handling systems: the transport of coal and waste products away from the active production area, and the transport of the necessary materials, equipment, supplies, and workers to service the extraction system. (3) Ventilation: the development and operation of an air distribution system to provide the quantity, quality, and velocity of air where and when needed, to meet health and safety requirements. (4) Ground control: the control of the behavior of underground and surface openings developed by the extraction of coal. (5) Reclamation: the restoration of the mined area to its approximate original state or to an approved state.

To properly plan, design, and engineer a production system, knowledge of the geology of the deposit and the chemical and physical properties of the coal must be assembled and assessed. Basic information on the geology of the deposit is obtained from surface prospecting and mapping, and borehole drilling. This information is used to determine the size and shape of the coal area, the geologic column above and below all minable seams, the continuity and persistence of geologic features throughout the deposit, the presence of water or methane gas, and other special conditions. Proximate chemical analyses are made to determine coal characteristics, which affect its utilization. Tests are made to determine the cleaning, grinding, and handling properties of the coal. Ultimate chemical analyses are made to determine the fundamental chemical constituents of the coal. Maps are drawn to summarize this information, and are used for scheduling and sequencing production. *See* ANALYTICAL CHEMISTRY; ENGINEERING GEOLOGY; PROSPECTING; ROCK MECHANICS; SOIL MECHANICS; SPECTROSCOPY.

Surface Mining

When a coal seam lies sufficiently close to the ground surface, a surface mining method may be employed. The geographic location and geologic column—in particular, the ratio of the thickness and quality of the overburden and interseam waste to be removed, to the thickness and quality of the coal to be produced—are the initial considerations. Site conditions, which affect the production method,

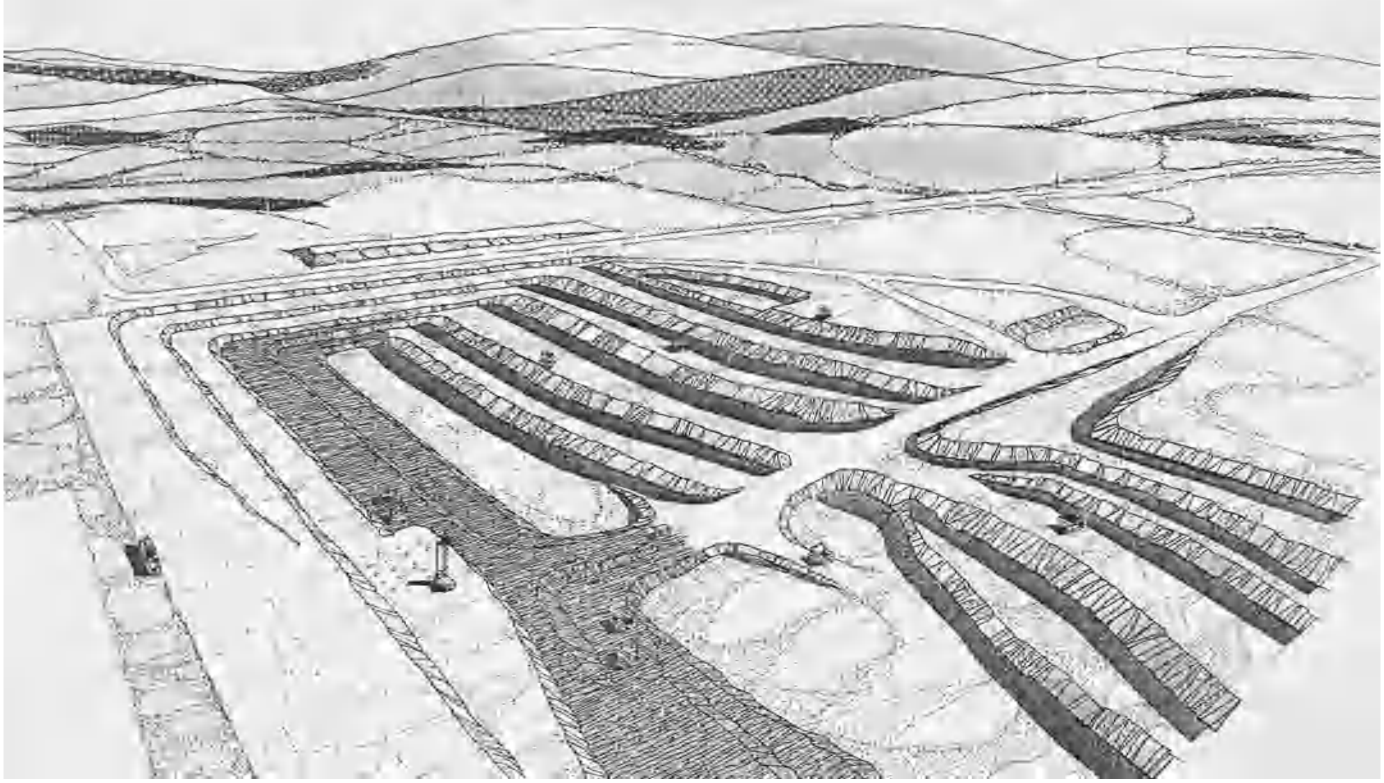

Fig. 1. Diagram of a terrace pit coal mine, showing terrace pit stripping and reclamation. (*After U.S. Department of Energy, The Development of Optimal Terrace Pit Coal Mine Systems, DOE Rep. FE/10023-1, January 1971*)

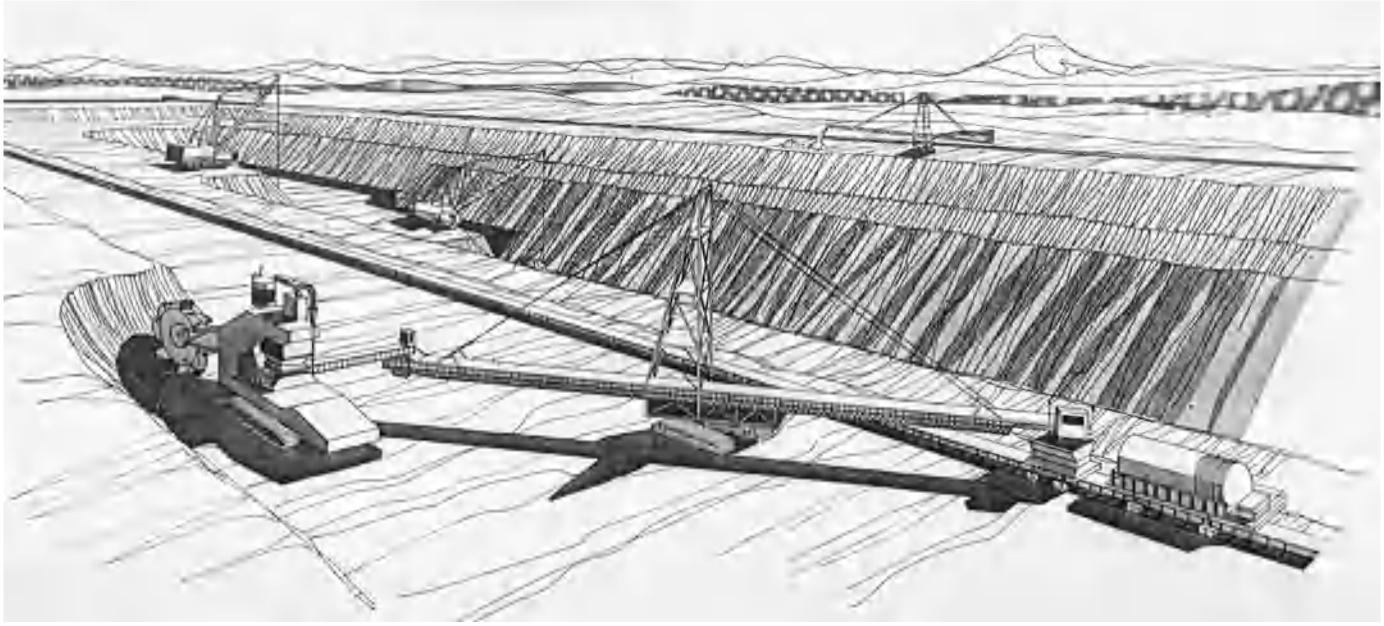

Fig. 2. Diagram of a strip coal mine, showing bucket-wheel excavator prestripping for draglines. (*After U.S. Department of Energy, The Development of Optimal Terrace Pit Coal Mine Systems, DOE Rep. FE/10023-1, January 1971*)

include types of terrain, temperature range, altitude, and rainfall and snowfall. Overburden and interseam waste characteristics affecting the production methods are material weight, stickiness, and swell; ability to form a stable highwall and spoil pile; ratio of rock and other material requiring blasting, to soil in the overburden; and need for special handling of waste materials for reclamation purposes. The presence of thicker and good-quality coal that commands higher prices can justify the removal of thick overburden.

Surface coal mines involve area mining or modified open pit mining, contour mining and mountaintop removal, and auger mining. Removal of overburden is called stripping, and hence the term "strip mining" is often applied to surface coal operations (**Figs. 1** and **2**). Area mining is applicable in relatively flat to gently undulating terrain where coal seams are of considerable area and may be at various dips. Contour mining and mountaintop removal are used in hilly and mountainous country and can be modified to handle coal seams at any dip. Auger mining follows the other surface methods when overburden removal becomes uneconomic, and is generally limited to more or less horizontal coal seams. *See* SURFACE MINING.

Area or modified open pit. In a typical area mine the layout is roughly rectangular with adjustments made to fit the boundaries of the property. The length of the pit varies depending on the rate of planned production, but may range to about 2 mi (3 km) or more. Extraction operations involve topsoil and subsoil removal, overburden removal, and coal loading. Drilling and blasting or ripping of the overburden and coal may be required.

The equipment used in topsoil and subsoil removal and in stripping overburden is selected based on the characteristics of the soil and rock to be removed. In soft digging, bulldozers, wheel loaders, and elevating scrapers may be used to excavate the soil and overburden and to load it into trucks (**Fig. 3**). In many parts of Europe, where the geologic column consists of soft-digging materials, bucket wheel excavators, used singly and in tandem, excavate and convey the soil and overburden to storage areas. Pan scrapers are found to be useful both in soil and overburden removal and in reclamation. When rock is present, drilling and blasting or ripping are required to loosen and break out the overburden. Draglines (**Fig. 4**) and power shovels (**Fig. 5**) are used to dig the harder and more consolidated materials.

Since outcrops rarely occur where area surface mining is practiced, mining begins with an opening or box cut, with the spoil from the cut being

Fig. 3. Front-end loader.

Fig. 4. Small dragline.

cast to one side or removed to a stockpile, and the uncovered coal is mined. Then an adjoining parallel cut of overburden is removed and deposited in the previous excavation, and the exposed coal is mined. Mining proceeds in this fashion until an economic, technologic, or property limit is reached.

The box cut is usually taken where the coal has the least overburden and in an orientation which allows the pit to advance toward coal with the greatest overburden. In a single-bench operation the box cut is designed to allow for a pit floor width which will accommodate the in-pit equipment and the initial overburden spoil used in backfilling, which must lie at a safe angle of repose. In a dragline or stripping shovel operation the toe of the spoil is adjacent to the coal seam in order to minimize the required operating radius for the equipment. Where multiple benches or terraces are developed for overburden and coal removal, the box cut width varies at each bench or terrace level.

In a single-bench, simple sidecasting dragline operation, there is no rehandling of material, and it is therefore a widely practiced and economical method for overburden excavation. Coal is mined by loading shovels or wheel loaders and is hauled by truck. The dragline may be operated so as to make a rough separation between soil and overburden and hence aid in reclamation of the mined area. Large power shovels are also used for stripping overburden in this type of operation.

Draglines have been used exclusively since the 1960s. The superiority of the dragline (**Fig. 6**) is its long reach and dumping, which permits thicker overburden to be mined and the spoil to be placed at a greater distance and in higher piles; and the large capacity of its buckets, which determines the productivity of the machine.

Multiple bench or terraced pits may be developed by using different combinations of equipment, but a shovel-truck combination or a shovel-truck-dragline combination is usually high on the list of feasible options. In a typical shovel-truck combination, overburden is removed with power shovels and loaded into trucks. A bulldozer works with each power shovel for cleanup, leveling, and bench preparation. The overburden benches are about 50 ft (15 m) in height and are mined in 200-ft (60-m) pushbacks. Shovels advance the pushback on the top level first and then proceed to the lower benches. Trucks haul the overburden up ramps on the highwall side of the

Fig. 5. Power shovel loading coal trucks.

Fig. 6. Dragline working from the surface of the ground. (*Morrison Knudsen Co.*)

pit, then around the pit on the spoil side, advancing the spoil dump at the same rate as the highwall. Spoil from the box cut is stockpiled for later use in reclamation.

Overburden drilling is done by rotary drills with bits of 6.78–12.12-in. (17.5–31.8-cm) diameter. Coal drilling is done with truck-mounted rotary drills using 6-in.-diameter (15-cm) bits. Blastholes are loaded with ANFO (ammonium nitrate–fuel oil) explosive, usually from bulk mixing trucks, which mix and meter the amount of explosive for each hole. After blasting, coal is loaded, with either power shovels or wheel loaders, onto bottom dump trucks of 100–150-ton (90–135-metric ton) capacity which are favored for coal hauling because of their low body height. Coal benches are about 30 ft (9 m) high and 200 ft (60 m) wide, and are advanced in 100-ft (30-m) pushbacks. *See* DRILLING AND BORING, GEOTECHNICAL.

A dragline may be added to the shovel-truck combination after the box cut is excavated and backfilling with spoil has begun. A bench is excavated for the dragline at the appropriate level above the seam. Operating from this bench, the dragline excavates the overburden above the seam and sidecasts it into the pit floor area from which coal has been extracted.

A number of variations on the shovel-truck combination are possible. For example, an around-the-pit conveyor transport system may be used to reduce or eliminate truck haulage. Excavated overburden may be loaded directly or may be transported by truck to a hopper equipped with a fixed grizzly screen to reject oversize material. From the hopper, the spoil is fed to a shiftable conveyor system, which carries the spoil out of the pit to a stacker-spreader. This in turn spreads the material along a spoil bench in the pit. The conveyor system is shifted forward in 100-ft (30-m) increments as the benches advance.

Bucket wheel excavators are useful in certain mining conditions. Essentially a bucket wheel excavator consists of (1) a large wheel with toothed buckets pinned to the circumference and mounted on the end of a maneuverable boom; (2) a discharge boom supporting a belt conveyor; (3) a revolving frame mounted on crawler supports; and (4) electric motors and control devices. Material is excavated by moving the rotating wheel into the overburden or coal and swinging it on the maneuverable boom through an arc. Material is cut, chopped, or scraped into the buckets, and as the wheel continues to rotate, the buckets are emptied. The excavated material is transported away from the wheel by a system of conveyors, and finally moves up the discharge conveyor to the discharge point. The conveyor system may consist of an around-the-pit conveyor incorporating a shiftable conveyor section. The shiftable conveyor must be periodically moved to keep it within the discharge range of the bucket wheel excavator. A mobile transfer conveyor may be added to the system to improve the continuity of material flow. In all cases, however, material flow is more or less continuous.

Bucket wheel excavators are capable of high production under favorable conditions with outputs in the range of 1600–12,000 yd^3 (1200–9200 m^3) per hour. However, they have difficulty in handling hard, consolidated material even when blasted; alternating the hard and soft formations slows production. Also, large boulders, buried vegetation, and sticky materials clog the buckets, transfer points, and machinery. However, bucket wheel excavators are widely used in Europe for the mining of brown coals. The rock strata, consisting of unconsolidated earth, soft shale, and siltstone overlying thick beds of brown coal, is ideally suited to the capabilities of bucket wheel excavators. The brown coals extend over large areas and may be found in thicknesses of 600 ft (180 m) or more, interbedded with sand and clay zones. Area pit dimensions may be a number of miles, and coal and spoil transport to delivery points is by belt conveyor or rail.

Bucket wheel excavators have found limited application in the United States. *See* OPEN PIT MINING.

Contour mining and mountaintop removal. This method of surface mining is used in the hilly and mountainous areas of the Appalachians, where coal seams are numerous and are generally flat-lying or subhorizontal, outcropping on the steeply sloping valleys and ridges. The geologic column consists of shales, sandstones, and limestones of varying thickness and hardness.

Now illegal, conventional contour mining started with an initial cut along the outcrop line on the mountainside. The overburden was indiscriminately cast over the side of the hill and the coal extracted. This procedure was continued into the mountainside and along the outcrop line until an economic, technical, or property limit was reached. The resulting

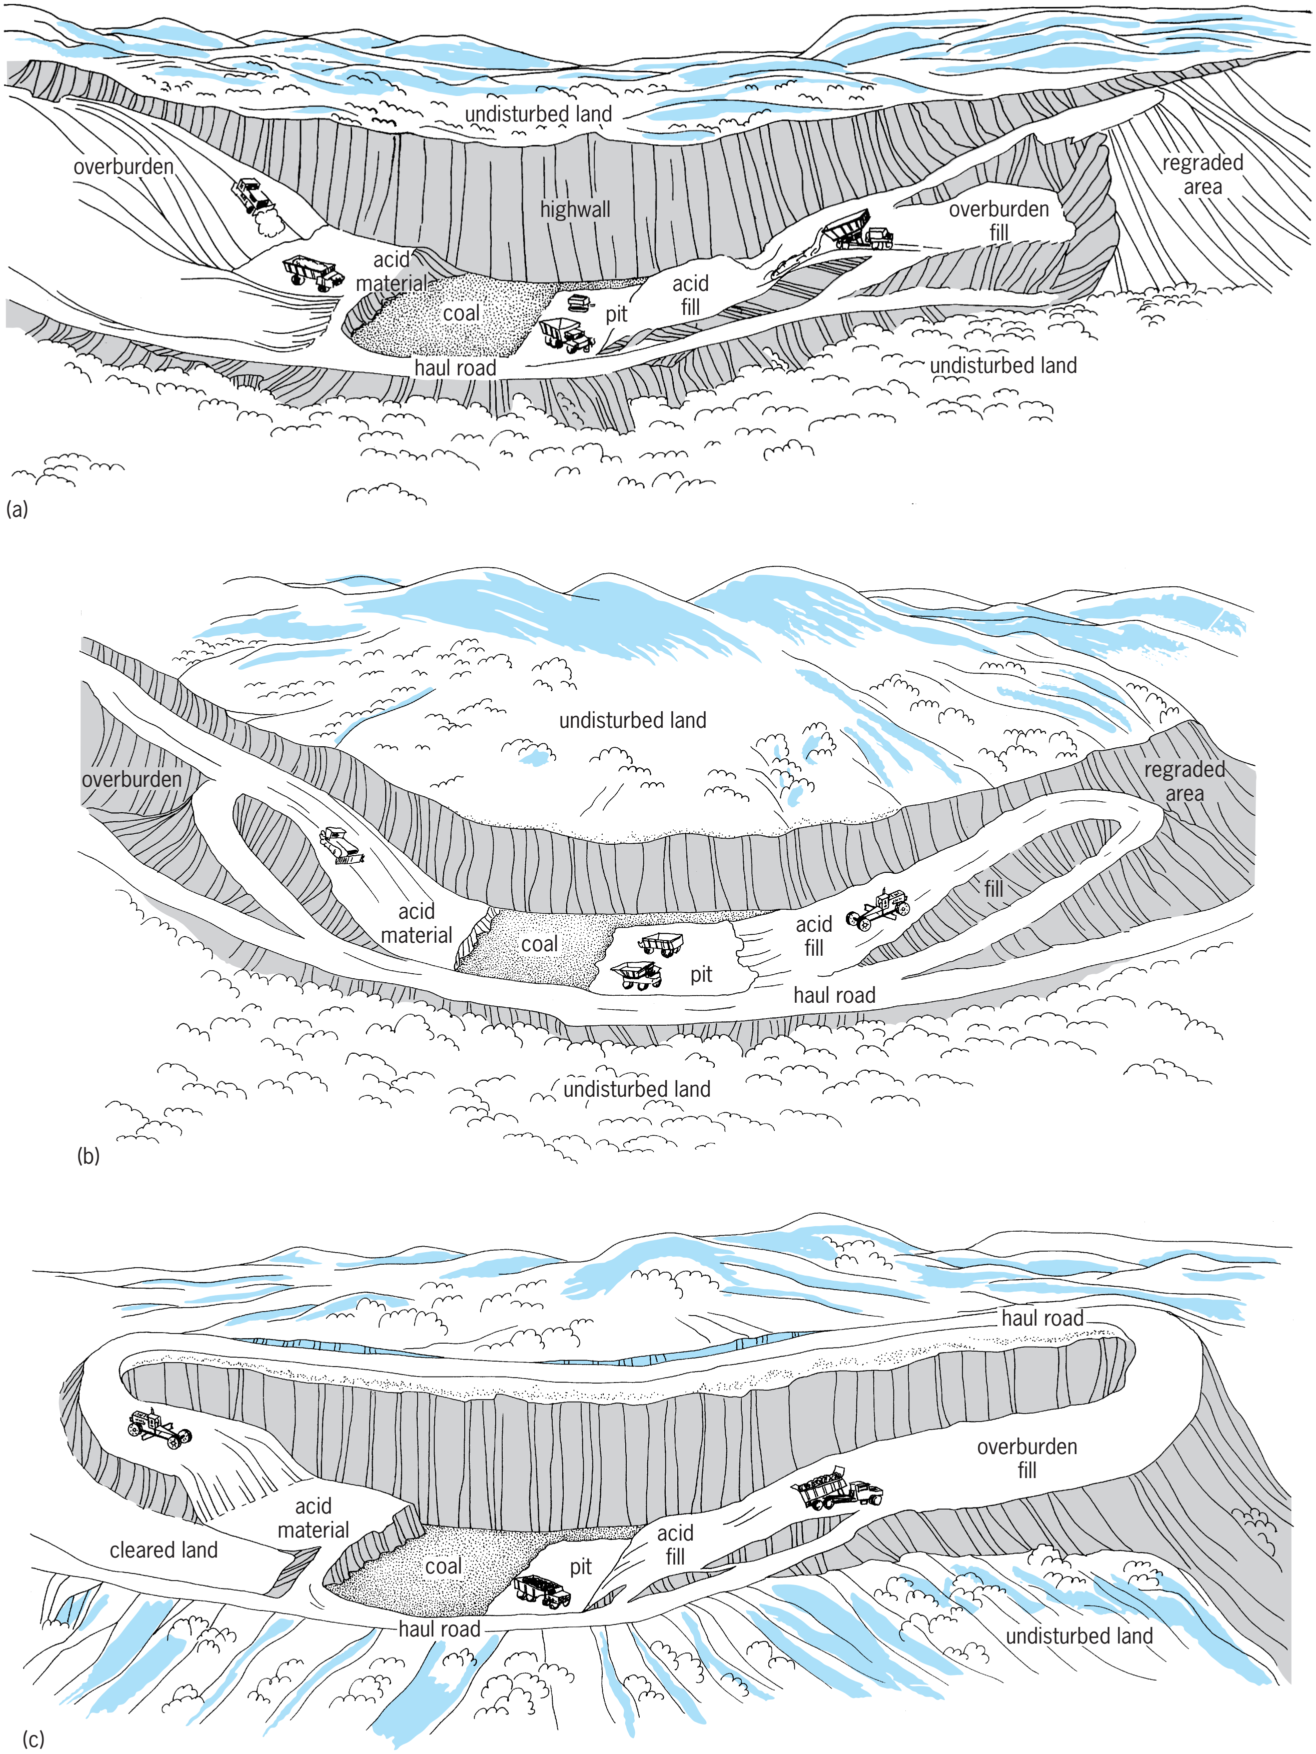

Fig. 7. **Typical haulback or lateral movement methods. (*a*) Truck. (*b*) Scraper. (*c*) Truck and scraper. (*After R. Stefanko, Coal Mining Technology, Theory and Practice, Society of Mining Engineers, AIME, 1983*)**

excavation left a collar around the mountain consisting of a highwall, bench, and castover spoil bank.

The haulback method of contour mining is environmentally sound because it eliminates the casting-over of spoil and provides for concurrent reclamation (**Fig. 7**). The initial cut is made into the mountainside to the highwall limit, and the excavated overburden is hauled to a prepared storage area. The initial cut serves the same purpose as the box cut in area mining. Mining proceeds along the outcrop line, with overburden, subsoil, and topsoil being trucked and placed as coal is removed. The method leads to minimum disturbance of the land and allows for contemporaneous reclamation.

In the haulback method the layout of haul roads and the design and construction of the spoil storage area are critical. Haul roads are designed and situated so as to assist in the control of water flow from the pit and the spillage of spoil on the downslope. Spoil storage areas are generally located in hollow valleys or low areas, and provisions must be made for prevention of contamination of streams by the spoil material and for stability of the material.

The equipment used in the haulback method is small in comparison to that found in an area mine. Wheel loaders, trucks, dozers, and scrapers are used in various combinations, and sometimes power shovels are employed. Drilling and blasting are done with rotary rigs and ANFO. Overburden is drilled and blasted, then wheel-loaded into trucks for haulage to the mined-out pit. Subsoil and topsoil that have been removed by dozers are then placed on top of the overburden, and the spoil materials are graded, seeded, and revegetated.

Mountaintop removal might be considered as an extension of area mining techniques to the mountainous and hilly terrains. A box cut is made across the ridge or mountain, and the spoil from this cut is placed in hollow or valley spoil-storage areas. The pit is advanced from the box cut by excavating parallel slices, with the spoil from the new cut being placed in the adjacent excavated cut. If multiple seams are to be extracted, a bench or terrace pit is developed. The equipment is similar to that in contour mining. The result of mountaintop removal is the transformation of a rugged topography into more level land, but in the process total coal recovery is obtained. Future use of this method will depend upon its perceived advantages in comparison with other techniques.

Auger mining. This method consists of boring large-diameter holes as far as possible into more or less horizontal coal beds, with hole diameter and spacing depending on seam thickness and geologic conditions. The level bench left from a conventional contour mine provides an ideal platform for equipment operation; otherwise a bench must be developed along the coal outcrop line. The auger consists of a cutting head and a set of twisted flights, resembling a carpenter's wood bit or drill. It can be extended by additional flight sections: the drive unit is uncoupled and withdrawn, allowing another flight to be lowered into place for making another advance. As boring proceeds, the coal is moved along the flights and discharged onto an elevating conveyor and then into trucks. Auger mining is attractive because it recovers coal from the highwall side of the contour mine that might otherwise be lost,

Fig. 8. Highwall miner. (*Superior Highwall Miners*)

and it does this with minimal capital and labor cost. Reclamation and environmental problems can significantly affect the cost of auger mining.

A variation in auger mining, called highwall mining, is a system that can be adapted for varying coal seam thickness (**Fig. 8**). Instead of the typical auger cutting head, a continuous miner or a similar arrangement cuts the coal and loads it onto a conveyor. The mined coal is loaded directly on a truck behind the highwall miner, much the same as in the auger mining system.

Future trends. Surface mining has steadily increased its share of the United States market, and this trend is expected to continue into the foreseeable future. The fundamental extraction and materials-handling systems that have evolved present a range of methods that appear capable of coping with future mining problems. Coal lying under deeper and more difficult geologic columns may require some modification in extraction techniques and methods, but it does not appear that a new generation of large equipment needs to be developed. Emphasis will be placed on better planning and managing of the existing methodologies and automation of cyclic operations, where feasible, to obtain highly efficient mines. Moreover, the development of highly productive and efficient underground mines will provide an economic limit to surface mines. *See* LAND RECLAMATION.

Underground Mining

When a coal seam does not lie close to the surface, it must be extracted by underground methods. The methods may be classified as room-and-pillar, longwall, and others. In each method, modifications to the basic techniques are needed to cope with varying geologic conditions and seam factors. Irregular seam thickness, steep dips, changing rock quality, seam partings, and other factors have a marked influence on the mine geometry and equipment specifications. Seams dipping between 0 and 10° and with regular seam thickness are assumed in the following discussion of room-and-pillar and longwall mining.

Mine development. In developing a particular extraction system, development openings and production openings must be driven. Development openings provide the primary access to various parts of the coal deposit and are called mains. In room-and-pillar mining, the production openings are the rooms driven in the panel and the extraction cuts made during pillar retrieval. In longwall mining, the production openings are the longwall faces. In general, the term "development" includes all openings and other work which precedes production.

Main access to a horizontal or near-horizontal coal seam is usually by drift entry when the coal seam outcrops on a mountainside; otherwise, slope and shaft entries are used. Slopes are preferred over shafts when the seam is not too deep because conveyor belt haulage can be used. In addition, mining machinery can usually be brought underground with less disassembling. From the foot of these access openings, a set of parallel main entries (usually 7–10 individual headings) are driven, and when these have advanced 3000–4000 ft (915–1220 m) a set of submain entries are driven to the right and left of the main entries. This entire set of entries divides the coal property into large blocks, which are further divided by panel entries driven off the submains.

Because of ventilation restrictions, mining machinery movements, and ground conditions, connections between entries are made at intervals. These are called crosscuts. The crosscuts divide the coal block between entries into pillars, often called chain pillars, which provide the primary support for the ground overlying the coal deposit. Since main and submain entries must remain open and stable for long periods of time, the design of the pillars and the roof support in the entries is a critical item in mine planning.

Panel entries, up to 17,000 ft (5180 m) or longer, divide the large coal blocks into rectangular blocks (panels) for production mining. Barrier pillars are left between the mains, the submains, and the rectangular panels in order to minimize the effect of the coal extraction associated with production on the stability of the mains.

Room-and-pillar mining. In the room- and-pillar system (**Fig. 9**) the mining methods may be by either continuous or conventional. The essential differences between the two methods are in the equipment spectrum and the cycle of face operations that the equipment dictates.

In continuous mining, the cycle of operations begins with a continuous miner sumping into the coal face. A shuttle car is positioned behind the miner to receive and transport the cut coal to the belt feeder. When the shuttle car is filled, it moves out and is replaced by the next shuttle car. This operation continues until the continuous miner operator reaches the last roof support. The continuous miner is then withdrawn, and safety posts or hydraulic jacks are placed in the excavated opening. The miner then widens the room to its final size (usually 18–20 ft or 5.5–6 m) by cutting the adjacent strip. The miner moves onto the next working place—a room or a crosscut—and roof-bolt support is installed. Continuous miners equipped with roof-bolting capabilities eliminate this intermediate step and continue to widen the room without the installation of hydraulic jacks. The final roof-bolting pattern is completed after the continuous miner moves to the next room. The face ventilation system is adjusted to compensate for the freshly cut room and the new working location of the continuous miner. Electric cables to the equipment, the power center, the belt feeder, and other items must be adjusted and moved forward as the overall mining section advances.

In conventional mining, the breaking out of the coal from the face is done by undercutting, drilling, and blasting operations. First, the cutting machine saws a 10–12-ft-deep (3–4-m) slice horizontally across the room width at the bottom and then moves out to the next place to be cut. Then the drilling machine (**Fig. 10**) moves in and drills holes into the

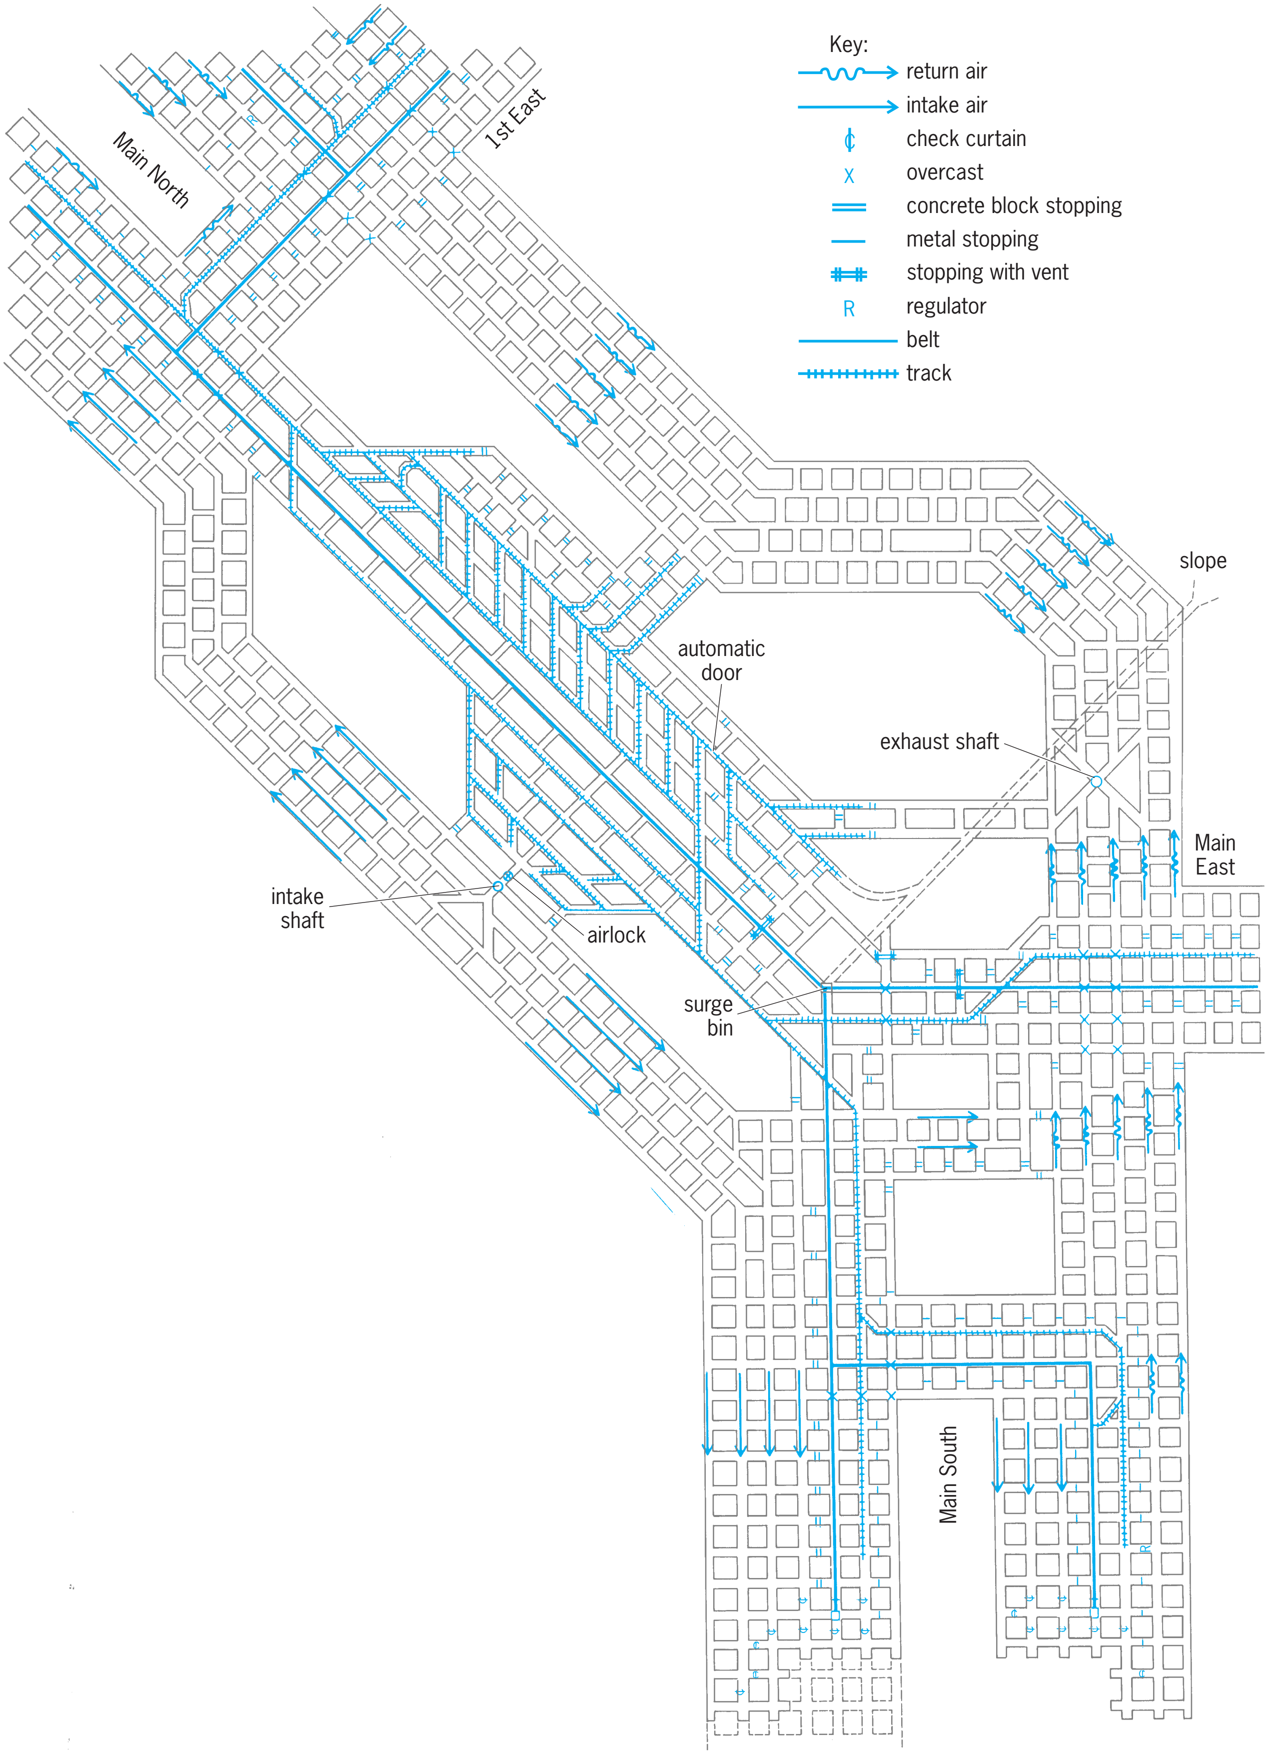

Fig. 9. Plan of a room-and-pillar mining operation. (*After R. Stefanko, Coal Mining Technology, Theory and Practice, Society of Mining Engineers, AIME, 1983*)

cut face, and this is followed by the blasting operation. After the area is examined for safety, the loading machine and shuttle cars move in and load out the coal. Sufficient working places should be available to minimize the idle time of equipment. Ventilation, electric cables, power center, belt feeder, and other items must be adjusted and moved forward as the overall mining section advances.

Retreat mining. The system of rooms and crosscuts driven in the production panels divides the panel into a series of coal pillars of approximately equal size. These coal pillars are extracted by methods that allow the mining operation to retreat toward the panel entries. As the pillars continue to be extracted, the bridging span of the immediate roof and then of the main roof is exceeded and the ground caves into the opening. This caved rock is called the gob. Since methane gas may accumulate in the gob, a bleeder system of entries is established at the top of the panel to allow a portion of the ventilating air to circulate through the gob.

Fig. 11. Remote-controlled continuous miner.

There are four basic pillar extraction techniques: split-and-fender, pocket-and-wing, outside lift, and open end. The first two are suited for continuous mining methods. Open end is utilized with conventional mining equipment, and outside lift is primarily used to extract long, thin pillars.

In the split-and-fender method, the pillar is split into two fenders of coal by driving a room parallel to the long side of the pillar. Because of roof control restrictions, which do not allow the splitting of the pillar by a single pass of the continuous miner, two pillars are mined simultaneously. The continuous mining unit, operating in an alternating fashion, mines a cut in each pillar. Rock bolts are used for roof support in the splitting operation, but breaker posts and cribs are used for roof control when the fenders of coal are removed. Check curtains are used to direct the ventilating current to the working faces.

The cuts used in the outside lift method are similar to those used in removing a fender of coal.

In the pocket-and-wing method, two working places can be sequenced in the same pillar. The pillar is alternately split transversely, then longitudinally, producing three fenders. These are then removed by using breaker posts for roof control. Ventilation is controlled by check curtains.

In the open-end method of pillar extraction, the sequence of extraction cuts is made adjacent to the gob without a protecting fender of coal.

Equipment. Continuous miners (**Fig. 11**) consist of a cutting head, a coal-gathering system, and a scraper conveyor system; the whole piece of equipment is electrically powered and mounted on a crawler-supported carrier. The cutting heads of various designs rip, bore, or auger the coal from the face. The ripper type of miner is most popular. Rippers have drum cutting heads mounted horizontally and fitted with steel bits. The cutting head, which is supported by arms that allow it to be positioned in a vertical plane, is crowded into the face by moving the carrier forward. Coal is ripped from the face, drops to the floor, and is gathered onto the scraper conveyor by a set of rotating disks or gathering

Fig. 12. Shuttle car for transporting coal within the mine.

Fig. 13. Diesel scoop in operation. (*WVA Mining Equipment Co.*)

arms. The scraper conveyor transports the coal into the positioned shuttle car. Geologic conditions, especially the seam height and the presence of in-seam rock, influence the operation and design of the miner.

A shuttle car is a low-bodied diesel or electrically powered unit (**Figs. 12** and **13**) that carries the coal to a nearby belt conveyor system that takes the coal out of the mine.

Roof bolts are an essential component of both continuous and conventional mining. They are used to provide ground control for the immediate roof strata overlying the mined room, and a means of support that does not obstruct the mine opening. Roof bolters are used to drill the holes and install the bolts. Roof bolting is a prime bottleneck in room-and-pillar mining and a dangerous operation; hence roof-bolting equipment must be fast and efficient and provide temporary support to the mine roof while the operator is installing the bolt.

A cutting machine is a large chain saw mounted on a rubber-tired carrier. A universal cutter can be maneuvered to cut a slice at any angle to the horizontal. Blasthole drilling in coal is done with electrically driven augers. Blasting may be done with special coal mine explosives, compressed air, or carbon dioxide cartridges. The loading machine consists of a gathering system, which sweeps the coal off the mine floor onto an inclined scraper conveyor for transport to the shuttle car. A belt feeder has a toothed roll crusher for sizing the coal, which is then fed at a uniform rate by a scraper conveyor onto the section belt conveyor.

Ventilation. The primary function of mine ventilation is to dilute, render harmless, and carry away the gas and dust produced in the underground mining of coal. Federal law requires the following conditions to be met: (1) Minimum air velocity in the working place must be at least 60 ft (18 m) per minute. (2) Minimum air volume at the last open crosscut must by 9000 ft^3 (255 m^3) per minute. (3) Minimum air volume reaching each working face must be 3000 ft^3 (85 m^3) per minute. (4) Respirable dust levels in the mine air cannot exceed an average of 2 mg/m^3. (5) Air used to ventilate belt conveyors cannot be used to ventilate working faces and must be vented to return airways. (6) Methane accumulations cannot be allowed to exceed 1% in the working area.

The mine ventilation system is composed of three subsystems: (1) the primary distribution system, which consists of main fans and the main intake and return entries; (2) the face ventilation system (**Fig. 14**), which controls airflow throughout the active production area; and (3) control devices to direct the air through the mine. Main fans are required to be installed on the surface, and usually pull air through the mine. They do this by developing a pressure gradient between the intake air entries and the return air entries in the mine. Hence, crosscuts between these two sets of main entries must be closed off by permanent stoppings. Splitting the intake air at each set of submains allows different areas of the mine to have their own independent air, and also serves to minimize power costs. Return air from these splits must be carried over the intake mains by air bridges or overcasts. The flow of air within a split can be controlled by increasing the resistance to flow with regulators placed at strategic locations in various entries and rooms.

The production area of the mine generates the most gas and dust, and hence requires constant

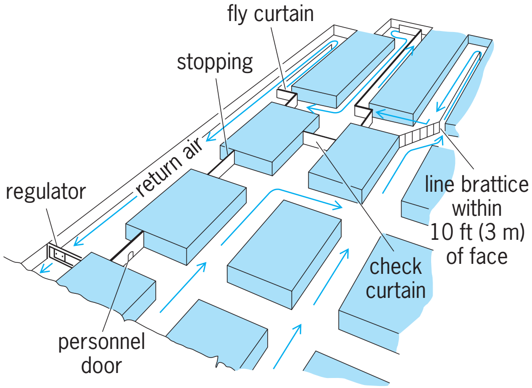

Fig. 14. Diagram of a blower line-brattice face ventilation. Arrows indicate direction of flow of air. (*After R. Stefanko, Coal Mining Technology, Theory and Practice, Society of Mining Engineers, AIME, 1983*)

examination and modification of the airflow pattern to cope with the changing situation developed by the advancing faces. The blind room headings ahead of the last open crosscut may be ventilated by line brattices (nylon-plastic curtains which are installed so as to split the blind room heading longitudinally) or auxiliary fans. Air is then directed up one side and down the other. The line brattices are also used to direct the movement of air throughout the production area by acting as check curtains in certain rooms. In order to do an effective job of diluting and sweeping dust and gas from the working face, line brattices must be kept close to the face. Auxiliary fans and tubing in a push-pull arrangement are alternatives to line brattices, and better diffuse air across the working face but introduce other problems.

Ground control. The rock strata above the coal seam may be divided into an immediate roof and a main roof. The immediate roof responds quickly to the removal of the coal support and collapses unless some artificial support is installed to prevent and control the deformation. The main roof shows stability for long periods of time. In general, the boundary between these two roofs is formed at the contact zone defined by fairly thick competent rocks, such as sandstone and limestone, and thinly bedded incompetent rocks, such as shale and coal. The function of the pillars of coal developed by driving rooms and crosscuts is to provide support for the total roof structure over both the pillars and the mined openings. The ground load immediately over the pillars is transferred directly to the pillars, but the ground load over the rooms and crosscuts must transfer its load to the pillars. This mechanism of load transfer is called the bridging action of the rocks; competent rocks have good bridging action and incompetent rocks have poor bridging action. Artificial support is used to assist, enhance, or develop the bridging action of the rocks in the immediate roof.

Simple posts with cap pieces were the first roof supports used. The concept is to decrease the overall bridging span between posts. More posts with larger cap pieces and three-piece sets are added to control less competent roof strata. Posts for roof control are still used in pillar recovery work or retreat mining. However, for the highly mechanized continuous and conventional mining of entries, rooms, and crosscuts, timber posts and three-piece sets cannot be used because they restrict the movement of equipment and may be knocked down.

Prop-free openings with the immediate roof spanning the full entry width can be developed with the aid of roof bolts. The most commonly used roof bolt is an expansion-shell-anchored, 5/8-in.-diameter (1.6-cm), extrastrength, square-head steel bolt. The law specifies that the bolt must be a minimum of 30 in. (76 cm) in length. The function of the bolt is to bind together the various laminae in the immediate roof and make them act as a unit in developing bridging action. The bolts, when anchored in competent rock, also prevent sagging of the immediate roof. The binding and suspension action of the bolt is developed when tension is produced in the bolt by tightening it into the anchoring shell. A number of variations of this basic bolt are in use.

Ground control in main entries or in areas where roof bolts cannot develop the desired support is done by other means. Room and entry intersections often exceed mandated limits on roof bolts, so steel sets or steel beams resting on wood cribs or concrete blocks are used for the support of the intersections. In some main entries, steel arches or yielding steel arches are used. Where rapid temporary support is required, screw jacks or hydraulic props are easy to install and make excellent supports.

In the United States, federal law mandates that each mine operator have an approved roof control plan, a history of all unintentional roof falls, and a systematic evaluation of the roof control system in use. The roof control plan must show the geologic column, and identify the rock type and thickness above and below the coal seam. Further, the plan must describe the sequence of mining and installation of supports, including temporary supports, and must designate the area of the mine covered by the roof control plan.

Longwall mining. Longwall mining (**Fig. 15**) is the basic underground coal mining method practiced in Europe, and it enjoys wide acceptance throughout the world. It has a greater production potential than room-and-pillar systems, and is safer since mining takes place beneath a complete overhead steel canopy (**Fig. 16**) that moves as the face is mined. Longwall methods were tried in the United States for a number of years, but could not compete with the room-and-pillar system until modern longwall mining was introduced in 1960. Since that time, longwall mining has gained wide acceptance by coal producers in the United States. More coal is being produced now by longwall mining than any other underground mining method in the United States. Longwall systems are classified as retreat or advancing systems based on whether the panel is completely developed by panel entries before panel extraction commences.

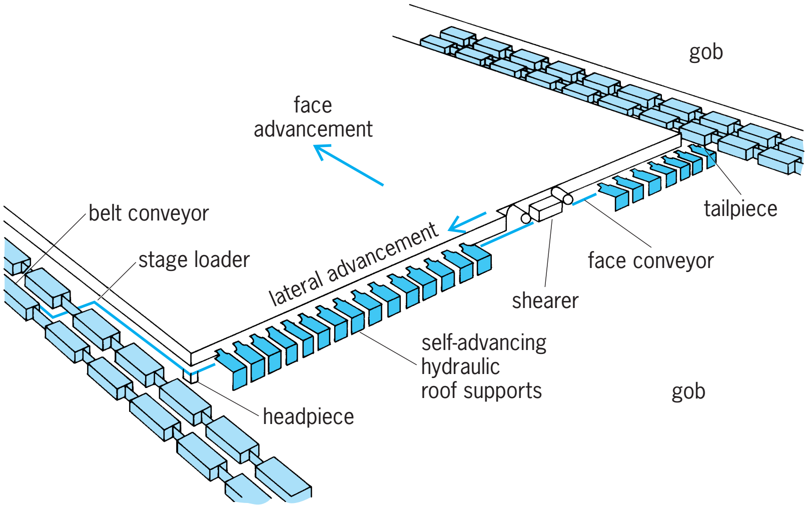

Fig. 15. Diagram showing the basic equipment components on a longwall face. (*After R. Stefanko, Coal Mining Technology, Theory and Practice, Society of Mining Engineers, AIME, 1983*)

Fig. 16. Longwall shearer and hydraulic roof support.

In the modern retreat system, entries (gates or roadways) are driven to block out a coal panel. Coal is then retreat-mined from the far end of the panel back to the submains. In the advancing system, development entries are kept only a short distance ahead of the working face which advances to the far end of the panel. In the United State, panels are usually 600–1100 ft (180–330 m) wide and 3000–17,000 ft (915–5180 m) long.

Regulatory constraints in the United States require longwall panels to be developed by multiple entries similar to those used in room-and-pillar mining. These entries are usually developed by continuous mining methods. Bleeder entries as well as a longwall equipment setup entry are driven across the top of the panel and connect panel entries. The panel entry containing the beltline, electrical and hydraulic equipment, and other items is called the head gate. Its complement on the other side of the panel is called the tail gate. Panels are arranged so that the previous panel's head gate is the new panel's tail gate.

Single head and tail gate entries are common in Europe. When retreat mining is practiced, full-face tunneling machines are used to drive the entries and rock bolts are used for support. These will be supplemented with steel arches or some other method of support as conditions change due to mining. When advance mining is practiced, an in-team miner or stable driving equipment is used. One aspect of longwall mining on the advance is that the head and tail gate must be established and maintained through the gob. This usually means that the roof or floor of these entries must be ripped and the entry cross section reestablished and supported.

Three pieces of equipment are fundamental to modern longwall mining: armored face conveyors, powered supports, and the coal cutting machine. The cycle of face operations is based on the movement of this equipment. The armored face conveyor is erected along the coal face, and is connected to powered supports by means of double-acting hydraulic jacks. The cutter-loader usually slides along the top of the armored conveyor and breaks out a strip of coal 20–30 in. (50–75 cm) wide along the face and then pushes the broken coal onto the conveyor. As the cutter-loader progresses, it leaves a web 20–30 in. (50–75 cm) wide into which the armored conveyor is pushed by the hydraulic jacks on the powered supports. The hydraulic jacks supporting the overhead steel canopy are retracted, freeing the powered supports from roof pressure. These supports are advanced up to the armored conveyor by using the double-acting hydraulic jacks connecting the two, and are then reset. When the cutter-loader completes a pass across the face, it is reset to take a cut as it returns across the face, and the cycle is repeated. As coal is extracted and the powered supports are moved forward, more and more of the roof is left unsupported. The immediate roof collapses and is followed by the main roof collapsing or settling on the broken rock in the gob.

Equipment. An essential element of the modern longwall system is the armored face conveyor, sometimes called a snaking conveyor because in plan it can be curved around behind the cutter-loader into the web that is created as the cutter-loader advances along the face. The face conveyor is a steel trough running the length of the coal face and strong enough to carry the weight of the cutter-loader. One or more endless chains within the trough pull steel flights (paddles) that drag the coal to the head end, where it discharges into the head gate transportation system. The face conveyor may be driven by single or multiple drive units situated at the head and tail gate ends and on either side or both sides of the conveyor. Each drive unit consists of a motor, fluid coupling, and reduction gearing. The overall bulk of these units has an influence on the width of the head and tail gates. The preferred alternative of having drive units at both ends usually cannot be met because the excessive ground pressure on the tail gate makes it difficult to maintain the necessary room for tail drives. Face lengths are limited by the drive arrangements, the chain pull needed to move the coal, and other factors. The face conveyor does not dump directly onto the belt conveyor taking coal out of the panel. Instead it dumps onto a stage loader which serves as a feeder-breaker system for changing the direction and velocity of coal travel and breaking large lumps of coal and rock.

The good roof control developed by powered supports is a key to successful longwall mining. Powered supports have evolved, with a number of different features being introduced as the need arose. A very popular version in the United States is called a shield support. The unit consists of a set of hydraulic props placed between a steel floor beam and a roof beam with the beams pin-connected to a steel caving shield so that the individual members may rotate with respect to each other. Control valves, hydraulic hoses, and a double-acting jack complete the assembly. The caving shield linking the two beams is arranged so that adjacent supports provide skin-to-skin protection against broken rock in the gob flushing into the traveling way and working area of the face. The roof beam cantilevers over the traveling way and working area of the face, completing the steel canopy protecting workers and giving a prop-free front face. The design principles of the shield allow it to cope with both vertical and lateral movements of the immediate roof as it responds to coal extraction. Powered supports have not been designed to work in thin coal seams.

Cutter-loaders are of two types: shearers and plows. A shearer (Fig. 16) consists of a drum fixed to the end of the ranging arm, and the combined unit is connected through gearing to a power unit riding on the conveyor. The drum is a spiral arrangement fitted with picks for breaking out the coal. A cowl is attached to the machine at the back end of the drum, and the combination of spiral drum and cowl acts as a screw conveyor moving the newly mined coal into the face conveyor. A shearer may have two drums mounted at each end of the power unit. Double-drum shearers with cowls that can be repositioned make bidirectional mining feasible as well as allowing the shearer to accommodate to variable seam height. The shearer moves across the face by a rack-and-pinion mechanism between the shearer and the face conveyor.

The coal plow (planer) is pulled back and forth across the face by an endless chain system. It is designed to travel in the space between the face conveyor and the coal, and cuts a layer of coal 2–6 in. (5–15 cm) thick. The coal is deflected or plowed onto the face conveyor. The plow is held against the face by hydraulic jacks located between the conveyor frame and the plow. An operator does not follow the plow along the face, and the plow does not cut as thick a web as the shearer, so planers can probably work under more difficult roof conditions than shearers.

Ventilation and ground control. The speed of coal production and the length of the longwall face give rise to difficulties in face ventilation. Shearers not only produce a fine product and create dust, but also develop a deep web. The net effect of these factors is an increase in methane liberation. Part of the input face ventilation escapes into the gob, and hence is not used to sweep away and dilute these products. Methane that escapes and collects in the gob area may be drained away by a system of boreholes.

Ground control problems usually result from seam factors. Soft floors may have insufficient bearing capacity for support loads. Massive roof strata with long bridging spans will not cave and overload face support. Variations in seam height and uneven floor conditions can unbalance face support systems. Thick seams must be mined by successive lifts. Tail entries are subjected to severe ground pressures and require heavy timbering and hydraulic prop support.

Other methods. Two of the numerous variations on the basic room-and-pillar and longwall methods will be described. Shortwall mining, using equipment from both room-and-pillar and longwall methods, is an attempt to handle the technical and economic alternatives in choosing an extraction system. The shortwall layout is similar to the longwall panels except that the panel width is 150–200 ft (46–60 m) wide. A continuous miner, loading shuttle cars, substitutes for the cutter-loader-face conveyor system, and the roof beams of the powered supports need to give cantilever action over a wider working area. Shortwall mining is considered when the coal seam is relatively shallow but is overlain by massive roof strata; when a large, relatively homogeneous and undisturbed area of coal is not available for longwall panels; or when ventilation difficulties from dust preclude face personnel from working downwind from the cutter-loader.

Hydraulic mining uses large quantities of water at high pressure to break and convey the coal from the working area. It is most effectively applied to a steeply dipping, relatively thick coal seam that is bounded by an immediate roof and floor and breaks into large pieces. Jets of water are directed tangentially along the coal face to break off lumps of coal. The coal is washed into a system of troughs for conveying away from the working area. Subsequently the coal may be dewatered and moved by conveyor belt, or it may remain in troughs or be pumped to its final location. Hydraulic mining is successfully applied in China, Russia, the United States, and Canada.

Remote control and teleoperation. Remote control enables the operation of mining machines at some distance from the operator. In underground coal mining, remote control of continuous mining machines is a common practice. In all cases, the operator keeps visual contact with the machine, particularly with the cutting head. In cases where visual contact would be limited or impossible, this practice would have little or no advantage. In coal mining, other remotely controlled equipment includes loaders, longwall shearers, belt conveyors, highwall mining machines, roof bolters, and mobile roof support systems. Although health and safety improvements have been made using remotely controlled equipment, efficiency improvements are limited since operation of these systems still requires manual control and visual contact.

In teleoperation, mining machinery is controlled from a remote location without direct visual contact. Ideally, the operator is at the surface or at a relatively safe area and does not enter the work area at all. Some examples have been demonstrated for metal mining, but no applications in coal mining have been implemented. *See* REMOTE-CONTROL SYSTEM.

Future trends. New equipment and equipment modifications to meet the challenges of difficult underground mining conditions will dominate the future. Remotely controlled longwall systems and continuous miners are expected to proliferate for their improved safety and higher productivity. How to mine thin seams, thick seams, steeply dipping seams, seams at greater depths, extremely gassy seams, and seams under bodies of water, or combinations of these needs to be solved. Integration of extraction, haulage, ventilation, ground control, and reclamation systems into an economic and ecologically sound plan is the challenge for future mining engineers. *See* MINING; UNDERGROUND MINING.

Coal paleobotany

A special branch of the paleobotanical sciences concerned with the origin, composition, mode of occurrence, and significance of the fossil plant materials that occur in, or are associated with, coal seams. Information developed in this field of science provides knowledge useful to the biologist in efforts to describe the development of the plant world, aids the geologist in unraveling the complexities of coal measure stratigraphy in order to reconstruct the geography of past ages and to describe ancient climates, and has practical application in the coal, coke, and coal chemical industries. *See* COAL CHEMICALS.

Nature of coal seams. All coal seams consist of countless fragments of fossilized plant material admixed with varying percentages of mineral matter. The organic and inorganic materials initially accumulate in some type of swamp environment. Any chemical or physical alteration experienced by the organic fragments during the course of transportation and deposition is followed by another series of changes effected by the chemical, physical, and microbiological agents characterizing the environment in which the particle comes to rest. Subsequent burial beneath a thick cover of sediment induces further physical and chemical alteration of the particles comprising the coal seam. Usually a consolidated layer of well-bonded fragments results. In some instances, crustal deformation and even volcanism add their modifying effects. Thus, the chemical composition, size, shape, and orientation of the fossilized plant remains are influenced both before and after death by biological processes and by the chemical and physical processes attending their postdepositional history. Even in coal seams that have been metamorphosed to anthracitic rank, certain of the constituents remain recognizable as portions of particular plant organs, tissues, or cells. Such entities are classed as phyterals, and in paleobotanical descriptions of coal seams these are identified as specifically as possible as megaspores, cuticles, periderm, and so on. In seams of peat, lignite, and high-volatile bituminous coal, entities are more readily recognized as particular phyterals than they are in higher-rank deposits. This is partly because fewer are destroyed by the metamorphic processes and partly because of the distinctiveness of the substances composing the entity.

In some instances, the fossilized plant fragments can be recognized as remnants of a plant of some particular family, genus, or species. When this is possible, information can be obtained on the vegetation extant at the time the source peat was formed and such data aid greatly in reconstructing paleogeographies and paleoclimatic patterns. Perhaps the most extensive studies of this type are those conducted on the Tertiary brown coals of the Rhine Valley in Germany. From these, detailed reconstructions have been prepared, describing and illustrating the three major swamp environments that gave rise to the sedimentary layers comprising these spectacular coal seams.

Plant fossils in coal seams. Pollen grains and spores are more adequately preserved in coals than are most other plant parts. Recognition of this fact, coupled with an appreciation of the high degree to which these fossils are diagnostic of floral composition, has led to the rapid development of the paleobotanical subscience of palynology. Fruits, seeds, and identifiable woods also occur as coalified fossils and are deserving of more attention than has been accorded them in the past. Often minute structural details are preserved (see **illus.**). Identifiable leaf fossils are comparatively uncommon, although the coalified cuticles of leaves are frequently encountered and their botanical affinities determined. Occasionally, coal seams contain fossil-rich coal balls. Essentially all types of plant fossil, including entire leaves, cones, and seeds, are encountered in these discrete nodular masses. Within the coal ball, the altered but undistorted plant tissues are thoroughly impregnated with mineral matter, usually with calcite or dolomite. Comparatively few coal seams have been encountered with large concentrations of coal balls, but these seams have provided a wealth of detailed information on the nature of the plants which gave rise to the coals concerned. *See* COAL BALLS; FOSSIL SEEDS AND FRUITS; PALYNOLOGY.

Sedimentary units of coal seams. As implied previously, coal seams generally are composed of several superposed sedimentary layers, each having formed under somewhat different environmental conditions. The coal petrologist and paleobotanist recognize these layers because of their distinctive textural appearance and because each consists of a particular association of organic and inorganic materials. Accordingly, each coal seam usually contains several types of coal. These coal types, or lithotypes, possess characteristic suites of physical properties, and knowledge of these properties is very profitably employed in manipulating coal composition in coal preparation and beneficiation plants.

A given lithotype may form several of the constituent layers of lithobodies of a coal seam. Each lithobody often possesses a characteristic assemblage of botanically identifiable fossil plant fragments rendering the unit recognizable to the coal paleobotanist without reference to its textural or compositional features. Paleobotanical descriptions of coal beds may relate to the entire thickness of the seam

without regard for the seam's composite nature, or the fossils may be described in relation to the particular lithobody sequence. The more detailed type of description is required if paleoecological interpretations are to be made or if detailed stratigraphic work is involved.

Interrelations with coal petrology. Another facet of coal paleobotany concerns the nature of the substances which compose the coalified plant fragments. When focusing attention upon such matters, the coal paleobotanist is indistinguishable from the coal petrologist and both begin to encroach on the province of the coal chemist. It is noteworthy, however, that the paleobotanist tends to concentrate attention on the genetic relationships of the various coal substances and hence upon the steps in the derivation and subsequent evolution of maceral materials. The initial stages of coalification tend to be ignored by the coal chemist and petrologist, and the study of these has, quite properly, been thought of as an integral part of coal paleobotany. Thus, through the study of the botanical character of coalified fossils and by means of investigating the substances produced by the coalification process, coal paleobotanists extend knowledge of the organically derived sediments of the Earth's crust. *See* COAL.

William Spackman

Coalbed methane

Coalbed methane production, sometimes referred to as coal degasification, is the process of extracting natural gas from underground coal formations (coalbeds or coal seams). This extraction is accomplished with production technology similar to that used in the conventional natural gas industry. The objectives of producing the natural gas from a coal seam are to improve mine safety, to sell the natural gas, or both. *See* COAL; NATURAL GAS.

Coalbed methane production is a leading form of unconventional production in terms of annual gas production and reserves. Other unconventional gas resources include low-permeability sandstones, Devonian shales, geopressured aquifers, and gas-hydrate reservoirs.

Historical development. The behavior of explosive gases in coal seams has been investigated since the inception of the underground coal mining industry. In 1845, Michael Faraday identified the chain of events leading to devastating mine explosions. First, a localized methane outburst generates a cloud of fine coal particles in the mine. This coal dust may then be ignited through the ignition of the original methane outburst, the ignition of a subsequent methane outburst, or continued mine activity. Clouds of fine coal particles can have an explosive force comparable to black powder. Most of the early coalbed methane production was conducted with the objective of improving mine safety.

With the onset of the energy crisis in the 1970s, a second objective of coalbed methane production was identified: the production of a valuable natural resource, gaseous hydrocarbons.

In 1980, nonconventional fuel tax credits were enacted in the United States to provide economic incentives to stimulate the development of new energy resources.

In 1985, approximately 1×10^9 standard cubic feet of gas were produced from United States coal seams. A standard cubic foot is that volume of gas measured at standardized conditions, for example, 14.7 lb/in^2. (1.5 megapascals) at 60°F (16°C). Due to the increased number of coalbed methane wells and to improvements in production technology, approximately 1.6×10^{11} standard cubic feet of gas were produced from domestic coal seams in 2003. With the success of the United States coalbed methane industry in the 1980s, other governments and international energy companies began investigating the viability of producing natural gas from coal seams outside the United States.

Production and reserves. In 2003, coalbed methane production accounted for approximately 8.0% of the United States' annual natural gas production and 10% of its total proven natural gas reserves. In addition, natural gas production from all of the unconventional gas resources accounted for approximately 33% of the United States' total annual production. **Table 1** provides the annual growth of coalbed

methane proven reserves from 1989 to 2003, while **Table 2** provides the annual coalbed methane production during this period.

Coal seam reservoirs. Coal seam reservoirs are generally characterized as a dual-porosity system (**Fig. 1**). That is, most coal seams contain a primary porosity system (micropores) and a secondary porosity system (macropores, cleat system, or natural fracture system). The primary porosity system consists of the void space within the solid coal matrix. This porosity system is a result of the processes that occur during the deposition of the original organic matter which, over the geological time scale, is eventually converted to coal. Due to the dimensions of the pores (diameters range from 0.8 to 2.0 nanometers), the primary porosity system is inaccessible to ground water and, consequently, is fully saturated with gas. *See* GROUND-WATER HYDROLOGY.

The secondary porosity system of the coal seam consists of the void space in the fractures created after deposition. This fracture system is a result of shrinkage during the coalification process (by which organic matter is converted to coal). Natural fracturing may also be induced by localized tectonic forces. In general, the secondary porosity system in coal seams is composed of two types of fractures: the face cleat and butt cleat. The face cleat is continuous throughout the coal seam, while the butt cleat is discontinuous, generally ending at an intersection with the face cleat. Typically, the face cleat and butt cleat intersect at approximately 60–90° angles with a fairly uniform cleat spacing. Both ground water and gas may exist in the secondary porosity system of coal.

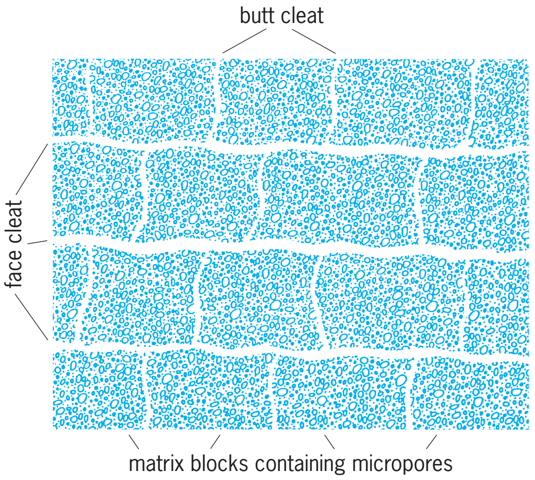

Fig. 1. Plan view of the dual porosity characterization of coal.

Natural gas in coal seams. The natural gas associated with coal is a by-product of the coalification process. Therefore, coal-seam reservoirs are different from conventional natural gas reservoirs; the coal seam is both the source rock and reservoir rock for the gas. Although no universal correlation exists, it has been observed that the original gas content of a coal seam tends to increase with increasing rank (a measure of the maturity and chemical structure of the coal) and increasing depth.

The natural gas associated with coal is composed of low-molecular-weight hydrocarbon gases, predominantly methane, and inorganic gases such as carbon monoxide, carbon dioxide, hydrogen sulfide, and oxygen. The compositions of gases from several coal seams in the United States are listed in **Table 3**. Samples of gas from virgin coal seams have a heat content greater than 950 British thermal units per standard cubic foot, making them of commercial quality with little processing.

Gas storage mechanisms. Gas is stored in coal seams in one of three states: as an adsorbed gas on the pore walls of the coal matrix, as a free gas within the pore structures of the coal, and as gas in solution in resident brine.

* Chemical composition in mole percent.
† British thermal units/standard cubic foot.

Due to the dimensions of the pores in the primary porosity system and the organic, carbon-rich nature of coal, a large internal surface area containing many potential adsorption sites is present in the coal matrix. The majority of gas stored in coal exists as a physically adsorbed, molecular monolayer on the walls of the primary porosity system. The gas adsorption phenomenon in coal conforms to Langmuir theory and is commonly modeled with a Langmuir adsorption isotherm. *See* ADSORPTION.

In addition to adsorbed gas, free gas may exist in the secondary porosity system of the coal seam. Free-gas storage results from the compressible nature of gas in the presence of the hydrostatic pressure exerted by local ground water. This is the gas storage mechanism that typically dominates in conventional natural gas reservoirs. Free-gas storage is generally modeled with the real gas law.

To a lesser extent, gas is stored in solution in the ground water within the secondary porosity system. The amount of gas dissolved in connate water is dependent on the water salinity and on the temperature and pressure of the coal seam.

Gas transport mechanisms. With gas and water production and the resulting pressure depletion, gas is desorbed from the pore walls of the coal matrix and migrates through the primary porosity system to the natural fractures. The gas is then transported, along with ground water, through the natural fracture system to the production wells. Thus, the natural fracture system acts both as a low-pressure sink to the primary porosity system and as a conduit to the production wells. Gas transport through coal seams is a two-stage process (**Fig. 2**).

Due to low permeability and small pore dimensions, the principal gas-transport mechanism in the primary porosity system is diffusion. Within the primary porosity system, gas can be transported by bulk diffusion (where molecule–molecule interactions dominate), Knudsen diffusion (where molecule–surface interactions dominate), or surface diffusion of the adsorbed gas layer (where molecular movement from adsorption site to adsorption site dominates). Regardless of the dominant diffusion mechanism, gas transport through the primary porosity system obeys Fick's law. The potential that drives the diffusion process is the partial pressure (concentration) gradient. *See* DIFFUSION; RAREFIED GAS FLOW.

Within the secondary porosity system of the coal seam, gas and water are transported by Poiseuille, or forced, flow. For porous media such as the secondary

Fig. 2. Transport of gas through coal. (*a*) Gas desorption from coal grains in the coal matrix. (*b*) Step 1: diffusion through the primary porosity system to the cleat system. (*c*) Step 2: Poiseuille flow through the cleat system to production wells.

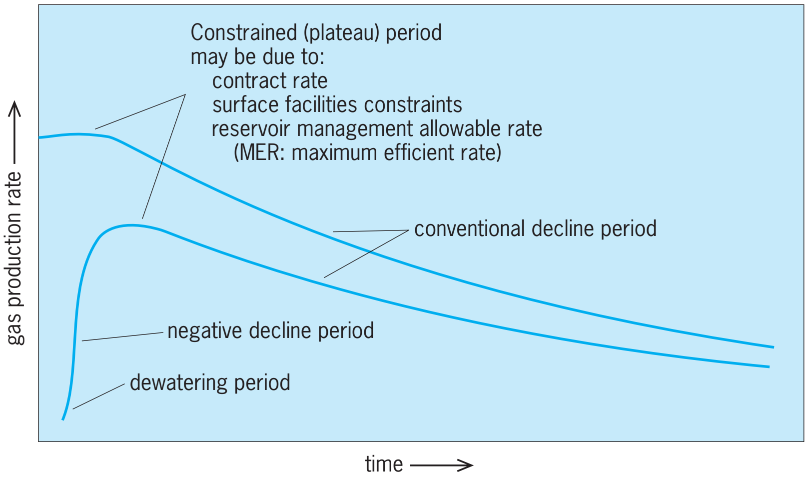

Fig. 3. Comparision of typical gas production rates of a coalbed methane well and a conventional natural gas well.

porosity system in a coal seam, Poiseuille flow is typically modeled with Darcy's law. The potential that drives Poiseuille flow is the total pressure gradient. This is the transport mechanism that normally dominates in conventional natural gas reservoirs. *See* SOIL MECHANICS; VISCOSITY.

Production technology. The drilling technology used for coalbed methane wells is identical to the technology used for conventional natural gas wells. The production technologies, however, do differ in well completions. The well completion is the portion of the well that connects the wellbore to the reservoir. Specialized well completions are required for coalbed methane wells because of the unique mechanical properties of coal.

There are two well completions commonly used in coalbed methane wells: open-hole cavity completions and hydraulically stimulated completions. In the open-hole cavity completion, the well is injected with high-pressure gas and water and is then rapidly depressurized. This process is repeated several times to break down the coal in order to create a large effective well radius, or cavity, in the coal seam.

In the hydraulic stimulation process, a high-pressure fluid (usually a gelled liquid, foam, or gas) is injected into the well along with a proppant (generally sand). The injection of the fracturing fluid either creates and propagates a fracture from the well into the coal seam, or opens preexisting, near-wellbore fractures. The proppant is used to keep the fractures open once the well is put into production. The hydraulic stimulation process used for coalbed methane wells differs from the hydraulic fracturing process used for conventional natural gas wells in that stimulation treatment must be optimized for the low-bulk modulus of coal. Most of the conventional hydraulic fracture technology has been developed for high-bulk modulus clastic and carbonate reservoirs.

Two characteristics distinguish gas production from coalbed methane wells: (1) a dewatering period, which may take up to several months, is often required to initiate the desorption process and, eventually, gas production; and (2) a "negative" gas-decline period, during which the gas production rate increases with time. This is in contrast to the conventional behavior in which gas production normally decreases with time. The dewatering and negative gas-decline periods are a direct result of the unique mechanisms of gas storage and transport in coal seams (**Fig. 3**).

Coastal engineering

A branch of civil engineering concerned with the planning, design, construction, and maintenance of works in the coastal zone. The purposes of these works include control of shoreline erosion; development of navigation channels and harbors; defense against flooding caused by storms, tides, and seismically generated waves (tsunamis); development of coastal recreation; and control of pollution in nearshore waters. Coastal engineering usually involves the construction of structures or the transport and possible stabilization of sand and other coastal sediments.

The successful coastal engineer must have a working knowlege of oceanography and meteorology, wave mechanics, geomorphology, soil mechanics, statistics, and structural mechanics. Tools that support coastal engineering design include analytical theories of wave motion, wave-structure interaction, diffusion in a turbulent flow field, and so on; numerical and physical hydraulic models; basic experiments in wave and current flumes; and field measurements of basic processes such as beach profile response to wave attack, and the construction of works. Postconstruction monitoring efforts at coastal projects have also contributed greatly to improved design practice.

Environmental forces. The most dominant agent controlling coastal processes and the design of coastal works is usually the waves generated by the wind. Wind waves produce large forces on coastal structures, they generate nearshore currents and the alongshore transport of sediment, and they mold beach profiles. Thus, a primary concern of coastal engineers is to determine the wave climate (statistical distribution of heights, periods, and directions) to be expected at a particular site. This includes the annual average distribution as well as long-term extreme characteristics. In addition, the nearshore effects of wave refraction, diffraction, reflection, breaking, and runup on structures and beaches must be predicted for adequate design. *See* OCEAN WAVES.

Other classes of waves that are of practical importance include the astronomical tide, tsunamis, and waves generated by moving ships. The tide raises and lowers the nearshore water level and thus establishes the range of shoreline over which coastal processes act. It also generates reversing currents in inlets, harbor entrances, and other locations where water motion is constricted. Tidal currents which often achieve a velocity of 3–6 ft/s (1–2 m/s) can strongly affect navigation, assist with the maintenance of channels by scouring sediments, and dilute polluted waters. *See* TIDE.

Tsunamis are quite localized in time and space but can produce devastating effects. Often the only solution is to evacuate tsunami-prone areas or suffer the consequences of a surge that can reach elevations in excess of 33 ft (10 m) above sea level. Some attempts have been made to design structures to withstand tsunami surge or to plant trees and construct offshore works to reduce surge velocities and runup elevations. *See* TSUNAMI.

The waves generated by ships can be of greater importance at some locations than are wind-generated waves. Ship waves can cause extensive bank erosion in navigation channels and undesirable disturbance of moored vessels in unprotected marinas.

On coasts having a relatively broad shallow offshore region (such as the Atlantic and Gulf coasts of the United States), the wind and lower pressures in a storm will cause the water level to rise at the shoreline. Hurricanes have been known to cause storm surge elevations of as much as 16 ft (5 m) for periods of several hours to a day or more. Damage is caused primarily by flooding, wave attack at the raised water levels, and high wind speeds. Defense against storm surge usually involves raising the crest elevation of natural dune systems or the construction of a barrier-dike system. *See* STORM SURGE.

Besides the cyclic variations in the mean sea level along the coast that are caused by the tide, tsunamis, and storm surge, there are longer-term sea-level variations owing to land uplift or subsidence with a superimposed rise in water levels that has been associated with atmospheric warming trends. The result in most coastal locations is a net sea-level rise relative to the land. In turn, there is a slow recession of the shoreline owing to the raised water level and to the beach profile's response to this raised mean sea level.

Other environmental forces that impact on coastal works include earthquake disturbances of the sea floor and static and dynamic ice forces. Direct shaking of the ground will cause major structural excitations over a region that can be tens of kilometers wide surrounding the epicenter of a major earthquake. Net dislocation of the ground will modify the effect of active coastal processes and environmental forces on structures. *See* EARTHQUAKE.

Ice that is moved by flowing water and wind or raised and lowered by the tide can cause large and often controlling forces on coastal structures. However, shore ice can prevent coastal erosion by keeping wave action from reaching the shore.

Coastal processes. Wind-generated waves are the dominant factor that causes the movement of sand parallel and normal to the shoreline as well as the resulting changes in beach morphology. Thus, structures that modify coastal zone wave activity can strongly influence beach processes and geometry.

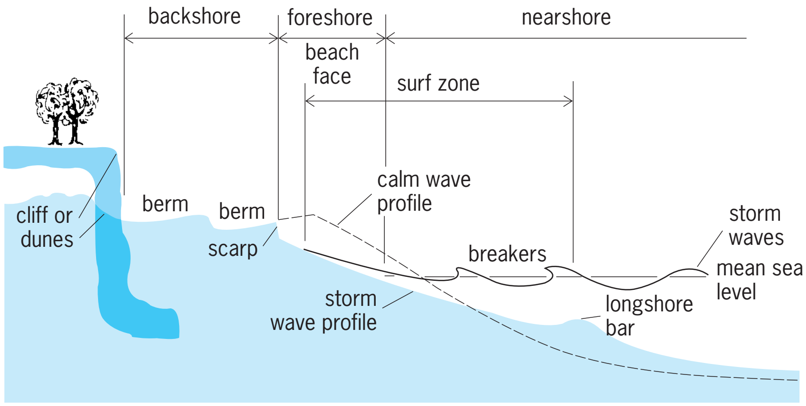

Fig. 1. Typical beach profiles (vertical scale is exaggerated).

Active beach profile zone. In typical beach profiles found at a sandy shoreline (which may be backed by a cliff or a dune field), the backshore often has one or two berms with a crest elevation equal to the height of wave runup during high tide (**Fig. 1**). When low swell, common during calm conditions, acts on the beach profile, the beach face is built up by the onshore transport of sand. This accretion of sand adds to the seaward berm. On the other hand, storm waves will attack the beach face, cut back the berm, and carry sand offshore. This active zone of shifting beach profiles occurs primarily landward of the 33-ft (10-m) depth contour. If the storm tide and waves are sufficiently high, the berms may be eroded away to expose the dunes or cliff to erosion. The beach profile changes (Fig. 1) are superimposed on any longer term advance or retreat of the shoreline caused by a net gain or loss of sand at that location.

Any structure constructed along the shore in the active beach profile zone may retain the sand behind it and thus reduce or prevent erosion. However, wave attack on the seaward face of the structure causes increased turbulence at the base of the structure, and usually increased scour which must be allowed for or prevented, if possible, by the placement of stone or some other protective material.

It is desirable to keep all construction of dwellings, recreational facilities, and other such structures landward of the active beach profile zone, which usually means landward of the frontal dunes or a good distance back from retreating cliffs. It is also desirable to maintain and encourage the growth of the frontal dune system by planting grass or installing sand fencing.

In addition to constructing protective structures and stabilizing the dune system, it is common practice to nourish a beach by placing sand on the beach face and nearshore area. This involves an initial placement of sand to develop the desired profile and periodic replenishment to make up for losses to the profile. Often shore stabilization structures are constructed along with beach nourishment to increase the stability of the nourished beach section. A common source for sand, which should be clean and at least as coarse as the native sand, is the offshore area near the nourishment site. Sand for beach nourishment has also been obtained from bays and estuaries and from land quarries.

Alongshore current and transport. Waves arriving with their crest oriented at an angle to the shoreline will generate a shore-parallel alongshore current in the nearshore zone. The current flows in the direction of the alongshore component of wave advance and has the highest velocity just inside the breaker line. It may be assisted or hindered by the wind and by tidal action, particularly along sections of the shore adjacent to tidal inlets and harbor entrances. There is a continuous accumulation of flow in the downcoast direction which may be relieved by seaward-flowing jets of water known as rip currents.

The alongshore current transports sand in suspension and as bed load, and is assisted by the breaking waves, which place additional sand in suspension. Also, wave runup and the return flow transports sand particles in a zigzag fashion along the beach face. Coastal structures that obstruct these alongshore transport processes can cause the deposition of sand. They do this by blocking wave action from a section of the shore and thus removing the wave energy required to maintain the transport system; by interfering with the transport process itself; or by directly shutting off a source of sand that feeds the transport system (such as a structure that protects an eroding shoreline).

The design of most coastal works requires a determination of the volumetric rate of alongshore sand transport at the site—both the gross rate (upcoast plus downcoast transport) and the net rate (upcoast minus downcoast transport). The most reliable method of estimating transport rates is by measuring the rate of erosion or deposition at an artificial or geomorphic structure that interrupts the transport. Also, field studies have developed an approximate relationship between the alongshore transport rate and the alongshore component of incident wave energy per unit time. With this, net and gross transport rates can be estimated if sufficient information is available on the annual wave climate. Typical gross transport rates on exposed ocean shorelines often exceed 500,000 yd^3 (382,000 m^3) per year.

Primary sources of beach sediment include rivers discharging directly to the coast, beach and cliff erosion, and artificial beach nourishment. Sediment transported alongshore from its sources will eventually be deposited at some semipermanent location or sink. Common sinks include harbors and tidal inlets; dune fields; offshore deposition; spits, tombolos, and other geomorphic formations; artificial structures that trap sand; and areas where beach sand is mined.

By evaluating the volumetric transports into and out of a segment of the coast, a sediment budget can be developed for the coastal segment. If the supply exceeds the loss, shoreline accretion will occur, and vice versa. When a coastal project modifies the supply or loss to the segment, geomorphic changes can be expected. For example, when a structure that traps sediment is constructed upcoast of a point of interest, the shoreline at the point of interest can be expected to erode as it resupplies the longshore transport capacity of the waves.

Harbor entrance and tidal inlet control structures built to improve navigation conditions, stabilize navigation channel geometry, and assist with the relief of flood waters will often trap a large portion of the alongshore sand transport. This can result in undesirable deposition at the harbor or inlet entrance and subsequent downcoast erosion. The solution usually involves designing the entrance structures to trap the sediment at a fixed and acceptable location and to provide protection from wave attack at this location so a dredge can periodically pump the sand to the downcoast beach. *See* NEARSHORE PROCESSES.

Computer models. Computer modeling of wave and coastal processes has greatly enhanced the ability of coastal engineers to more realistically and accurately define the effects of these processes. Specific examples of computer models in common use are models for the forecasting of wind-generated wave action caused by hurricanes and extratropical storms; prediction of wave transformation as waves propagate from deep water to the shore; prediction of related surge levels during storms; and prediction of beach morphology changes over a coastal segment caused by incident wave action. Computer models are also available that will predict the changing wave characteristics as the tide and tsunami waves enter the coastal zone, as well as the resulting resonant response of harbors and estuaries to these waves.

Coastal structures. Coastal structures can be classified by the function they serve and by their structural features. Primary functional classes include seawalls, revetments, and bulkheads; groins; jetties; breakwaters; and a group of miscellaneous structures including piers, submerged pipelines, and various harbor and marina structures.

Seawalls, revetments, and bulkheads. These structures are constructed parallel or nearly parallel to the shoreline at the land-sea interface for the purpose of maintaining the shoreline in an advanced position and preventing further shoreline recession. Seawalls are usually massive and rigid, while a revetment is an armoring of the beach face with stone rip-rap or artificial units. A bulkhead acts primarily as a land-retaining structure and is found in a more protected environment such as a navigation channel or marina.

A key factor in the design of these structures is that erosion can continue on adjacent shores and flank the structure if it is not tied in at the ends. Erosion on adjacent shores also increases the exposure of the main structure to wave attack. Structures of this class are prone to damage and possible failure caused by wave-induced scour at the toe. In order to prevent this, the toe must be stabilized by driving vertical sheet piling into the beach, laying stone on the beach seaward of the toe, or maintaining a protective beach by artificial nourishment. Revetments that are sufficiently porous will allow leaching of sand from behind the structure. This can lead to structure slumping and failure. A proper stone or cloth filter system must be developed to prevent damage to the revetment. In an attempt to develop low-cost shore protection, a number of novel materials have been used for shoreline revetments, including cinder blocks, tires, sand-filled rubber tubes, woven-fiber mattresses, and soil-cement paving. *See* REVETMENT.

Groins. A groin is a structure built perpendicular to the shore and usually extending out through the surf zone under normal wave and surge-level conditions. It functions by trapping sand from the alongshore transport system to widen and protect a beach or by retaining artificially placed sand (**Fig. 2**). Typical groin alongshore spacing-to-length ratios vary from 1.5:1 up to 4:1.

There may be erosion downcoast of the groin field, the volume of erosion being approximately equal to the volume of sand removed by the groins from the alongshore transport system. Groins must be sufficiently tied into the beach so that downcoast erosion superimposed on seasonal beach profile fluctuations does not flank the landward end of a groin. Even the best-designed groin system will not prevent the loss of sand offshore in time of storms.

Jetties. Jetties are structures built at the entrance to a river or tidal inlet to stabilize the entrance as well as to protect vessels navigating the entrance channel. Stabilization is achieved by eliminating or reducing the deposition of sediment coming from adjacent shores and by confining the river or tidal flow to develop a more uniform and hydraulically efficient channel. Jetties improve navigation conditions by eliminating bothersome crosscurrents and by reducing wave action in the entrance.

At many entrances there are two parallel (or nearly parallel) jetties that extend approximately to the seaward end of the dredged portion of the channel. However, at some locations a single updrift or downdrift jetty has been used, as have other arrangements such as arrowhead jetties (a pair of straight or curved jetties that converge in the seaward direction). Jetty layouts may also be modified to assist sediment-bypassing operations. A unique arrangement is the weir-jetty system in which the updrift jetty has a low section or weir (crest elevation about mean sea level) across the surf zone. This allows sand to move over the weir section and into a deposition basin for subsequent transport to the downcoast shore by dredge and pipeline.

Breakwaters. The primary purpose of a breakwater is to protect a shoreline or harbor anchorage area from wave attack (**Fig. 3**). Breakwaters may be located completely offshore and oriented approximately parallel to shore, or they may be oblique and connected to the shore where they often take on some of the functions of a jetty. At locations where a natural inland site is not available, harbors have been developed by the construction of shore-connected breakwaters that cover two or three sides of the harbor.

The offshore breakwater intercepts incident waves, thus trapping the predominantly southeastern longshore sand transport; it provides a protected area where a dredge can operate to bypass sediment; and it provides protection to the harbor entrance. A series of shore-parallel offshore breakwaters (with or without artificial nourishment) has been used for shore protection at a number of locations. If there is sufficient fill or trapped material, the tombolo formed in the lee of each breakwater (Fig. 3) may grow until it reaches the breakwater.

Breakwaters are designed to intercept waves, and often extend into relatively deep water, so they tend to be more massive structures than are jetties or groins. Breakwaters constructed to provide a calm anchorage area for ships may have a high crown elevation to prevent overtopping by incident waves and subsequent regeneration of waves in the lee of the breakwater.

Rubble mound structures. Groins, jetties, and breakwaters are most commonly constructed as rubble mound structures (**Fig. 4**). The breakwater has an outer armor layer consisting of the largest stones or, if sufficiently large stones are not available, the armor units may be molded of concrete with a special shape. Stone sizes decrease toward the core and base in order to develop a filter system so that the fine core stone and base sand are not removed by wave and current action. The core made of fine stone sizes is provided to diminish wave transmission through

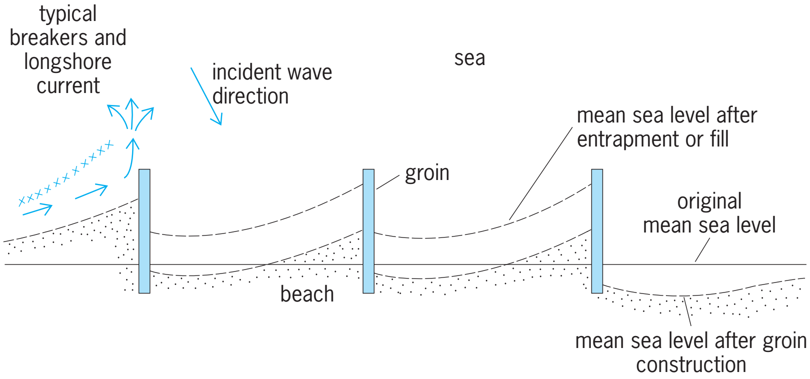

Fig. 2. Groin system and beach response.

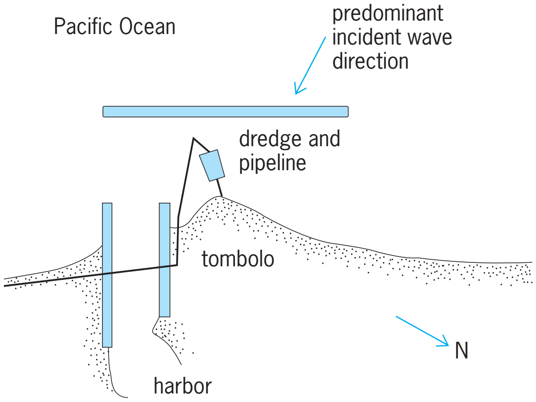

Fig. 3. Overhead view of breakwater and jetty system at the entrance to Channel Islands Harbor, California.

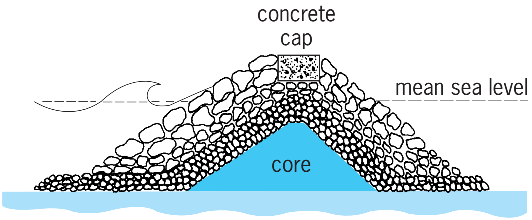

Fig. 4. Cross section of a typical rubble mound breakwater placed on a sand foundation.

the structure. Jetties and groins have a simpler cross section, consisting typically of only armor and core layers. Breakwaters, groins, and jetties have also been constructed of steel or concrete caissons with sand and gravel fill; wood, steel, and concrete sheet piles; and sand-filled bags.

A different type of breakwater that can be effective where incident wave periods are short and large water-level fluctuations occur (as in a reservoir marina) is the moored floating breakwater. This type has been constructed of hollow concrete prisms, scrap tires, logs, and a variety of other materials.

Economic, environmental, and esthetic considerations have resulted in some changes in the types of rubble mound structures being constructed along the coast. Rather than structures with several defined layers (Fig. 4) including an armor layer of large stone designed to remain stable during wave attack, berm breakwaters and revetments have been constructed in regions where large stones are not readily available. The armor layer in these structures consists of smaller stones with a larger size variation that is expected to remold itself to a stable profile in the same manner that a beach profile responds to wave attack. This armor layer must be thicker to allow for this remolding action.

Also, there has been a trend in offshore shore-parallel breakwaters to build the structure with its crest below sea level. This approach saves on stone costs and is visually more acceptable. During calm wave conditions, most of the wave action reaches the shore, a positive condition for shore recreation. However, the larger storm waves are broken and reflected by the structure so that storm-induced beach erosion is reduced. Robert M. Sorensen

Coastal landforms

The characteristic features and morphology of the land in the coastal zone. They are subject to processes of erosion and deposition as produced by winds, waves, tides, and river discharge. The interactions of these processes and the coastal environments produce a wide variety of landforms. Processes directed seaward from the land are dominated by the transport of sediment by rivers, but also include gravity processes such as landslides, rockfalls, and slumping. The dominant processes on the seaward side are wind, waves, and wave-generated currents. Mixed among these locations are tidal currents which also carry large volumes of sediment.

All of these processes are relatively continuous or rapid. Some processes that influence coastal development are much slower. Changes in sea level are important over centuries and millennia with rates of a few millimeters per year. Over thousands of years these changes have resulted in an increase or decrease in sea level of as much as 100 m (330 ft). Another process that influences coastal development is plate tectonics, which has a time frame of millions of years. Although not a process, the geologic framework and geomorphology both seaward and landward of the shoreline are also factors in the development of coastal landforms. *See* GEOMORPHOLOGY; PLATE TECTONICS.

Subcontinental- to continental-scale coastal landform patterns are related to plate tectonics. A landmark paper by D. Inman and C. Nordstrom relating coastal development to plate tectonics provided a simple but useful approach to classification of coasts on this scale. It showed that there are three general geologic framework types into which all coasts can be classified. Some coasts are associated with plate boundaries and others are not. The three major tectonic coastal types are leading-edge, trailing-edge, and marginal sea coasts. Leading-edge coasts are associated with colliding plate boundaries where there is considerable tectonic activity. Trailing-edge coasts are on stable continental margins, and marginal seas have fairly stable coasts with plate margins, commonly characterized by island arcs and volcanoes, that form their seaward boundaries. *See* CONTINENTAL MARGIN.

Leading-edge coasts. The primary characteristic of these coasts is the rugged and irregular topography, commonly displaying cliffs or bluffs right up to the shoreline (**Fig. 1**). Seaward, the topography reflects this with an irregular bottom and deep water near the shoreline. The geology is generally complex with

Fig. 1. Rugged, high-relief coast in central Oregon, an example of a leading-edge coast.

Fig. 2. Central Atlantic coastal plain and coast of the United States, showing large estuaries bounded on the seaward side by a system of long barrier islands. (*NASA*)

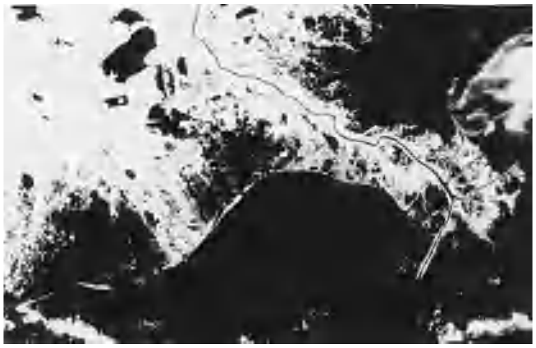

Fig. 3. Mississippi Delta, an example of a large muddy coast landform in a marginal sea.

numerous faults and folds in the strata of the coastal zone. These coasts tend to be dominated by erosion with only local areas of deposition, typically in the form of small beaches or spits between headlands. Waves tend to be large because of the deep nearshore water, and form wave-cut platforms, terraces, notches, sea stacks, and caves.

Trailing-edge coasts. The most diverse suite of coastal landforms develops along trailing-edge coasts. These coasts are generally developed along the margin of a coastal plain, they are fed by well-developed and large river systems, and they are subjected to a low-to-modest wave energy because of the gently sloping adjacent continental shelf. The overall appearance is little topographic relief dominated by deposition of mud and sand. The spectrum of environments and their associated landforms includes deltas, estuaries, barrier islands (**Fig. 2**), tidal inlets, tidal flats, and salt marshes. *See* BARRIER ISLANDS; COASTAL PLAIN; DELTA; FLOODPLAIN; SALT MARSH.

Although there is typically only low-to-moderate wave energy along such coasts, there is potential for considerable change in landforms through the passage of intense storms, including hurricanes. It is common for such events to cause more change in the coast in one or two days than might take place in a century or more under so-called normal conditions.

These trailing-edge coasts are subdivided into three categories based upon the maturity of the continental margin: neo-trailing-edge coasts, Afro-trailing-edge coasts, and Amero-trailing-edge coasts. The neo-trailing-edge coast develops only a short time after the splitting and spreading apart of a landmass. There has been insufficient time for development of a coastal plain, and the continental margin is narrow and steep but not tectonically very active. The Red Sea that separates Africa from the Middle East is an excellent example of this type. The Afro-trailing-edge coast has a significant level of maturity and a well-developed continental margin and is characterized by both the west coast and southeast coast of Africa. The Amero-trailing-edge coast is one where a very long geological time has passed since the plates separated. Both the continental margin and the coastal plain are wide and well developed. The east coasts of North and South America are excellent examples.

Marginal sea coasts. Some coastal settings are along a stable continental mass and are protected from open ocean processes, commonly an island arc system or other form of a plate boundary. The consequence is a coastal zone that tends to be subjected to small waves and where considerable mud is allowed to accumulate in the coastal zone. Many coastal landforms are present in much the same fashion as on the trailing-edge coasts. Marginal sea coasts tend to have large river deltas (**Fig. 3**). Examples are the eastern margin of Asia along the Gulf of Korea and the China Sea, the entire Gulf of Mexico, and the Mediterranean Sea. *See* DEPOSITIONAL SYSTEMS AND ENVIRONMENTS; NEARSHORE PROCESSES.

Nordstrom, On the tectonic and morphologic classification of coasts, *J. Geol.*, 79:1–21, 1971; J. S. Pethick, *Introduction to Coastal Geomorphology*, 1983.

Coastal plain

An extensive, low-relief area that is bounded by the sea on one side and by some type of relatively high-relief province on the landward side. The geologic province of the coastal plain actually extends beyond

Fig. 1. Coastal plains of the United States.

the shoreline across the continental shelf. It is only during times of glacial melting and high sea level that much of the coastal plain is drowned. *See* CONTINENTAL MARGIN.

The coastal plain is a geologic province that is linked to the stable part of a continent on the trailing edge of a plate. The extent and nature of the coastal plains of the world range widely. Some are very large and old, whereas others are small and geologically young. For example, the Atlantic and Gulf coasts of the United States are among the largest in the world. They extend continuously from the New Jersey area beyond the border with Mexico (**Fig. 1**). In some areas the coastal plain is hundreds of kilometers wide. In the United States it extends back about 100 million years. By contrast, local coastal plains in places like the east coast of Australia and New Zealand are only 1 or 2 million years old and extend only tens of kilometers landward from the shoreline.

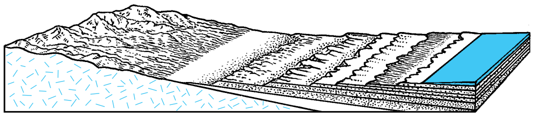

Fig. 2. Block diagram of a coastal plain showing the gentle dip of the strata and the erosional ridges.

The typical character of a coastal plain is one of strata that dip gently and uniformly toward the sea. There may be low ridges that are essentially parallel to the coast (**Fig. 2**) and that have developed from erosion of alternating resistant and nonresistant strata. These strata are commonly a combination of mudstone, sandstone, and limestone, although the latter is typically a subordinate amount of the total. These strata resulted from deposition in fluvial, deltaic, and shelf environments as sea level advanced and retreated over this area. Coastal plain strata have been a source of considerable oil and gas as well as various economic minerals. Although the coastal plain province is typically stable tectonically, there may be numerous normal faults and salt dome intrusions. *See* COASTAL LANDFORMS; DELTA; GEOMORPHOLOGY; PLAINS. Richard A. Davis, Jr.

Coati

Any of three species of carnivorous mammals assigned to the raccoon family Procyonidae. The common or ring-tailed coati (*Nasua nasua*) ranges through the forests of Central and South America (see **illustration**), the mountain coati (*Nasuella olivacea*) is found only in South America, while *Nasua nelsoni* is confined to Cozumel Island in Central America.

The coatis are characterized by their elongated snouts, body, and tail, which is held erect when they walk. They are adept at climbing trees in search of birds and lizards, and their diet also includes fruit, insects, and larvae. *Nasua nasua* roams in bands of females and young during the day in search of food. The males are excluded from the band except during the brief breeding season, when a single male is allowed to join. He is aggressive toward any other male but subordinate to the females. After mating, the male leaves and the female builds an isolated nest in a tree. Here, following a gestation period of 11 weeks, a litter of about five young are born and cared for by the female away from the group. After about 1 month the female and her young rejoin the band. *See* CARNIVORA. Charles B. Curtin

Coaxial cable

An electrical transmission line comprising an inner, central conductor surrounded by a tubular outer conductor. The two conductors are separated by an electrically insulating medium which supports the inner conductor and keeps it concentric with the outer conductor. One version of coaxial cable has periodically spaced polyethylene disks supporting the inner conductor (**Fig. 1**). This coaxial is a building block of multicoaxial cables used in L-carrier systems. *See* TRANSMISSION LINES.

The symmetry of the coaxial cable and the fact that the outer conductor surrounds the inner conductor make it a shielded structure. At high frequencies, signal currents concentrate near the inside surface of the outer conductor and the outer surface of the inner conductor. This is called skin effect. The depth to which currents penetrate decreases with increasing frequency. Decreased skin depth improves the cable's self-shielding and increases transmission loss. This loss (expressed in decibels per kilometer) increases approximately as the square root of

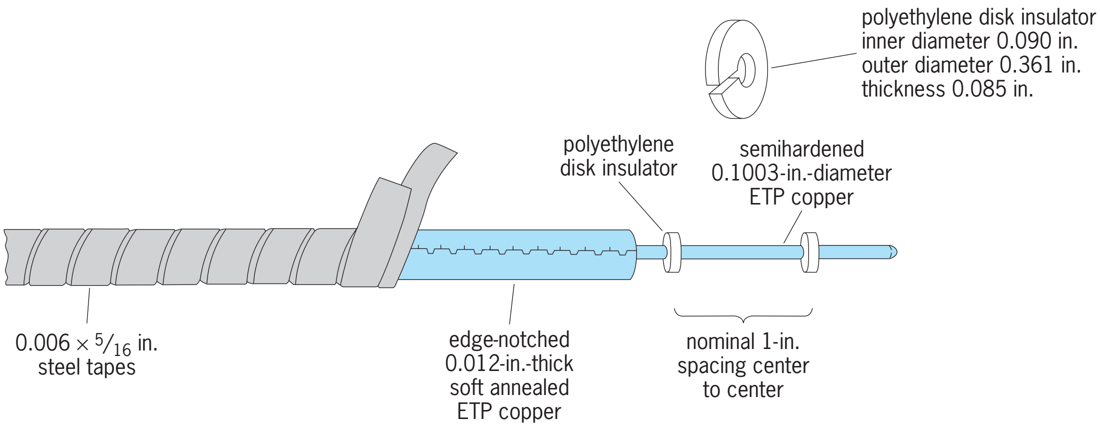

Fig. 1. Air dielectric disk-insulated coaxial cable. 1 in. = 25 mm.

frequency because of the skin effect. *See* ELECTRICAL SHIELDING; SKIN EFFECT (ELECTRICITY).

Coaxial cables can carry high power without radiating significant electromagnetic energy. In other applications, coaxial cables carry very weak signals and are largely immune to interference from external electromagnetic fields.

A coaxial cable's self-shielding property is vital to successful use in broadband carrier systems, undersea cable systems, radio and TV antenna feeders, and community antenna television (CATV) applications.

Coaxial units are designed for different mechanical behavior depending upon the application. Widely used coaxials are classified as flexible or semirigid.

Materials. Conductors for coaxial cable are generally made of copper or aluminum. The low resistivity of these metals results in low cable loss. A typical dielectric material is polyethylene; special grades are made with very low dielectric loss. Where mechanical factors allow, much of the space between inner and outer conductor is occupied by air. This may be done by using spaced insulating disks (Fig. 1) or expanded or spiraled insulation. *See* ALUMINUM; CONDUCTOR (ELECTRICITY); COPPER; POLYOLEFIN RESINS.

Flexible coaxials. These generally have a braided outer conductor and a stranded inner conductor. Insulation is made of solid or expanded plastic of a low-loss electrical grade. Since a single layer of braid has some air gaps between intersecting wires, a second layer of braid is placed over the first when shielding requirements are severe.

Flexible coaxials are used for high-frequency patch cords and intra- and interbay cabling. Very small-diameter coaxials are used to interconnect components on printed wiring boards. Since runs are short in these applications, loss is not generally important.

Semirigid coaxials. This class of coaxials finds the most extensive use in communications systems, such as cables used in long-distance terrestrial and undersea communications. Also, CATV and closed-circuit television often use semirigid coaxials. To minimize cable loss, the insulation may be of expanded plastic, effectively using air bubbles for up to 80% of the dielectric.

Terrestrial coaxials. The coaxial unit in the L3, L4, L5, and L5E carrier systems uses polyethylene disks spaced 1 in. (2.5 cm) apart to keep the inner conductor centered (Fig. 1). The outer conductor is then precision-formed around the disk-insulated inner conductor. Two layers of steel tape are overlapped to complete the unit. The tapes give the assembly mechanical stability and provide added shielding at low frequencies.

Such a coaxial unit has low loss and excellent impedance characteristics. In the L5E system a pair of such coaxial units can carry 13,200 telephone calls. Cables carrying 20 of these coaxial units are used in L-carrier systems (**Fig. 2**), and a 22-unit coaxial

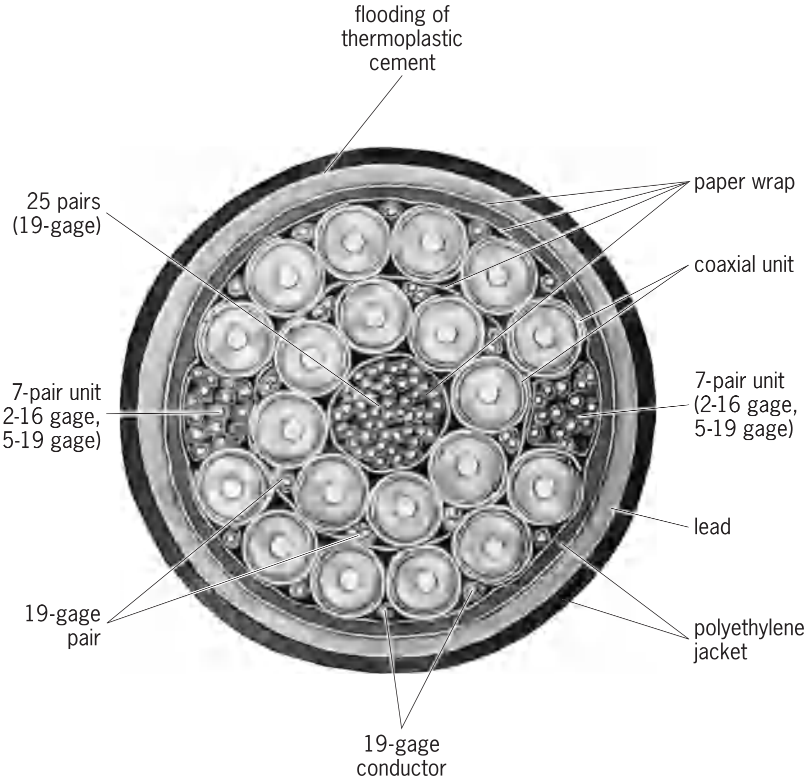

Fig. 2. Construction of multicoaxial transmission line with twenty 0.375-in. (9.5-mm) coaxial units.

version of this cable was used in later L5E installations. Fully equipped, this cable provides 132,000-telephone-channel capacity over the 10 working coaxial pairs. The eleventh pair provides service protection for the 10 working pairs.

Two coaxial cables span the United States from east to west, with many intermediate and shorter installations. For current and future use, optical fiber cables are playing the key role earlier played by coaxial cables.

Undersea coaxials. To function reliably in a high-performance system in the ocean environment, undersea coaxials must meet severe requirements. Some of these are (1) stable dimensions and predictable transmission characteristics under pressures of up to 11,000 lb/in.^{2} (76 megapascals); (2) 25-year service lifetime; and (3) ability to withstand handling and scuffing. A solid polyethylene core withstands ocean pressure which would crush a cable with any air fill. The use of inert materials that resist attack by marine organisms assures the desired lifetime. The high-strength (300,000-lb/in.^{2} or 2-gigapascal) steel strand and high-density jacket assure survival and continuity despite severe handling.

In coaxial cables used in fourth-generation analog undersea cable systems, the high-tensile steel strand provides longitudinal strength needed to lay or recover the cable in ocean depths of up to 4 nautical miles (7 km). The inner conductor is a high-conductivity copper tube, 0.48 in. (12 mm) in diameter, which is formed and swaged over the steel strand. Low-loss polyethylene is extruded over the inner conductor assembly to form the 1.7-in.-diameter (43.2-mm) cable core. To achieve an accurate (±0.001 in. or 0.025 mm) core diameter, the core is extruded slightly oversize and mechanically shaved.

In a further manufacturing operation, the 10-mil-thick (0.010-in. or 0.25-mm) copper outer conductor is formed over the cable core with an overlapped seam. A high-density polyethylene jacket, 2 in. (50 mm) in diameter, is extruded over the outer conductor to complete the cable. *See* COMMUNICATIONS CABLE; SUBMARINE CABLE.

S. Theodore Brewer

Cobalt

A lustrous, silvery-blue metallic chemical element, Co, with an atomic number of 27 and an atomic weight of 58.93. Metallic cobalt was isolated in 1735 by the Swedish scientist G. Brandt, who called the impure metal cobalt rex, after the ore from which it was extracted. The metal was shown to be a previously unknown element by T. O. Bergman in 1780.

Cobalt is a transition element in the same group as rhodium and iridium. In the periodic table it occupies a position between iron and nickel in the third period. Cobalt resembles iron and nickel in both its free and combined states, possessing similar tensile strength, machinability, thermal properties, and electrochemical behavior. Constituting 0.0029% of the Earth's crust, cobalt is widely distributed in nature, occurring in meteorites, stars, lunar rocks, seawater, fresh water, soils, plants, and animals. *See* PERIODIC TABLE; TRANSITION ELEMENTS.

Cobalt and its alloys resist wear and corrosion even at high temperatures. The most important commercial uses are in making alloys for heavy-wear, high-temperature, and magnetic applications. Small amounts of the element are required by plants and animals. The artificially produced radioactive isotope of cobalt, ^{60}Co, has many medical and industrial applications.

Cobalt, with a melting point of 1495°C (2723°F) and a boiling point of 3100°C (5612°F), has a density (20°C; 68°F) of 8.90 g·cm^{-3}, an electrical resistivity (20°C) of 6.24 microhm·cm, and a hardness (diamond pyramid, Vickers; 20°C) of 225. It is harder than iron and, although brittle, it can be machined. The latent heat of fusion is 259.4 joules/g, and the latent heat of vaporization is 6276 J/g; the specific heat (15–100°C; 59–212°F) is 0.442 J/g · °C. Cobalt is ferromagnetic, with the very high Curie temperature of 1121°C (2050°F). The electronic configuration is $1s^22s^22p^63s^23p^63d^74s^2$. At normal temperatures the stable crystal form of cobalt is hexagonal close-packed, but above 417°C (783°F) face-centered cubic is the stable structure. Although the finely divided metal is pyrophoric in air, cobalt is relatively unreactive and stable to oxygen in the air, unless heated. It is attacked by sulfuric, hydrochloric, and nitric acids, and more slowly by hydrofluoric and phosphoric acids, ammonium hydroxide, and sodium hydroxide. Cobalt reacts when heated with the halogens and other nonmetals such as boron, carbon, phosphorus, arsenic, antimony, and sulfur. Dinitrogen, superoxo, peroxo, and mixed hydride complexes also exist. In its compounds, cobalt exhibits all the oxidation states from −I to IV, the most common being II and III. The highest oxidation state is found in cesium hexafluorocobaltate(IV), Cs_2CoF_6, and a few other compounds.

There are over 200 ores known to contain cobalt; traces of the metal are found in many ores of iron, nickel, copper, silver, manganese, and zinc. However, the commercially important cobalt minerals are the arsenides, oxides, and sulfides. Zaire is the chief producer, followed by Zambia. Russia, Canada, Cuba, Australia, and New Caledonia produce most of the rest. Zaire and Zambia together account for just over 50% of the world's cobalt reserves. Nickel-containing laterites (hydrated iron oxides) found in the soils of the Celebes, Cuba, New Caledonia, and many other tropical areas are being developed as sources of cobalt. The manganese nodules found on the ocean floor are another large potential reserve of cobalt. They are estimated to contain at least 400 times as much cobalt as land-based deposits. *See* MANGANESE NODULES.

Since cobalt production is usually subsidiary to that of copper, nickel, or lead, extraction procedures vary according to which of these metals is associated with the cobalt. In general, the ore is roasted to remove stony gangue material as a slag, leaving a speiss of mixed metal and oxides, which is then reduced electrolytically, reduced thermally with aluminum, or leached with sulfuric acid to dissolve iron, cobalt, and nickel, leaving metallic copper behind. Lime is used to precipitate iron, and sodium hypochlorite is used to precipitate cobalt as the hydroxide. The cobalt hydroxide can be heated to give the oxide, which in turn is reduced to the metal by heating with charcoal.

Cobalt ores have long been used to produce a blue color in pottery, glass, enamels, and glazes. Cobalt is contained in Egyptian pottery dated as early as 2600 B.C. and in the blue and white porcelain ware of the Ming Dynasty in China (1368–1644).

An important modern industrial use involves the addition of small quantities of cobalt oxide during manufacture of ceramic materials to achieve a white color. The cobalt oxide counteracts yellow tints resulting from iron impurities. Cobalt oxide is also used in enamel coatings on steel to improve the adherence of the enamel to the metal. Cobalt arsenates, phosphates, and aluminates are used in artists' pigments, and various cobalt compounds are used in inks for full-color jet printing and in reactive dyes for cotton. Cobalt blue (Thenard's blue), one of the most durable of all blue pigments, is essentially cobalt aluminate. Cobalt linoleates, naphthenates, oleates, and ethylhexoates are used to speed up the drying of paints, lacquers, varnishes, and inks by promoting oxidation. In all, about a third of the world's cobalt production is used to make chemicals for the ceramic and paint industries. *See* CERAMICS; DYE; INK; METAL COATINGS.

Cobalt catalysts are used throughout the chemical industry for various processes. These include hydrogenations and dehydrogenations, halogenations, aminations, polymerizations (for example, butadiene), oxidation of xylenes to toluic acid, production of hydrogen sulfide and carbon disulfide, carbonylation of methanol to acetic acid, olefin synthesis, denitrogenation and desulfurization of coal tars, reductions with borohydrides, and nitrile syntheses, and such important reactions as the Fisher-Tropsch method for synthesizing liquid fuels and the hydroformylation process. Cobalt catalysts have also been used in the oxidation of poisonous hydrogen cyanide in gas masks and in the oxidation of carbon monoxide in automobile exhausts. *See* CATALYTIC CONVERTER.

Although cobalt was not used in its metallic state until the twentieth century, the principal use of cobalt is as a metal in the production of alloys, chiefly high-temperature and magnetic types. Superalloys needed to stand high stress at high temperatures, as in jet engines and gas turbines, typically contain 20–65% cobalt along with nickel, chromium, molybdenum, tungsten, and other elements.

In parts of the world where soil and plants are deficient in cobalt, trace amounts of cobalt salts [for example, the chloride and nitrate of Co(II)] are added to livestock feeds and fertilizers to prevent serious wasting diseases of cattle and sheep, such as pining, a debilitating disease especially common in sheep. Symptoms of cobalt deprivation in animals include retarded growth, anemia, loss of appetite, and decreased lactation.

The principal biological role of cobalt involves corrin compounds (porphyrin-like macrocycles). The active forms contain an alkyl group (5′-deoxyadenosine or methyl) attached to the cobalt as well as four nitrogens from the corrin and a nitrogen from a heterocycle, usually 5,6-dimethylbenzimidazole. These active forms act in concert with enzymes to catalyze essential reactions in humans. However, the corrin compounds are not synthesized in the body; they must be ingested in very small quantities. Vitamin B_{12}, with cyanide in place of the alkyl, prevents pernicious anemia but is itself inactive. The body metabolizes the vitamin into the active forms. Although the cobalt in corrins is usually Co(III), both Co(II) and Co(I) are involved in enzymic processes. Roughly one-third of all enzymes are metalloenzymes. Cobalt(II) substitutes for zinc in many of these to yield active forms. Such substitution of zinc may account, in part, for the toxicity of cobalt. *See* ENZYME; VITAMIN B_{12}.

Coca

Shrubs of the genus *Erythroxylum* in the coca family (Erythroxylaceae). The genus contains over 200 species, most in the New World tropics. Two species, *E. coca* (*see* **illus.**) and *E. novogranatense*, are cultivated for their content of cocaine and other alkaloids. Leaves of cultivated coca contain 14 alkaloids, chiefly cocaine, and significant amounts of vitamins and minerals. The cocaine content averages 0.5%, rarely exceeding 1.0%.

Millions of South American Indians "chew" coca every day as a mild stimulant by placing dried leaves in the mouth and masticating with various alkalies such as lime or plant ashes to promote the release of the alkaloids, which are swallowed. Coca is

Flowering branch of coca (*Erythroxylum coca*).

important in the folk medicine of Andean Indians, especially as a treatment for gastrointestinal disorders. It may regulate carbohydrate metabolism in a useful way and supplement an otherwise deficient diet. Coca also has great magical and religious significance in Andean societies. Although it has long been the focus of political debate, especially in Peru, ritualized use of the leaf in traditional cultures is not inconsistent with good physical health and social productivity. *See* COCAINE; COLA; LINALES.

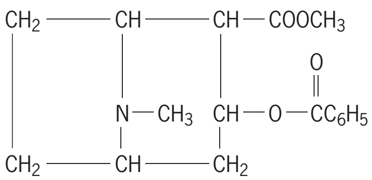
Cocaine

The principal alkaloid of coca leaves, a topical anesthetic and stimulant, and popular illicit drug. The molecular formula is given below. Cocaine was first



isolated by A. Niemann in 1860. In 1884 C. Koller demonstrated its efficacy as an anesthetic in eye surgery, introducing the age of local anesthesia. For the next decade cocaine enjoyed the status of a wonder drug and panacea. It fell into disfavor with increasing reports of acute toxicity and long-term dependence. Today it is used as a topical anesthetic in the eye, nose, mouth, and throat; for injection anesthesia it has been replaced by synthetic drugs with fewer central nervous system effects. *See* ANESTHESIA; COCA.

Cocaine increases heart rate and blood pressure and causes feelings of alertness and euphoria. It stimulates noradrenergic pathways by blocking reuptake of norepinephrine at the synapse, and also stimulates dopaminergic pathways. In animals it can be shown to be strongly reinforcing. It does not produce physical dependence, as alcohol and opiates do, but many people find it hard to use in a stable and moderate fashion if they have access to it in quantity. Although it is quite active orally, most users of illicit cocaine take it intranasally by snuffing; few inject it intravenously. Aside from local irritation of the nasal membranes, occasional users suffer few adverse effects. The psychological consequences of frequent use can be devastating. The soluble hydrochloride salt is the common form. Insoluble cocaine free base, that is, the free alkaloid form of the drug, may be smoked, a practice that increases the toxicity of the drug and is more likely to be associated with dependence. *See* ADDICTIVE DISORDERS; ALKALOID; NORADRENERGIC SYSTEM.

Coccidia

A subclass of the class Telosporea. These protozoa are typically intracellular parasites of epithelial tissues in both vertebrates and invertebrates. The group is divided on the basis of life cycles into two orders, the Protococcida (in which there is only sexual reproduction) and the Eucoccida (in which there is both sexual and asexual reproduction). There are only a few species in Protococcida, and all are parasites in marine invertebrates. There are hundreds of species in Eucoccida; these are parasites in both invertebrates and vertebrates. The Eucoccida contains three suborders: Adeleina, which occur mostly in invertebrates and in which there is usually one host for the sexual stages and a different host for the asexual stages (an example is *Hepatozoon muris*, found in rats and transmitted by mites); Haemosporina, which occur mainly in vertebrates and which have their sexual stages in invertebrates (an example is *Plasmodium falciparum* which causes malaria in humans and is transmitted by mosquitoes); and Eimeriina, which occur mostly in vertebrates and in which the sexual and asexual stages occur in the same host (an example is *Eimeria*, species of which cause coccidiosis in many domestic animals and wildlife, and which are transmitted by filth). The malaria parasites and coccidia are of direct importance to humans, and also cause important losses in chickens, cattle, sheep, and other domesticated animals. *See* EUCOCCIDA; PROTOCOCCIDA; PROTOZOA; SPOROZOA; TELOSPOREA.

Elery R. Becker; Norman D. Levine

Coccolithophorida

A group of unicellular, biflagellate, golden-brown algae characterized by a covering of extremely small (1–35 micrometers) interlocking calcite (the hexagonal form of calcium carbonate) plates called coccoliths. The plates show extinction crosses in a polarizing light microscope; however, detailed study requires the use of electron transmission or electron scanning microscopes. The Coccolithophorida are usually considered plants but possess also some animal characteristics. Botanists assign them to the class Haptophyceae (based on the possession of a haptonema, a threadlike organ of attachment) of the phylum Chrysophyta, and zoologists to the class Phytamastigophorea, superclass Mastigophora, subphylum Sarcomastigophora of the phylum Protozoa. *See* CILIA AND FLAGELLA; PHYTAMASTIGOPHOREA; PROTOZOA.

Classification. The Coccolithophorida are mainly classified by the shape of their coccoliths into two groups: the holococcoliths, with simple rhombic or hexagonal crystals arranged like a mosaic; and the heterococcoliths, with complex crystals arranged into boat, trumpet, basket, or collar-button shapes. Classification is complicated by the presence of polymorphism (more than one type of coccolith per cell) and complex life cycles involving alternation of generations either with different types of coccoliths or with none at all (see **illus.**).

Life cycle. Reproduction occurs mostly by fission. Haploid and diploid phases, motile versus nonmotile phases, resting spores, and ameboid and filamentous stages have been noted but their interrelationships require further study.

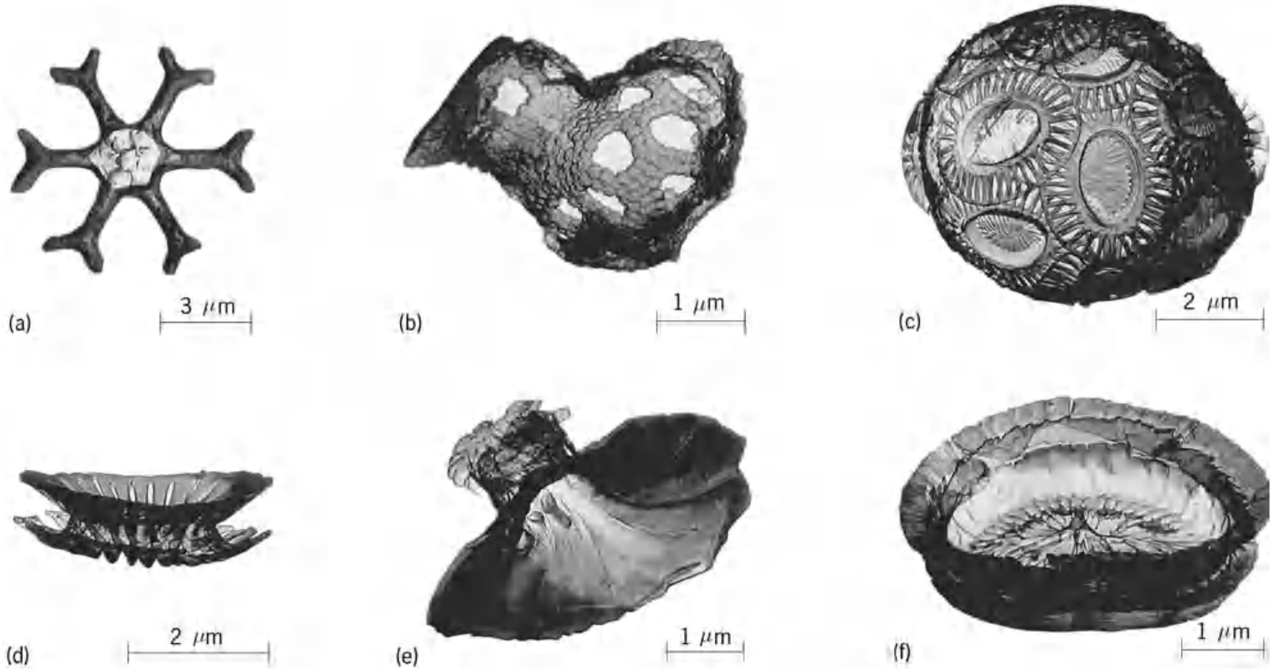
Ecology. Chiefly photosynthetic, although epiphytism, phagotrophism, and saprophytism have also been shown, the Coccolithophorida form a significant percentage of the nannoplankton (plankton of less than 74-μm size) of the tropic through subarctic-subantarctic waters of all oceans; a few brackish and fresh-water species also exist. Together with the diatoms they constitute the primary producers of the open ocean food chain. *See* BACILLARIOPHYCEAE; PHYTOPLANKTON.

Coccoliths. Ease of culture makes these organisms a prime choice for studying biologic calcification. Research shows that coccoliths are extruded to the cell surface after being formed intracellularly on an organic matrix located between the nucleus and a “reticular body,” which plays some yet undiscovered but essential role, and that the process is light-dependent and linked to photosynthesis. Coccolith formation has been introduced in naked cells by lowering the nitrogen content of the culture medium, and coccolith-bearing cells have lost their covering with the addition of carbon dioxide to their medium.

The function of coccoliths is unknown, but one worker suggests that they serve as a shield against excessive sunlight.

Fossil record. Coccoliths preserve well and have a fossil record dating back into the Jurassic, 180,000,000 years ago. They make up limestone and chalk deposits such as the White Cliffs of Dover on land and up to 30% of the sediments underlying tropical to arctic-antarctic ocean waters.

Their long and involved evolutionary record makes them useful for dating ancient sediments. The onset of the Pleistocene, or glacial, period is marked by the appearance of new coccolith species and



Examples of Coccolithophorida. (*a*) *Discoaster*; (*b*) a holococcolith; (*c*) a coccosphere; (*d*) a coccolith; (*e, f*) heterococcoliths. (*A. McIntyre, Lamont-Doherty Geological Observatory of Columbia University*)

the disappearance of older forms, including the discoasters, a group of star-shaped members prominent during the Tertiary. Extinction of the latter in a sedimentary sequence is a classic marker of the Pliocene-Pleistocene boundary.

Because they live in surface waters, coccoliths are under direct climatic control. Thus many modern species with relatively long fossil records are excellent temperature indicators. Research indicates that these can be used to unravel the climatic variations of the Pleistocene period that evolved into present weather patterns. *See* MICROPALEONTOLOGY.

Cocoa powder and chocolate

Products derived from the seeds of the tropical tree *Theobroma cacao*, which grows within a narrow belt along both sides of the Equator. There are three basic varieties: Criollo, which was native to Central and South America; Forastero, which constitutes the bulk of the world supply and is mostly cultivated in West Africa and Brazil; and Trinitario, consisting of various hybrids. *See* CACAO.

The seeds, contained in pods which grow on the trunks and lower branches of the trees, are surrounded by a mucilaginous pulp. They are whitish in color and have no normal chocolate flavor. Each mature bean is about $^3/_4$–1 in. (2–2.5 cm) in length with an average weight not less than 0.04 oz (1 g). The shell (testa) is about 12% of the total bean weight, the nib (cotyledon) 87%, and germ 1%—the last being the point at which germination would have commenced in the live bean. The main constituents of the dried nib are approximately the following: fat (cocoa butter) 54%; protein 12–14%; starch, other carbohydrates, and mucilage 20%; tannins 6%; theobromine 1.3%; caffeine 0.2%; and moisture 3–5%. Good-quality beans show a brown or purplish-brown color and striations in the sliced cotyledon. Unfermented beans have a dense structure and slaty color. *See* SEED.

Processing. To develop a chocolate flavor, the beans are first subjected to a fermentation process. The pods are split open and the seeds and pulp placed in heaps surrounded by plantain leaves or in "sweat boxes." Under these conditions microbiological and enzymatic action occurs, with a rise in temperature to about 120°F (50°C).

After 4–6 days, during which the beans are turned over, they develop a purplish-brown color, and the outer shell and nib become more distinct. The pulp liquefies and drains away, and precursors of the true chocolate flavor are formed. After fermentation the beans are sun-dried in shallow trays that are protected from rainstorms by sliding canopies; in very wet climates, such as that found in Cameroon, various forms of artificial drying are used. After drying, the product is described commercially as cocoa or cocoa beans and should have a moisture content of 6–7%.

A series of well-defined operations are used to produce good-quality cocoa or chocolate.

Cleaning. Machines, by a combination of sieving and air elutriation, remove stones, sand, bag fiber, stalks, and immature beans. Without this treatment, grit would pass to subsequent processes, resulting in machine damage and poor-quality products.

Roasting. In this essential process the chocolate flavor is fully developed from the precursors, the shell loosened from the nib, and the moisture content reduced.

There are many roaster designs. One type is a rotating drum with external heating, which may handle single batches or have a continuous throughput. Other roasters use high-temperature air passing through a continuous stream of beans. Roasting temperatures vary greatly, ranging from 200 to 300°F (95 to 150°C). The temperature used is related to the time of roasting and the type of product required. The shell should never be burned.

In two-stage roasting, the beans are heated at a low temperature in a closed, moist atmosphere, and then a higher temperature and drying follow.

Winnowing. After roasting, the winnowing process separates the shell from the nib. The ideal is complete separation with full recovery of the nib, but in practice this is not possible. Winnowing machines have been greatly improved. A modern system uses a bank of vibrating sieves with an air lift to remove shell pieces at the discharge end of each sieve (**Fig. 1**). At the machine entry the beans are broken by hexagonal impact rollers which minimize the production of fine dust. The shell is a waste product that is used as a boiler fuel and an agricultural mulch.

Liquor milling. The roasted nibs are ground at a temperature above the melting point of the cocoa butter constituent (93–95°F or 34–35°C) to produce a dark brown liquid called liquor, mass, or unsweetened chocolate. Finely ground liquor is the basis for manufacture of cocoa powder and chocolate.

Different machines are used for this purpose. Pin and hammer mills in conjunction with roller refiners are frequently used. Other machines include horizontal disk mills with three stages and the vertical ball mill. In the ball mill partially ground liquor is fed through a vertical cylinder containing hard steel or ceramic balls rotated at high speed by means of a central spindle and attached plates.

Cocoa powder manufacture. To manufacture cocoa powder, liquor is subjected to hydraulic pressing, which separates some of the cocoa butter from the solid cocoa matter. The pressing machine consists of a number of pots arranged horizontally, each provided with a filter and linked to a hydraulic ram capable of providing pressures of over 6000 lb/in.^{2} (10^8 pascals). The pots are filled automatically with hot liquor, and when the ram operates liquid cocoa

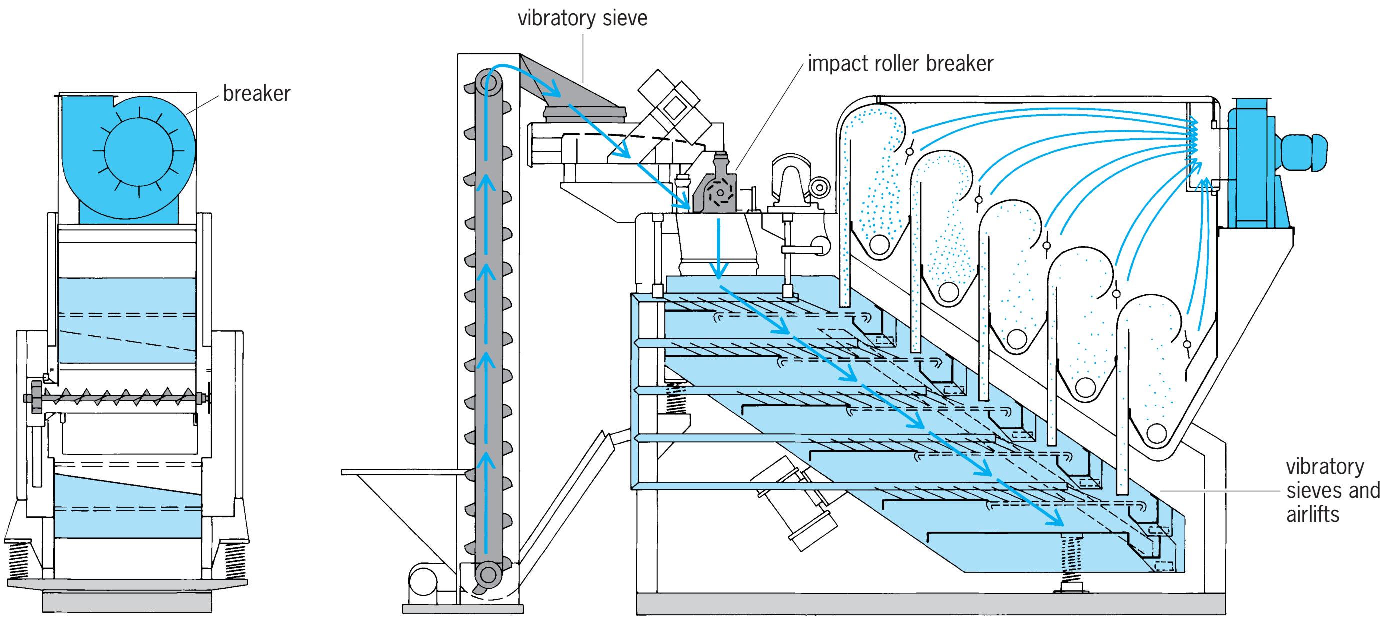

Fig. 1. **Two views of winnowing machine. (*Bauermeister Maschinen Fabrik*, *Hamburg*, *Germany*)**

butter is forced through the filters and into a common channel at the base of the press. The amount of cocoa butter pressed out is determined by control of time and pressure.

At the end of the pressing cycle the ram is reversed, thus opening the pots and releasing compressed cocoa cakes. To make cocoa powder, these cakes are first mechanically broken into small pieces called kibbled cake and then put through pulverizers which, in conjunction with air separators, produce a very fine powder. Such cocoa powder is called natural cocoa.

Additionally, if dark brown or reddish-brown cocoas are required, the liquor, kibbled cake, or preferably the nibs are subjected to a process called alkalization or dutching. This consists of saturating the nibs (or other intermediate) with a solution of potassium or sodium carbonate followed by drying and roasting. In most countries, the amount of added alkali permitted is limited to 3% of the nib.

Color is controlled by the degree of roast of the nib and the quantity and concentration of the alkali used. Alkalization also serves to neutralize the natural acidity of the nib.

Commercial cocoa powders may have a residual cocoa butter content of 10–22%. They are used extensively as ingredients in cookies, biscuits, chocolate syrups and spreads, and vegetable fat coatings.

Chocolate manufacture. Dark, bitter, or sweet chocolate is manufactured from liquor (or nibs), sugar, and cocoa butter—the cocoa butter being obtained from cocoa powder manufacture. Cocoa butter is a very stable, natural fat; it melts just below body temperature and has a narrow melting range. It displays good contraction on solidifying from the liquid state, which enables chocolate to be molded into various shapes. Its melting properties impart good texture in the mouth and flavor release.

Milk chocolate is made from liquor, sugar, milk solids, and cocoa butter. The milk solids are derived from liquid milk, usually by a spray-drying process. Another milk product often used, called milk crumb, is prepared by concentrating and drying liquid milk in the presence of sugar and liquor. This gives a caramelized milk flavor which has proved very popular. *See* MILK.

Refining. In the manufacture of chocolate, the solids are mixed mechanically with liquor and some cocoa butter to give a plastic paste. This paste is fed to refiners, which consist of five steel rolls mounted vertically with the bottom feed roll offset to enable the paste to be delivered continuously from the mixers. The rolls work on a system in which the speed of rotation increases from the bottom to the top roll, thereby obtaining a grinding shear between the roll surfaces and enabling the paste to travel upward from one roll to the next. The refined paste is scraped off the top roll by a sharp blade. In some instances refining is done in two stages. **Figure 2** shows a mixing and double refining system.

Conching. The final process in chocolate making is called conching, which removes moisture and volatile substances that would produce acid and harsh flavors. Conching also reduces viscosity and contributes a smoothness to the eating qualities of the chocolate.

At one time conching was carried out in machines which consisted of a heated tank with a flat bottom over which a roller traveled backward and forward through the liquid chocolate. While these were effective, much time was necessary to produce good chocolate; the process also took much energy, and extra cocoa butter was needed to give fluidity.

Later it was shown that with more powerful machinery it was possible to directly conche the friable

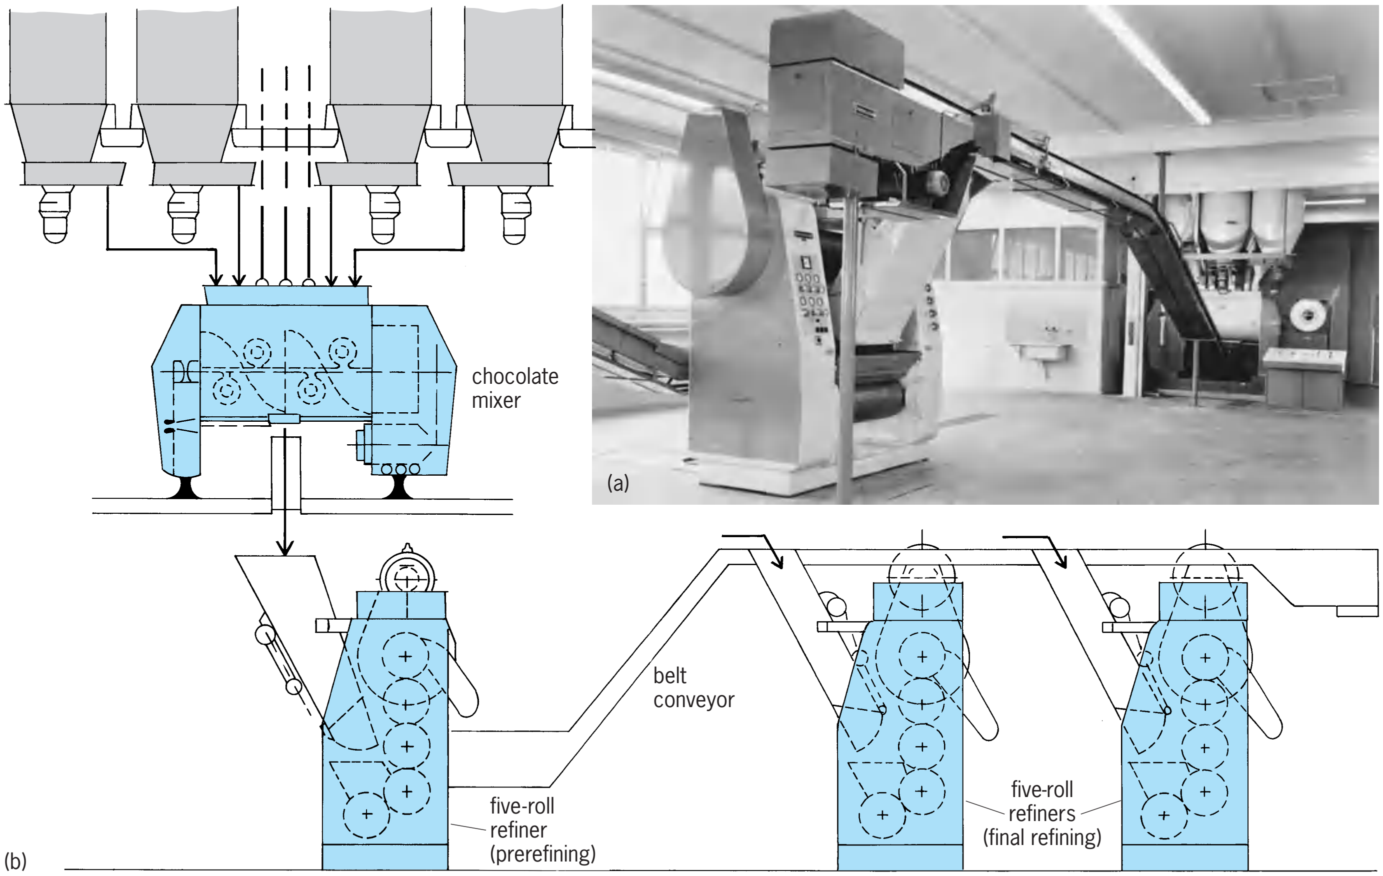

Fig. 2. Modern chocolate-making plant. (*a*) Mixer, conveyor, and refining rolls. (*b*) Diagram of operation of this equipment. (*Buhler-Miag*, *Uzwil*, *Switzerland*)

flake from the refining rolls. This is known as dry conching, a process which removes the volatiles in a much shorter time. Extra fluidity is obtained by mechanical mixing alone. Dry conching is now mostly done in rotary conches (**Fig. 3**), taking about 4 h. Then extra cocoa butter is added and the speed of rotation increased for a further period of 6–12 h depending on the type of chocolate desired.

Fig. 3. Modern rotary conche. (*Petzholdt*, *Frankfurt*, *Germany*)

Besides mechanical improvements, the use of emulsifiers has reduced costs by obtaining the correct fluidity with less cocoa butter. The universally used emulsifier is natural lecithin obtained from the soya bean; in most countries the amount permitted by law is limited to 0.5% of the final chocolate product. About 1 h before the end of the conching period, the emulsifier is added, and the viscosity is checked and adjusted by the addition of more cocoa butter. The final viscosity depends on whether the chocolate is to be used for molding bars or coating confectionery centers.

Tempering. In both refining and conching, the chocolate must be subjected to tempering before it is applied to confectionery centers or deposited into molds. Cocoa butter is polymorphic, which means it crystallizes in several forms on solidifying. Some forms are unstable, and these will transform to the stable form slowly if the chocolate is not tempered, resulting in an unsightly grayish surface film called bloom.

To temper chocolate it is necessary to seed the liquid chocolate with the stable form of crystal. There are several ways of doing this. The most common way is to reduce the temperature of the liquid chocolate from about 100 to 84°F (38 to 29°C), with constant stirring, until cocoa butter seed is formed, and then raising the temperature again to 90–91°F (32–33°C), which will melt out the remaining unstable forms and render the chocolate sufficiently fluid for application. Modern machines called enrobers or coaters carry out this process. *See* FOOD MANUFACTURING. Bernard W. Minifie

Coconut

A large palm, *Cocos nucifera* (in the family Areacaceae), widely grown throughout the tropics and valuable for its fruit and fiber. Usually found near the seacoast, it requires high humidity, abundant rainfall (60 in. or 1.5 m), and mean annual temperature of about 85°F (31°C). Southern Florida, with mean temperature of 77°F (25°C), is at the limit of successful growth. The origin of the coconut has been in dispute, but strong evidence points to southern Asia with wide dispersal by ocean currents and human migrations. *See* ARECALES.

The fruit, 10 in. (25 cm) or more in length, is ovoid and obtusely triangular in cross section (**Fig. 1**). The tough, fibrous outer husk (exocarp) encloses a spherical nut consisting of a hard, bony shell (endocarp) within which is a $^1/_2$-in. (1.25-cm) layer of fleshy meat or kernel (endosperm). The meat is high in oil and protein and, when dried, is the copra of commerce.

Production and culture. Principal commercial producers are the Philippines, Indonesia, Malaya, Ceylon, and Oceania. Although many trees grow along the seashore and in native villages without special care, the crop lends itself to plantation culture with control of weeds, fertilization, and protection from diseases, insects, and animal pests.

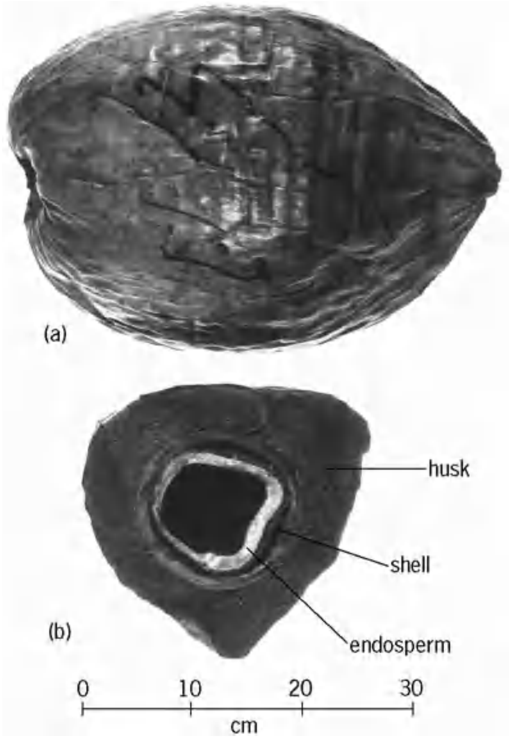

Fig. 1. Coconut. (*a*) Fruit. (*b*) Cross section of fruit showing husk, shell, and endosperm (meat). 2.5 cm = 1 in.

Palms begin to bear nuts the sixth year after planting and reach full bearing about the eighth year. Individual nuts mature about a year after blossoming and normally fall to the ground. In plantation culture, clusters of mature nuts are cut from the trees with knives on long poles just before maturity. Picking individual nuts by climbing the trees is sometimes practiced.

Processing and products. The thick husks are removed from the nuts, which are then split open with a heavy knife and partially dried to loosen the meat. This is pried out of the shell and dried to about 7% moisture either in the sun, if conditions are favorable, or in kilns with additional heat often furnished by burning the husks and shells.

The oil from the dried coconut meats, or copra, is widely used for margarine, soap, and industrial purposes. High-quality copra may be shredded for confectionery and the baking trade. The residue, after oil removal, is used for animal feed.

Coconut husks are an important source of fiber called coir. In coir production, mostly limited to India, the nuts are harvested about a month before maturity and the husks retted in brackish water for 8–10 days to rot away the soft tissues between the fibers. The fiber is cleaned and washed by hand and dried. Recently the industry has become partially mechanized. The various grades of coir are used for ropes, mats and matting, and upholstery filling. *See* COIR.

In the tropics of both the Orient and the Occident the coco palm is the most useful of all plants to the native population. An important source of food and drink, it also furnishes building material, thatch, hats, dishes, baskets, and many other useful items. *See* NUT CROP CULTURE. Laurence H. MacDaniels

Diseases. Cadang-cadang (**Fig. 2**), a disease confined to certain islands of the Philippines, is caused by a viroid. This same agent is also present in the African oil palm and in the Buri palm. No vector is yet known. Since the disease affects mature palms, control is based on replanting with early maturing palms.

Red ring is caused by the nematode *Rhadinaphelenchus cocophilus* and is confined to tropical America. Transverse sections of stems from diseased palms show a typical ring. The disease is always lethal, causing death shortly after infection. The nematode is spread by a palm weevil (*Rhyncophorus palmarum*) which in turn is attracted by damaged palm tissues. Control is effected through sanitation and by the application of insecticides.

Heart rot is confined to tropical America and is caused by a trypanosomatid flagellate protozoon of the genus *Phytomonas*. This organism also attacks the African oil palm. Many of the symptoms resemble lethal yellowing. No effective control is known.

Bud rot is worldwide and is caused by the fungus *Phytophthora palmivora*, which attacks the

Fig. 2. Midstage symptoms of cadang-cadang. Fronds assume an erect position in the crown, and no nuts are being produced.

growing point and causes it to rot. There is no effective control.

Kerala wilt is a debilitating disease of coconut palms in southern India. It results in production of fewer buttons and nuts, reduction of nut size, and thinner husks. The cause is unknown.

Blast and dry bud rot affect young palms in the nurseries and right after planting. Both diseases seem most serious in newly released hybrids. Mycoplasma organisms have been suggested as the cause of blast in the Ivory Coast, where the insect *Ricelia mica* is the vector. *See* PLANT PATHOLOGY.

Coelacanthiformes

An order of lobefin fishes placed in the subclass Coelacanthimorpha and well known as fossils. Coelacanthiformes and the fossil suborders Rhizodontimorphi and Osteolepimorpha (rhipidistians) were once grouped as the subclass Crossopterygii. However, since it is now believed this assemblage is artificial, the coelacanth fraction was elevated to the subclass Coelacanthimorpha, with one order (Coelacanthiformes), four fossil families, and one extant family (Coelacanthidae).

Members are easily recognized by the two dorsal fins, by the paired pectoral and pelvic fins, and the anal fin, and by their symmetrical caudal fin with small central prolongation (**Fig. 1**). The only living fish with such features is *Latimeria chalumnae*; it is also the only extant fish with an intracranial joint, which otherwise occurs only in fossil rhipidistians. In 1952 its habitat was discovered to be the deep waters around the Comoro Islands. A new population of *Latimeria* was discovered in 1998 north of Sulawesi in the Indonesian archipelago.

Anatomy. The Coelacanthiformes (or Actinistia) are the only fishes with a special rostral organ, a deep postcoronoid in the lower jaw, a tandem double articulation of the lower jaw, a postspiracular bone, and an additional bone, the extracleithrum, in the shoulder girdle. Like lungfish, coelacanths lack the marginal upper jaw bone, the maxilla, and possess a short dentary. Except for two Devonian (*Miguashaia* and *Gavinia* with heterocercal tail) and a Carboniferous (*Allenypterus* with diphycercal tail) genus, coelacanths have a caudal fin with equal-sized upper and lower lobe of unbranched fin rays separated by an axial notochordal lobe (triphycercal tail).

On the snout are the three paired openings of the rostral organ in addition to the two paired openings of the nasal sacs (**Fig. 2**). The rostral organ has a central chamber from which three tubes diverge to both sides. It is an electroreceptive organ, unique in its shape and concentration of electroreceptors among fishes.

The lateral side of the lower jaw is formed by angular and splenial bones; a short toothed dentary lies above the splenial bone. The coronoid bones on the dorsal margin of the lower jaw and the prearticular on the inner side of the jaw carry small pointed teeth. The deep postcoronoid reaches high above the dorsal margin of the lower jaw and does not carry teeth. The posterior end of the lower jaw forms a double groove for the articulation (joint) of the double condyle (the rounded process at the end of a bone) of the quadrate and another groove for the symplectic bone (**Fig. 3**).

The posterior moiety (otico-occipital region) of the endocranium carries the brain with labyrinth (the hollow in the temporal bone); a long extension of the pituitary gland (pituitary foot) surpasses the articulation between posterior and anterior moieties and reaches to the base of the anterior. Below the brain cavity the notochord extends in a tube to the posterior end of the anterior moiety. A paired basicranial muscle connects ventrolaterally the anterior with the posterior moiety. The basicranial muscle together with jaw and gill arch muscles acts in the movement of the anterior moiety against the posterior (lifting the snout) and in the opening of the mouth (**Fig. 4**).

The shoulder girdle is composed of anocleithrum, cleithrum, clavicle, and extracleithrum (**Fig. 5**). An unpaired interclavicle unknown in *Latimeria* is

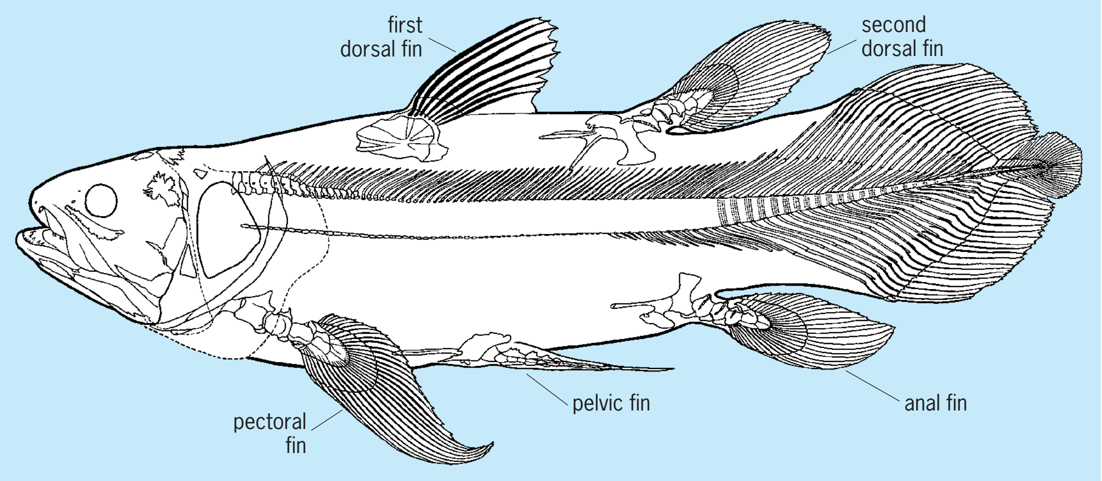

Fig. 1. Overall shape and internal structures of *Latimeria chalumnae*.

known from at least two fossil forms. The endoskeletal scapulocoracoid forms a knob on which the first mesomer of the axial endoskeletal elements of the pectoral fin articulates. Superficial muscles reach from the scapulocoracoid to the distal end of the axial skeleton and the bases of the fin rays; muscles connect internally the axial elements. This fleshy lobe is covered by small scales. The pelvic, second dorsal, and anal fins show the same structure. The first dorsal fin lacks axial elements and the fleshy lobe. The fin rays are articulated but not branched except for one Devonian genus. The exposed surface of the round scales is covered by ridges or tubercles converging toward the median posterior tip of the scales. The vertebral column is formed by an unrestricted notochord with neural arches and spines dorsally and with hemal arches and spines ventrally in the caudal region; ribs occur in some fossil forms. The notochordal fluid is considered by some Far Eastern people to be a life-prolonging elixir. The lung of *Latimeria* is an elongated oil organ well adapted to a deep-water existence. In contrast, fossil coelacanths were shallow-water dwellers with a much larger ossified lung. The intestine is formed as a scroll or longitudinal valve. The rectal gland is a salt-excreting organ which developed in parallel to that of cartilaginous fishes and serves for osmoregulation with high retention of urea. Coelacanths are carnivorous; fish are known to be stomach content in the extant *Latimeria* and in fossil forms.

Reproduction. *Latimeria* shows sexual dimorphism; the female is longer (measuring up to 1.8 m or 6 ft) than the male (up to 1.4 m or 5 ft). Reproduction is by internal fertilization even though the male has no intermittent organ. *Latimeria* has the largest eggs (9 cm or 3.6 in. in diameter) of any bony fish. It is ovoviviparous; up to 30 developing juveniles have been found in one female. Ovovivipary occurs also in Mesozoic coelacanths. Yolk-sac-carrying juveniles of comparatively small Paleozoic coelacanths have been found fossilized; these finds, in addition to the occurrence of unhatched specimens, indicate egg-laying early coelacanths.

Fossil record. Coelacanths are known since the Middle Devonian. They reach high diversity in the Early Triassic and Late Jurassic. Coelacanths acquired their common structure in the Carboniferous. The number of morphological changes is minor thereafter. There is no fossil record for the last 80 million years. The last known fossil coelacanths from the Upper Cretaceous of North America are also the largest known (estimated length of 3.5 m or 11 ft for *Megalocoelacanthus*). Fossil coelacanths are distributed worldwide; Paleozoic forms are known exclusively from the Northern Hemisphere, whereas Mesozoic forms have been found also in southern continents. Most fossil records refer to marine forms;

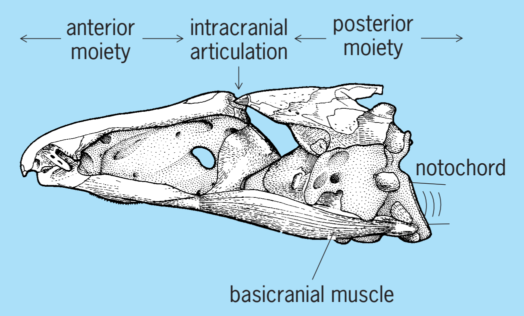

Fig. 4. Endocranium of *Latimeria*.

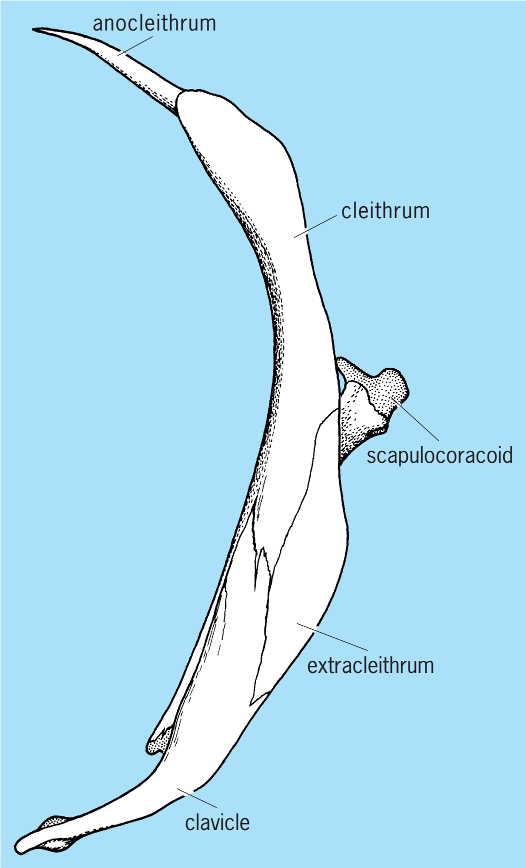

Fig. 5. Shoulder girdle of *Latimeria*.

nevertheless, some coelacanths were able to enter fresh water. *See* FOSSIL.

Relationship. The phylogenetic position of the coelacanthiforms within sarcopterygian fishes is debated. Within extant fishes, they may be closer to tetrapods than to the lungfish, or vice versa. Even the possibility that both coelacanthiforms and lungfish are more closely related to each other than each is to tetrapods is postulated. In any case, both are not close relatives of tetrapods; the latter are related to rhipidistian fishes, especially Elpistostegalia. The living coelacanth is not, as often written, a survivor of human ancestry. *See* OSTEICHTHYES; SARCOPTERYGII.

Coelom

The coelom is the mesodermally lined body cavity of most animals above the flatworms and nonsegmented roundworms. Its manner of origin provides one basis for classifying the major higher groups.

Annelida. Annelids, arthropods, and mollusks have a coelom which develops from solid mesodermal bands. Within the trochophore larva of annelids, a single pole cell proliferates two strips of mesoblast lying on either side of the ventral midline. These bands subdivide transversely into bilateral solid blocks, the somites. Each somite then splits internally to form a hollow vesicle, the cavity of which is the coelom. The somitic vesicles of each side expand until their surfaces become apposed above and below the gut, thus forming its supporting mesenteries. The anteroposterior surfaces of contact between somites form the septa between segments of the body. In some of the annelids which have developed a parasitic mode of life, as the leeches, septa disappear between segments, and the coelom is much reduced by encroachment of mesenchymatous tissue. *See* ANNELIDA.

Mollusca. The mollusks also form bands of mesoderm from a single pole cell, but these bands do not segment. They split internally to form single right and left coelomic sacs, but the cavities are soon reduced and the surrounding mesoblast disperses as separate cells, many of which become muscle. The only remnants of the coelom in the adult are the pericardial cavity and the cavities of the gonads and their ducts. *See* MOLLUSCA.

Arthropoda. In arthropods paired bands of mesoblast may proliferate from a posterior growth center or may separate inward from a blastoderm, a superficial layer of cells, on the ventral surface of the egg. These bands divide into linear series of somites which then hollow out. Their cavities represent the coelom. The upper wall of each somite moves dorsally to meet its partner from either side and fuse into a longitudinal tube, the heart. The outer and inner somitic walls give rise to muscles of the body wall and gut, respectively. The lower wall may form fat body or move into the appendages to form excretory organs or glands. In adult arthropods the coelom persists only as small cavities within the segmental excretory organs or glands and as the cavities of the gonads and gonoducts. *See* ARTHROPODA.

Echinodermata and Chordata. Echinoderms and chordates constitute a second major group, characterized by the origin of the coelom from outpocketings of the primitive gut wall. In echinoderms one pair of bilateral pouches evaginates and separates from the archenteron or primitive digestive cavity. Each pouch constricts into three portions, not homologous to the metameres of other animals. Of these the left middle coelom assumes major importance, giving rise to the water-vascular system and primordia of the radii of the adult. Contributions to the stone canal and axial sinus are made by the left anterior coelom. The rearmost cavities are converted into the main perivisceral coelom of the adult. *See* CHORDATA; ECHINODERMATA.

Protochordata. The protochordates of the groups Hemichordata and Cephalochordata exemplified by *Balanoglossus* and *Branchiostoma*, respectively, have three coelomic pouches formed by separate evaginations of the archenteral roof. The first or head cavity is single and median in origin, the other bilateral and paired. In hemichordates the head cavity remains single as the cavity of the proboscis and has a pore to the exterior on each side. The second pouches form cavities within the collar and also acquire external pores. The third pair is contained within the trunk and forms the major perivisceral cavity.

Cephalochordata. In cephalochordates the head cavity divides into lateral halves. The left side communicates, by a pore, to an ectodermal pit called the wheel organ. The second pair of pouches forms the pair of mesoblastic somites, and the third pouches subdivide transversely to give rise to the remainder of the linear series of somites. The upper or myotomic portion of each somite remains metameric and forms the segmental muscles. As it enlarges, the coelomic space is displaced ventrally and expands above and below the gut to form the perivisceral cavities and mesenteries, as described for annelids. However, the transverse septa perforate and disappear between adjacent somites, so that a continuous anteroposterior body cavity is formed on either side of the gut.

Vertebrata. In vertebrates the mesoderm arises as a solid sheet from surface cells that have been involuted through the blastopore. Lateral to the notochord, beginning at about the level of the ear, the mesoderm subdivides into three parts: (1) the somites; (2) the nephrotomic cord, temporarily segmented in lower vertebrates, which will form excretory organs and ducts; and (3) the unsegmented lateral plate. The coelom arises as a split within the lateral plate. In lower vertebrates the split may continue through the nephrotome into the center of the somite, thus resembling the condition in *Branchiostoma*. Such dorsal extensions are soon lost. The lateral plate expands to meet its partner of the other side, thus forming the body cavity and mesenteries of the gut. *See* GASTRULATION; INVERTEBRATE EMBRYOLOGY.

Howard L. Hamilton

Coelomycetes

Filamentous fungi that reproduce asexually by making spores inside microscopic fruiting bodies. Estimates of the number of genera range up to 1000, with the number of species between 7000 and 10,000. They are especially numerous on living or decomposing plants, but they can occur on several other substrata. Many are plant pathogens. A few have been isolated in clinical or veterinary settings. Although all members of the group reproduce asexually by making their spores (conidia) via mitosis, some species also have known sexual states (teleomorphs) which produce spores via mating and meiosis.

Taxonomy and identification. The group Coelomycetes was accorded formal status in traditional fungal taxonomy, but it has long been recognized that this group is artificial (nonphylogenetic, that is, encompassing multiple evolutionary lineages). Most members are asexual states of fungi traditionally classed as ascomycetes (Ascomycota), and a very few are asexual states of basidiomycetes (Basidiomycota). Some mycologists now prefer to write the name in lowercase (coelomycetes) to accentuate the nonphylogenetic nature of the group. The coelomycetes are one of three groups of fungi (coelomycetes, hyphomycetes, and mycelia sterilia) reproducing asexually and collectively referred to as imperfect fungi or deuteromycetes. Other names for this collective group are anamorphic fungi or, for those producing conidia, mitosporic fungi. By convention, asexual states of ascomycetes and basidiomycetes are included in deuteromycetes, and asexual states of Zygomycetes are usually excluded. *See* ASCOMYCOTA; BASIDIOMYCOTA; ZYGOMYCETES.

The traditional orders are Melanconiales, Sphaeropsidales, and Pycnothyriales, which correspond to coelomycetes producing fruiting bodies that are disklike with wide apical openings (acervuli, **Fig. 1**), globose with restricted apical openings (pycnidia, **Fig. 2**), or flattened with small apical openings (pycnothyria). Members of the first two orders are much more common and more important as plant pathogens than members of the third order. Each order is also nonphylogenetic, so

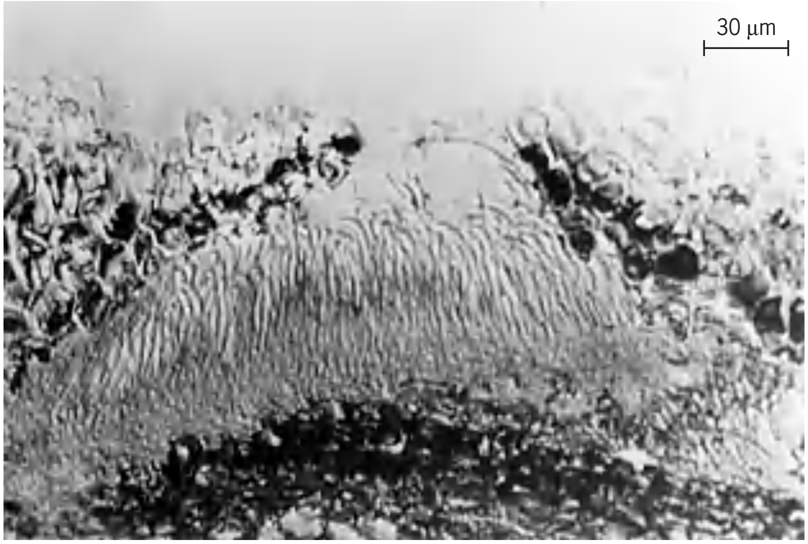

Fig. 1. Section of a typical acervulus, produced by the fungus *Cryptosporiopsis curvispora*, a cause of branch canker and fruit rot of apple.

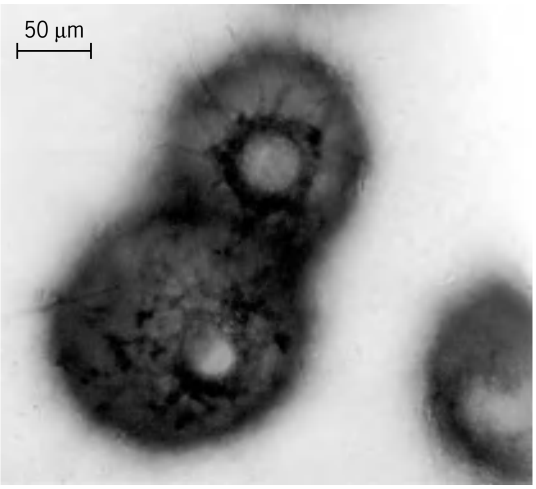

Fig. 2. Surface view of typical pycnidia, produced by the fungus *Ascochyta pinodella*, a cause of stem and leaf spot of pea.

contemporary mycologists often abandon the formal names of the orders and simply refer to acervular, pycnidial, or pycnothyrial fungi. For some fungi, the morphology of the fruiting bodies (conidiomata) is variable or otherwise nonconforming to the above terminology. In such instances, all the above terms may be discarded, and the conidiomata are described in terms of the number of cavities (locules), shape and dimension, wall construction, color, and so on. Of equal or greater importance in modern classification is the structure of the cells that produce the conidia (conidiogenous cells). This approach, first formulated for hyphomycetes by S. J. Hughes, was applied to the coelomycetes by B.C. Sutton, whose name became synonymous with coelomycete taxonomy. Contemporary identification relies on structure and color of the conidia, conidiogenous cells, conidiomata, and proper identification of the host plant. Routine diagnosis still depends on taxonomic keys and descriptions, especially those of Sutton, or the taxonomically more conservative keys of J. A. von Arx, plus literature specific to a given host. Increasingly, DNA sequence data are used in research. Commercial identification kits utilizing molecular-genetic technology are available for a small number of coelomycetes. *See* HYPHOMYCETES.

Cultivation and preservation. Most common coelomycetes can be grown on a variety of artificial, agar-based media. However, the ability to produce conidia or other reproductive structures (such as thick-walled spores called chlamydospores or multicellular structures called sclerotia) may be enhanced by the proper choice of medium. Some coelomycetes may not produce in culture the structures that characterize their growth on plants, and this is especially true of fungi that are acervular *in planta*. Prolonged growth and repeated transfers on artificial media may impair formation of structures or pathogenic abilities. Coelomycetes producing abundant conidia on artificial media usually can be preserved for many years by lyophilization, in glycerol in ultralow-temperature freezers, or in liquid nitrogen vapor. Alternatively, some species will produce conidia on sterilized filter paper squares placed on top of an agar medium. The squares can be removed, desiccated, placed in sterile envelops, and stored in a conventional freezer (approximately −15 to −20°C).

Biology, economic importance, and control. Plant pathogenic genera from temperate and tropical climates have received the greatest attention. Among those with highest impact are *Ascochyta, Colletotrichum*, and *Phoma* species on fruits and vegetables, and *Septoria* and *Stagonospora* species on cereal grains. A given species may parasitize leaves, stems, or fruits of the growing plant, or may be a postharvest pathogen on stored produce. Several genera (for example, *Cryptosporiopsis, Marssonina, Phomopsis*) cause stem cankers on berry bushes or on trees producing fruits or nuts. *Diplodia, Macrophoma*, and *Phomopsis* cause diseases on grape vines or grapes. Species in some genera (such as *Phomopsis, Sphaeropsis*) attack forest trees. *Colletotrichum, Cryptocline, Phomopsis*, and *Sphaceloma* present disease problems for the ornamental flower industry. *Ascochyta, Selenophoma, Septoria,* and *Stagonospora* afflict turf grasses. Fiber crops are attacked by *Colletotrichum* (on cotton, flax, and jute) and *Ascochyta* and *Phomopsis* (on hemp). For important species in which the teleomorph is abundant, much research has focused on the implications that sexual recombination of genes has for generation of new races, fungicide resistance, or enhanced aggressiveness. Sometimes epidemics in field crops are initiated by wind-blown sexual spores (ascospores), in which case control of the sexual stage becomes as important as control of the conidial state. Conidia are usually produced later in the season, are more abundant than ascospores, and tend to be produced in sticky masses dispersed by rain splash or irrigation. Control may be via breeding of resistant plant cultivars, fungicide applications, or cultural practices. In clinical situations, infection by coelomycetes usually occurs through wounds. Itraconazole, an antifungal compound, has been used successfully for therapy. A few coelomycetes are parasitic on lower animals; for example, *Aschersonia* is known as a pathogen of scale insects and whiteflies. Species with saprophytic capabilities can become destructive if colonizing manufactured materials, such as occurs with some *Phoma* species on carpet, paper, or plastics. However, coelomycetes are also recovered in studies of decaying plant litter, where they probably play a beneficial role. Frank Dugan

Coenopteridales

True ferns which span the Late Devonian through Permian time between the recognizable beginnings of fernlike morphology and the earliest-appearing extant filicalean families (Gleicheniaceae, Osmundaceae). A true fern is a relatively advanced type of vascular land plant with distinct stem, fronds, roots, and foliarborne annulate sporangia. Coenopterid ferns are mostly small and simple in contrast to late Paleozoic tree ferns of the Marattiales. All well-known genera of the Coenopteridales in the Pennsylvanian Period exhibit fronds with circinate vernation (croziers), laminate vegetative foliage, and annulate sporangia. Their stems are mostly protostelic with a few siphonostelic species, and one genus (*Zygopteris*) has secondary growth. These ferns are better from anatomically preserved specimens, especially from peat beds, than from coalified compressions, but they occurred in a variety of habitats mostly known on Northern Hemisphere continents. Their fronds have distinct vascular strands, useful in identifying genera (**Fig. 1**).

There are two major distinct groups. Zygopterid ferns are the most ancient and diverse, and apparently a dead-end evolutionary line; they differ the most from other ferns. *Zygopteris* (Zygopteridaceae: Etapteroideae) had dichotomous rhizomes with distantly spaced erect fronds exhibiting three-dimensionally arranged primary pinnae in four rows. Sessile sori of elongate multiseriate sporangia with paired annuli and with sclerotic nests in their interannular walls were borne abaxially on laminate foliage in *Corynepteris* or trailed from pinnae on slender stalks in *Biscalitheca* (**Fig. 2**). Coenopterid ferns are usually placed in the Anachoropteridaceae and Botryopteridaceae, or in one of several extinct families assigned to the Filicales. Coenopterid ferns *sensu stricto* are probably ancestral to, and consequently form an imperceptible transition with, the Filicales. The best-known genera, *Anachoropteris* and *Botryopteris*, commonly have semierect (like *Osmunda*), protostelic rhizomes with closely spaced fronds bearing two rows of branched pinnae, occasional to frequent buds or vegetative shoots, laminate foliage except on some fertile pinnae, and small to large clusters of uniannulate sporangia. Some of the Pennsylvanian-age fern genera (*Sermaya, Doneggia*) with *Anachoropteris*-like anatomy have been assigned to the filicales as members of an extinct family, Sermayaceae.

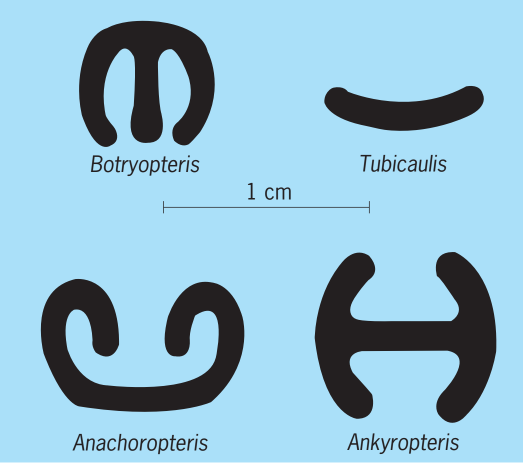

Fig. 1. Diagrammatic cross sections of petiolar vascular strands of representative coenopterid genera, oriented so the parent stem would appear below each diagram.

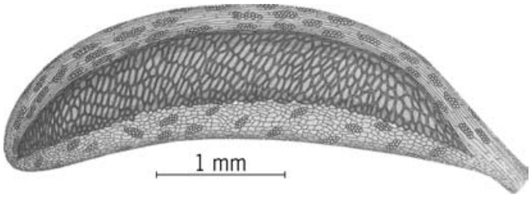

Fig. 2. Side-view reconstruction of ***Biscalitheca musata***, a zygopterid sporangium with dorsiventral symmetry, two lateral multiseriate annuli, and small nests of thickened cells in the sporangial wall. (***After S. H. Mamay, Amer. J. Bot., 44(3):236, 1957***)

Evolution of stelar morphology from protostelic to siphonostelic, with or without leaf gaps, is demonstrated in the Anachoropteridaceae and Botryopteridaceae in the Pennsylvanian. Sporangia of various coenopterid genera are osmundoid, gleichenioid, or schizaeoid, generalized and simple morphological types.

The Zygopteridaceae appear in Late Devonian time, the Botryopteridaceae in Visean (Mississippian), the Anachoropteridaceae in the lower Westphalian A (Pennsylvanian), and all families extend into the Permian. *See* PALEOBOTANY.

Coenurosis

The infection by the larval stage of several species of *Taenia* from canids, such as *T. multiceps, T. serialis*, and *T. brauni*. It is rare in humans. A bladder as large as a hen's egg and containing scolices (protoscolices) forms and daughter bladders bud off either internally or externally, attached by stalks. In subcutaneous or ocular locations the bladders are unilocular, but in the central nervous system they are frequently multilocular (racemose). Symptoms are the result of toxic and allergenic metabolites and pressure effects. Surgery may be attempted; chemotherapy may be effective, but secondary effects still render a poor prognosis.

Herbivores feeding on grass contaminated by the parasite's eggs also develop coenurosis. If the central nervous system is involved (as is frequent in sheep) neurological signs appear and the animal staggers and circles. Such an animal is said to be giddy (thus the origin of the term "gid tapeworm"). Economic losses in sheep-raising regions due to coenurosis are considerable. The disease could be controlled by treatment of shepherd dogs. *See* CYCLOPHYLLIDEA.

José F. Maldonado-Moll

Coenzyme

An organic cofactor or prosthetic group (nonprotein portion of the enzyme) whose presence is required for the activity of many enzymes. In addition, many enzymes need metal ions, such as copper, manganese, and magnesium, for activation. The prosthetic groups attached to the protein of the enzyme (the apoenzyme) may be regarded as dissociable portions of conjugated proteins. The conenzymes usually contain vitamins as part of their structure. Neither the apoenzyme nor the coenzyme moieties can function singly, since dissociation of the two results in inactivation. In general, the coenzymes function as acceptors of electrons or functional groupings, such as the carboxyl groups in α-keto acids, which are removed from the substrate. Some of the well-known coenzymes are mentioned below. *See* PROTEIN; VITAMIN.

The pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), function as hydrogen acceptors for a large number of dehydrogenase enzymes. Thiamine pyrophosphate (TPP), or cocarboxylase, the prosthetic group of carboxylase, is responsible for the decarboxylation of α-keto acids in the body. Flavin mononucleotide (FMN) and flavinadenine dinucleotide (FAD) act as hydrogen acceptors in aerobic dehydrogenases. Pyridoxal phosphate, also known as codecarboxylase and cotransaminase, serves as coenzyme for various racemases in reactions involving the decarboxylation of α-amino acids, and also functions in transamination.

Iron protoporphyrin (hemin) acts as coenzymes of catalase, peroxidases, and cytochromes. The uridine phosphates are involved in carbohydrate metabolism. Uridine diphosphate (UDP) is the chief transferring coenzyme for carbohydrates. UDP-glucose is responsible for the interconversion of glucose and galactose, is used in the synthesis of glycogen, and can be oxidized to UDP-glucuronate for the synthesis of glucuronides and chrondroitin or converted to UDP-galactose for the synthesis of lactose and chrondroitin.

Adenosine triphosphate (ATP), adenosine diphosphate (ADP), and adenosine monophosphate (AMP), the phosphorylated derivatives of adenylic acid, can be active in phosphate transport or transphosphorylation or both. Lipoic acid functions in acyl-generating and in acyl-transfer reactions. In combination with TPP and NAD, it functions in oxidative decarboxylation of α-keto acids. Coenzyme A (CoA), a coenzyme in certain condensing enzymes, acts in acetyl or other acyl group transfer and in fatty acid synthesis and oxidation. Folic acid coenzymes are involved in the metabolism of one carbon unit. Biotin is the coenzyme in a number of carboxylation reactions, where it functions as the actual carrier of carbon dioxide. *S*-Adenosylmethionine, active methionine, functions is transmethylation reactions. *See* ADENOSINE DIPHOSPHATE (ADP); ADENOSINE TRIPHOSPHATE (ATP); BIOCHEMISTRY; BIOLOGICAL OXIDATION; BIOTIN; CARBOHYDRATE METABOLISM; CYTOCHROME; ENZYME; HEMOGLOBIN; NICOTINAMIDE ADENINE DINUCLEOTIDE (NAD); NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE (NADP); URIDINE DIPHOSPHOGLUCOSE (UDPG).

Coesite

A naturally occurring mineral of wide interest, the high-pressure polymorph of SiO_2. Coesite was first discovered and identified in various meteorite impact craters and in some tektites. Because it requires a unique physical condition, extremely high pressure, for its formation, its occurrence is diagnostic of a special natural phenomenon, in this case, the hypervelocity impact of a meteorite.

Coesite occurs in grains that are usually less than 5 micrometers in size and are generally present in small amounts. The properties of the mineral are known mainly from studies of synthesized crystals. It is colorless with vitreous luster and has no cleavage. It has a specific gravity of 2.915 ± 0.015 and a hardness of about 8 on Mohs scale. It is biaxial positive with $2V$ about 64°. Its indices of refraction are α 1.5940, β 1.5955, and γ 1.5970 ± 0.0005. Its dispersion is horizontal, with r less than v (weak). The optical orientation is $X = b$, $Z \angle C = 4\text{–}6^\circ$, and $\beta = 120^\circ$. Synthetic crystals occur as euhedral to subhedral hexagonal platelets, and laths with positive elongation. Simple contact twins occur with (021) as twin and composition plane.

Natural coesite can be identified from thin sections of rocks by its peculiar habit and high index of refraction. However, its positive identification must rest on the x-ray powder diffraction technique.

Coesite has as yet no evident commercial use and therefore has no obvious economic value. As a stepping-stone in scientific research, it serves in at least two ways: where it occurs naturally, coesite is diagnostic of a past history of high pressure; the natural occurrence of coesite suggests that shock as a process can transform a low-density ordinary substance to one of high density and unique properties.

Coesite has been found in materials ejected from craters formed by the explosion of 500,000 tons (450,000 metric tons) of TNT. The study of coesite and craters is important to the understanding of the impact craters on the Earth as well as those on the Moon. Edward C. T. Chao

Coffee

A tropical evergreen shrub or small tree of the genus *Coffea* (Rubiaceae), a native of northeast Africa and adjacent southwest Asia. The beverage known as coffee is made by the hot-water extraction of solubles from the ground roasted beans (seeds) of the shrub. *Coffea* grows mainly between the Tropic of Cancer and Tropic of Capricorn at elevations of 2000–6000 ft (600–1800 m) above sea level, at temperatures near 70°F (21°C), and with annual rains near 60 in. (150 cm).

Annual international commerce is about 75 million bags (standard of 130 lb or 60 kg per bag) of green coffee beans, that is, coffee beans that have been cultivated, harvested, and are ready for commercial processing. The supply generally is a third each from Brazil, Africa, and all other countries. The United States and Europe consume 85% of all world exports. Coffee beverage has no nutritive value and is consumed for its flavor and stimulating effects. The stimulating ingredient in coffee is caffeine. The two main coffee varieties are Arabica with about 1.1% caffeine and Robusta with 2.2%. *See* CAFFEINE.

History. The *C. arabica* shrub (**Fig. 1**) is native to Ethiopia, where it grows wild in rainforests, and its seeds have been used by the native populations since before recorded time. The *C. robusta* shrub grows taller (to 20 ft or 6 m) than the Arabica shrub and is more productive and hardy. It grows in warmer climates and is native to the Congo area south of Ethiopia. About A.D. 900, Arabs planted the Ethiopian coffee shrub in Yemen, and for 700 years coffee propagation was limited to this area.

Fig. 1. *Coffea arabica* branch.

Commercial coffee cultivation was started by the Dutch in Java and Ceylon in the late 1600s; by the French, English, and Spanish in the West Indies in the early 1700s; in Mexico, Central America, and Hawaii in the early 1800s; in Colombia about 1900; and in Africa in the late 1940s. Brazil had been the dominant supplier since the early 1800s, but its dominance receded in favor of African coffee. However, Brazil has become a large producer of soluble coffee powder, producing over 60 million pounds (27 million kilograms) per year.

Green coffee cultivation. The coffee plant is a shrub or relatively small tree, often controlled to a height of 15–18 ft (4.5–5.5 m). *Coffea arabica* (milds) accounts for 69% of world production; *C. canephora* (robustas), 30%; and all others, 1%. Each species includes several varieties.

After the spring rains, the plant produces white flowers. About 6 months later the flowers are replaced by fruit the size of a small cherry (Fig. 1). The cherries can be underripe, ripe (red, yellow, and purple color), and overripe; and they can be selectively picked to harvest only ripe ones, or strip-picked to yield mostly ripe but also some over- or underripe fruit. The green coffee beans are the two halves of the seed derived from the processed cherries. Franklin Kramer

Diseases. There are more than 350 known diseases of coffee, and new ones are still being discovered on *C. arabica*, *C. robusta*, *C. liberica*, and *C. excelsa* in widely separated tropical lands. Probably no crop grows under more varied conditions or is subjected to so many unknown diseases.

Leaf rust (caused by *Hemileia vastatrix*), one of the most important diseases of the crop worldwide, was described as early as 1869 in Ceylon, where there were once flourishing coffee plantations. Rust became so damaging that, in the absence of control measures, coffee production had to be abandoned. In Eastern and African coffee-producing countries, rust restricted cultivation of coffee to particular altitudes and districts, rendering cultivation more expensive and difficult. As a consequence, the center of the world's potential coffee production shifted to Brazil and other South and Central American countries, where leaf rust was unknown until 1970. Control of the disease can be achieved by fungicidal sprays, but this inevitably increases production costs. Development of resistant varieties is complicated because of the existence of many different races of the coffee rust fungus, but some new introductions show promise.

Other diseases, which are less widespread than leaf rust, have also been extremely damaging. In East Africa, bark disease (caused by *Fusarium stilboides*) destroyed the once-flourishing coffee

Fig. 2. Coffee berry disease (caused by *Colletotrichum coffeanum*). Berries, which may be infected at any stage of development, are completely destroyed.

industry of Malawi and, in the late 1960s, berry disease (caused by *Colletotrichum coffeanum*; **Fig. 2**) devastated the crop in Kenya and threatened the viability of the coffee production. Fungicidal sprays now give control. Berry disease spread from Kenya to all other African coffee-producing countries, but is unknown outside the African continent.

American leaf spot (caused by *Mycena citricolor*) is very serious but is found only in the Americas, whereas Cercospora leaf spot and the leaf rot caused by *Pellicularia koleroga* occur in both hemispheres. The last two diseases are controlled by spraying.

Fruit, stem, and branch infections are injurious. Wilts and trunk cankers, caused by *Gibberella, Nectria*, and *Ceratocystis*, are troublesome. Probably six *Rosellinias*, a few *Fusaria*, two *Armillarias*, and fungi like *Fomes, Ganoderma*, and *Polyporus* attack roots. Root and trunk infections are reduced by good cultural practices. Coffee is also affected by some half dozen viruses, a few bacteria, and numerous parasitic mistletoes. *See* FUNGISTAT AND FUNGICIDE; PLANT PATHOLOGY; PLANT VIRUSES AND VIROIDS.

Ellis Griffiths

Coffee cherry processing. Coffee cherries are processed by either dry or wet methods. Dry-method products are so-called natural coffees, while wet-method products are usually the more uniform and higher-quality washed coffees.

The dry method is used in Brazil and in other countries where water is scarce in the harvesting season. The cherries from strip picking are spread on open drying ground and turned frequently to permit thorough drying by the sun and wind. Sun drying usually takes 2–3 weeks, depending on weather conditions. Some producing areas use hot air, indirect steam, and other machine-drying devices. When the coffee cherries are thoroughly dry, they are transferred to hulling machines that remove the skin, pulp, parchment shell, and silver skin (a thin cellulosic layer that envelops the coffee bean) in a single operation. In Colombia, freshly picked ripe coffee cherries are fed to a tank for initial washing and removal of stones and other foreign material. The cherries are then transferred to depulping machines that remove the outer skin and most of the pulp, although some pulp mucilage clings to the parchment shells that encase the coffee beans. This is removed in fermentation tanks, usually containing water, a process that may last from 12 h to several days. Because prolonged fermentation may cause undesirable flavors and odors in the beans, enzymes may be used to speed up the process.

The beans are then dried, either in the sun or in mechanical dryers. Machine drying has become more popular in spite of higher costs, because it is faster and independent of weather conditions. After drying, the coffee is further processed in machines that remove silver skins, producing green coffee beans. The coffee beans are then machine graded by screens, oscillating tables, and airveying (pneumatic conveying) into large, medium, and small beans. Damaged beans or foreign materials are removed by hand or by mechanical sorting devices. The beans are then further graded according to appearance, color, and cupping of roasted samples. After processing, the green beans have 10–12% moisture and maintain acceptable quality for about a year.

Coffee chemistry. Chemical analysis of green coffee reveals a complex chemical composition (**Table 1**). The main differences between milds and robustas are caffeine content (higher for robusta coffee), lipids (higher for milds), chlorogenic acid (higher for robusta), trigonelline (higher for milds), and sucrose (higher for milds).

Green coffee has no desirable taste or aroma—these qualities result from roasting. Many complex physical and chemical changes occur during roasting, including the change in color from green to brown. In the first stage of roasting, free water is removed. In the second stage, chemical reactions lead to the formation of compounds associated with aroma and flavor.

Some reactions during roasting are exothermic. These produce a rapid rise in temperature, usually accompanied by a sudden expansion or puffing of the beans, with a volume increase from 50 to 100% depending on the bean variety and roasting conditions. The relatively high value of caffeine in brewed and instant coffee solids (**Table 2**) is due to the very high solubility of caffeine in hot water compared to the other constituents in the roasted beans. The total solids content in a brewed cup of coffee is 0.7–1.2%; espresso coffee has about 3–5% solids. Most aromatic compounds are lost or changed in the instant coffee

TABLE 1. Typical analyses of green coffee, %

Constituent[*]	Type[†]	
	C. canephora (robustas)	*C. arabica* (milds)

[‡] Others by difference.

processing steps. Instant coffee producers are particularly interested in the nature of these compounds and how to capture and include them in the final product.

Green-bean processing. A series of basic bean processing steps is required to produce the major types of commercial coffee products (**Fig. 3**). First, the green beans are weighed and cleaned, and then they are stored in silos, each containing a single bean type. Green coffee beans to be used for decaffeinated coffee products are processed separately to remove the required amount of caffeine (usually 97% in the United States) and then stored in special silos before further processing.

Roasting and grinding technology. Roasting and grinding are key steps in producing all coffee products.

Roasting. The roasting step, including the type of beans, roasting machinery, and operating parameters (particularly temperature and time), is the most important operation in defining the final product characteristics. Roasting is performed with individual bean types, blended beans, decaffeinated beans, and beans with additional ingredients—for example, sugar and chicory may be added to form specialized flavored coffees.

Roasting is usually conducted by use of hot combustion gases in rotating cylinders or fluidized-bed systems. Infrared and microwave energy has been used to a limited extent in the Far East. The hot-gas roasters are designed for batch and continuous operations. Batch cylinder roasters, which continue to be used only by smaller producers and for specialty products, traditionally have had roasting times of 10–20 min. Fluidized-bed batch roasters roast beans for 2–5 min. Continuous roasters, which are available in cylinder and fluidized-bed form and can achieve very short roasting times, are best suited for large producers that are roasting a consistent blend.

After moisture has been eliminated and the bean

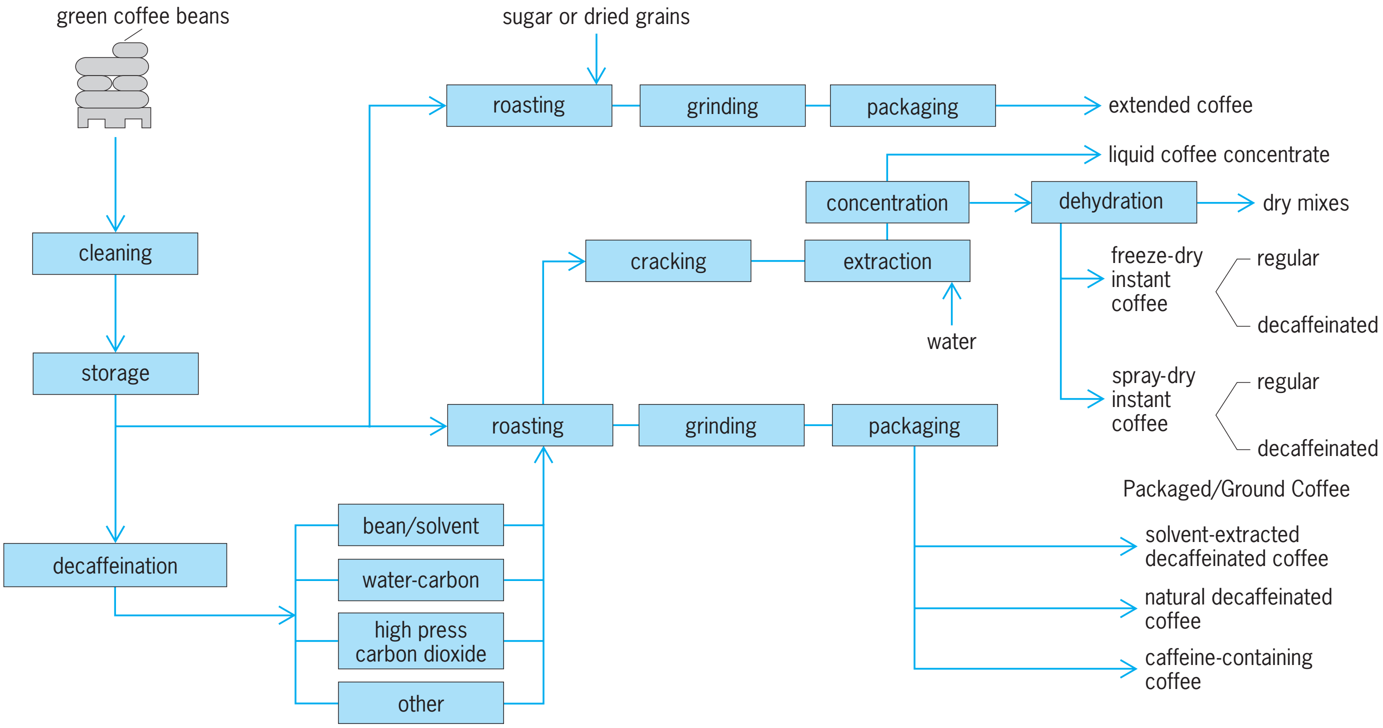

Fig. 3. Flow chart showing the basic processing steps for producing coffee products from green coffee beans.

temperature has reached 330°F (166°C), the reaction changes from endothermic to exothermic, and the required features of the roasted product begin to develop while the beans swell to as much as twice their original size. When the bean temperature reaches 375–475°F (190–246°C), roasting is terminated by rapidly adding a water quench. The final roast temperature is the critical control point that fixes the flavor and color of the product, and it must be consistent for good quality control. Periodic photometric reflectance tests on a ground sample are used for fine-tuning the required bean temperature just before quenching. The water quench adds moisture (usually 2–4%) to the roasted beans.

The faster fluidized-bed roasters are used for producing high-yield coffee. This method provides faster roasting with significantly lower combustion gas temperatures, resulting in more uniform temperature within the beans and hence a larger percentage of soluble solids. Such coffees lend themselves to the low-weight packaged roast and ground coffee, and offer higher yield opportunities for instant coffee processes. Roasting gas temperatures range from 450 to 750°F (230 to 400°C). The exhausted roaster gas normally requires afterburners to remove particulates to conform with environmental regulations. *See* FLUIDIZATION.

The quenched beans are air cooled and conveyed to storage bins for moisture and temperature equilibration prior to grinding. Residual foreign material (mostly stones) that has passed through the initial cleaning step is removed in transit to the storage bins by means of a high-velocity air lift, which leaves the heavier debris behind. The separation is much more efficient at this point because bean density has been reduced by the roasting step.

Grinding. Grinding of the roasted coffee beans is tailored to the requirements of the intended beverage preparation. For example, only coarse cracking of the beans is needed for instant coffee, whereas finer grinds are required for packaged roast and ground coffee.

The most commonly used grinder is a multistep steel roll mill. After passing through a pair of coarse cracking rolls, the broken beans pass through two successive sets of paired longitudinally scored rolls that are operated at speeds designed to cut, rather than crush, the particles. The second set of rolls are more finely scored and operate at higher speeds. The final part of the roll grinder is the normalizer mixing section, to provide a uniform distribution. Particle size is controlled by regulation of roll separation.

Instant coffee processing. Instant coffee comprises the dried solids made from water extraction of the soluble solids in roasted and partially ground (cracked) coffee. The extraction process follows the same principle as home brewing using a filter-drip percolator, except that it is much more efficient and results in very high solid-extraction yields. The countercurrent staged extraction system consists of a battery of 5–10 vertical columns connected by appropriate manifolds of pipes and valves. The water, heated under pressure to 300–350°F (150–180°C), circulates countercurrent to the cracked roasted coffee by intermittent column stage position changes. The columns do not move, but by valve changes the flow of water is stepwise from the final fresh column to the fully extracted first position, each step lasting 30–45 min. The flowing extract is cooled just prior to the final fresh column so that the finished extract is collected at 150–180°F (66–85°C). Yields of 40–60% by weight of roasted coffee are achieved, depending on the flow rates, type of coffee used, and heat input. *See* EXTRACTION.

The coffee extract is concentrated from about 20–35% to 50% by using multiple-effect vacuum evaporators or freeze concentration, or a combination of both. The flavor of the final dry product can be enhanced by recovering the aroma and flavor compounds prior to, or as part of, the concentration process and then introducing these to the concentrated extract just before drying. The method of drying defines the instant coffee as either spray dried or freeze dried. Spray drying involves spraying the concentrated aroma-enhanced extract into a concurrently flowing stream of hot combustion gases. The amount of flavor retained is greater as the concentration of sprayed droplets increases. The dry product is collected at the bottom of the dryer as a powder of spherical particles. Its appearance and solubility are improved by forming agglomerates of the particles, usually by mixing them with a flow of steam that condenses on them to provide adhesive. The excess moisture is then removed by air drying.

Freeze drying uses special high-vacuum equipment to remove water from the frozen extract by sublimation. The vacuum has to be maintained below 0.5 mmHg (67 pascals). The very low temperature maintained during the drying period minimizes flavor changes and aroma losses. Freeze-dried coffee is more expensive to produce and requires a much higher investment than the spray-dried product. *See* DRYING.

Decaffeinated coffees. Decaffeinated coffees represent about 18% of the total coffee consumption in the United States. Decaffeinated coffee was commercially developed in Europe about 1900. The early process involved direct contact of water-moistened beans with a solvent. The principle of moisturizing green coffee before decaffeination remains a key process step for all decaffeination processes, because it facilitates transport of caffeine through the cell walls. The older European process requires removing the solvent from beans by steam distillation, followed by air drying to remove the water. The caffeine that is removed, after refining to United States Phamacopeia (USP) standards, is a valuable by-product for pharmaceuticals and soft drinks. Though solvent decaffeination has been considered undesirable, solvents not found harmful by various government laboratories continue to be used. In fact, much of the commercial decaffeinated coffee is made from processes closely resembling the original European method. Other processes have been developed to improve coffee quality as well as to minimize solvent residues.

A water extraction process was developed in the United States in 1943 which provided a decaffeinated coffee with improved flavor and with very low solvent residues, in the parts-per-million range. This process used water to extract solids from green beans in a countercurrent staged column system. The green extract was then decaffeinated by extraction with a non-water-miscible solvent, such as methylene chloride, which had solubility characteristics that favored caffeine over the other soluble solids. The decaffeinated green extract was steam stripped to remove residual solvent and then returned to the extraction system. The caffeine-rich solvent extract was concentrated and recovered for reuse.

Natural decaffeination processes were invented and commercialized from the mid-1970s through the 1980s in response to increasing demand for

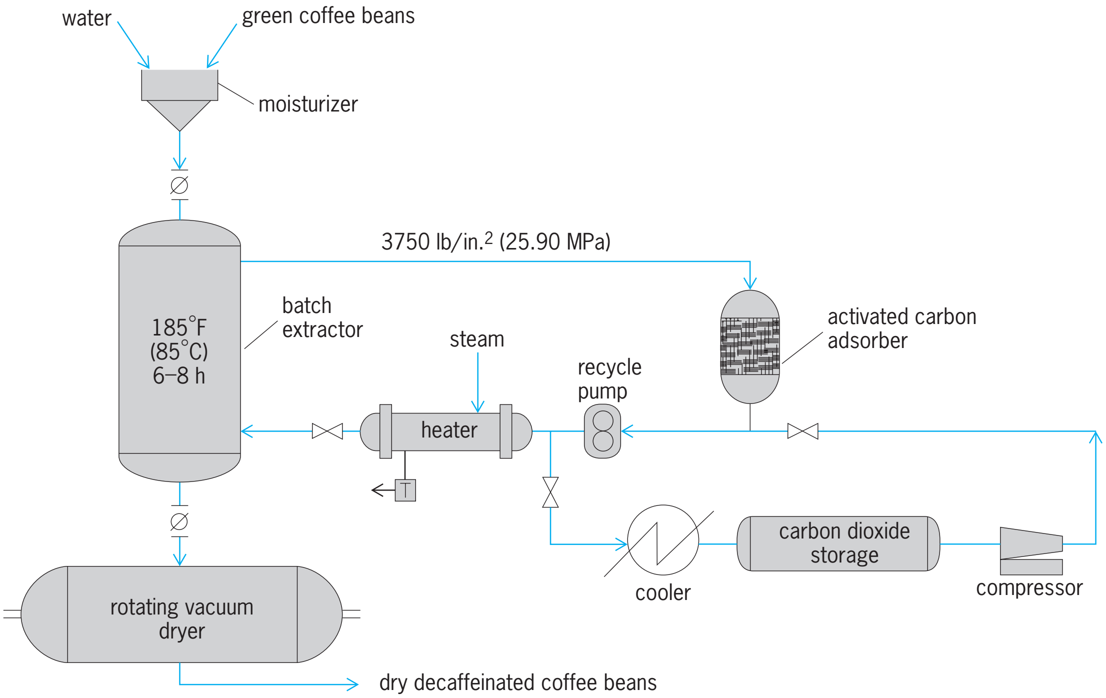

Fig. 4. Flow chart for coffee decaffeination with supercritical carbon dioxide.

decaffeinated coffee that had the same characteristics and quality as regular brewed coffee. Also, decaffeinating solvents, even in trace amounts, were considered to be harmful. Three processes for natural decaffeinated products are commercially available.

Water-carbon process. Referred to as the water process, this method is in many ways the same as the earlier water extraction process. However, instead of using a solvent to remove caffeine from a green coffee extract, the extract is decaffeinated by adsorption using activated carbon. The attraction by the carbon for many of the noncaffeine solids is partially reduced by sugar-coating the carbon. One disadvantage of this process is the inability to recover the caffeine. *See* ACTIVATED CARBON; ADSORPTION.

Supercritical CO_2 processes. Carbon dioxide (CO_2) above its critical temperature (supercritical CO_2) can be used to remove caffeine from green coffee beans (**Fig. 4**). It is a batch operation requiring pressures of about 3500 lb/in. (25.9 megapascals). Supercritical CO_2 is a very specific solvent for caffeine in moistened green beans, but few noncaffeine compounds are removed. Activated carbon adsorbs all the caffeine in the recirculating gas. Even at moderate extraction temperatures, times of 5–8 h are sufficient to obtain the desired degree of caffeine removal. After saturation, the carbon can be regenerated, but the caffeine cannot be recovered. An improved version of the supercritical CO_2 process features two major differences: (1) It simulates a continuous process by intermittently (15-min intervals) removing decaffeinated coffee from the bottom of an extraction tower and then filling space formed at the top of the tower with fresh green coffee. (2) Water is used instead of carbon to remove caffeine from the recirculating supercritical CO_2. The caffeine is then recovered, purified, and dried for reuse.

Other processes. Other so-called natural processes are similar to older solvent processes but use solvents (such as ethyl acetate) considered to be natural, based on the designation "generally regarded as safe" (GRAS) by the U.S. Food and Drug Administration.

Standards. Regulations for decaffeinated coffee differ. The European Economic Community requires that roasted decaffeinated coffee contain no more than 0.1% caffeine (dry basis). This differs from the United States standard, which states "97% caffeine removed," meaning less than 0.03% caffeine in milds and 0.06% in robustas. The United States standard is actually more rigorous, and more difficult to achieve and control.

Product stability and quality. All types of coffee products get stale rapidly when exposed to air, specifically oxygen. Therefore, raw materials, process materials, and the final product must have minimal exposure to oxygen. Although green beans are stable for long periods of time, once roasted, they grow stale in about 7–10 days. Ground coffee becomes stale very rapidly in air and therefore requires vacuum or modified atmospheric packaging (less than 1% oxygen). Once consumer coffee packages are opened, they should be kept refrigerated or in a freezer for extended shelf life.

The instant coffees are less subject to staling but require some of the same packaging and use concerns. The main concern is moisture adsorption due to their hygroscopic nature. Because so-called jar aroma is frequently added, it is desirable to minimize exposure to oxygen. Aromatized instant coffees for consumer sales are normally packaged in nitrogen-flushed jars. *See* FOOD ENGINEERING; FOOD MANUFACTURING.

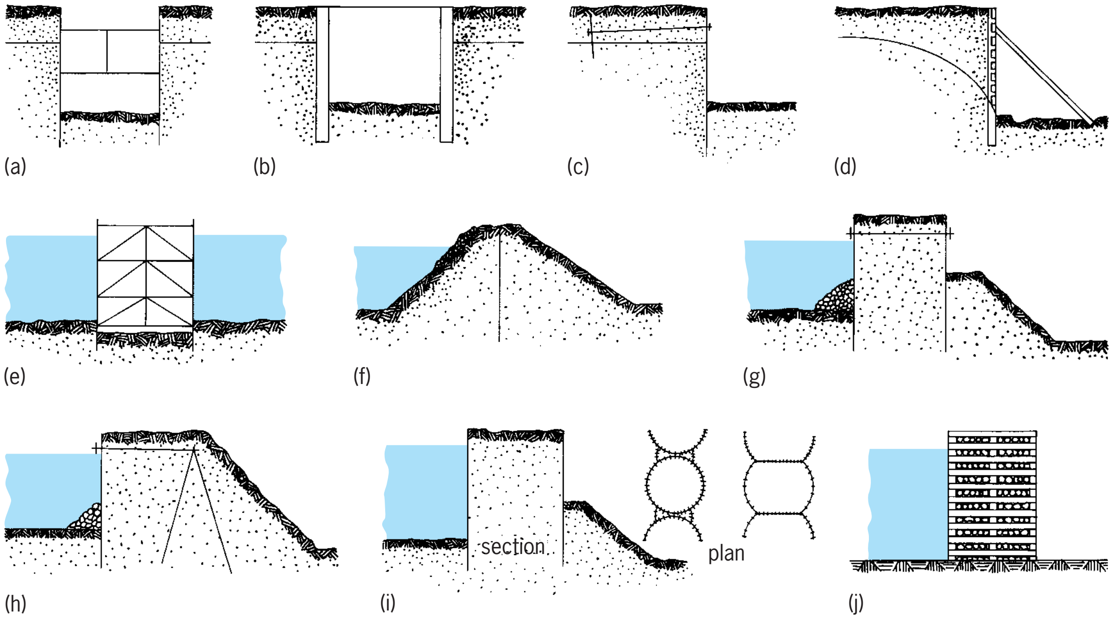
Cofferdam

A temporary wall-like structure which keeps water and soil out of a building site so that construction can proceed under dry conditions. Cofferdams are used in the construction of foundations, bridge piers, dams, dry docks, and similar structures which require dewatering and excavation of an area. The dewatered area can be completely surrounded by a cofferdam structure or a combination of earth slopes and cofferdam structure. The type of construction is dependent on the site depth, soil conditions, fluctuations in water level, availability of materials, working conditions inside the cofferdam, and location either on land or in water. In most situations, since safety, ease of construction, and convenience are the most important considerations, and economy of materials is less important, refined methods of analysis may not be justified. However, an understanding of soil and water pressure against the cofferdam walls is necessary for even the most approximate design. Other important considerations in cofferdam design are the hydraulic analysis of seepage conditions (including filtering), and erosion of the bottom (scour) in streams and rivers.

Where the cofferdam structure can be built on a layer of low-permeability soil (which minimizes the passage of water), the area within the cofferdam can be essentially sealed off. Where the foundation soils are pervious, flow of water into the cofferdam cannot be stopped economically, and the water must be pumped out to maintain dry working conditions.

Types. The **illustration** shows the types of cofferdam construction: *a*, *b*, and *e* are used to enclose small areas, such as individual bridge piers where cross bracing, consisting of steel, wood, or concrete beams and struts, to the opposite wall is practical; the other types are for large areas such as dams,



Types of cofferdams. For use on land: (*a*) cross-braced sheet piles; (*b*) cast-in-place concrete cylinder; (*c*) anchored sheet piles; (*d*) braced vertical piles with horizontal sheeting. For use in water: (*e*) cross-braced sheet piles; (*f*) earth dam; (*g*) tied sheet piles; (*h*) anchored sheet piles with earth berm; (*i*) steel sheet-pile cellular cofferdam; (*j*) rock-filled crib.

river locks, or large buildings, where cross bracing is impractical or undesirable. Cross bracing can be replaced with steel or concrete rings acting in compression when a circular form is used for *a* and *e*.

Sheeted cofferdams are made of sheets of steel, timber, or concrete, driven vertically or placed horizontally. The sheeting may be made reasonably watertight by using interlocking, overlapping, or grouted joints. In gravel or boulders, where sheeting cannot be driven to the required depth, steel H piles are driven vertically into the ground and timber sheeting is placed horizontally between or against the vertical piles (illus. *d*) as the excavation progresses. Watertight cofferdams are designed for a full hydrostatic head of water, plus the pressure of earth when they are on land. Nonwatertight cofferdams have a reduced hydrostatic pressure because of seepage.

Another type of cofferdam suitable for use in gravel or boulders is constructed of cast-in-place concrete. Illustration *b* shows this type in a cylindrical form.

Most sheet-pile cofferdams, with the exception of the cellular type (illus. *i*), require a foundation soil into which the sheets are embedded to give the walls stability. A cellular cofferdam, consisting of interlocking steel sheet piling driven as a series of interconnecting cells, is independently stable when filled and may be constructed on either rock or soil. The cells of the circular type may be filled individually. The cells of the straight-wall diaphragm type must be filled systematically to avoid a differential height of fill that would deform the diaphragms.

The filled crib (illus. *j*) is an open, boxlike structure of timber, precast concrete, or fabricated steel sections, filled with a suitable material. A rock-filled crib is suitable for construction on a rock bottom in swiftly flowing waters. Sheeting or an impervious core provides the necessary watertightness. Earth dams (illus. *f*) can be constructed of soil or rock, but if pervious, a cutoff is required to control seepage.

Another type of cofferdam for a large open building area is a slurry wall anchored back to the earth (illus. *c*). The slurry wall is constructed by pouring a concrete mix into a trench dug along the proposed wall before excavating the cofferdam area.

Uses. When cofferdams are required for year-round construction in waters subject to flooding, they are made sufficiently high to exclude the flood waters. To guard against instability, scour must be prevented along the stream side of cofferdams in swiftly flowing waters by protecting the stream bed. A rock fill, shown in illus. *g* and *h* on the stream side, may be used to provide such protection. In addition, the berms shown in illus. *g*, *h*, and *i* on the dewatered side furnish additional stability and reduce seepage of water under the cofferdam.

The cofferdam in illus. *b* has been used to form a mine shaft 220 ft (66 m) deep. Type *d* was used extensively in subway construction in New York City.

A nautical application of the term cofferdam is a watertight structure used for making repairs below the waterline of a vessel. The name also is applied to void tanks which protect the buoyancy of a vessel. *See* BRIDGE; DAM; FOUNDATIONS.

Cogeneration systems

Systems in which combined production of electrical power and useful thermal energy is achieved by the sequential use of a fuel or fuels. The electrical power is produced by a generator that is most often powered by a prime mover such as a steam turbine, gas turbine, or reciprocating (piston) engine. Examples of useful thermal energy include hot exhaust gases, hot water, steam, or chilled water. Other names for cogeneration systems are combined heating and power (CHP), district heating, and total energy. *See* DISTRICT HEATING; ELECTRIC POWER GENERATION; GENERATOR; PRIME MOVER; STEAM TURBINE; TURBINE.

The use of cogeneration systems has a number of benefits, including energy efficiency, monetary savings, and reduced environmental emissions. Cogeneration systems may have overall efficiencies of up to about 90%, depending on the application. Because of these high efficiencies, less fuel is consumed and less pollution is generated relative to conventional power plants. Any facility that uses electrical power and has thermal energy needs is a candidate for cogeneration. The basic consideration in determining the feasibility of cogeneration for a particular facility is whether the savings on thermal energy costs is sufficient to justify the capital expenditure. Facilities that may be considered for cogeneration include those in the industrial, commercial, and institutional sectors.

The technology for cogeneration exists for sizes ranging from less than 100 kilowatts to over 100 megawatts. The major equipment requirements include a prime mover, electrical generator, electrical controls, heat-recovery systems, and other typical power-plant equipment. These components are well developed, and the procedures to integrate them into cogeneration systems are well established.

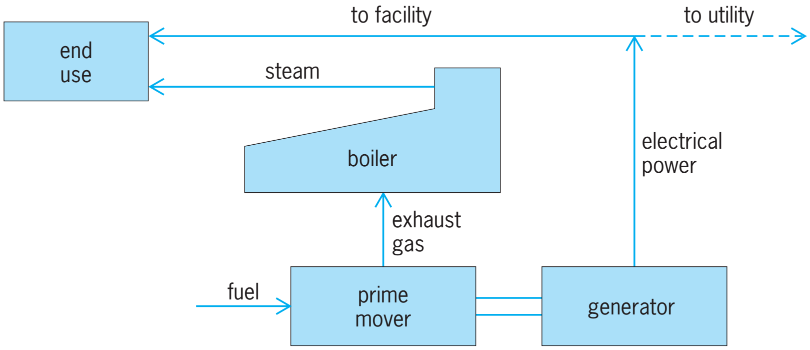

Fig. 1. Cogeneration topping-cycle system.

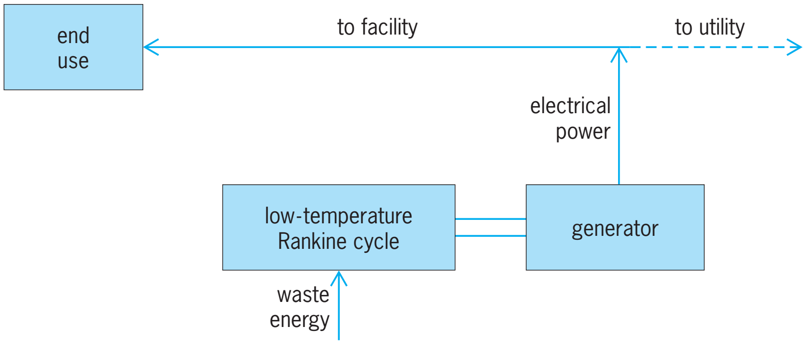

Fig. 2. Cogeneration bottoming-cycle system.

Cogeneration is not new. In the early twentieth century, many industrial facilities generated their own electrical power and often supplied power to nearby communities. They used the thermal energy that was available during the electrical power production to provide or supplement process or building heat. These industrial facilities were the first "cogenerators." As electricity became widely available and less expensive, facilities often stopped generating their own electrical power. It is estimated that from 1954 to 1976 industrial cogenerated electrical power decreased from about 25% to 9% of the total electrical power generated in the United States. Since about the mid-1980s, cogenerated electrical power has been fairly constant at about 5%.

Although arguments for cogeneration technology are persuasive, a number of obstacles constrain the implementation of these systems, including the relatively low cost of electricity, high cost of fuels, high cost of capital investment, environmental regulations, and difficulties working with local utilities. In many cases, these obstacles can be minimized or eliminated, and cogeneration facilities can be developed.

Topping and bottoming cycles. A cogeneration system may be classified as either a topping cycle system (**Fig. 1**) or a bottoming cycle system (**Fig. 2**). For topping-cycle systems, a prime mover uses fuel to power an electrical generator to produce electricity. In one configuration, the hot exhaust gases are directed to a heat-recovery steam generator (HRSG) to produce steam or hot water. This cogeneration system is classified as a topping cycle because the electrical power is generated first at the higher (top) temperature associated with the fuel combustion process, and then the rejected or exhausted energy is used to produce useful thermal energy (such as the steam or hot water in this example). The majority of cogeneration applications are based on topping-cycle systems.

In bottoming-cycle systems (Fig. 2), the high-temperature combustion gases are used first in a high-temperature thermal process (such as high-temperature metal treatment), and then the lower-temperature gases are used in a special low-temperature cycle to produce electrical power. Bottoming-cycle cogeneration systems have fewer applications than topping-cycle systems, and must compete with waste-heat-recovery systems, such as feedwater heaters, recuperators, and process heat exchangers. One of the difficulties with bottoming-cycle systems is the low-temperature electrical power–producing cycle. These cycles are generally much less efficient than conventional-power cycles, often involve special equipment, and use working fluids that are more expensive.

Combined cycles. One power-plant configuration, known as a combined cycle, is based on a form of a topping cycle and is widely used in industry and by electrical utilities. Typically, a gas turbine generates electrical power, and the exhaust gas is ducted to a partially fired heat-recovery boiler. The produced steam drives a steam turbine that produces additional electrical power. In this example, the majority of the steam is then condensed and pumped back to the boiler. To classify as a cogeneration application, some steam would need to be used to satisfy a thermal requirement.

Heat-recovery equipment. Several configurations of heat-recovery devices, or heat-recovery steam generators (HRSGs), are available. HRSGs are often divided into unfired, partially fired, and fully fired. An unfired HRSG is essentially a convective heat exchanger. A partially fired HRSG may include a "duct burner," which often uses a natural-gas burner upstream of the HRSG to increase the exhaust gas temperature. A fully fired HRSG is a boiler that simply uses the exhaust gas as preheated air. These devices can produce hot water, saturated steam, or superheated steam at a range of pressures and temperatures, depending on the need. *See* CONVECTION (HEAT); HEAT EXCHANGER; HEAT TRANSFER.

For chilled water (such as for building cooling), absorption chillers may be used. Absorption chillers use special fluids and a unique thermodynamic cycle to produce low temperatures without the requirement of a vapor compressor that is used in mechanical chillers. Instead of the vapor compressor, an absorption chiller uses liquid pumps and energy from low-temperature sources, such as hot water, steam, or exhaust gas.

Governmental regulations. In 1978 the United States government passed the National Energy Act (NEA), which included the Public Utility Regulatory Policies Act (PURPA). PURPA defined cogeneration systems to include those power plants that supplied a specified fraction of their input energy as useful thermal output in addition to a mechanical or electrical output. For a cogenerating facility to qualify for the privileges and exclusions specified in PURPA, the facility must meet or exceed certain legislated standards. A qualified facility is eligible to use the provisions outlined in PURPA regarding nonutility electrical power generation. In particular, these provisions enhance the interactions between cogenerators and utilities.

Other regulatory legislation directed at managing air and water quality significantly affects the installation of cogeneration systems. Based on the type of fuel and generation process incorporated, the air pollutants regulated for a specific project include nitrogen oxides (NOx), sulfur oxides (SOx), hydrocarbons (HC), carbon monoxide (CO), and particulates. The regulation of emissions from power generation is determined by several different agencies at the federal, state, and local levels. The regulations in some geographical areas have become complex and numerous. For example, certain regions may need to meet limits imposed by new source review or by prevention of significant deterioration.

In addition to air quality standards, most facilities must meet water-quality and solid waste–disposal standards. Generally for these standards, compliance is routine. *See* AIR POLLUTION; WATER POLLUTION.

Pollution control. The reduction of emissions for power-generating equipment may be accomplished by a number of methods depending on the level of reductions required, the pollutant of concern, and the specific equipment. Generally, emissions control equipment either reduces the initial amount of the pollutants generated, referred to as combustion modification control, or reduces the amount of pollutants in the combustion exhaust gas, known as postcombustion control. For gas turbines, combustion modification methods to reduce nitric oxides include steam or water injection, lean premixed combustion, and combustion designs known as "low NOx burners." An example of postcombustion control is selective catalytic reduction, which uses a catalyst and the injection of an ammonia species in the exhaust gas. At the appropriate temperature and conditions, the catalyst reduces nitric oxide to molecular nitrogen (N_2).

Project development/financing. Even with a reliable technical design and favorable economics, the successful completion of a cogeneration project often depends on acceptable financial arrangements. Financing is critical to the success of a cogeneration project, and it is best to determine early on the financial arrangement to be used. The selected financial arrangement will be intimately linked to the ownership structure. The ownership may be structured in a variety of ways. By increasing the number of participants in the project, the individual risk decreases, but the venture is more difficult to organize and the individual potential gains decrease. A cogeneration system may be owned by the facility, by a third-party entity, or by a partnership. In this context, the facility refers to the entity with the electrical and thermal loads. This is sometimes called the thermal consumer, heat consumer, or thermal host. A third party refers to an entity separate from the thermal load owner (first party) and from the local utility (second party).

The thermal and electrical loads of a facility are the items that might motivate others to be involved in developing a cogeneration system. In one respect, these loads represent the opportunity for financial gains. There are a number of potential project participants that could conceivably have an interest in the development of the cogeneration system. These potential participants include equipment manufacturers, power-plant operators, investors (such as banks, insurance companies and pension funds), electrical utilities, fuel suppliers, engineering firms, and governmental agencies. In general, the ownership structure and the financial arrangement are selected to provide the highest profits, lowest risks, and greatest tax benefits.

External participants, partners, and investors will examine a number of issues before deciding to be involved in the project. These issues include the overall economics, the revenue from thermal and electricity sales, the accuracy of the capital costs and operating expenses, the experience of the participants, the projected availability of the plant, the previous success of the proposed technology, the assurance that permits, contracts, and agreements will be obtained on a timely basis, and the availability and cost of fuel. A net positive assessment of these issues will be necessary for any external participation. Jerald A. Caton

Cognition

The internal structures and processes that are involved in the acquisition and use of knowledge, including sensation, perception, attention, learning, memory, language, thinking, and reasoning. These behaviors are studied by cognitive scientists, a group that includes, but is not limited to, researchers in the areas of cognitive psychology, philosophy, linguistics, computer science, and cognitive neuroscience. Cognitive scientists propose and test theories about the functional components of cognition based on observations of an organism's external behavior in specific situations.

Sensation, perception and attention. Cognition throughout life can be broadly described as an interaction between top-down, knowledge-driven processes and bottom-up, sensory processes, and between controlled processes and automatic processes. When environmental input impinges on an organism's sensors, such as eyes or ears, that sensory information is used to construct an internal representation of the object or event causing the input. This representation undergoes several transformations as more knowledge is activated to make sense of an event. Over time, there is a trade-off between the amount of surface information that is retained in the representation (bottom-up processing) and the amount of meaning that is incorporated (top-down processing).

Following exposure to a stimulus, a sensory representation (sometimes called an image, icon, or echo) is constructed that encodes nearly all the surface characteristics of the stimulus (for example, color, shape, location, pitch, and loudness). The information is short lived, lasting less than a second. Much evidence suggests that extraction of information from this veridical representation takes place in two stages, a feature analysis stage and an object recognition stage. *See* MEMORY; PERCEPTION.

The first stage, sometimes called a preattentive stage, involves the segregation of pattern subcomponents into figures and background by feature analysis. This process is sometimes called parsing the input. A small number of primitive features are extracted from the sensory patterns, including color, size, contrast, tilt, curvature, line ends, movement, stereoscopic depth, and closure. These features are extracted independently by different parts of the visual system, and only in the second stage are they combined to form complete images of three-dimensional objects. For example, if a matrix of T's is juxtaposed next to a matrix of tilted T's, the boundary between the vertical and tilted T's stands out for the viewer. The boundary between juxtaposed matrices of T's and L's, however, does not. These different effects indicate that line orientation (vertical or tilted) is an important feature in early visual processing but the conjunctions of lines (that is, the way vertical and horizontal lines are combined to make up T's and L's) are not. A more surprising feature of object recognition and feature analysis is closure. When jumbles of tilted lines and angles are presented very briefly (200 ms) to viewers, they seldom report seeing triangles. But if small circles (that is, closed geometric figures) are distributed among the lines and angles, the viewers frequently report seeing triangles. When parsing normal triangles, the visual system apparently detects tilted lines, angles, and the abstract feature "closed" (a triangle is a closed geometric figure). The circles in the latter display provide this feature to the viewers' visual systems, along with the lines and angles, allowing them to see illusory triangles. These primitive features, once extracted from the visual input, are combined in the second stage to form objects. It is during this stage that attention (controlled processing) and previous knowledge come into play. For example, the time it takes to indicate whether a slide of O's also contains a Q increases linearly with the number of O's in the display. This relationship suggests that viewers scan the slide serially, focusing attention on each object or location in turn in order to identify each object. Viewers can complete these tasks faster and more accurately when familiar rather than unfamiliar objects are used, demonstrating the influence of top-down processes. Selecting particular objects from among others requires selective attention, that is, the ability to focus on certain inputs and ignore or inhibit processing of others.

Learning and memory. Information from the second-stage image rapidly decays. Typically, no more than five to nine pieces of information can be identified and maintained from the stimulus presented. Aspects of this short-term memory representation that become permanent constitute long–term memory. These aspects include items that mark the beginning and end of events, repeated events, and events that are particularly meaningful to the individual.

There are two independent memory systems. The first is called explicit or declarative memory. It comprises memories that can be consciously recollected, such as facts, episodes, and images. Explicit memories have the self as the agent or experiencer of the event in question and require controlled processing in order to be formed and retrieved. Implicit or nondeclarative memories, in contrast, constitute information acquired during skill learning, habit formation, classical conditioning, emotional learning, and priming. Implicit memories are expressed through performance rather than through conscious recollection. They do not necessarily depend on awareness or attention for their formation or retrieval (automatic processing). While learning to drive a car, a person focuses attentional resources on each subcomponent, such as depressing the clutch, shifting gears, and checking mirrors and blind spots. Once each skill is mastered, however, driving proceeds almost effortlessly, requiring few attentional resources. Such automatic skills or procedures are easier to do than to describe because they consist of memorized sequences of interconnected motor commands that are coordinated for action and executed as a single, fluid movement. *See* LEARNING MECHANISMS.

Conceptual knowledge. Conceptual knowledge is needed to classify objects and events in the world. Some aspects of conceptual knowledge are innate or emerge very early in development, while others are acquired through learning and inference. Advances in the understanding of innate knowledge have come about through an experimental procedure called the habituation technique. In this technique, a preverbal infant or animal is presented with a novel stimulus, which usually elicits a change in some observable behavior, such as directed looking, electrical skin conductance, brain wave activity, or changes in heart rate and blood pressure. The stimulus is presented repeatedly until the response in question declines to half of its initial value. At this point, the subject is said to have habituated to the stimulus. A new, similar stimulus is then presented. If the subject dishabituates and response levels of the subject return to their prehabituation levels, the subject is said to have detected the difference between the old and new stimuli.

By using this technique, human infants have been found to be able to detect differences in small numerosities shortly after birth, indicating innate sensitivity to the concept of number. Six-month-olds have been shown to recognize numerical equivalence across sense modalities, and infants as young as 5 months are capable of adding and subtracting small numbers. By 3 months, infants realize that solid objects cannot occupy the same location at the same time, cannot pass through each other, continue to exist even when out of sight, and cannot influence the trajectory of other objects without direct contact (no action at a distance). In contrast, they do not seem to appreciate the properties of gravity or inertia until about 9 months of age.

Also early to emerge is a sensitivity to ontological category. Studies that explore this type of knowledge typically employ verbal tasks, so it is not clear how early such knowledge develops. By the age of 2 years, however, infants make clear distinctions in their inductive generalizations between objects and substances; by 3 or 4 years, sensitivity is evidenced to distinctions among plants, animals, nonliving natural objects, and human-made artifacts. For example, 4-year-olds believe that a coffee pot can become a bird feeder with a little surgery, but they do not believe that a porcupine can become a cactus. Similarly, if they are told that the human body contains an omentum, they believe that dogs are likely to have one, too, but not human-looking dolls, flowers, or rocks.

Categorization learning is augmented by bottom-up processes, such as grouping together objects that share detectable common features or uses. These groupings typically show graded structure, with objects containing many typical features forming the core, or prototype, of the category. For example, when subjects are asked to list features that typify birds, sparrows, and penguins, the lists generated for sparrow and bird are found to have more features in common than the lists generated for penguin and bird, indicating that sparrows are more typical of the category "bird" than penguins. Because sparrows are closer to the prototype for a bird, people typically classify sparrows as birds more quickly and with fewer errors than they classify penguins as birds. Early on, individuals become sensitive to the ontological distinctions among living things, but learn to form precise categories for members within these distinctions by detecting common features.

Communicating, reasoning, and problem solving. A primary cognitive function of all social species is communication, which can be accomplished by a combination of vocal, gestural, and even hormonal signals. Of all species on Earth, only humans have developed a communication system based on abstract signs. This evolutionary development is closely tied to the greater reasoning capacity found among members of the species as well. All reasoning can be broadly described as pattern recognition and search. People search their conceptual knowledge for relevant information in order to draw a conclusion, solve a problem, or guide behavior. Thinking often takes the form of a chain of associations among concepts in long-term memory, with one thought retrieving others to which it is related. The most common reasoning strategies include direct retrieval, imaging, means-ends analysis, analogy, classification, deduction, and formal procedures.

Reasoning by direct retrieval involves retrieving a known fact from memory to solve a problem, such as determining how much three times three is or where something is located. Reasoning imagistically involves constructing or retrieving images from conceptual memory and examining or manipulating them to solve a problem. For example, individuals reason imagistically when they determine how many windows there are in their living rooms by retrieving an image of the room and counting the windows in the image.

Means-ends analysis is typically employed when solving problems in unfamiliar domains. When a solution is not immediately apparent, reasoners typically compare the goal to the current situation and select means with which to reduce the differences between the two situations. A simple example is getting into a car. The current situation involves an individual standing outside a car with the door locked. The goal situation involves sitting inside the car. The primary difference between the two is the individual's position, inside versus outside the car. To reduce this difference requires opening the car door. If the door is locked, a subgoal is generated to unlock the door. The goal state is an unlocked door, and the current state is a locked door. A search is made for an operator, that is, a means to achieve the end of opening the door. Possible operators includes keys, coat hangers, and bricks. Applying the operator (such as the car key) accomplishes the subgoal of opening the door.

Insight involves the restructuring of a problem representation that allows an available means to be used in a novel way or a seemingly unrelated bit of knowledge to be accessed to solve the problem. For example, scissors can be used not just to cut a string in half but also to serve as a weight to set one of the pieces swinging like a pendulum—a handy solution if a person needs to pass the string or scissors to someone standing out of arm's reach.

Reasoning by analogy is used when a current situation allows an individual to recall another, similar situation that has a known solution or other information relevant to the task at hand. It is a technique that is powerful but error prone. Without proper constraints on the analogy process, irrelevant or incorrect information can be transferred between the target and source analogs. For example, if told "The structure of the atom is like the solar system," the reasoner might also conclude that the nucleus of the atom is hot, just like the Sun.

Reasoning by classification involves making inferences about an object or event based on its category membership. For example, when asked to estimate the likelihood that each of a series of descriptions refers to an engineer or a lawyer, people have been found to base their estimates on the similarity of the descriptions to stereotypes for these professions—regardless of the base rates for the two types of professionals in the pool. Persons described as being interested in mathematical puzzles and reserved in manner were assigned a high likelihood of being engineers, regardless of whether the percentage of engineer descriptions in the pool was reported to be 30% or 70%. Neutral descriptions, such as successful or average weight and height, were judged to have a 50% probability of being an engineer, again regardless of whether subjects were told the percentage of engineers in the pool was 30% or 70%. Judgments like these are called reasoning fallacies because they violate formal rules of reasoning. Ignoring base rates violates Bayes' theorem, a formal model for computing conditional probabilities.

Deductive reasoning involves drawing a conclusion based on its logical relation to one or more premises. A common example is Modus Ponens (If p, then q/p/Therefore, q). Sufficient evidence exists that the Modus Ponens reasoning rule is part of cognitive architecture. Errors on this type of argument rarely occur, judgments are extremely rapid even when other tasks are performed concurrently, and evidence of use of Modus Ponens emerges early in development and independently of formal training. Such unequivocal and converging evidence exists for a scant few other formal rules of deduction.

A second common use for deduction is testing hypotheses. Naive reasoners typically commit a reasoning fallacy termed confirmation bias when testing their hypotheses. For example, when asked to determine the rule used to generate the number series 2, 4, 6, most subjects hypothesized that the rule was even ascending numbers. Importantly, they tested this hypothesis by seeking to confirm their hypothesis rather than trying to disprove it. They did so by generating only instances that were consistent with their hypothesis (8, 10, 12; 22, 24, 26). The correct rule was any ascending sequence. Discovering this required testing a sequence that disconfirmed their hypothesis.

Formal procedures for reasoning and for solving problems have been developed over the centuries. These include logic, mathematics, probability theory and statistics, and scientific investigation. Understanding of the behavior and properties of physical, biological, and cognitive systems has been greatly enhanced through the use of these techniques. *See* PSYCHOLINGUISTICS.

Cognition and the brain. By using noninvasive techniques such as positron emission tomography (PET scan), magnetic resonance imaging, electrical skin conductance, invasive surgical and chemical investigations of animal brains, and data from clinically observed syndromes associated with brain injury, cognitive neuroscientists have pieced together a good deal of information concerning the role that specific brain regions play in the processing of emotional and cognitive events. High-level visual processing, such as object recognition, takes place in the occipital lobes of the cortex (back of the head), although recognition of certain highly complex visual stimuli, such as faces, is handled by the right cerebral hemisphere. Auditory stimuli in general are processed by the temporal lobes of the cortex (near the ears), and written and spoken word recognition and syntactical components of language processing are handled by certain regions of the left hemisphere of the cerebral cortex, notably Broca's and Wernicke's areas; while emotional, idiomatic, and prosodic aspects of language are handled by corresponding regions in the right hemisphere. Higher cognition, such as reasoning and problem solving, involves the frontal lobes of the cortex. Memory and the processing of emotional stimuli are handled by the combined effort of the cortex (notably the anterior and frontal regions) and subcortical structures (notably the limbic system).

One particular subcortical structure—the hippocampus—plays a major role in the formation of new explicit memories. By using positron emission tomography scanning, conscious recollection of events can be seen to involve increased blood flow to the hippocampal region, while implicit memory tasks produce increased blood flow to posterior, extrastriate areas of the cerebral cortex. Damage to the hippocampal region and the medial temporal lobe produces profound amnesic syndrome in which the patient displays normal perceptual linguistic and intellectual functioning but cannot consciously remember recent events (such as having lunch or playing a round of golf). Such patients do, however, show implicit memory for recent events, including the acquisition of new motor skills, habits, and emotional preferences. It is believed that an intact hippocampus is needed to temporarily bind together distributed sites of activation in the cortex that together make up a whole, explicit memory for an event. *See* BRAIN; COMPUTERIZED TOMOGRAPHY.

Computer models. Theories of cognition are often tested by building computer models that embody the theories and then comparing the model's performance with human performance on selected tasks. These models tend to be of two types. Rule-based models simulate cognition as the execution of condition-action rules. The models consist of a long-term memory containing rules which specify actions to take in the presence of particular input patterns, a short-term memory that encodes input patterns and temporarily stores data structures constructed by the rules, and a control structure that guides the process and resolves conflicts when more than one rule applies to the current input. Rule-based models have successfully simulated expert performance in a variety of domains. Neural network models simulate cognition as a strengthening and weakening of associations among cognitive events. They are called neural networks because they learn in a way that is analogous to the way in which brains learn (by modifying synaptic connections among neurons) and have proven to be excellent models of perception and memory. Neural networks consist of a network of interconnected nodes, a mathematical formula for modifying the connections, and a mathematical formula for propagating activation through the network. *See* EXPERT SYSTEMS; INFORMATION PROCESSING (PSYCHOLOGY); INTELLIGENCE; NEURAL NETWORK; PROBLEM SOLVING (PSYCHOLOGY).

Coherence

The attribute of two or more waves, or parts of a wave, whose relative phase is nearly constant during the resolving time of the observer. The concept has been developed most extensively in optics, but is applicable to all wave phenomena.

Coherence of two beams. Consider two waves, with the same mean angular frequency ω, given by Eqs. (1) and (2). These expressions as they stand

$$\Psi_A(x,t) = A\ \exp\{i[k(\omega)x - \omega t - \delta_A(t)]\} \quad (1)$$

$$\Psi_B(x,t) = B\ \exp\{i[k(\omega)x - \omega t - \delta_B(t)]\} \quad (2)$$

could describe de Broglie waves in quantum mechanics. For real waves, such as components of the electric field in light or radio beams, or the pressure oscillations in sound, it is necessary to retain only the real parts of these and subsequent expressions. Assume that the frequency distribution is narrow, in the sense that a Fourier analysis of Eqs. (1) and (2) gives appreciable contributions only for angular frequencies close to ω. This assumption means that, on the average, $\delta_A(t)$ and $\delta_B(t)$ do not change much per period. For any actual wave, however, they must undergo some change; only waves that have existed forever and that fill all of space can have absolutely fixed frequency and phase. *See* ELECTROMAGNETIC RADIATION; QUANTUM MECHANICS; SOUND.

Suppose that the waves are detected by an apparatus with resolving time T; that is, T is the shortest interval between two events for which the events do not seem to be simultaneous. For the human eye and ear, T is about 0.1 s, while a fast electronic device might have a T of 10^{-10} s. If the relative phase $\delta(t)$, given by Eq. (3), does not, on the average, change

$$\delta(t) = \delta_B(t) - \delta_A(t) \quad (3)$$

noticeably during T, then the waves are coherent. If during T there are sufficient random fluctuations for all values of $\delta(t)$, modulus 2π, to be equally probable, then the waves are incoherent. If during T the fluctuations in $\delta(t)$ are noticeable, but not enough to make the waves completely incoherent, then the waves are partially coherent. These distinctions are not useful unless T is specified. Two waves for which the relative phase changes appreciably in 0.01 s would seem incoherent to unaided human perception, but would seem highly coherent to a fast electronic device.

The degree of coherence is related to the interference patterns that can be observed when the two beams are combined. The following variations of Young's two-slit interference experiment illustrate several possibilities. *See* INTERFERENCE OF WAVES.

Young's two-slit experiment. In the usual Young's experiment (**Fig. 1**) beams A and B come from the same point source and pass through separated slits in a screen. Near a point P equidistant from the slits, for linear wave phenomena, the resultant wave $\Psi(x,t)$ is the sum of $\Psi_A(x,t)$ and $\Psi_B(x,t)$. The observable

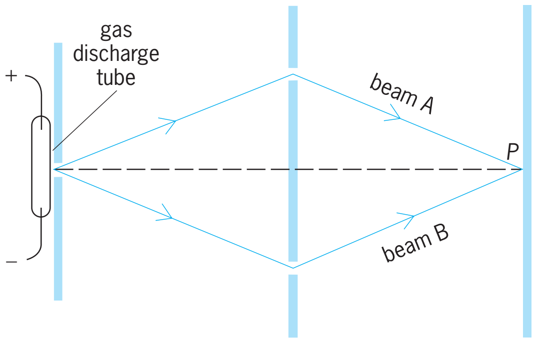

Fig. 1. Young's experiment. If beams *A* and *B* come from the same point source and traverse the same distance, they are coherent around *P* and produce there an interference pattern that has high visibility.

intensity is proportional to $|\Psi|^2$, the square of the magnitude of Ψ. This observable intensity is the energy density or the mean photon density for electromagnetic waves, the energy density for acoustic waves, and the mean particle density for the wave functions of quantum mechanics. With the wave forms of Eqs. (1) and (2), for real A and B, it is given by Eq. (4). The first term gives the intensity of beam A

$$\begin{aligned} |\Psi|^2 &= |\Psi_A + \Psi_B|^2 \\ &= A^2 + B^2 + 2AB\ \cos\ \delta(t) \end{aligned} \qquad (4)$$

alone, the second gives the intensity of B alone, and the third term depends on the relative phase, given by Eq. (3).

The mean life of a typical excited atomic state is about 10^{-8} s. Collisions and thermal motion reduce the effective time of undisturbed emission to around 10^{-10} or 10^{-11} s in standard discharge tubes. The phase $\delta_\mathrm{A}(t)$ of beam A therefore dances about erratically, with substantial changes occurring perhaps 10^{11} times per second. However beam B comes from the same atoms and travels nearly the same distance, and the changes in $\delta_\mathrm{B}(t)$ are the same as those in $\delta_\mathrm{A}(t)$. The relative phase is always zero at the exact midpoint P and takes on other time-independent values in the neighborhood of P. For each point in that neighborhood, $|\Psi|^2$ has a constant value that satisfies inequality (5). A clear interference pattern

$$|A - B|^2 \leq |\Psi|^2 \leq |A + B|^2 \qquad (5)$$

is observed even with a large-T detector such as a photographic plate.

Independent sources. Instead of a single source, two independent sources can be used to produce the two beams (**Fig. 2**). If the two sources are standard discharge tubes, $\delta_\mathrm{A}(t)$ and $\delta_\mathrm{B}(t)$ independently change erratically around 10^{11} times per second. Equation (4) is still valid, but the observed quantity is $|\Psi|^2$ averaged over the resolving time T, denoted by $\langle|\Psi|^2\rangle_\mathrm{T}$. When the average of Eq. (4) is formed, the last term on the right contributes nothing because $\cos\,\delta(t)$ randomly takes on values between $+1$ and -1 and thus obeys Eq. (6). The two beams are incoherent, the observed intensity is simply the sum of the separate intensities, and the superposition does not produce a visible interference pattern. In general, if incoherent waves Ψ_A, Ψ_B, Ψ_C, ... , are combined, much the same argument applies because the average over T of each cross term is zero, so that the observed intensity is given by Eq. (7).

$$\langle\cos\delta(t)\rangle_T = 0 \qquad (6)$$

$$\langle|\Psi|^2\rangle_T + \langle|\Psi_A|^2\rangle_T + \langle|\Psi_B|^2\rangle_T + \langle|\Psi_C|^2\rangle_T + \cdots \qquad (7)$$

The argument that results in Eq. (6) depends on there being random independent changes in the separate phases during times much shorter than T. If the discharge tubes are replaced by very well stabilized lasers, or by loudspeakers or radio transmitters, then the separate phases $\delta_A(t)$ and $\delta_B(t)$ can be made nearly constant during 0.1 s. The relative phase $\delta(t)$ is then also nearly constant, an interference pattern is visible, and the two waves can be called coherent. *See* LASER.

Effect of path length difference. In another arrangement (**Fig. 3**), the two beams are again emitted by the same

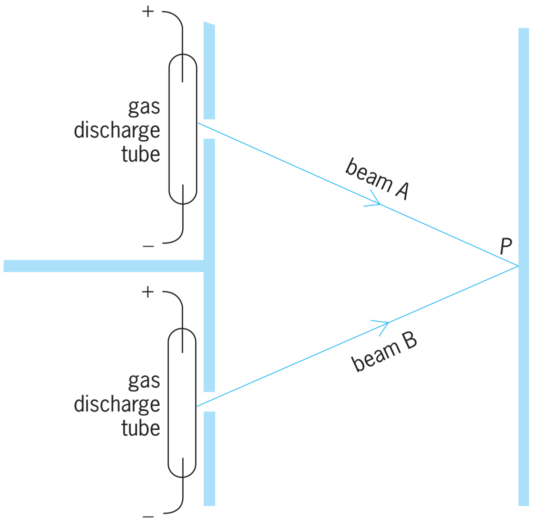

Fig. 2. Independent sources that change their phases frequently and randomly during the resolving time *T* are incoherent, and their superposition does not produce a visible interference pattern.

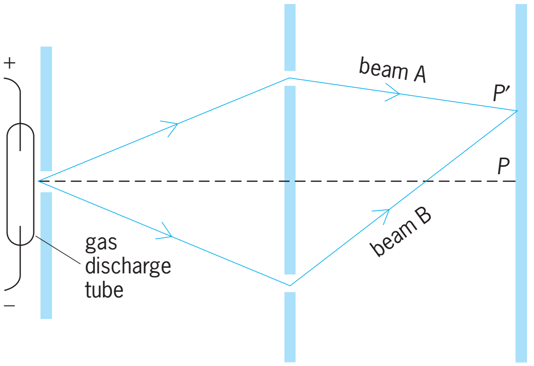

Fig. 3. If the difference between the distances traversed by beams *A* and *B* is of the order of the coherence length, then the beams are partially coherent at *P* ′.

point source and are therefore coherent at their origin. Here, however, the distance from the source to the point P' of wave addition is larger along beam B than along beam A by an amount l. In this arrangement, the path length difference is due to the observation point P' not being near the central axis, but it could equally well be caused by the insertion of different optical devices in the two beams.

The waves that arrive at P' via path B at any instant must have left the source earlier by a time $\tau = l/c$, where c is the wave speed, than those that arrive via path A. Suppose again that the source is a standard discharge tube, so that the phase changes randomly about 10^{11} times per second. For $\tau < 10^{-11}$ s, the coherence between A and B at P' is not spoiled by the path length difference, and there is a visible interference pattern around P'. For $\tau > 10^{-11}$ s, the light that arrives via A left the source so much later than that which arrives via B at the same instant that the phase changed many times in the interim. The two beams are then incoherent, and their superposition does not produce a visible interference pattern around P'. For $\tau \simeq 10^{-11}$ s, perfect coherence is spoiled but there is less than complete incoherence; there is partial coherence and an interference pattern that is visible but not very sharp. The time difference that gives partial coherence is the coherence time Δt. The coherence time multiplied by the speed c is the coherence length Δl. In this example, Δl is given by Eq. (8).

$$\Delta l \simeq 10^{-11}\text{s} \times 3.0 \times 10^{10}\ \text{cm/s} = 0.3\ \text{cm} \quad (8)$$

Effect of extended source. The original arrangement can also be modified by making a large hole in the collimator in front of the discharge tube, so that there is an extended source rather than a point source (**Fig. 4**). Consider two regions of the source, S near the center and S' near one end, separated by a distance y. During times longer than the coherence time, the difference between the phases of the radiation from the two regions changes randomly. Suppose that, at one moment, the radiation from S happens to have a large amplitude while that from S' happens to be negligible. The waves at the two slits are then in phase because S is equidistant from them, and interference at P gives a maximum. Suppose that a few coherence times later the radiation from S happens to be negligible while that from S' happens to have a large amplitude. If the path length along A' differs from that along B' by half of the wavelength λ, then the waves at the two slits are out of phase. Now interference at P gives a minimum, and the pattern has shifted in a few coherence times. If the resolving time T is much larger than the coherence time Δt, the consequence is that beams A and B are not coherent at P.

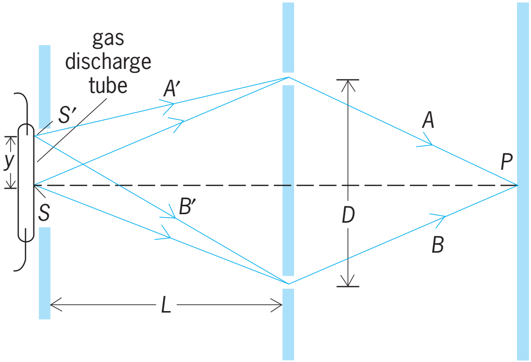

Fig. 4. If the lateral extent *y* of the source is of the order of *L*λ/*D*, then the beams are partially coherent at *P*.

The condition that there be a path length difference of $\lambda/2$ between B' and A' is given by Eq. (9),

$$\sqrt{L^2 + (y + D/2)^2} - \sqrt{L^2 + (y - D/2)^2} = \lambda/2 \quad (9)$$

and for D and y both much smaller than L, expansion of the square roots gives Eq. (10). This argument is

$$2Dy = L\lambda \quad (10)$$

rather rough, but it is clear that a source that satisfies Eq. (11) is too large to give coherence and too

$$y \simeq \frac{L\lambda}{D} \quad (11)$$

small to give complete incoherence; it gives partial coherence.

Coherence of a single beam. Coherence is also used to describe relations between phases within the same beam. Suppose that a wave represented by Eq. (1) is passing a fixed observer characterized by a resolving time T. The phase δ_A may fluctuate, perhaps because the source of the wave contains many independent radiators. The coherence time Δt_W of the wave is defined to be the average time required for $\delta_A(t)$ to fluctuate appreciably at the position of the observer. If Δt_W is much greater than T, the wave is coherent; if Δt_W is of the order of T, the wave is partially coherent; and if Δt_W is much less than T, the wave is incoherent. These concepts are very close to those developed above. The two beams in the arrangement with independent sources are incoherent with respect to each other if one or both have $\Delta t_W < T$, but are coherent with respect to each other if both have $\Delta t_W > T$ (Fig. 2).

The degree of coherence of a beam is of course determined by its source. Discharge tubes that emit beams with Δt_W small compared to any usual resolving time are therefore called incoherent sources, while well-stabilized lasers that give long coherence times are called coherent sources.

Consider two observers that measure the phase of a single wave at the same time. If the observers are close to each other, they will usually measure the same phase. If they are far from each other, the phase difference between them may be entirely random. The observer separation that shows the onset of randomness is defined to be the coherence length of the wave, Δx_W. If this separation is in the direction of propagation, then Δx_W is given by Eq. (12), where

$$\Delta x_W = c\Delta t_W \quad (12)$$

c is the speed of the wave. Of course, the definition of Δx_W is also applicable for observer separations perpendicular to the propagation direction.

The coherence time Δt_W is related to the spectral purity of the beam, as is shown by the following argument. The wave can be viewed as a sequence of packets with spatial lengths around Δx_W. A typical packet requires Δt_W to pass a fixed point. Suppose that n periods of duration $2\pi/\omega$ occur during Δt_W, as expressed in Eq. (13). The packet can be

$$\Delta t_W \frac{\omega}{2\pi} = n \tag{13}$$

viewed as a superposition of plane waves arranged to cancel each other outside the boundaries of the packet. In order to produce cancellation, waves must be mixed in which are in phase with the wave of angular frequency ω in the middle of the packet and which are half a period out of phase at both ends. In other words, waves must be mixed in with periods around $2\pi/\omega'$, where Eq. (14) holds. The difference

$$\Delta t_W \frac{\omega'}{2\pi} = n \pm 1 \tag{14}$$

of Eqs. (13) and (14) gives Eq. (15), where the spread

$$\Delta t_W \Delta\omega = 2\pi \tag{15}$$

in angular frequencies $|\omega - \omega'|$ is called $\Delta\omega$. This result should be stated as an approximate inequality (16). A large Δt_W permits a small $\Delta\omega$ and therefore

$$\Delta t_W \Delta\omega \gtrsim 1 \tag{16}$$

a well-defined frequency, while a small Δt_W implies a large $\Delta\omega$ and a poorly defined frequency.

Quantitative definitions. To go beyond qualitative descriptions and order-of-magnitude relations, it is useful to define the fundamental quantities in terms of correlation functions.

Self-coherence function. As discussed above, there are two ways to view the random fluctuations in the phase of a wave. One can discuss splitting the wave into two beams that interfere after a difference τ in traversal time, or one can discuss one wave that is passing over a fixed observer who determines the phase fluctuations. Both approaches concern the correlation between $\Psi(x,t)$ and $\Psi(x, t + \tau)$. This correlation is described by the normalized self-coherence function given by Eq. (17). The brackets

$$\gamma(\tau) \equiv \frac{\langle \Psi(x, t+\tau)\Psi^*(x, t)\rangle}{\langle \Psi(x, t)\Psi^*(x, t)\rangle} \tag{17}$$

$\langle\,\rangle$ indicate the average of the enclosed quantity over a time which is long compared to the resolving time of the observer. It is assumed here that the statistical character of the wave does not change during the time of interest, so that $\gamma(\tau)$ is not a function of t.

With the aid of the self-coherence function, the coherence time of a wave can be defined quantitatively by Eq. (18). That is, Δt_W is the root-mean-squared

$$(\Delta t_W)^2 \equiv \frac{\displaystyle\int_{-\infty}^{+\infty} \tau^2 \, |\gamma(\tau)|^2 \, d\tau}{\displaystyle\int_{-\infty}^{+\infty} |\gamma(\tau)|^2 \, d\tau} \tag{18}$$

width of $|\gamma(\tau)|^2$. The approximate inequality (16) can also be made precise. The quantity $|g(\omega')|^2$ is proportional to the contribution to Ψ at the angular frequency ω', where $g(\omega')$ is the Fourier transform of Ψ, defined by Eq. (19). The root-mean-squared width

$$g(\omega') \equiv \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} \Psi(0, t) e^{-i\omega' t} dt \tag{19}$$

$\Delta\omega$ of this distribution is given by Eq. (20), where ω

$$(\Delta\omega)^2 = \frac{\displaystyle\int_0^{\infty} (\omega' - \omega)^2 \left|g(\omega')\right|^2 d\omega'}{\displaystyle\int_0^{\infty} \left|g(\omega')\right|^2 d\omega'} \tag{20}$$

is again the mean angular frequency. With these definitions, one can show that inequality (21) is satisfied.

$$\Delta t_W \Delta\omega \geq {}^1/_2 \tag{21}$$

The symbol $\gtrsim$ has become $\geq$; no situation can lead to a value of $\Delta t_W \Delta\omega$ that is less than $^1/_2$. Relation (21) multiplied by Planck's constant is the Heisenberg uncertainty principle of quantum physics, and can in fact be proved in virtually the same way. *See* NONRELATIVISTIC QUANTUM THEORY; UNCERTAINTY PRINCIPLE.

Complex degree of coherence. To describe the coherence between two different waves Ψ_A and Ψ_B, one can use the complex degree of coherence $\gamma_{AB}(\tau)$, defined by Eq. (22), where the averaging process $\langle\,\rangle$

$$\gamma_{AB}(\tau) \equiv \frac{\langle \Psi_A(t+\tau)\Psi_B{}^*(t)\rangle}{\left[\langle \Psi_A{}^*(t)\Psi_A(t)\rangle \langle \Psi_B{}^*(t)\Psi_B(t)\rangle\right]^{1/2}} \tag{22}$$

and the assumptions are the same as for the definition of $\gamma(\tau)$. If beams A and B are brought together, interference fringes may be formed where the time-averaged resultant intensity $\langle|\Psi|^2\rangle$ has maxima and minima as a function of position. The visibility of these fringes, defined by Eq. (23), can be shown, for

$$V = \frac{\langle|\Psi|^2\rangle_{\max} - \langle|\Psi|^2\rangle_{\min}}{\langle|\Psi|^2\rangle_{\max} + \langle|\Psi|^2\rangle_{\min}} \tag{23}$$

the usual interference studies, to be proportional to $|\gamma_{AB}(\tau)|$.

Examples. The concept of coherence occurs in a great variety of areas. The following are some application and illustrations.

Astronomical applications. As is shown in the above discussion, extended sources give partial coherence and produce interference fringes with visibility V [Eq. (23)] less than unity. A. A. Michelson exploited this fact with his stellar interferometer (**Fig. 5**), a modified double-slit arrangement with movable mirrors that permit adjustment of the effective separation D' of the slits. According to Eq. (11), there is

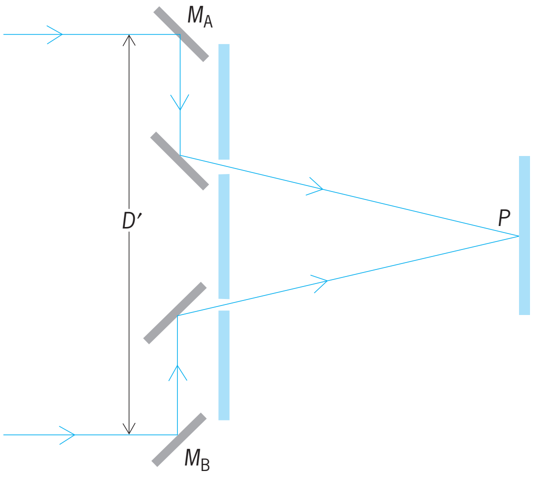

Fig. 5. Michelson's stellar interferometer. The effective slit separation D' can be varied with the movable mirrors M_A and M_B. The angular size of the source can be calculated from the resulting change in the visibility of the interference fringes around P.

partial coherence if the angular size of the source is about λ/D'. It can be shown that if the source is a uniform disk of angular diameter Θ, then the smallest value of D' that gives zero V is $1.22\lambda/\Theta$. The interferometer can therefore be used in favorable cases to measure stellar diameters. The same approach has also been applied in radio astronomy. A different technique, developed by R. Hanbury Brown and R. Q. Twiss, measures the correlation between the intensities received by separated detectors with fast electronics. *See* INTERFEROMETRY; RADIO ASTRONOMY.

Lasers and masers. Because they are highly coherent sources, lasers and masers provide very large intensities per unit frequency, and double-photon absorption experiments have become possible. As a consequence, atomic and molecular spectroscopy were revolutionized. One can selectively excite molecules that have negligible velocity components in the beam direction and thus improve resolution by reduction of Doppler broadening. States that are virtually impossible to excite with single-photon absorption can now be reached. *See* LASER SPECTROSCOPY; MASER.

Musical acoustics. Fortunately, for most musical instruments the coherence time is much less than human resolving time, so that the separate contributions in an orchestra are perceived incoherently. Equation (7) applies, and 20 violins seem to provide 20 times the intensity of 1 violin. If human resolving time were much shorter, the perceived intensity would drift between 0 and 400 times the intensity of a single violin. *See* MUSICAL ACOUSTICS.

Thermodynamic treatment of radiation. Coherence must be considered in thermodynamic treatments of radiation. As one should expect from the connection between entropy and order, entropy is reduced by an increase in coherence. The total entropy of two beams that are coherent with respect to each other is less than the sum of the entropies of the separate beams, because coherence means that the beams are not statistically independent. *See* ENTROPY; THERMODYNAMIC PRINCIPLES.

Quantum physics. In quantum physics, a beam of particles can for some purposes be described by Eq. (1) without the phase $\delta A(t)$. If the wavelength is well defined, measurables such as barrier transmission coefficients and scattering cross sections of sufficiently small targets do not depend on phases and coherence. If, however, the scattering object is large, these aspects may have to be considered.

Electrons emitted by hot filaments show coherence times of roughly 10^{-14} s. In low-energy electron diffraction, where speeds on the order of 10^8 to 10^9 cm/s are used, the coherence length is then on the order of 10^{-5} cm, and the structure can be seen clearly only if the region being studied does not introduce a path length difference greater than this distance. *See* ELECTRON DIFFRACTION.

Most nuclear and particle physics experiments deal with energies so high that the wavelengths of the projectiles are less than 10^{-12} cm, far less than the amplitudes of motions of the scattering nuclei. The many nuclei therefore contribute to the scattered beam incoherently. Equation (7) applies, and the intensity of the scattered beam is proportional to the scattering cross section per nucleus times the number of nuclei. Rolf G. Winter

Photon statistics. Photon statistics is concerned with the probability distribution describing the number of photons incident on a detector, or present in a cavity. By extension, it deals with the correlation properties of beams of light.

According to the quantum theory of electromagnetism, quantum electrodynamics, light is made up of particles called photons, each of which possesses an energy E of $\hbar\omega$, where $\hbar$ is Planck's constant divided by 2π and ω is the angular frequency of the light (the frequency multiplied by 2π). In general, however, the photon number is an intrinsically uncertain quantity. It is impossible to precisely specify both the phase $\phi = \omega t$ of a wave and the number of photons $n \approx E/(\hbar\omega)$ that it contains; the uncertainties of these two conjugate variables must satisfy $\Delta n \Delta\phi \geq {}^1/_2$. For a beam to be coherent in the sense of having a well-defined phase, it must not be describable in terms of a fixed number of particles. (Lacking a fixed phase, a single photon may interfere only with itself, not with other photons.) *See* PHOTON; QUANTUM ELECTRODYNAMICS.

The most familiar example of this uncertainty is shot noise, the randomness of the arrival times of individual photons. There is no correlation between photons in the coherent state emitted by a classical source such as an ideal laser or radio transmitter, so the number of photons detected obeys Poisson statistics, displaying an uncertainty equal to the square root of the mean. The shot noise constitutes the dominant source of noise at low light levels, and may become an important factor in optical communications as well as in high-precision optical devices (notably those that search for gravitational radiation). *See* DISTRIBUTION (PROBABILITY); ELECTRICAL NOISE.

Instead of considering light in terms of phase and photon number, one may equivalently discuss the amplitudes of the two quadrature components, cos *ωt* and sin *ωt*. Another uncertainty relation applies between these conjugate variables, implying that even in the so-called vacuum state (zero photons) these two field amplitudes cannot both be precisely zero. Shot noise may be seen as a relic of these ever-present vacuum fluctuations.

Coherent states (in which the two quadratures are determined to equal accuracy) and states in which the photon number is known precisely may both seem somehow ideal. Until the invention of the laser, essentially all light sources fell far from this ideal: In stars, candles, and light bulbs, the randomness of thermal fluctuations leads to more noise than the minimum required by the uncertainty principle. This noise may be described in terms of bunching. To every process in which a photon can be emitted spontaneously, there corresponds a process in which an already-present photon can stimulate the emission of a second photon, with probability equal to that of the spontaneous process. Once a photon is observed in a thermal beam, the probability of detecting another photon is thus twice the mean probability of photon detection in the beam as a whole. *See* BOSE-EINSTEIN STATISTICS.

Antibunching effects, in which detection of one photon makes detection of subsequent photons less likely, cannot be explained by any classical wave theory. Such behavior is precisely what would be expected for a beam of a fixed number of particles. If a single photon is incident on a beam splitter, it may be detected at either output, but never both. Single-photon states have been created in the laboratory, and their indivisibility has been observed.

So-called squeezed states are those in which the uncertainty of a given variable (for example, the number, phase, or a given quadrature) is smaller than it would be for a coherent state, while the uncertainty for the conjugate variable is larger. The noise in certain measurements is thus reduced below the so-called standard quantum limit, while the uncertainty principle is still obeyed. *See* SQUEEZED QUANTUM STATES.

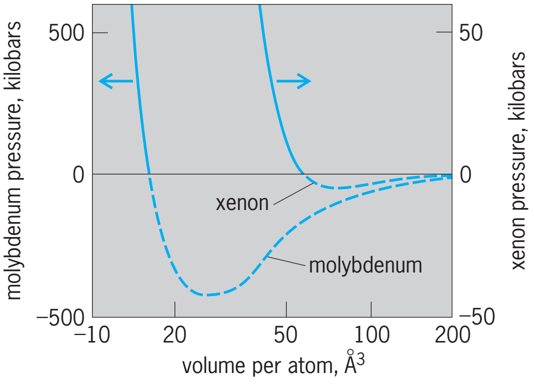
Cohesion (physics)

The tendency of atoms or molecules to coalesce into extended condensed states. This tendency is practically universal. In all but exceptional cases, condensation occurs if the temperature is sufficiently low; at higher temperatures, the thermal motions of the constituents increase, and eventually the solid assumes gaseous form. The cohesive energy is the work required to separate the condensed phase into its constituents or, equivalently, the amount by which the energy of the condensed state is lower than that of the isolated constituents. The science of cohesion is the study of the physical origins and manifestations of the forces causing cohesion, as well as those opposing it. It is thus closely related to the science of chemical bonding in molecules, which treats small collections of atoms rather than extended systems. *See* CHEMICAL BONDING; INTERMOLECULAR FORCES.

When the constituent atoms or molecules are far separated, an attractive force is present. This force is due, directly or indirectly, to the electrostatic interactions of the negatively charged electrons and the positively charged ions. However, when the distances between the constituents become very short, a strong repulsive force results, which is due to the quantum-mechanical kinetic energy of the electrons. The competition between the attractive and repulsive forces determines the equilibrium density for the condensed state (see **illus.**). A positive pressure at a given volume means that pressure must be applied to the solid to keep it at this volume; thus the forces between the atoms are predominantly repulsive. Similarly, the pressure is negative when the forces are predominantly attractive. Both molybdenum and xenon have attractive interactions at large volumes. As the volume drops, the attractive forces reach a maximum and then begin to be canceled by the repulsive forces. The equilibrium volume of the solid is that for which the cancellation is complete, or the pressure vanishes. The equilibrium point actually occurs when the pressure equals the atmospheric pressure, which is approximately 1 bar (100 kilopascals). However, this pressure is effectively zero on the pressure scale of the illustration. *See* COULOMB'S LAW; QUANTUM MECHANICS.



Calculated pressure-volume curves for molybdenum and xenon at absolute zero. Negative-pressure portions of curves are represented by broken lines because they cannot be directly measured. 1 kilobar = 0.1 GPa; 1 Å^3 = 0.001 nm^3.

Attractive forces. The origin and magnitude of the attractive forces depend on the chemical nature of the constituent atoms or molecules. Strong attractive interactions are usually associated with constituents having valence electron shells which are partly filled or open; if the valence electron shells are completely filled or closed, the interactions are weaker. *See* VALENCE.

Open-shell constituents. This is most easily understood for atomic systems. As the atoms approach, the electron energy levels on different atoms begin to interact, forming a complex of energy levels in the solid. Some of these are below the atomic energy levels and some above. Since the atomic shells are partly filled, the lower energy levels in the solid are filled, but at least some of the higher levels are empty. Thus the average energy of the occupied levels in the solid is lower than that in the isolated atoms, resulting in an attractive force. Bonding in open-shell systems can be approximately divided into three categories, although most cases involve a combination *See* BAND THEORY OF SOLIDS; FERMI-DIRAC STATISTICS; SOLID-STATE PHYSICS; VALENCE BAND.

1. *Covalent bonding*. This type of bonding is most similar to the molecular bond. The electron energy levels in the solid are split into a lower and a higher portion, with the states in the lower one filled and the higher one empty. Covalent bonds are strongly directional, with electron charge accumulating around the bond centers. Materials bonded in this fashion typically form structures with low coordination numbers, prototypical materials elements in group 14 of the periodic table, the insulator carbon, and the semiconductors silicon and germanium. *See* PERIODIC TABLE; SEMICONDUCTOR.

2. *Metallic bonding*. In this case, there is no split between the lower and higher states of the electrons in the solid; rather, they occupy levels from the bottom up to a cutoff point known as the Fermi level. For example, in transition metals, the electron states in the solid derived from the atomic *d* orbitals form a complex which is gradually filled with increasing atomic number. The bulk of the cohesive energy is due to this complex. The metallic bond is less directional than the covalent bond, with a more uniform distribution of electronic charge. Metals usually form closely packed structures. *See* FERMI SURFACE; FREE-ELECTRON THEORY OF METALS.

3. *Ionic bonding*. This occurs in compounds having at least two distinct types of atoms. One or more of the species of atoms (the cations) have only a small number of electrons in their valence shells, whereas at least one species (the anions) has a nearly filled valence shell. As the atoms approach each other, electrons drop from the cation valence states into holes in the anion valence shell, forming a closed-shell configuration in the solid. The different types of atoms in the solid have net charges; a strong attractive force results from the interaction between unlike charges. For example, in sodium chloride (NaCl), the sodium atoms acquire positive charges, and the chlorine atoms acquire negative charges. The closest interatomic separations in the solid are between sodium and chlorine, so that the attractive electrostatic interactions outweigh the repulsive ones. *See* IONIC CRYSTALS; SOLID-STATE CHEMISTRY.

Closed-shell constituents. In these systems the above effects are greatly reduced because the atomic or molecular shells are basically inert. The constituents retain their separate identities in the solid environment. If the constituents are atomic, as in rare-gas solids, the cohesion is due to the van der Waals forces. The positions of the electrons in an atom fluctuate over time, and at any given time their distribution is far from spherical. This gives rise to fluctuating long-ranged electric fields, which average zero over time, but can still have appreciable effects on neighboring atoms. The electrons on these atoms move in the direction of the force exerted by the electric field. The net result is that the interactions between unlike charges (electrons and nuclei) are increased in the solid, whereas the interactions between like charges are reduced. Thus the solid has a lower energy than the isolated atoms.

In solids made up of molecules, there are additional electrostatic interactions due to the nonspherical components of the molecular charge density. These interactions are strongest if the molecules are polar. This means that the center of the positive charge on the molecule is at a different point in space from that of the negative charge. Polar molecules, such as water (H_2O), form structures in which the positive charge on a molecule is close to the negative charges of its neighbors. For nonpolar molecules, the electrostatic interactions are usually weaker than the van der Waals forces. The nonspherical interactions in such cases are often so weak that the molecules can rotate freely at elevated temperatures, while the solid is still held together by the van der Waals forces.

Repulsive forces. The repulsive forces in the condensed phase are a dramatic illustration of the combined action of two quantum-mechanical principles, the exclusion principle and the uncertainty principle.

The exclusion principle states that the quantum-mechanical wave function for the electrons in the solid must be antisymmetric under the interchange of the coordinates of any two electrons. Consequently, two electrons of the same spin are forbidden from being very close to each other. *See* EXCLUSION PRINCIPLE.

The uncertainty principle states that if the motion of an electron is confined, its kinetic energy must rise, resulting in a repulsive force opposing the confinement. The kinetic energy due to the confinement is roughly inversely proportional to the square of the radius of the region of confinement. According to the exclusion principle, the motion of an electron in a solid is partially confined because it is forbidden from closely approaching other electrons of the same spin. Thus the uncertainty principle in turn implies a repulsive force. *See* UNCERTAINTY PRINCIPLE.

The magnitude of the repulsive force always exceeds that of the attractive force when the volume per atom becomes sufficiently small. This is most readily understood in the simple metals, which are, roughly, metals in groups 1 through 14. In these metals the electrons can be approximately treated as if they were spread uniformly throughout the solid. If the metal is compressed, the repulsive kinetic energy due to the electron confinement is approximately proportional to d^{-2}, where d is the interatomic separation. The energy due to the attractive force, in contrast, is proportional only to d^{-1}. Thus the repulsive force due to the kinetic energy dominates if d is sufficiently small.

Variations between materials. There are enormous variations between materials in the strength of the cohesive forces. For example, the maximal attractive force in molybdenum, an open-shell solid, corresponds to a negative pressure of nearly 500,000 bars (50 gigapascals); that in xenon, a closed-shell solid, is roughly 100 times smaller (see illus.) This is reflected in a much larger equilibrium volume per atom for xenon, even though the size of an isolated molybdenum atom exceeds that of a xenon atom. The variations in the cohesive forces are also reflected in the boiling point, which is the highest temperature at which a condensed state exists. This can be over 5000°C (9000°F) in open-shell systems, and is usually higher than 200°C (400°F). In elemental closed-shell systems, in contrast, the boiling point is usually below 0°C (32°F); in helium it is −269°C (−452°F), or 4°C (7°F) above absolute zero. Many other properties correlate with the strength of the cohesive forces, including the melting point, elastic moduli, and the energies required to form defects such as vacancies and surfaces. The variations in these properties from material to material have a large impact on their technological applications. *See* CRYSTAL DEFECTS.

Weakening of attractive forces. In analyzing the mechanical properties of solids, it is often conceptually useful to think of the force on a particular atom as being the sum of independent forces due to neighboring atoms. Such a picture is justified for solids consisting of closed-shell atoms or molecules, but is often an inaccurate representation of the forces in open-shell systems, particularly in metals. The attractive force in a solid metal can be several times weaker than that in a dimer molecule, because the atoms interact too strongly with each other to maintain their separate identities; the electrons, instead of being localized on individual atoms, are in states that extend throughout the solid. The weakening of the attractive forces in the solid manifests itself in the atomic geometries around defects. For example, the attractive forces in the vicinity of vacancies or surfaces are intermediate in strength between those in the solid and those in the dimer molecule. This usually results in shorter interatomic separations around these defects, if it is possible for the bonds to contract. In addition, a major contribution to the surface tensions of solids results from changes in the attractive forces near the surface. Anders E. Carlsson

Coining

A cold metalworking process in a press-type die. Coining is used to produce embossed parts, such as badges and medals, and for minting of coins. It is also used on portions of a blank or workpiece to form corners, indentations, or raised sections, frequently as part of a progressive die operation. The work is subjected to high pressure within the die cavity and thereby forced to flow plastically into the die details. The absence of overflow of excess metal from between the dies is characteristic of coining and is responsible for the fine detail achieved. However, because this action requires highly accurate dies and higher-than-usual die pressures, only essential surfaces are coined. *See* METAL FORMING.

Ralph L. Freeman

Coir

A natural fiber, also known as coco fiber, obtained from the husks of the coconut (*Cocos nucifera*). Although coconuts are grown for copra throughout the tropics and into the subtropics, more than 95% of the coir exports are from Sri Lanka and India. Small amounts are exported from Thailand, Tanzania, Mexico, the Philippines, Malaysia, Kenya, Trinidad, and Tobago. A few other countries produce small amounts of fiber for their own use.

The cells of coir average about 0.028 in. (0.7 mm) in length and about 20 micrometers in width. The cells may have either blunt or pointed ends, and the cell wall has numerous pits. The lumen width and the cell wall thickness are about equal. Coir is a highly lignified fiber and becomes more lignified as it matures.

The outstanding characteristic of coir fiber is its resistance to rot. For example, a coir fiber doormat can stay out in the weather for years. Coir is only intermediate in strength among the vegetable fibers, but its elongation at break is greater than any of the bast or hard fibers.

Types. There are three main types of coir—yarn fiber, bristle fiber, and mattress fiber. Nearly all the yarn fiber comes from southern India; much of the mattress fiber and essentially all the bristle fiber come from Sri Lanka.

Only the finest and longest fiber is suitable for spinning into yarn. It is obtained from the husks of unripe nuts and is the main cash crop rather than a byproduct. The bristle fiber and most of the mattress fiber come from mature nuts and are by-products of copra production.

Production. The yarn and bristle fiber and much of the mattress fiber extraction starts with a natural bacteriological process called retting. The loosened fibers are later separated from the nonfibrous material by mechanical action. Immature husks are used for yarn fiber, while mature husks are used to make bristle and mattress fiber.

Yarn fiber. Within a week after harvest the husks are separated from the shell containing the copra and split into four or five pieces which are put into water for retting, to decompose the nonfibrous materials. Retting usually takes 5 to 6 months but sometimes it requires as long as 10 months. The favored retting centers are in the brackish waters of river estuaries, but many husks are retted in tanks, ponds, lakes, and streams. The circulation of water through the husks—either as a result of a tide, the flow of a stream, or changing the water in a tank—improves the quality of the fiber.

After retting, the husks are washed, air-dried, and then beaten with mallets, stones, or sticks to loosen the fiber and remove the nonfiber materials that have decomposed. Some combing is usually done, either by steel combs mounted on wooden wheels or by stationary combs. Then the fiber is spun by hand into single- or two-ply yarn.

Bristle and mattress fiber. For these fibers, the period of retting is much shorter. Before retting, the nuts are frequently allowed to mature further after harvesting so as to even out the quality of the copra produced from them.

The bristle and mattress fiber is usually separated from retted husks by machines, although the separation still requires extensive hand labor. An increasing number of establishments, especially in new areas, are extracting the fiber from green or dry, unretted husks by automatic machines. However, fiber obtained in such a manner is shorter than fiber obtained by traditional processes and is irretrievably mixed so it must be sold as mattress fiber.

Sorting and grading. Coir fiber ranges in color from light tan to dark brown. Bristles are sorted according to length, which ranges from about 6 to 14 in. (15 to 35 cm), and are packed into bundles of about 17.5 oz (500 g) each. Mattress fiber is packed in small bales of about 11 lb (5 kg) each, and yarn is put up in skeins. Before these packages are put into large bales for shipment, the fiber is graded and sometimes resorted. The fiber is graded on the basis of length, stiffness, color, and cleanliness. Long, clean fibers and light color are desirable for any purpose, but stiffness is desirable in bristles and undesirable for yarn.

Uses. In developed countries, yarn fiber is used chiefly in mats and mattings; in the United States, for instance, its best-known use is in light-brown tufted doormats. In Asia it is used extensively for ropes and twines, and locally for hand-made bags. The principal outlet for bristle fiber has been in brush making, but the market has declined and most bristle fiber is now used in upholstery padding. Mattress fiber is used chiefly in innerspring mattresses, though it has found uses as an insulating material. *See* COCONUT; NATURAL FIBER. Elton G. Nelson

Coke

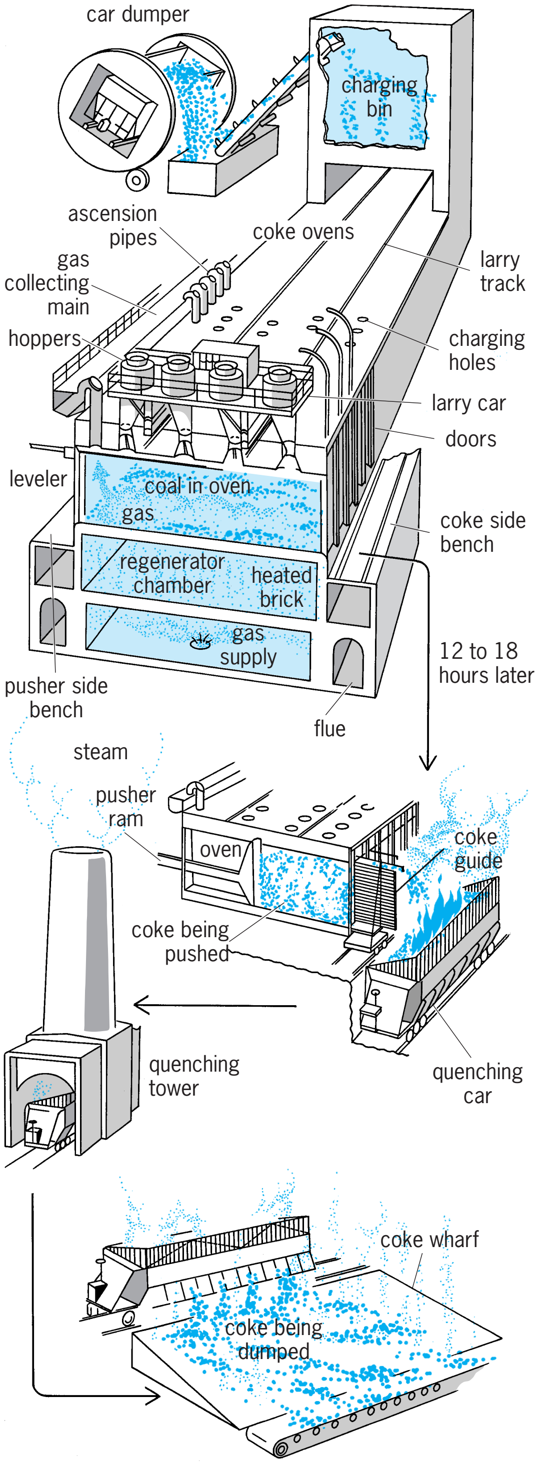
A coherent, cellular, carbonaceous residue remaining from the dry (destructive) distillation of a coking coal. It contains carbon as its principal constituent, together with mineral matter and residual volatile matter. The residue obtained from the carbonization of a noncoking coal, such as subbituminous coal, lignite, or anthracite, is normally called a char. Coke is produced chiefly in chemical-recovery coke ovens (see **illus.**), but a small amount is also produced in beehive or other types of nonrecovery ovens.

Uses and types. Coke is used predominantly as a fuel reductant in the blast furnace, in which it also serves to support the burden. As the fuel, it supplies the heat as well as the gases required for the reduction of the iron ore. It also finds use in other reduction processes, the foundry cupola, and househeating. About 91% of the coke made is used in the blast furnace, 4% in the foundry, 1% for water gas, 1% for househeating, and 3% for other industries, such as calcium carbide, nonferrous metals, and phosphates. Approximately 1300 lb (560 kg) of coke is consumed per ton of pig iron produced in the modern blast furnace, and about 200 lb (90 kg) of coke is required to melt a ton of pig iron in the cupola.

Coke is classified not only by the oven in which it is made, chemical-recovery or beehive, but also by the temperature at which it is made. High-temperature coke, used mainly for metallurgical purposes, is produced at temperatures of 1650–2100°F (900–1150°C). Medium-temperature coke is produced at 1380–1650°F (750–900°C), and low-temperature coke or char is made at 930–1380°F (500–750°C). The latter cokes are used chiefly for househeating, particularly in England. The production of these is rather small as compared to high-temperature coke and usually requires special equipment. Coke is also classified according to its intended use, such as blast-furnace coke, foundry coke, water-gas coke, and domestic coke.

Production. Coke is formed when coal is heated in the absence of air. During the heating in the range of 660–930°F (350–500°C), the coal softens and then fuses into a solid mass. The coal is partially devolatilized in this temperature range, and further heating at temperatures up to 1830–2000°F (1000–1100°C) reduces the volatile matter to less than 1%. The degree of softening attained during heating determines to a large extent the character of the coke produced.

In order to produce coke having desired properties, two or more coals are blended before charging into the coke oven. Although there are some exceptions, high-volatile coals of 32–38% volatile-matter content are generally blended with low-volatile coals of 15–20% volatile matter in blends containing 20–40% low-volatile coal. In some cases, charges consist of blends of high-, medium-, and low-volatile coal. In this way, the desirable properties of each of the coals, whether it be in impurity content or in its contribution to the character of the coke, are utilized.



Steps in the production of coke from coal. After the coal has been in the oven for 12–18 h, the doors are removed and a ram mounted on the same machine that operates the leveling bar shoves the coke into a quenching car for cooling. (*American Iron and Steel Institute*)

The low-volatile coal is usually added in order to improve the physical properties of the coke, especially its strength and yield. In localities where low-volatile coals are lacking, the high-volatile coal or blends of high-volatile coals are used without the benefit of the low-volatile coal. Insome cases, particularly in the manufacture of foundry coke, a small percentage of so-called inert, such as fine anthracite, coke fines, or petroleum coke, is added.

In addition to the types of coals blended, the carbonizing conditions in the coke oven influence the characteristics of the coke produced. Oven temperature is the most important of these and has a significant effect on the size and the strength of the coke. In general, for a given coal, the size and shatter strength of the coke increase with decrease in carbonization temperature. This principle is utilized in the manufacture of foundry coke, where large-sized coke of high shatter strength is required.

Properties. The important properties of coke that are of concern in metallurgical operations are its chemical composition, such as moisture, volatile-matter, ash, and sulfur contents, and its physical character, such as size, strength, and density. For the blast furnace and the foundry cupola, coke of low moisture, volatile-matter, ash, and sulfur content is desired. The moisture and the volatile-matter contents are a function of manner of oven operation and quenching, whereas ash and sulfur contents depend upon the composition of the coal charged. Blast-furnace coke used in the United States normally contains less than 1% volatile matter, 85–90% fixed carbon, 7–12% ash, and 0.5–1.5% sulfur. If the coke is intended for use in the production of Bessemer or acid open-hearth iron, the phosphorus content becomes important and should contain less than 0.01%.

The requirements for foundry coke in analysis are somewhat more exacting than for the blast furnace. The coke should have more than 92% fixed carbon, less than 8% ash content, and less than 0.60% sulfur.

Blast-furnace coke should be uniform in size, about $2^{1}/_{2}$–5 in. (6.4–13 cm), but in order to utilize more of the coke produced in the plant, the practice has been, in some cases, to charge separately into the furnace the smaller sizes after they were closely screened into sizes such as $2^{1}/_{2} \times 1^{3}/_{4}$ in. (6.4×4.5 cm), $1^{3}/_{4} \times 1$ in. (4.5×2.5 cm), down to about $^{3}/_{4}$ in. (1.9 cm) in size. There is now a trend, when pelletized ore is used, to crush and screen the coke to a more closely sized material, such as $2^{1}/_{2} \times {}^{3}/_{4}$ in. (6.4×1.9 cm).

The blast-furnace coke should also be uniformly strong so that it will support the column of layers of iron ore, coke, and stone above it in the furnace without degradation. Standard test methods, such as the tumbler test and the shatter test, have been developed by the American Society for Testing and Materials for measuring strength of coke. Good blast-furnace cokes have tumbler test stability factors in the range of 45 to 65 and shatter indices (2-in. or 5-cm sieve) in the range of 70 to 80%. These are not absolute requirements since good blast-furnace performance is obtained in some plants with weaker coke—but with the ore prepared so as to overcome the weakness.

Foundrymen prefer coke that is large and strong. The coke for this purpose ranges in size from 3 to 10 in. (7.6 to 25 cm) and larger. The size used usually depends upon the size of the cupola and, in general, the maximum size of the coke is about one-twelfth of the diameter of the cupola. High shatter strength is demanded by the cupola operator; shatter indices of at least 97% on 2-in. (5-cm) and 80% on 3-in. (7.6-cm) sieves have been specified.

Other important requirements of foundry coke are high reactivity toward oxygen so that carbon dioxide is produced with high heat evolution, and low reactivity toward carbon dioxide so that the amount of carbon monoxide formed is minimized.

The requirements for coke intended for house-heating vary in different localities. Usually the coke is of a narrow size range, and the size used depends upon the size and type of appliance. In general, a high ash-softening temperature is desirable (more than 2500°F or 1370°C).

Coke intended for water-gas generators should be over 2 in. (5 cm) in size, and should have an ash content below 10% and a moderately high ash-softening temperature. *See* CHARCOAL; COAL; COAL CHEMICALS; DESTRUCTIVE DISTILLATION; FOSSIL FUEL; PYROLYSIS. Michael Perch

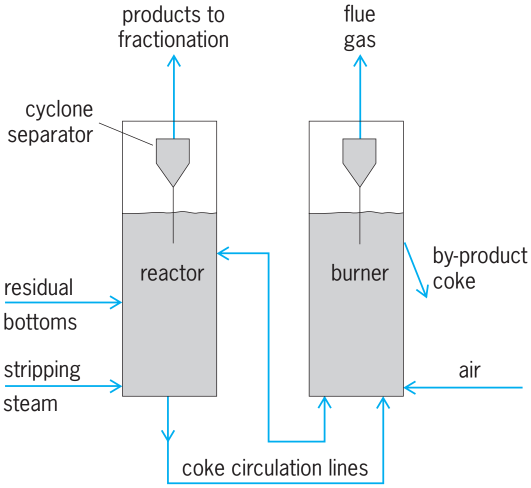
Coking (petroleum)

In the petroleum industry, a process for converting nondistillable fractions (residua) of crude oil to lower-boiling-point products and coke. Coking is often used in preference to catalytic cracking because of the presence of metals and nitrogen components that poison catalysts. There are various coking processes: delayed coking, fluid coking, and flexicoking as well as several others. *See* CRACKING.

Delayed coking. The oldest and most widely used coking process, delayed coking has changed very little in the five or more decades that it has been on-stream in refineries. In the semicontinuous process, the residuum or other heavy feedstock is heated to the cracking/coking temperature (>350°C or 660°F, but usually at temperatures on the order of 480°C or 895°F), and the hot liquid is charged, usually by upflow, to the coke drum, where the coking reactions occur. Liquid and gaseous products pass to the fractionator for separation, and the coke deposits in the drum. The coke drums are arranged in pairs, one on-stream and the other off-stream; and they are used alternately to allow continuous processing. Thus they can be operated on a cycle, typically 24–48 h.

The overhead oil is fractionated into fuel gas (ethane and lower-molecular-weight gases), propane-propylene, butane-butene, naphtha, light gas oil, and heavy gas oil. Yields and product quality vary widely because of the broad range of feedstock types charged to the delayed coking process.



Fluid coking process.

The function of the coke drum is to provide the residence time required for the coking reactions and to accumulate the coke. Hydraulic cutters are used to remove coke from the drum.

Fluid coking. Fluid coking is a continuous fluidized solids process that cracks the feedstock thermally over heated coke particles in a reactor vessel to gas, liquid products, and coke. Heat for the process (see **illus.**) is supplied by partial combustion of the coke, with the remaining coke being drawn as product. The new coke is deposited in a thin fresh layer on the outside surfaces of the circulating coke particles.

Small particles of coke made in the process circulate in a fluidized state between the vessels and serve as the heat transfer medium. Thus the process requires no high-temperature preheat furnace. Fluid coking is carried out at essentially atmospheric pressure and temperatures in excess of 485°C (900°F) with residence times of the order of 15–30 s. The shorter residence time in the fluid coker is in contrast to the residence time of the delayed coker, where the coking reactions are allowed to proceed to completion. This difference is evident from the somewhat higher liquid yields observed in many fluid coking processes. However, the products from a fluid coker may be somewhat more olefinic and slightly less desirable for downstream processing.

Flexicoking. A modification of the fluid coking process, flexicoking also includes a gasifier adjoining the burner/regenerator to convert excess coke to a clean fuel gas with a heating value of about 90 Btu/ft^3 (335 joules/m^3). The coke gasification can be controlled to burn about 95% of the coke to maximize production of coke gas, or at a reduced level to produce both gas and a coke. This flexibility permits adjustment for coke market conditions over a considerable range of feedstock properties and coking processes.

Suitable feedstocks include vacuum residua of all types, asphalt, tar-sand bitumen, and visbreaker bottoms (volatile residues remaining from the viscosity-breaking process).

Uses. The liquid products from the coker, after cleanup via commercially available hydrodesulfurization technology, can provide large quantities of low-sulfur liquid fuels (less than 0.2 wt % sulfur). Another major application for the processes is upgrading heavy low-value crude oils into lighter products.

Petroleum coke is used principally as a fuel or, after calcining, for carbon electrodes. The feedstock from which the coke is produced controls the coke properties, especially in terms of sulfur, nitrogen, and metals content. A concentration effect tends to deposit the majority of the sulfur, nitrogen, and metals in the coke. Cokes exceeding around 2.5% sulfur content and 200 parts per million vanadium are mainly used, environmental regulations permitting, for fuel or fuel additives. The properties of coke for nonfuel use include low sulfur, metals, and ash as well as a definable physical structure. *See* PETROLEUM PROCESSING AND REFINING; PETROLEUM PRODUCTS. James G. Speight

Bibliography. J. G. Gary and G. E. Handwerk, *Petroleum Refining: Technology and Economics*, 3d ed., 1984; J. G. Speight, *The Chemistry and Technology of Petroleum*, 2d ed., 1991; J. G. Speight, *Fuel Science and Technology Handbook*, 1990.

Cola

A tree, *Cola acuminata*, of the family Sterculiaceae and a native of tropical Africa. Its fruit is a star-shaped follicle containing eight hard seeds, the cola nuts of commerce (see **illus.**). These nuts are an important masticatory in many parts of tropical Africa. They have a caffeine content twice that of coffee. The nuts also contain an essential oil and a glucoside, kolanin, which is a heart stimulant. Cola nuts, in combination with an extract from coca, are used in the manufacture of the beverage Coca-Cola. Cola is now cultivated in West Africa, Jamaica, Brazil, India, and other parts of tropical Asia. *See* COCA; MALVALES.

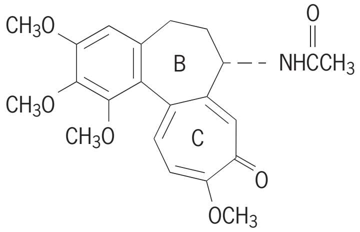
Perry D. Strausbaugh; Earl L. Core

Cola (*Cola acuminata*) branch.

Colchicine

The major alkaloid obtained from the seed capsules, corms, and bulbs of the meadow saffron (autumn crocus; *Colchicum autumnale*). Colchicine is a fairly abundant alkaloid in dried corms (0.03–0.08%) and seeds (0.6–0.9%). It has been isolated also from other species of *Colchicum* and a few related genera, but they are not important sources of alkaloid. *See* ALKALOID; LILIALES.

Colchicine has an unusual structure (shown below) containing two seven-membered rings. Ring C is a tropolone system, present also in some fungal metabolites. The molecule has been synthesized in several ways, by constructing the ring system in either the sequence A → AB → ABC or A → AC → ABC.



The use of the colchicum plant to relieve the pain of gout has been known since medieval times, and colchicine is still the standard treatment for gout, although it is an extremely toxic substance.

An important property of colchicine is its ability to interrupt the mitotic cycle before cell division occurs. This effect leads to cells with multiple chromosomes, which are of value in plant breeding. The antimitotic effect of colchicine is due to strong binding of the alkaloid to the protein tubulin, thus preventing the assembly of microtubules and formation of the mitotic spindle. *See* MITOSIS; POLYPLOIDY.

James A. Moore

Cold hardiness (plant)

The ability of temperate zone plants to survive subzero temperatures. This characteristic is a predominant factor that determines the geographical distribution of native plant species and the northern limits of cultivation of many important agronomic and horticultural crops. For example, plant hardiness zone maps (**Fig. 1**) are frequently used in recommending the selection of various horticultural crops, especially woody ornamentals (see **table**) and fruit trees, for various regions. Further, freezing injury is a major cause of crop loss resulting from early fall frosts, low midwinter temperatures, or late spring frosts. Problems of cold hardiness are of concern to farmers in diverse areas of agriculture—from coffee growers in Brazil to wheat farmers in Canada; from peach growers in Georgia to apple growers in New York; from tropical foliage plant growers in Florida to producers of woody ornamentals in the northeast; from viticulturists (grape growers) in France to citrus growers

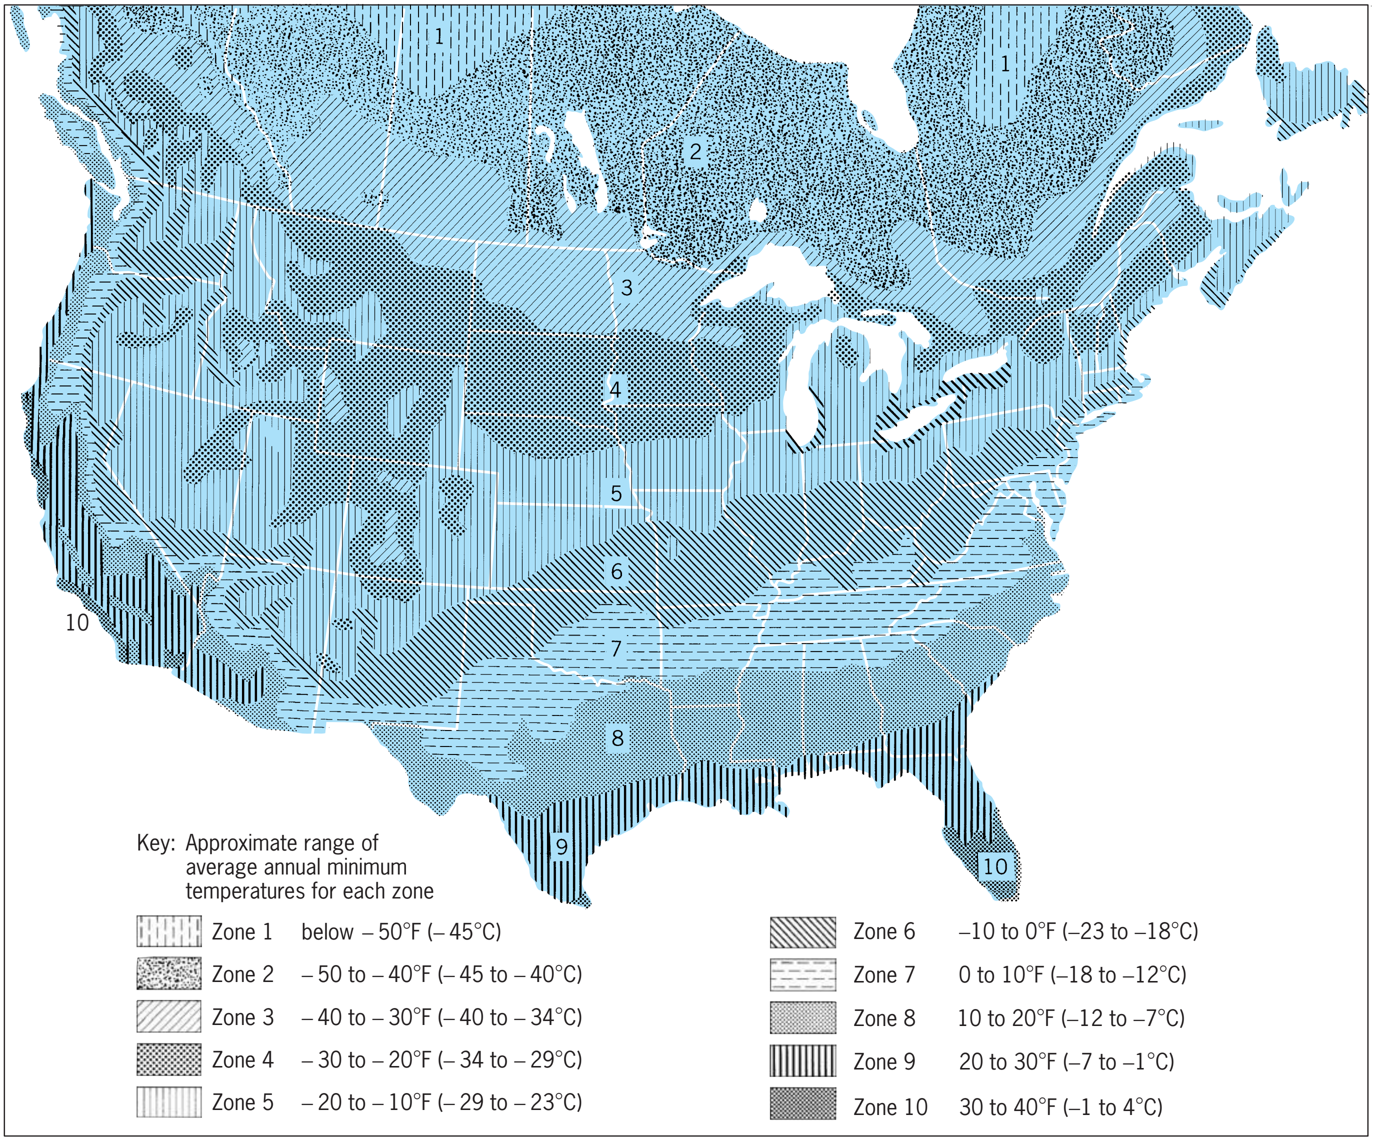


Fig. 1. Plant hardiness zone map of the United States based on isotherms of average minimum winter temperatures.

in Israel. As a result, the development of varieties of cultivated plants with improved cold hardiness is of long-standing concern.

Within the plant kingdom there is a wide range of diversity in low-temperature tolerance—from low levels of hardiness in herbaceous species such as potatoes (27 to 21°F or −3 to −6°C), to intermediate levels of hardiness for winter annuals such as wheat and rye (−4 to −22°F or −20 to −30°C), to extremely hardy deciduous trees and shrubs such as black locust and red osier dogwood that can withstand temperatures of liquid nitrogen (−321°F or −196°C). Within a given species, the range in hardiness can be substantial. For example, the cold hardiness of different varieties of deciduous fruit trees may vary by 18 to 36°F (10 to 20°C). Within a given plant there is a wide range in the cold hardiness of different tissues and organs. For example, roots are much less tolerant of subzero temperatures than shoots; flower buds are more sensitive than vegetative buds.

Environmental effects. The cold hardiness of a given species is an inherent genetic trait that requires certain environmental cues for its expression. With the shorter days and cooler nights of autumn, temperate zone plants become dormant and increase their cold hardiness. This process is referred to as cold acclimation. In the spring, increasing daylength and warmer temperatures result in the resumed growth and development of the plant and a corresponding decrease in cold hardiness. Thus, hardy species such as winter annuals, biennials, and perennials exhibit an annual periodicity in their low-temperature tolerance (**Fig. 2**). In the spring and summer these species are as susceptible to freezing temperatures as are nonhardy species.

Cold hardiness may be influenced by radiation, temperature, photoperiod, precipitation, and stage of development of the plant, with different optimum conditions for different species or cultivars and ecotypes within a species. The various environmental

Representative ornamental plants that will survive in the various hardiness zones

	Scientific name	Common name
Zone 1	*Betula glandulosa*	Dwarf birch
below −50° F (−45° C)	*Empetrum nigrum*	Crowberry
	Populus tremuloides	Quaking aspen
	Potentilla pennsylvanica	Pennsylvania cinquefoil
	Rhododendron lapponicum	Lapland rhododendron
	Salix reticulata	Netleaf willow
Zone 2	*Betula papyrifera*	Paper birch
−50° to −40° F (−45 to −40° C)	*Cornus canadensis*	Bunchberry dogwood
	Elaeagnus commutata	Silverberry
	Juniperus communis	Common juniper
	Picea glauca	White spruce
	Potentilla fruticosa	Bush cinquefoil
Zone 3	*Elaeagnus angustifolia*	Russian olive
−40 to −30° F (−40 to −34° C)	*Lonicera tatarica*	Tatarian honeysuckle
	Malus baccata	Siberian crabapple
	Parthenocissus quinquefolia	Virginia creeper
	Syringa vulgaris	Common lilac
	Thuja occidentails	American arborvitae
Zone 4	*Berberis thunbergi*	Japanese barberry
−30 to −20° C (−34 to −29° C)	*Hydrangea paniculata*	Panicle hydrangea
	Juniperus chinensis	Chinese juniper
	Ligustrum amurense	Amur River privet
	Spiraea vanhouttei	Vanhoutte spirea
	Taxus cuspidata	Japanese yew
Zone 5	*Cornus florida*	Flowering dogwood
−20 to −10° F (−29 to −23° C)	*Deutzia gracilis*	Slender deutzia
	Forsythia ovata	Early forsythia
	Parthenocissus tricuspidata	Boston ivy
	Rosa multiflora	Japanese rose
Zone 6	*Acer palmatum*	Japanese maple
−10 to 0° F (−23 to −18° C)	*Buxus sempervirens*	Common boxwood
	Forsythia suspensa	Weeping forsythia
	Hedera helix	English ivy
	Ilex opaca	American holly
	Ligustrum ovalifolium	California privet
Zone 7	*Azalea Kurume hyb. Hinodegiri*	Red Hussar azalea
0 to 10° F (−18 to −12° C)	*Cedrus atlantica*	Atlas cedar
	Cercis chinensis	Chinese redbud
	Chamaecyparis lawsoniana	Lawson cypress
	Cotoneaster salicifolia	Willowleaf cotoneaster
	Ilex aquifolium	English holly
Zone 8	*Arbutus menziesi*	Pacific madrone
10 to 20° F (−12 to −7° C)	*Choisya ternata*	Mexican orange
	Melia azedarach	Chinaberry
	Olearia haasti	New Zealand daisybush
	Prunus laurocerasus	Cherry laurel
	Viburnum tinus	Laurestinus
Zone 9	*Arbutus unedo*	Strawberry tree
20 to 30° F (−7 to −1° C)	*Eucalyptus globulus*	Tasmanian blue gum
	Grevillea robusta	Silk oak
	Myrtus communis	Myrtle
	Pittosporum tobira	Japanese pittosporum
	Quercus virginiana	Live oak
Zone 10	*Acacia baileyana*	Cootamundra wattle
30° to 40° F (−1 to 4° C)	*Arecastrum romanozoffianum*	Queen palm
	Bougainvillea spectabilis	Bougainvillea
	Casuarina equisetifolia	Horsetail beefwood (Australian pine)
	Eucalyptus citriodora	Lemon eucalyptus
	Ficus macrophylla	Moreton Bay fig

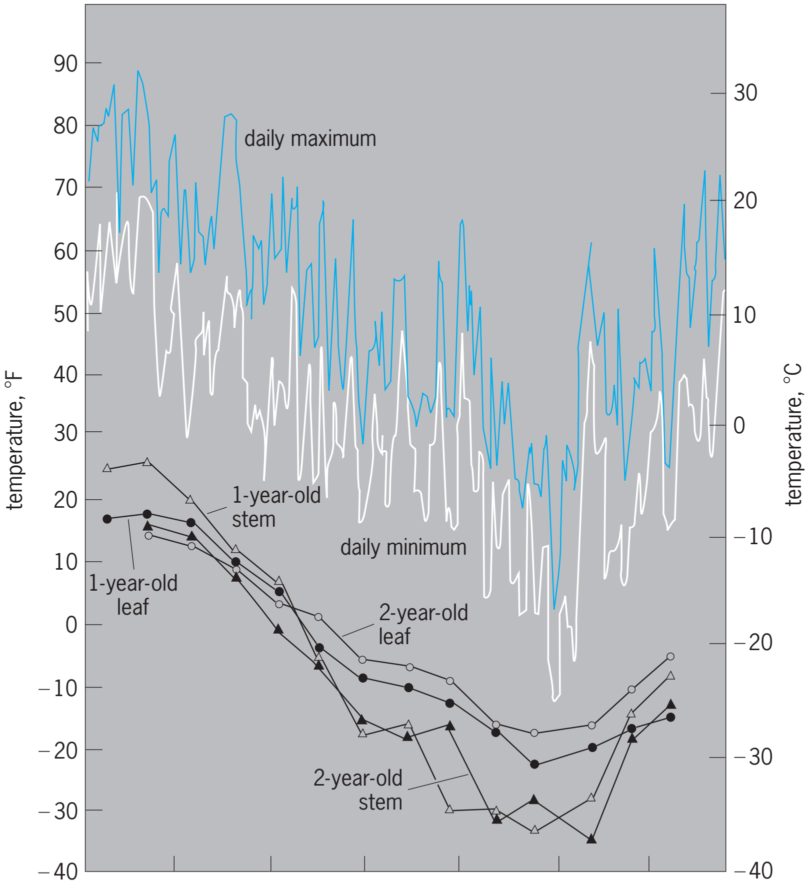

Fig. 2. **Development of cold hardiness of *Hedera helix* (English ivy). The curves show killing points for structures at different ages. (*From P. L. Steponkus and F. O. Lanphear, Factors influencing artificial cold acclimation and artificial freezing of Hedera helix "Thorndale," Proc. Amer. Soc. Hort. Sci., 91:735–741, 1967*)**

cues serve to synchronize plant development with the environment. This synchronization has taken centuries to evolve, and freezing injury in cultivated species can result from any factor that disrupts this synchrony. Some varieties may not be responsive to the prevailing environmental cues or may not respond rapidly enough; some may not develop a sufficient degree of hardiness; and some may deacclimate too rapidly. These factors may arise when individual varieties are introduced into areas that are vastly or even slightly different from their natural habitat, where centuries of selection pressures have evolved those individuals most closely synchronized with the prevailing environment.

Temperature is the key environmental parameter for increasing a plant's capacity to withstand freezing temperatures. Low, above-freezing temperatures are conducive to an increase in hardiness in the fall, and warm temperatures are responsible for the decrease in the spring. Generally, it is considered that most plants will acclimate as temperatures are gradually lowered below 50°F (10°C). However, during acclimation, the progressive decline in temperatures (from the relatively warm temperatures in early fall, followed by low, above-freezing temperatures in late fall and early winter, followed by freezing temperatures in winter) is extremely important. The development of cold hardiness may take 4 to 6 weeks.

Photoperiod is the second major factor influencing cold acclimation, but only in those species that are photoperiodically responsive in relation to growth cessation or induction of dormancy (a true physiological rest period). In other species, light is important only in providing sufficient photosynthetic reserves required for the cold acclimation process. In some cases (for example, germinating seeds), sufficient energy reserves are already present and acclimation can occur in the dark. *See* PHOTOPERIODISM.

There are conflicting reports on the role of moisture in relation to cold hardiness. High soil moisture may reduce the degree of cold acclimation; however, severe winter injury of evergreens will occur if soil moisture levels are too low. Most often tissue moisture levels will influence the survival to a given freeze-thaw cycle rather than directly influencing the process of cold acclimation. Thus, whereas temperature and light effects on hardiness are probably mediated through the development of hardiness (cold acclimation), tissue moisture content directly affects the stresses that are incurred during a freeze-thaw cycle. In addition, various cultural practices can influence the cold hardiness of a given plant. For example, late fall applications of fertilizer or improper pruning practices may stimulate flushes of growth that do not have sufficient time to acclimate. Conversely, insufficient mineral nutrition can also impair the development of maximum cold hardiness.

Freezing of plant tissues. Because plants are poikilotherms and assume the temperature of their surroundings, cold hardiness requires that they tolerate ice formation in tissues. When plant tissues freeze, the water they contain changes both its physical state and location. Ice formation may occur within cells (intracellular ice formation), in the intercellular spaces (extracellular ice formation), or in regions that separate different tissues or organs (extraorgan ice formation). In some organs and cells, such as floral buds or xylem ray parenchyma cells of deciduous forest species, ice formation may be precluded entirely. In these cases, the cytoplasm of the cell remains unfrozen below its freezing point (that is, supercooled) down to temperatures as low as −40°F (−40°C). The location of ice formation (intracellular versus extracellular) is strongly influenced by the rate of cooling, the minimum temperature attained, and the degree of hardiness of the plant.

During cooling, plant tissues initially supercool; that is, ice formation does not occur at the freezing point of the cytoplasm. Instead, ice nucleation occurs on the external plant surfaces because of the presence of foreign nucleating agents, such as ice crystals in the air or, in some cases, bacteria. Ice then propagates through the extracellular spaces, but the plasma membrane (the outer membrane of the cell) prevents seeding of the cytoplasm by the external ice. Because ice has a lower chemical potential than water at the same temperature, a gradient in water potential exists between the unfrozen cytoplasm and the extracellular ice. Water moves in response to

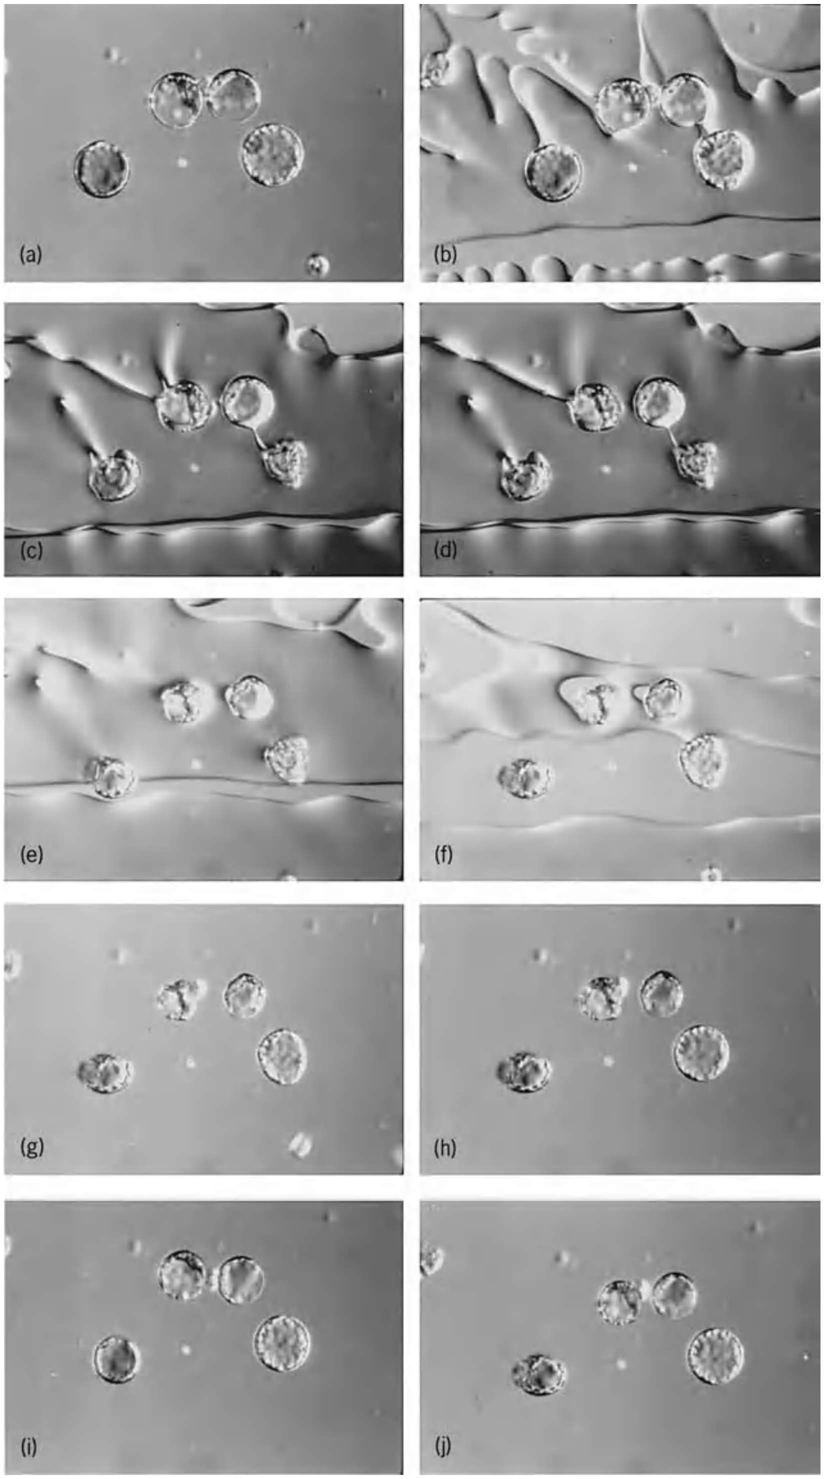

Fig. 3. Cryomicroscopic observations of isolated rye (*Secale cereale*) protoplasts during a freeze-thaw cycle. Cooling: (*a*) 32°F (0°C), (*b*) 28°F (−2°C), (*c*) 23°F (−5°C), (*d*) 14°F (−10°C). Warming: (*e*) 17°F (−8°C), (*f*) 25°F (−4°C), (*g*) 32°F (0°C). (*h–j*) Isothermal at 32°F (0°C). Note the extensive dehydration of the cell that occurs at subzero temperatures. (*Courtesy of Peter L. Steponkus*)

gradients in water potential; hence water will move from the cytoplasm to the extracellular ice and the cell will dehydrate. Because the plasma membrane is a semipermeable membrane that allows for the rapid efflux of water but does not permit the ready efflux of solutes, the cytoplasmbecomes more concentrated. With increasing solute concentration, the freezing point of the cytoplasm is progressively lowered and the intracellular solution remains unfrozen. During warming, the sequence of events is reversed. The extracellular ice melts and the extracellular solution becomes less concentrated than the intracellular solution. As a result, water will flow back into the cell. Thus, during a freeze-thaw cycle, the cells behave as osmometers in response to ice formation in the extracellular spaces. *See* CELL MEMBRANES; CELL WALLS (PLANT).

The osmometric behavior of plant cells depends on the semipermeable characteristics of the plasma membrane that allow for the rapid movement of water while retaining solutes within the cell and excluding extracellular ice crystals. This behavior is readily observed microscopically. Although microscopic observations of biological specimens at subzero temperatures have been reported for over a century, there has been a renaissance in cryomicroscopy since the early 1970s. This has occurred because of the development of sophisticated temperature-control systems and advances in video recording and computer-enhanced video image analysis. As a result, cryomicroscopy has emerged as a very powerful technique for quantifying and understanding cellular behavior during a freeze-thaw cycle. Although it has been nearly 100 years since the cooling-rate dependency of intracellular ice formation was observed in higher plants, quantitative studies of the volumetric behavior of higher plant protoplasts are only now being reported. *See* CRYOBIOLOGY.

Isolated protoplasts are obtained from plant tissues by the enzymatic digestion of the cell walls. The liberated protoplasts behave as ideal osmometers. Their spherical shape over a wide range of solute concentrations facilitates quantitative cryomicroscopic studies of their osmometric behavior. Direct measurements of volumetric behavior during a freeze-thaw cycle (**Fig. 3**) allow for the calculation of water efflux, the extent of supercooling, and water permeability of the plasma membrane. Coupled with a precise time and temperature history, such studies provide considerable insight into the causes and manifestations of freezing injury. Extensive dehydration of the cell occurs at subzero temperatures; following thawing of the suspending medium, the protoplasts rehydrate and osmotically increase in volume. Because the protoplasts in Fig. 3 were isolated from acclimated tissues, they survived the freeze-thaw cycle to a temperature of 14°F (−10°C).

Intracellular ice formation. Whether ice formation is restricted to the extracellular spaces or also occurs within the cells is of utmost importance because intracellular ice formation is invariably associated with lethal injury. In isolated rye protoplasts subjected to rapid cooling rates (9°F or 5°C per minute; **Fig. 4**), intracellular ice formation is manifested as a darkening of the cells (Fig. 4*c* and *d*). This optical darkening or flashing is commonly observed, and was long thought to be the result of the diffraction of light by small ice crystals. High-resolution cryomicroscopy of isolated protoplasts reveals that the optical darkening is due to the formation of gas bubbles following intracellular ice formation. Upon melting of the ice, some of the gas bubbles coalesce (Fig. 4*e*). More importantly, however, intracellular ice formation is associated with lethal injury as manifested by the ruptured protoplasts (Fig. 4*f*). Intracellular ice formation is associated with early frost injury of herbaceous plants, and may also occur when there are sudden temperature changes in deciduous fruit tree buds.

The incidence of intracellular ice formation is strongly dependent on the rate at which the tissue is cooled and the minimum temperature attained. At rapid cooling rates, efflux of water from the cell is limited by the water permeability of the plasma membrane or other impediments to water flux. As a result, concentration of the intracellular solutes and depression of the freezing point will not keep pace with the decreasing temperature, and the intracellular solution will become increasingly supercooled during cooling. With suspensions of isolated plant cells or protoplasts where the cells are surrounded by ice and the only barrier to water efflux is the plasma membrane, excessive supercooling will occur at cooling rates greater than 5°F (3°C) per minute. In intact tissues, rates greater than a few degrees per hour are sufficiently rapid to result in supercooling of the intracellular solution. This is because the ice crystals may be far removed from the intracellular solution and water flow is slowed by impediments resulting from tissue organization, contact of cell walls, or other barriers. Supercooling per se does not result in intracellular ice formation; it only predisposes the cell to this possibility. Nucleation or seeding of the supercooled solution is required for intracellular ice formation. This may occur by either homogeneous or heterogeneous nucleation or by seeding by the extracellular ice.

Homogeneous nucleation is a result of the spontaneous aggregation of water molecules to form ice nuclei and occurs only at temperatures below −38°F (−39°C). Thus, floral buds of some species or xylem ray parenchyma of some deciduous species will tolerate temperatures down to −38°F (−39°C) because they remain supercooled. At lower temperatures, however, intracellular ice formation occurs because of homogeneous nucleation. The sudden and rapid formation of ice is invariably lethal. There is a close relationship between the northern limits of many deciduous forest species that exhibit supercooling of the xylem ray parenchyma cells and the occurrence of temperatures below −40°F (−40°C).

Heterogeneous nucleation may occur at higher temperatures, but it requires the presence of foreign materials that are effective ice-nucleating agents. However, there is little evidence that such compounds are present in the cytoplasm. Instead, there is considerable evidence that intracellular ice formation is a consequence of seeding by extracellular ice as a result of perturbation or penetration of the plasma membrane. Direct cryomicroscopic observations of isolated protoplasts reveal that mechanical failure of the plasma membrane occurs immediately before intracellular ice formation. This occurs in the range of 23 to 5°F (−5 to −15°C) in nonacclimated plants. Thus, intracellular ice formation is a consequence of injury to the plasma membrane rather than a cause of injury.

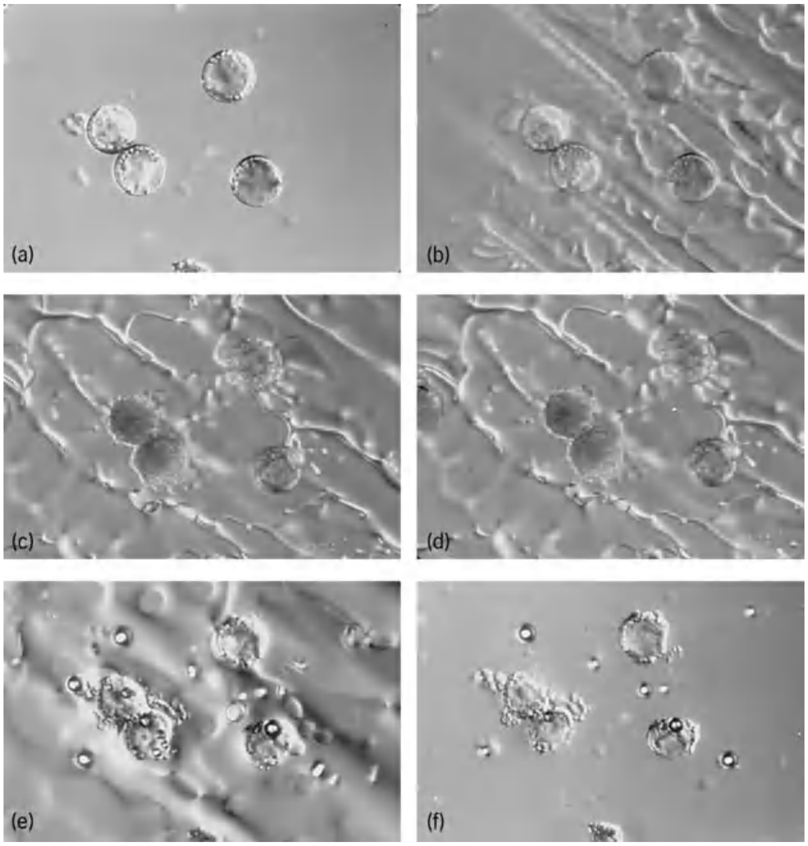

Fig. 4. Intracellular ice formation in isolated rye (*Secale cereale*) protoplasts. Cooling: (*a*) 32°F (0°C), (*b*) 28°F (−2°C), (*c*) 14°F (−10°C), (*d*)14°F (−10°C). Warming: (e) 28°F (−2°C), (*f*) 32°F (0°C). (*Courtesy of Peter L. Steponkus*)

Following cold acclimation, plants are less prone to intracellular ice formation. For many years it was assumed that this was because of an increase in the water permeability of the plasma membrane, which minimized the extent of supercooling. Recently, however, this was shown to be erroneous. Instead, cold acclimation decreases the incidence of intracellular ice formation because the stability of the plasma membrane at lower temperatures is increased and defers seeding by extracellular ice to temperatures as low as −40°F (−40°C).

Freezing injury due to cell dehydration. The visual symptoms of freezing injury—a darkened, water-soaked, flaccid appearance—are apparent immediately following thawing. The rapidity in which injury is manifested indicates that injury is not the result of metabolic dysfunction. Instead, the primary cause of freezing injury is the disruption of the plasma membrane. Manifestations of injury may range from alterations in the semipermeable characteristics to mechanical rupture, and injury can occur at various times during a freeze-thaw cycle (**Fig. 5**). The various forms of injury observed are (1) expansion-induced lysis during warming andthawing of the suspending

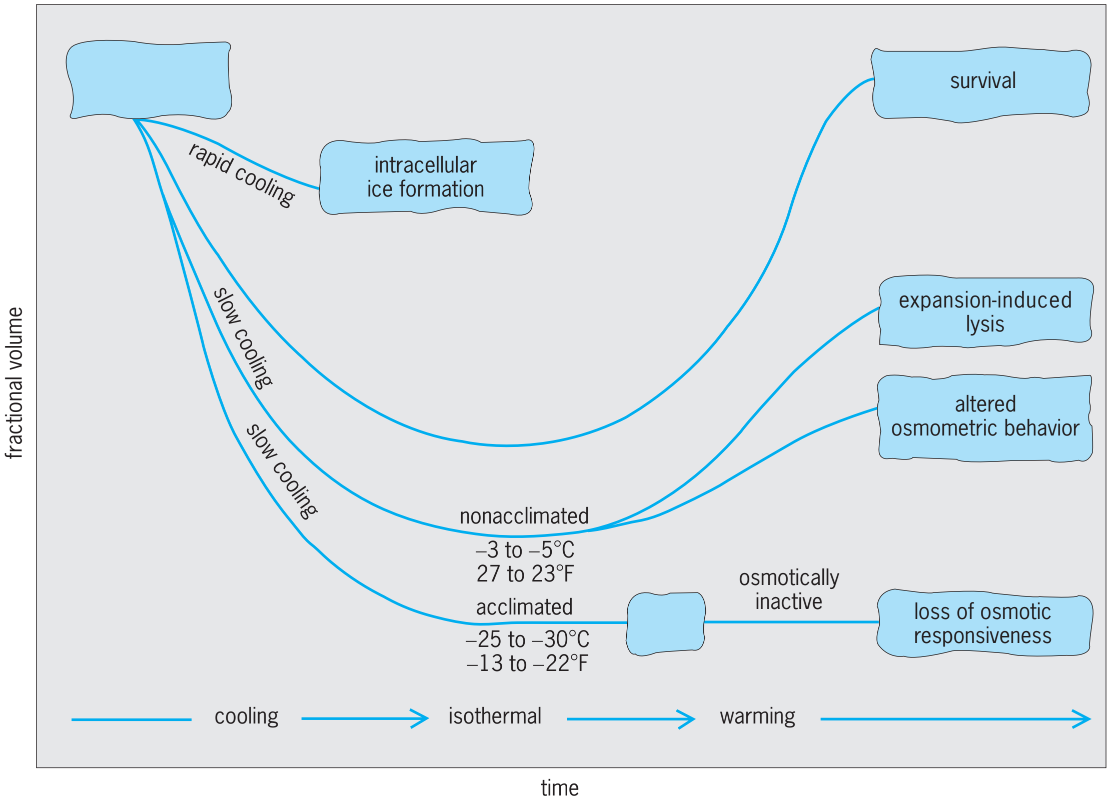

Fig. 5. Manifestations of freezing injury to the plasma membrane.

medium when the decreasing concentration of the suspending medium results in osmotic expansion of the protoplasts; (2) loss of osmotic responsiveness following cooling at slow rates so that the protoplast is osmotically inactive during warming; and (3) altered osmometric behavior during warming, suggestive of altered semipermeable characteristics or leakiness of the plasma membrane.

These symptoms of injury are not consequences of low temperatures per se because low temperatures in the absence of freezing are not injurious to hardy plants. Thus, thermal stresses that may result in membrane phase transitions are unlikely to contribute to freezing injury. Similarly, there is little evidence that injury occurs because of the presence of ice crystals. Instead, injury is primarily a consequence of cell dehydration, and there is a very good correlation between cold hardiness and the ability to withstand dehydration in the absence of freezing. There are, however, several consequences of cell dehydration that can result in injury to the plasma membrane.

In nonacclimated tissues, cell dehydration results in the deletion of membrane material from the plasma membrane in the form of membrane vesicles (**Fig. 6***a*). During contraction of the protoplast, these vesicles are detached from the membrane and become visible in the cytoplasm. Upon thawing, the tissue increases in volume, but the previously deleted membrane material is not reincorporated into the membrane, and rupture of the plasma membrane (lysis) occurs before the cells regain their original size. Hence, this form of injury is referred to as expansion-induced lysis or deplasmolysis injury, and is the predominant form of injury following cell dehydration in nonacclimated herbaceous tissues such as winter cereals (wheat or rye). Injury is largely a consequence of the mechanical stresses imposed on the plasma membrane during cell dehydration and rehydration.

Expansion-induced lysis is not observed in acclimated tissues because membrane deletion does not occur during contraction. Instead, extrusions of the plasma membrane that remain contiguous with the plasma membrane are formed (Fig. 6*b*). These extrusions are readily reincorporated into the plane of the membrane during expansion. Hence, mechanical stresses of the plasma membrane are not responsible for injury in acclimated tissues. Instead, injury is largely the result of chemical stresses associated with cell dehydration.

Loss of osmotic responsiveness occurs in protoplasts isolated from nonacclimated tissues when the protoplasts are cooled to 14°F (−10°C) or lower. At these temperatures severe freeze-induced dehydration occurs with a loss of nearly 90% of the intracellular water, and with a tenfold increase in the concentration of the intracellular solutes. The semipermeable properties of the plasma membrane are disrupted so that following thawing the protoplasts are osmotically unresponsive. In tissues, the cells appear to be plasmolyzed, and therefore this form of injury has been referred to as frost plasmolysis. However, this term is misleading in that the cells cannot be considered plasmolyzed if they are not osmotically responsive.

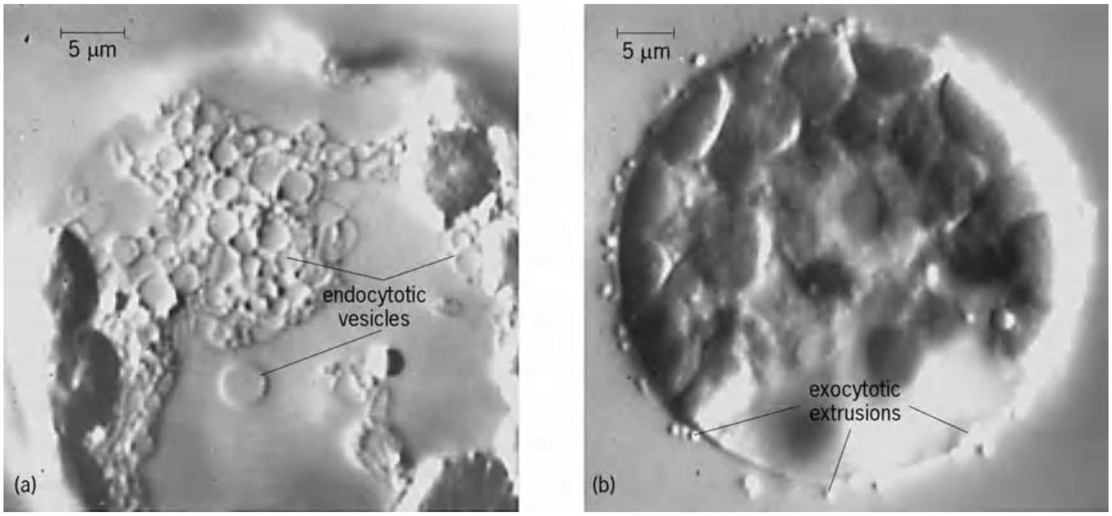

Fig. 6. High-resolution computer-enhanced differential interference contrast micrographs of (*a*) nonacclimated and (*b*) acclimated protoplasts subjected to hypertonic solutions. (*From P. L. Steponkus et al.*, *Destabilization of the plasma membrane of isolated plant protoplasts during a freeze-thaw cycle: The influence of cold acclimation*, *Cryobiology*, *20:448–465*, *1983*)

Loss of osmotic responsiveness is associated with several changes in the ultrastructure of the plasma membrane, including lateral phase separations and bilayer-to-nonbilayer transitions, such as the formation of inverted cylindrical micelles or hexagonal$_{\text{II}}$ phase. These changes occur as a consequence of the close approach (less than 2 to 3 nanometers) of membranes during cell dehydration. Normally, strongly repulsive hydration forces preclude the close approach of two bilayers. However, the high osmotic pressures that occur during freeze-induced dehydration overcome the hydration forces. Dehydration-induced lateral phase separations and the hexagonal$_{\text{II}}$ phase are not observed in protoplasts isolated from cold-acclimated tissues. The increased stability may be a consequence of alterations in the plasma membrane lipid composition that preclude dehydration-induced demixing of the lipids, and the accumulation of cytoplasmic solutes such as sucrose or proline.

Cold acclimation. The process of cold acclimation results in numerous biochemical changes within the plant. These include increases in growth inhibitors and decreases in growth promoters; changes in nucleic acid metabolism; alterations in cellular pigments such as carotenoids and anthocyanins; the accumulation of carbohydrates, amino acids, and water-soluble proteins; increases in fatty acid unsaturation; changes in lipid composition; and the proliferation of cellular membrane systems. Not all of these changes are involved in increased cold hardiness; some are merely changes in response to slower growth rates and decreased photosynthate utilization; others are changes associated with growth at low, above-zero temperatures; and still others are associated with other developmental phenomena, such as vernalization or the induction of dormancy, that also occur during the period of cold acclimation.

As cellular membranes are the primary site of freezing injury, it follows that cold acclimation must involve cellular alterations that allow the membranes to survive lower freezing temperatures. Such alterations may be in the cellular environment so that either the freezing stresses are altered or there is direct protection of the membranes. In addition, cold acclimation may involve changes in the membrane itself, so that its susceptibility to the freezing stresses is decreased.

Large increases in cellular solute concentrations are one of the most universal manifestations of cold acclimation. A doubling of the intracellular solute concentration, most notably sugars, is not uncommon. Such increases have several beneficial effects. First, they serve to depress the freezing point of the intracellular solution. This, however, is of limited advantage because such increases only lower the freezing point to the extent of 1.03°F/osmolal (1.86°C/osmolal).

More important is their effect on the extent of cell dehydration that occurs during freezing. A doubling of the initial intracellular solute concentration will decrease the extent of cell dehydration at any subzero temperature by 50%. An increase in intracellular solutes will also decrease the concentration of toxic solutes at temperatures below 32°F (0°C), because less water will be removed. During dehydration protective compounds, such as sugars, are concentrated along with toxic compounds, such as electrolytes. Because the total concentration of the intracellular solution is a function of the subzero temperature, the toxic compounds will account for only a portion of the total. If the ratio of protective to toxic compounds is initially greater, the final concentration of the toxic compounds at any subzero temperature will be lowered accordingly. In addition, there are some compounds, such as sucrose or proline, that may interact directly with cellular membranes to increase their stability either at low water contents or at high electrolyte concentrations.

Following cold acclimation there are substantial changes in the lipid composition of the plasma membrane. Although there are no lipid molecular species that are unique to the plasma membrane of either nonacclimated or acclimated rye leaves, cold acclimation alters the proportion of virtually every lipid component. This includes an increase in free sterols with corresponding decreases in steryl glucosides and acylated steryl glucosides, a decrease in the glucocerebroside content, and an increase in the phospholipid content. Although the relative proportions of the individual phospholipids (for example, phosphatidylcholine and phosphatidylethanolamine) do not change appreciably, there are substantial differences in the individual lipid molecular species. These include increases in species of phosphatidylcholine and phosphatidylethanolamine that contain two unsaturated fatty acids, whereas species with a single unsaturated fatty acid remain relatively unchanged. The complexity of the plasma membrane lipid composition and the numerous changes that occur during cold acclimation preclude the possibility that any simple correlative analysis of the changes will establish their role in the cold acclimation process; instead, a mechanistic analysis is required.

One approach has been to demonstrate that the differential behavior of the plasma membrane observed in protoplasts isolated from nonacclimated and cold-acclimated leaves (that is, the formation of endocytotic vesicles versus exocytotic extrusions during osmotic contraction and the differential propensity for dehydration-induced bilayer-to-nonbilayer phase transitions) is also observed in liposomes formed from plasma membrane lipid extracts of nonacclimated and acclimated leaves. Thus, the increased cryostability of the plasma membrane following cold acclimation is a consequence of alterations in the lipid composition. However, there are over 100 different lipid molecular species present in the plasma membrane, so that the problem is to determine which of the changes are responsible for the differential cryobehavior. In studies that have used a protoplast–liposome fusion technique to enrich the plasma membrane with specific lipids, it has been established that increases in the proportion of phosphatidylcholine species composed of one or two unsaturated fatty acids increase the freezing tolerance of protoplasts isolated from nonacclimated rye leaves. The increase in freezing tolerance is the result of a transformation in the cryobehavior of the plasma membrane during osmotic contraction so that exocytotic extrusions are formed rather than endocytotic vesicles. As a result, expansion-induced lysis is precluded. Thus, these studies demonstrate that although there are over 100 lipid molecular species in the plasma membrane, altering the proportion of a single species dramatically alters the cryobehavior of the plasma membrane. Similar membrane engineering studies have been undertaken for the other forms of freezing injury (for example, loss of osmotic responsiveness) and should ultimately provide a molecular understanding of the role of plasma membrane lipid alterations in increasing the cryostability of the plasma membrane. *See* ALTITUDINAL VEGETATION ZONES; PLANT PHYSIOLOGY; PLANT-WATER RELATIONS.
